Fig.4 Stream flow and sediment discharge

The lake drawdown began with a full lake at 8:00 am on April 9, 1994. During the experiment, the lake's water level was lowered 18 feet over a 1-week period from April 9 to 16. Drawdown rates were about 3 feet per day for the first 5 days, for a total of 15 feet. The lake was drawn down 2 feet between April 14 and 15 and 1 foot between April 15 and 16. A drawn down of 18 feet was reached 8:00 am on April 16, and then held at constant elevation for a week. The changes of lake level are shown in Fig.5, and were used as the downstream boundary condition. The particle-size distribution collected at ELD1 station was used. The distribution curve is shown in Fig.6.

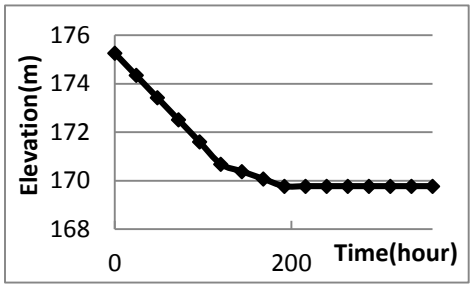

Fig.5 Downstream boundary conditions

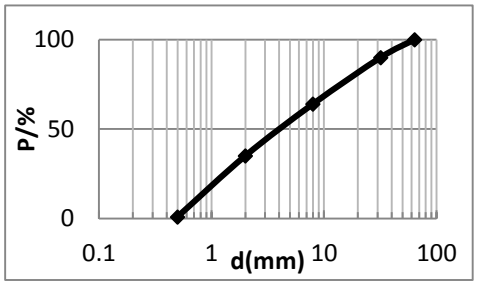

Fig.6 Particle-size distribution

The time step used for the three computational meshes is 5.0 s. The total simulation time is 360 hours. When the mesh size is decreased to 8 m, the SRH2D doesn't converge even reducing the time step to 0.01 s.

3 Simulation Results

The simulated bed elevations using the new mesh were compared with the measurements on April 23th, and shown in Fig.7. Only Yang's equation was used in this calculation in order to compare with the previous results by using only measured cross sections on April 8th, 1994. The final results at Section 3, 4, and 5 showed no erosion or deposition, the same as the measurements. At Section 6, the simulated results underestimated the deposition. From Section 7 to 11, two large channels are formed at both sides of the delta, while the simulated results also showed two channels formed on the delta, but the channel sizes cannot match the observed ones. The sizes of both channels are smaller than the observed ones. From Section 12 to 15, the simulated results considerably over-estimated the deposition comparing to observed bed elevation.

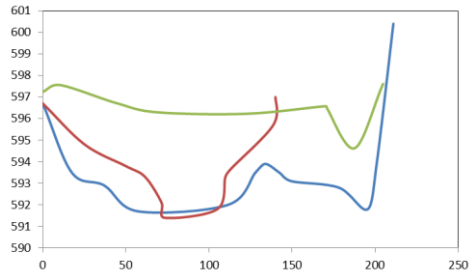

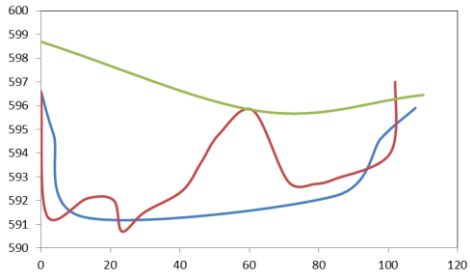

Fig.7 Simulated and measured bed elevation changes

The errors of simulated bed elevation changes may due to 1) local turbulence due to woody debris; 2) bank erosion induced channel changes have not been simulated; 3) avulsion or bifurcation processes may also need to be considered.

4. Conclusion

This study first applies the SRH2D model to simulate the experimental drawdown of Lake Mills in 1994. The simulated results showed no erosion or deposition within the reservoir at Section 3, 4, and 5, the same as the measurements. At the edge of exposed delta (Section 6), the simulated results underestimated the deposition. From Section 7 to 11 where delta is scoured by the drawdown flow, the simulated results showed two channels formed on the delta, but underestimated erosion occurred in the channels. At the delta upstream (Section 12 to 15), the simulated results considerably over-estimated the deposition comparing to observed bed elevation changes.

To test the sensitivities of modeling results to selected parameters, we chose three different mesh sizes using pure triangular, pure quadrilateral, and mixed triangular and quadrilateral meshes,

six different sediment transport equations, three different adaptation lengths, six combinations of roughness coefficients ranging from 0.02-0.06. The results showed that the modeling results are sensitive to sediment equations. Among selected equations, Yang (1973) relation yielded the maximum sedimentation and erosion at sections upstream of the delta, and the results are also sensitive to roughness coefficients. As roughness is increased, more erosion is predicted. However, the maximum roughness value in the simulation reach cannot exceed 0.06 according to field observations. The calibration of roughness coefficients will not lead to accurate results that match the observations. The modeling results are not sensitive to the selection of adaptation length, mesh types, and sizes.

In summary, SRH2D model approximately predicted the erosion in the delta front, in particularly, two side channels formed on the delta. However, the results of SRH2D underestimated the erosion due to water level drawdown that makes the simulated channel erosion much less than the observed.

5. Discussion

As seen from the simulated results, both SRH2D cannot accurately predicted the observed erosion due to lake level drawdown. As water withdraws from a lake, sediment erosion at channel bottom and bank collapse are visible. The model only predicted very small sediment transport rate due to very small bed shear stresses on the streamwise direction. Bed shear stress relates to both mean and near-bed turbulence flow (Biron *et al.* 2004, 2005; Huthnance *et al*. 2002, Kim et al., 2000). At present, we cannot tell if the under-predicted bed shear stress is due to the hydrodynamic model because there is no measured flow field that can verify the simulated flow velocity and water surface elevations. Whether or not the simulated flow fields, especially shear stress field, are accurate requires further experimental or field data verification. Therefore, we strongly recommend to verify SRH2D using a laboratory experimental case with measured flow field.

Secondly, currently sediment transport equations may not be able to predict sediment transport rate due to water surface drawn down. Water surface is down vertically that will cause an acceleration of vertical flow (Stelling 1984, Stelling and van Kester 1994). This vertical accelerated flow either directly entrains sediment from bottom or generates drag force that cause sediment transport. The erosion due to the vertical accelerated flow is the major erosion mechanism in lake level drawdown scenario. However, this mechanism was not considered in any sediment transport formula. The sediment transport rate in the model is determined by the horizontal shear stress, which is a function of depth-averaged horizontal velocity. Therefore, the model under-predicts or is unable to predict observed erosion.

Therefore, we recommend to verify the flow simulation of SRH2D model using a well-

defined laboratory experiment of lake level drawdown. If there is an existing laboratory experiment, it will be ideal. The physical experiment conducted at University of Minnesota can be a good choice, but needs to check if flow field measurements are available. After the simulated flow field is verified, we recommend modifications to sediment transport equations to account for the effect of vertical accelerated flow on sediment transport.

INTRODUCTION

Isleta Diversion Dam was constructed in 1934 by the Middle Rio Grande Conservancy District (MRGCD) as part of their irrigation system, and is located on the Rio Grande about 10 miles south of Albuquerque, New Mexico, immediately downstream from the Highway 147 Bridge (Figure 1). The diversion dam was rehabilitated by Reclamation in 1955 as part of the Middle Rio Grande Project, authorized by Congress in the 1948 and 1950 Flood Control Acts. The Middle Rio Grande (MRG) has long been recognized for its characteristics of high sediment loads and dynamic channel conditions (Happ, 1948; Lagasse, 1980; Makar, 2010). The Isleta Diversion Dam consists of 30 river gates, three headworks gates on the Peralta Main canal (east side), and four headworks gates on the Belen Highline canal (west side) of the dam (Figure 2). The headworks gates are located in a sluiceway with a downstream gate used to maintain a maximum diversion head. Gate operations are used to provide water to downstream irrigators, meet downstream flow requirements of the 2003 Endangered Species Biological Opinion (USFWS, 2003), and manage sediment. Within the context of these multiple water use needs, a one-dimensional (1D) and two-dimensional (2D) fixed bed hydraulic models, sluiceway hydraulics, and sediment incipient motion analysis has been completed to provide recommendations on gate operations that would help reduce sediment impacts. The objectives of these recommendations are to reduce sediment diversion through the headworks gates into the irrigation system, reduce the potential for downstream formation of vegetated islands, maintain an open channel as much as possible along the right bank of the river downstream of the diversion dam, and minimize upstream sediment accumulation. This analysis does not evaluate the effects of sediment supply and sediment transport capacity. Documentation of historical channel characteristics and changes, local knowledge and observation by the staff of the Isleta Pueblo, and the MRGCD is coupled with modeling and incipient motion analysis to interpret results.

CHANNEL DESCRIPTION

The MRG has historically had a high sediment load, causing the channel to fill, especially during hydrograph recession periods, resulting in over bank flooding during subsequent high flow events and avulsing to lower areas of the valley, leading to aggradation (raising of the river bed and floodplain due to sediment accumulation) across the floodplain (Scurlock, 1998; Lagasse, 1980; Happ, 1948). This condition is believed to have existed prior to the 1500s (Scurlock, 1998). The resulting river channel was wide and shallow and generally sand bedded with small pockets of gravel (Scurlock, 1998; Lagasse, 1980). The MRG has changed significantly over the last century as a result of human activities such as irrigation diversions, levee and riverside drain construction, channel rehabilitation (channelization) and maintenance, upstream sediment and flood control reservoirs, trans-mountain diversion, and urbanization. There have also been diminished flood peaks and sediment supply from large tributaries to the Rio Grande since the 1940s (Lagasse, 1980). The following reach descriptions are summarized from Makar (2010), and Baird and Strand (2013) and provide a context of channel conditions and sediment supply into Isleta Diversion Dam. The Albuquerque Reach, extending from Angostura Diversion Dam downstream to the Isleta Diversion Dam (see Figure 1) narrowed from about 600 feet wide in 1972 to about 390 feet in 2002, and the plan form is transitioning from a wide, low-flow braided channel to a single thread channel with vegetated bank-attached bars. Bed material is changing from sand to areas of gravel bed. It is expected that the existing trends of incision, narrowing, and bed coarsening will most likely continue. The suspended sediment load has reduced by about 75 percent. The Belen Reach extends from Isleta Diversion Dam to the mouth of the Rio Puerco (Figure 1) and was about 550 feet wide prior to 1972. This reach currently averages about 350 feet wide, and the channel is continuing to narrow through island and bar development and is transitioning to a single thread channel. The historic sand bed is coarsening to areas of gravel bed. Both the Albuquerque and Belen Reaches appear to have a sediment transport capacity greater than the amount of sediment being supplied, whereas historically the sediment transport capacity appeared to be less than supply. These reaches will likely continue to experience channel slope reduction, through bed degradation and lateral migration. This means there is less sediment being supplied to Isleta Diversion Dam by the river than historically.

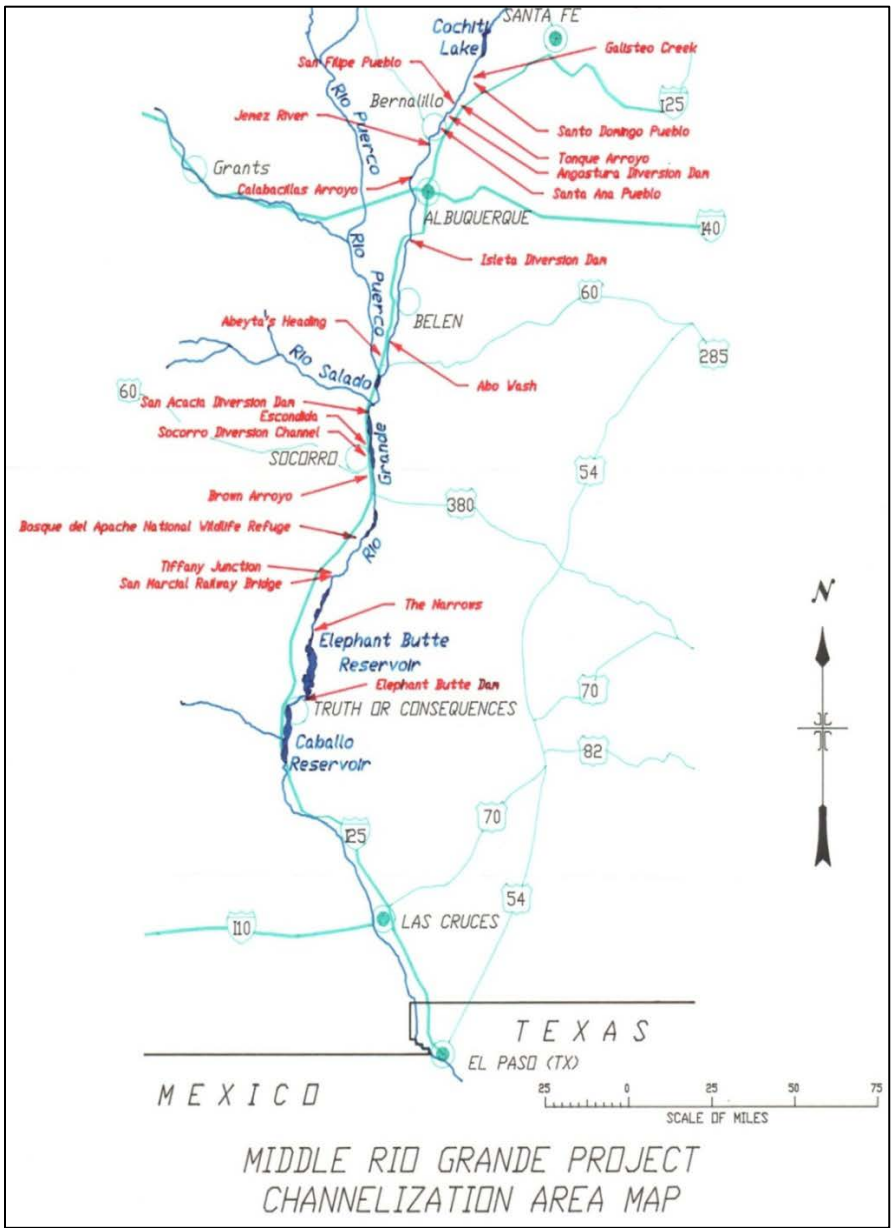

Figure 1. Location map.

MODEL SELECTION AND APPLICATIONS

The numerical models utilized for this study were HEC-RAS (v 4.1.0) and SRH-2D (v 3.0). HEC-RAS is a one-dimensional (1D) backwater step hydraulic model developed by the U.S. Army Corps of Engineers (USACE, 2008). This model simulated cross section averaged river hydraulics for a series of steady, gradually varied flows. The SRH-2D model utilized for this study is a two-dimensional (2D) fixed-bed hydraulic model specifically focused on the flow hydraulics of river systems (Lai, 2008). SRH-2D solves the depth-averaged dynamic wave equations with a depth-averaged parabolic turbulence model using a finite-volume numerical scheme. The model adopts a zonal approach for coupled modeling of channels and floodplains; a river system is broken down into modeling zones (delineated based on natural features such as topography, vegetation, and bed roughness), each with unique parameters such as flow resistance. One of the major features of SRH-2D is the adoption of an unstructured hybrid

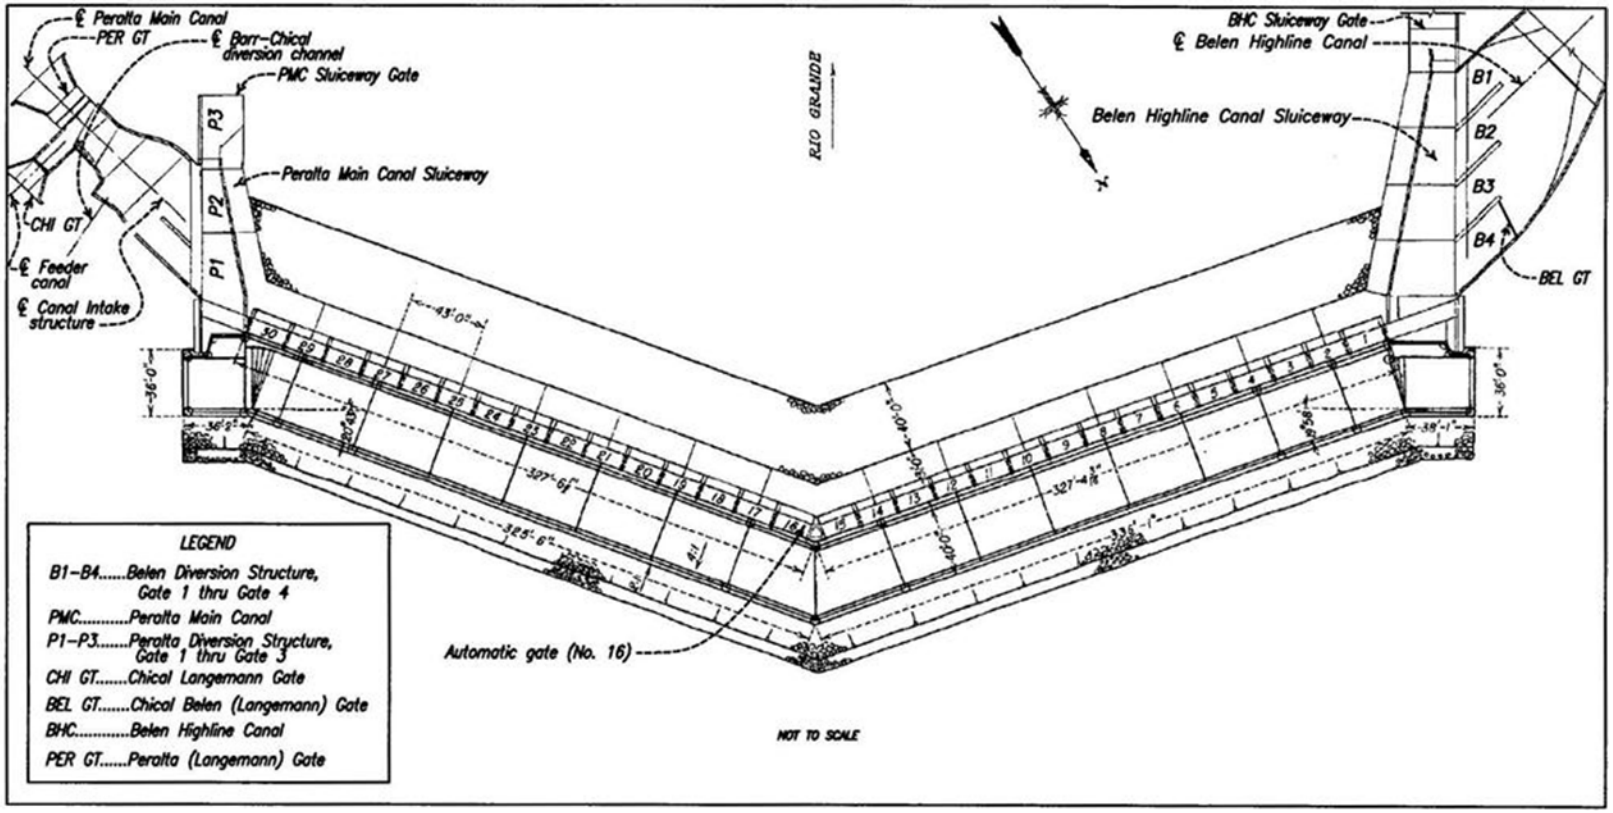

Figure 2. Isleta Diversion Dam plan view.

mixed element mesh, which is based on the arbitrarily shaped element method of Lai (2000) for geometric representation. This meshing strategy is flexible enough to facilitate the implementation of the zonal modeling concept; it allows for greater modeling detail in areas of interest, and ultimately leads to increased modeling efficiency through a compromise between solution accuracy and computing demand. HEC-RAS was utilized to set the downstream boundary in the SRH-2D model simulations, which consisted of a water surface elevation. At the time of this study, SRH-2D did not have the ability to model gates, while HEC-RAS did, so the HEC-RAS model was also utilized to formulate gate operations that made up a set of scenarios modeled in SRH-2D.

Topography Development: A combination of several data sets was utilized to construct the existing conditions topography of the study area. In-channel ground survey data were collected upstream and downstream of the diversion dam in 2005 and 2012 (exact dates are unknown) and supplemented with a more recent data set collected immediately upstream of the dam in June, 2013. These data were primarily used to represent the wetted portion of the channel (bathymetry). To supplement the survey data in the floodplain areas, a Digital Terrain Model (DTM) generated from Light Detection and Ranging (LiDAR) data collected in 2012 was utilized. By combining the interpolated survey data with the LiDAR data, a representative topographic surface was created in ArcGIS using a Triangulated Irregular Network (TIN) methodology. It is important to note that the channel bed near/around the diversion dam is extremely dynamic and based on river flows and operational strategy of the diversion dam gates; comparison of the 2012 and 2013 survey data showed that gate operations have a significant influence on the bed elevation upstream of the dam. During the data collection period in June 2013 all diversions were through the Peralta Main side of the dam, and sediment deposition was observed upstream of the Belen Highline headworks. The 2012 survey data upstream of the Belen Highline side was several feet lower than the 2013 data. Most likely during high flows, with both sluiceways open, both sides of the dam would have a lower bed elevation than when no diversion of flow through the gates adjoining the sluiceways is occurring. The lowest measured bed elevation on each side of the diversion dam was used in this study. A project was implemented to remove islands and widen the channel downstream of Isleta Diversion Dam. The topography downstream was based on the project design while the upstream topography remained the same for both the pre-project and post-project cases. The existing and post-island removal project topographic surfaces are shown in Figures 3 and 4.

Modeling to Establish and Evaluate Effects of Gate Operations: The HEC-RAS model was used to establish gate operations and resulting water stage at Isleta Diversion Dam. The diversion dam was represented through a series of radial gates. The sluiceway and accompanying canal diversions were not represented in the model. The 1D downstream boundary condition was set to a normal depth slope determined by the average bed slope near the lower end of the model domain dictated by the 2012 survey data. The 1Dupstream boundary condition consisted of various discharges related to the gate operational scenarios that were evaluated.

A SRH-2D fixed bed model was used to evaluate channel hydraulics for selected gate operations. Surface-water Modeling System (SMS) software was used to generate the 2D mesh which contains finer mesh cells near areas of interest, such as the diversion dam, and coarser mesh cells elsewhere. The mesh stores bed elevation information based on the topographic surface and consists of quadrilateral and triangular shaped elements. SMS was also utilized to delineate model roughness areas and assign model boundary conditions. Hydraulic roughness is the primary calibration parameter for hydraulic modeling assuming the channel and floodplain geometry is accurate. Roughness assignments included ‘main channel’, ‘vegetated overbanks-islands’, and ‘concrete’ (diversion dam and sluiceways). Lacking any new data to calibrate to the main channel and overbank roughness in the HEC-RAS model were set at 0.028 and 0.045, respectively based on prior modeling effort (Tetra Tech, 2012). The ‘concrete’ roughness value was assigned to be 0.015 according to values found in literature for a float finish (Sturn, 2001). Roughness values in a 2D model are often lower than those in a 1D model because the 2D model solves for eddy losses independently, as opposed to these losses being lumped into the roughness value or expansion/contraction loss coefficients. Therefore, roughness values were set slightly lower in the 2D model at 0.025, 0.045, and 0.015 for ‘main channel’, ‘vegetated overbanks/islands’, and ‘concrete’, respectively.

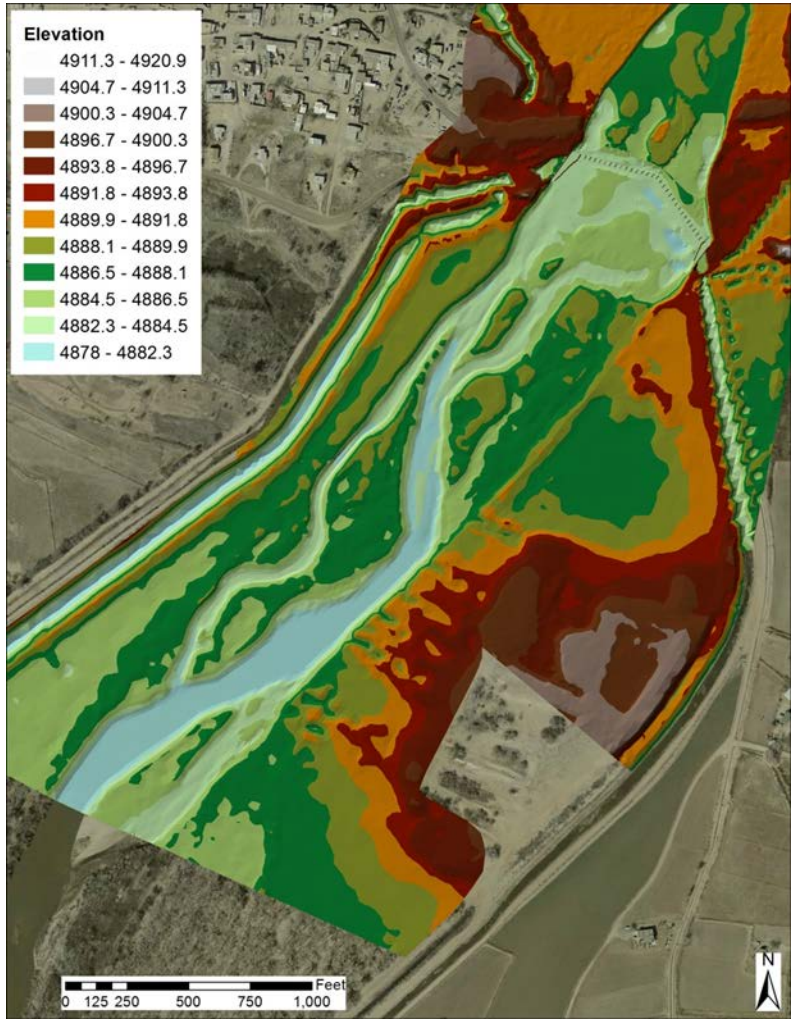

Figure 3. Existing conditions digital topographic surface.

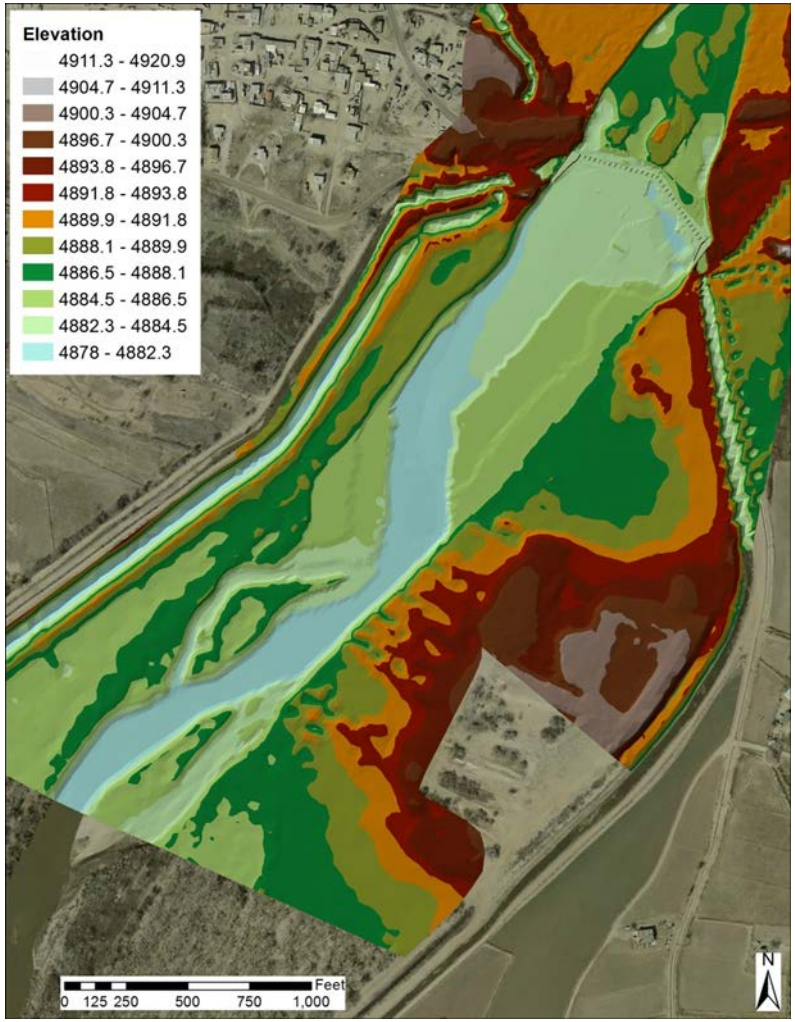

Figure 4. Post-project conditions digital topographic surface.

The 2D upstream boundary condition was specified as a steady flow input rate ranging from 500 to 5,000 cfs. The 2D downstream boundary condition was set to a corresponding water surface elevation based on output from the 1D model. Internal boundary conditions were also used to represent flow through each diversion dam and sluiceway gate as well as the sluiceway diversions. Maximum sluiceway diversions were 250 and 300 cfs down the Belen Highline and Peralta Main Canals, respectively. To ensure flow continuity, there were also a set of internal boundary conditions set up at the entrance to each sluiceway that controlled how much flow passed through each structure.

Sluiceway Hydraulics Methodology: The water surface elevation in both sluiceways predicted by SRH-2D for many of the flow scenarios was lower than required for full diversion head because the 2D model does not include hydraulic computations for pressurized flow through gates. Instead, local sluiceway velocity was evaluated using flow cross sectional area and discharge to solve the continuity equation (discharge= cross sectional area multiplied by the mean cross sectional velocity). For the Peralta Main sluiceway, diversions were equally divided for each headworks gate or bay (see Figure 2). For the Belen Highline sluiceway, all flows were diverted through the first and fourth headworks gate. The first headworks radial gate has been replaced by an automated Langaman gate which is used for all diversions (pers. communication David Gensler, 2013).

Sediment Incipient Motion Methodology: Incipient motion of sediment was computed to analyze the areas of potential sediment deposition, and sediment mobility. Incipient motion occurs when the shear stress (critical shear stress) acting on a particle of sediment overcomes the stabilizing force due to particle weight and size and the particle begins to move. The Shields Diagram (Shields, 1936) was used in this study to determine the critical shear which initiates sediment particle motion. Vanoni (1977) criterion was used to illustrate the velocity at which particles begin to move based upon extensive field and laboratory surveys. Bed sediment sizes upstream and downstream of Isleta Diversion Dam have coarsened from predominantly medium sand to coarse sand with some fine gravel, over time since about 1975 (Bauer, 2009). The most recent bed sediment sizes from the decade of the 2000s are shown in Table 1 which illustrates the median bed material size in the reach containing Isleta Diversion Dam is 0.6 mm (Bauer, 2009). Visual estimates from a recent field visit in 2013 validate similar sand sizes are present near Isleta Dam. One of the bed material measurements in Table 1 can be classified as fine gravel (4-8 mm). Visual observations of the downstream river bed indicate that gravel transport through the diversion dam delta is not likely at present. The upstream channel has degraded (bed lowered) but the delta length of about 2 miles has remained approximately the same between 1936 and 2002 (Baird and Strand, 2013). Because this study focus is mainly on sediment mobility in the island removal and channel widening area downstream of the Isleta Diversion Dam, only sand sizes were considered in this assessment.

Table 1 Median Bed Material Sizes (Bauer, 2009), Critical Velocity and Shear Stress for Incipient Motion Upstream and Downstream of Isleta Diversion Dam.

Direction from Isleta Diversion Dam	Distance from Isleta Diversion Dam (Miles)	Median Bed Material Size (mm)	Critical Velocity Hjulstrom (1935) ft/s	Critical Velocity (Vanoni, 1977) ft/s	Critical Shear Stress (Shields, 1936) lb/ft^2
Upstream	6.23	0.63	0.15	0.50	0.047
Upstream	3.54	5.72	N/A	N/A	N/A
Upstream	3.52	0.40	0.10	0.47	0.047
Upstream	3.53	0.40	0.10	0.47	0.047
Downstream	3.22	0.58	0.14	0.50	0.047
Downstream	3.23	0.80	0.20	0.55	0.047
Average		0.575 (Excluding Upstream Gravel Sizes)	0.14	0.50	0.05

Flow Scenario Gate Operations: Many different combinations of dam, sluiceway and headworks gate operations are used to meet water user, and Rio Grande Silvery Minnow flow requirements. Having 10-15 percent of the diverted flow pass through each sluiceway gate creates enough velocity and shear stress to nearly always eliminate sediment deposition in the Peralta Main and Belen Highline Canal headworks sluiceways. In this paper "sluicing" refers to having 10-15 percent of the diverted flow amount pass through each sluiceway gate (sluiceway outflow) and be released into the downstream river channel. Maximum sluiceway flows has been observed to maintain an open channel along the banks, especially the west (Belen Highline Canal) side. Opening every other gate has also been observed to minimize the propensity for downstream sediment bar deposition. Flow scenarios were selected to include representative peak diversions with maximum sluicing, representative minimum diversions with minimum sluicing (less than 10 percent), spring runoff peak river flows with maximum diversion, an inflow resulting in opening about ½ of the river gates, and maximum flows in each sluiceway. A summary of the above scenarios showing the magnitude of flows modeled in each scenario is shown in Table 2 followed by an example schematic of scenario #1 (Figure 5).

Table 2 Summary of modeled flow scenario gate operations.

Scenario ID	Scenario summary	Total flow upstream of the dam (cfs)	River gates flow (cfs)	Sluiceways	Sluiceway inflow (cfs)	Sluiceway diversion (cfs)	Sluiceway outflow (cfs)	Total flow downstream of the dam (cfs)
1	Maximum diversion with maximum sluicing	680	30 (Gate #16)	Peralta Main	345	300	45	130
				Belen Highline	305	250	55	
2	Minimum diversion (summer) with minimum sluicing	529	91 (Gate #16)	Peralta Main	235	220	15	124
				Belen Highline	203	185	18	
3	Typical spring runoff peak (non-drought) - all open gates	5,000	variable (all open)	Peralta Main	400	300	100	4,450
				Belen Highline	350	250	100	
4	Typical spring runoff peak (non-drought) - select open gates	2,820	1780 (10 gates at 178 each)	Peralta Main	520	300	220	2,270
				Belen Highline	520	250	270	
5	Maximum diversion - no open gates	1,565	0 (all gates closed)	Peralta Main	760	300	460	1,015
				Belen Highline	805	250	555	

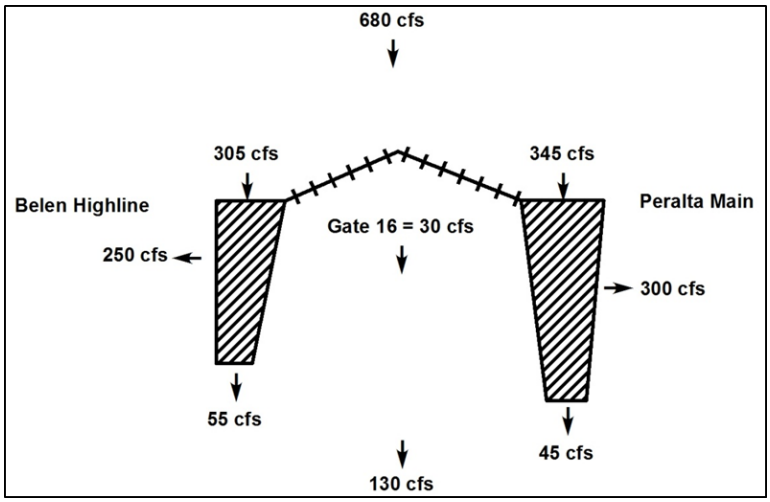

Figure 5 Schematic of scenario #1.

RESULTS AND DISCUSSION

This section compares and contrasts differences between each scenario for project topography. Also presented are sluiceway velocity and sediment incipient motion results for each scenario and the smallest sluiceway outflow volume which minimizes sediment deposition for all operations. Results and discussion for each scenario are presented first for scenarios with low likelihood, and second with high likelihood of bed change due to sediment deposition or transport. A qualitative evaluation of potential channel response to the island/attached bar lowering and channel widening project is also provided.

Potential for Deposition in Sluiceways: Flow velocity in the Peralta Main sluiceway is less than critical velocity, for median (0.6 mm) and larger sediment sizes, downstream of the third gate (P3 in Figure 2) in scenario #2, and in the Belen Highline sluiceway in front of gate #2 (B3 in Figure 2) and downstream of the fourth gate (B1 in Figure 2) for scenario #2. These results indicate a high likelihood of sediment deposition in both sluiceways when the operation has minimum summer diversions with minimum flow to pass through the sluiceway. The velocities were evaluated as being sufficient to transport sediment through the sluiceway in all other scenarios. For any diversion operation, the minimum sluiceway outflow discharge most likely to prevent sediment deposition in the Belen Highline sluiceway is 35 cfs, and 30 cfs in the Peralta Main sluiceway..

Gate Operation Effects on Potential Sediment Deposition and Erosion: This section provides results from the 2D model to evaluate the potential for sediment deposition versus erosion downstream of the dam for the proposed case where islands were removed and the channel widened (see Figures 3 and 4). The modeled water surface upstream of the diversion dam for all but scenario #3 was lower than needed to provide full diversion head. This resulted in larger velocities in the model results than actual field velocity. Therefore, this paper describes and uses model results downstream of the diversion dam for all scenarios except scenario #3. For scenario #3, all of the gates are open and upstream water surface elevations are accurate and consistent with field observations and HEC-RAS model results, and both upstream and downstream results are described. Model and incipient motion results are divided into two categories. Category 1 has a low likelihood for sediment erosion or deposition except in the immediate downstream vicinity of open gates. Category 1 includes scenario #1 and 2. Category 2 includes scenarios #3, 4, and 5 which have a high likelihood for sediment erosion or deposition. The proposed project topography results are shown and discussed for scenarios in each category with a qualitative discussion of likely channel response.

Category 1, scenarios #1 and 2 have a low likelihood of appreciable sediment deposition, due to the upstream sediment supply being low for this discharge. While there is low likelihood of erosion or deposition, if there was sediment supply from upstream tributaries this section describes potential areas change. Since scenario #1 and #2 have very similar hydraulic results, scenario #1 model results are used to represent both scenarios. The dark blue color in Figure 6 represents flow velocities which are up to the critical velocity of 0.5 ft/s for scenario #1 with the proposed channel widening downstream of the dam, and shows areas of potential sediment deposition. Zones of

potential sediment deposition are found in the first 400 ft. downstream of the dam between gates 16 and the Peralta left bank looking downstream of the left sluiceway (Figure 6). In the widened channel area there is a potential zone of deposition between about 1,000 ft. to about 1,900 ft. downstream of the dam apex, indicating a likelihood of sediment deposition which would potentially result in channel narrowing or areas where sediment would need to be excavated to maintain the channel width. Likely zones with small scour potential would be downstream of gate 16, downstream of the left sluiceway, between the right sluiceway and in the channel downstream of the right side sluiceway, and in the downstream channel center until the second bend (Figure 6).

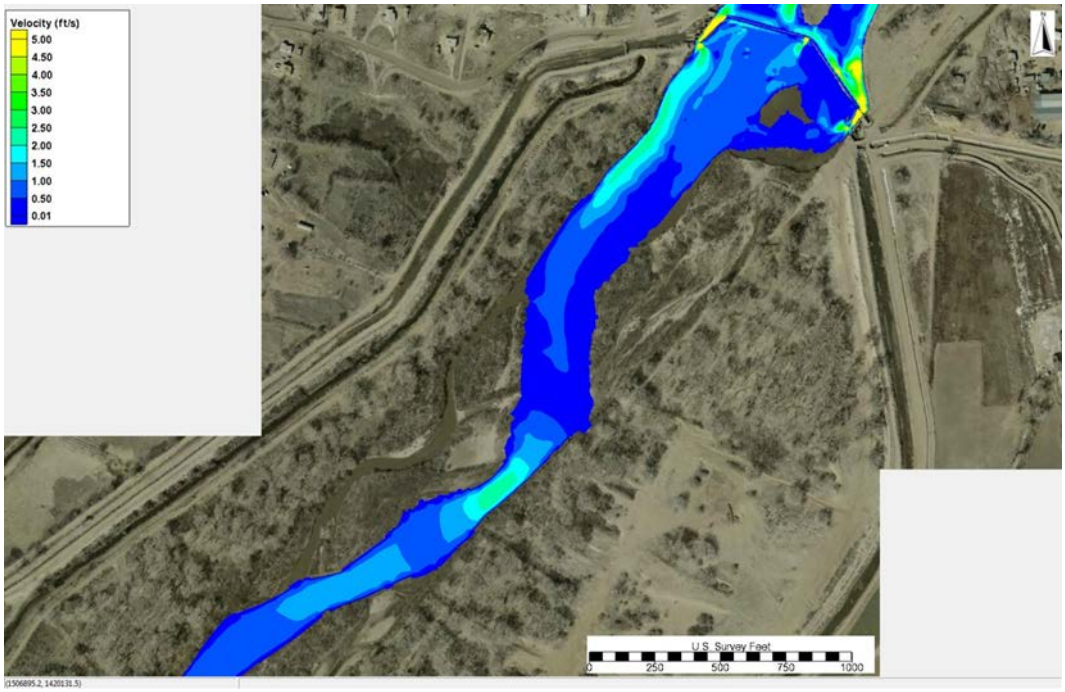

Figure 6 Proposed topography depth-averaged velocity contours for scenario #1.

Category 2 scenarios, #3, 4 and 5, each have a high likelihood of sediment deposition due to the sediment supply being relatively higher than for inflows to the diversion dam ranging from 1,565 to 5,000 cfs. Each of these scenarios has very different inflows and gate operations and results will be summarized separately. For Scenario #3, all river gates are open with 100 cfs flowing through each sluiceway; 4,450 cfs passes through the dam. Potential erosional areas would be around the upstream island (Figure 4). Flows near 4,450 cfs would provide the maximum opportunity for the widened channel to remain near the design width according to the SRH-2D model results and incipient motion criteria. The bank attached bars between 400 and 1500 ft. downstream of the Peralta Main sluiceway were lowered (Figures 3 and 4), and have velocities indicating potential for sediment deposition.

Scenario #4 has 1,780 cfs passing through 10 open river gates, and 220 cfs and 270 cfs flowing out the Peralta Main and Belen Highline sluiceways, respectively. One-to-three gates are closed between each open gate. The open gates are clearly shown in the velocity results (Figures 7 and 8). Flow velocity accelerates through the open gate contractions. Between open gates there are zones of low velocity and eddies (Figure 8). Deposition between open gates has been observed in the field. Downstream of each open gate there is high velocity with the potential for erosion. Zones of high velocity are found downstream of each sluicegate, and along the right main channel. The inundated portion of the east side bank attached lowered bar shows potential for sediment deposition. Flows near 1,780 cfs would provide opportunity for the widened channel to remain near the design width according to SRH-2D model results and incipient motion criteria. But not as much opportunity as 4,450 cfs flows in scenario #3. The bank attached bar on the left side between 400 and 1500 ft. downstream of the Peralta Main sluiceway was lowered (Figure 7 and 8) and made into two surfaces. These lowered surfaces are inundated at 1,780 cfs, and have velocities indicating potential for sediment deposition.

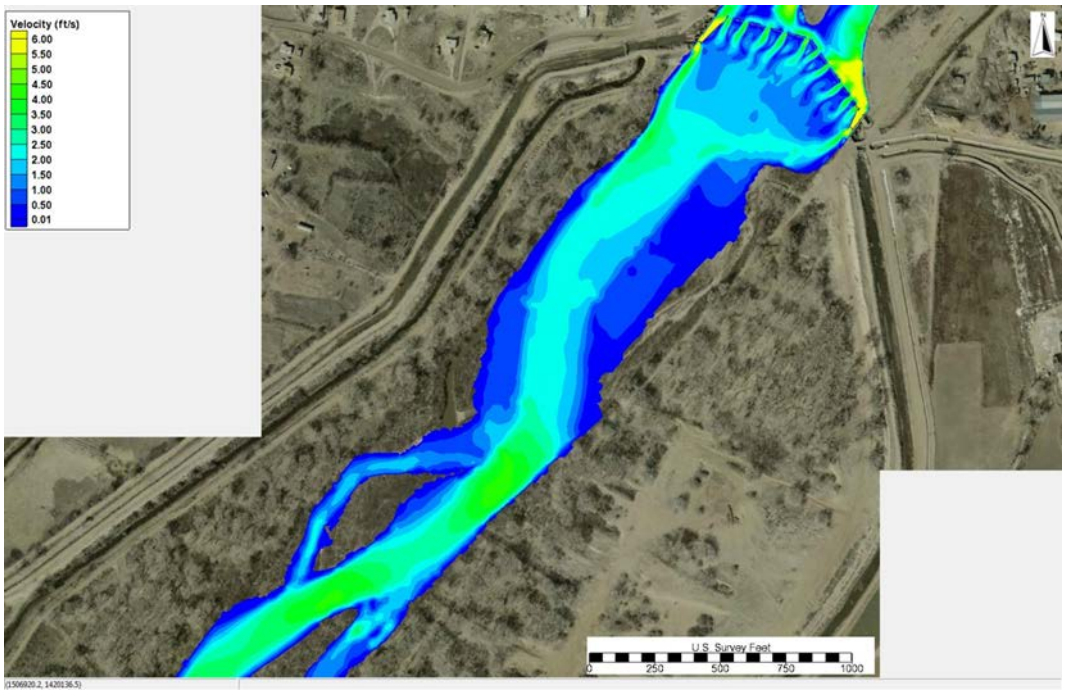

Figure 7 Project design topography depth-averaged velocity contours for scenario #4.

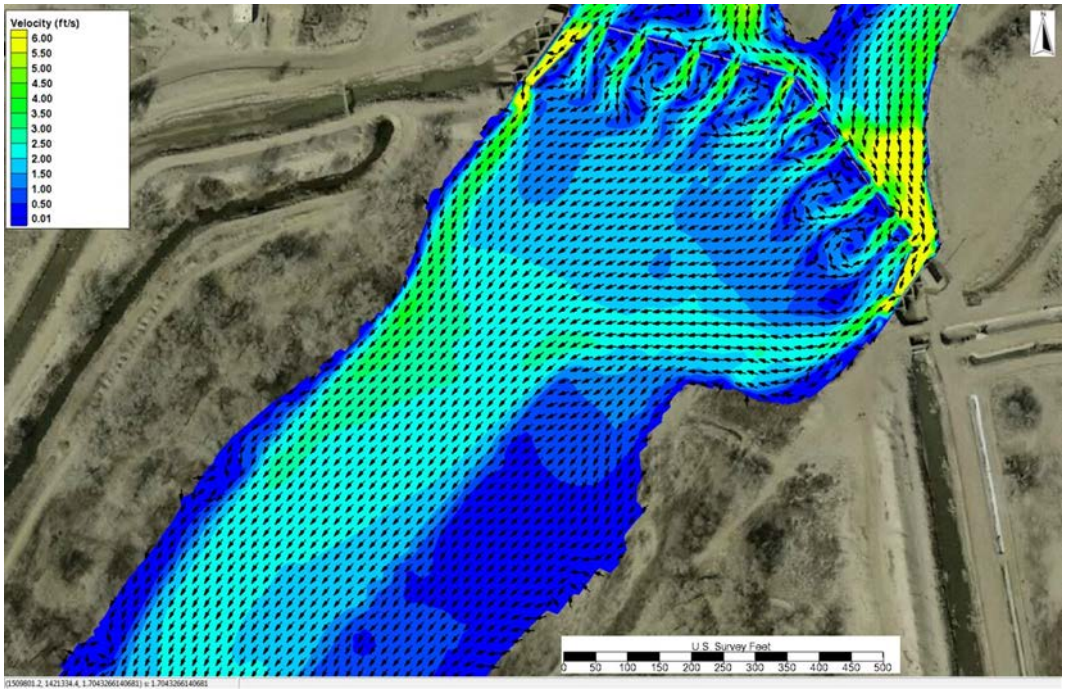

Figure 8 Project design topography depth-averaged velocity contours and vectors for scenario #4.

All river gates are closed in Scenario #5. Flow is maximized through each sluiceway in the amount of 460 cfs in the Peralta Main canal sluiceway, and 555 cfs in the Belen highline canal sluiceway. Maximum flow discharging through each sluiceway results in very high shear stress and velocity downstream of each sluiceway, especially the Belen Highline sluiceway. Downstream of the Belen Highline sluiceway the high velocity zone extends downstream about 600 ft. The majority of the zone downstream of the diversion dam between the sluiceways is depositional as a result of the formation of a slow velocity zone until the flow paths reconnect into the relatively

narrower downstream channel. Flow on the east abutment downstream of the sluiceway has the potential to cause scour extending across the east third of the distance across the channel below the dam. Scouring velocities also occur along the west bank downstream of the Belen Highline sluiceway downstream through the widened proposed topography reach. Flow in the left channel around the island shows potential for scour, while flow around the right side channel path shows potential for deposition and slight erosional tendencies.

These results are based upon the median sand sediment size of 0.6 mm requiring a velocity of 0.5 ft/s or larger to limit deposition (Table 1). Larger sediment particles could deposit in areas where velocity is between 0.5 and 1.0 ft/s, resulting in more areas of sediment deposition than described above. Results are also based upon fixed bed topography without potential bed elevation changes which would develop when considering sediment supply and sediment transport capacity.

SUMMARY AND CONCLUSIONS

A fixed bed two-dimensional hydraulic model was developed for Isleta Diversion Dam and the upstream and downstream channel. In addition a sluiceway hydraulic analysis was completed for the Belen Highline and Peralta Main canal sluiceways. Using the upstream and downstream median sand bed sediment sizes, the velocity which initiates sediment transport was estimated using the Vanoni, (1977) method. These results provide a quantitative basis for recommending gate operations to reduce sedimentation impacts.

Headworks sluiceway hydraulics and critical velocity analysis results indicate which scenario's result in sediment deposition or transportation through both headworks sluiceways. When the sluiceway outflow in the Peralta Main Canal is less than 30 cfs there is potential for sediment deposition. The Belen Highline Canal sluiceway velocity shows potential for sediment transport when sluiceway flows are 35 cfs or larger.

The SRH-2D model results and incipient motion analysis provided results to show velocity patterns and potential zones of sediment deposition or erosion for five flow scenarios ranging from 124 to 4,450 cfs river flows downstream of the diversion dam. In general maximizing flow volume in each sluiceway provides for potential erosion and high velocity flow along each bank downstream of each sluiceway and particularly along the west bank (Scenario #5). Opening every other or every third gate results in eddy currents and zones of potential deposition between gates. Operating only the sluiceways causes eddy currents near the downstream apex of the dam between sluiceways which indicates a potential for sediment deposition. The flow scenarios with river discharges equal to or greater than 1,780 cfs show potential for maintaining the widened channel. All flows inundating the lowered bank attached bars and islands showed potential for sediment deposition. Given the variable nature of Rio Grande hydrology, it is likely that the widened channel can be partially maintained with river flows, but supplemental mechanical widening may be needed to maintain the excavated hydraulic geometry.

ACKNOWLEDGEMENTS

The Albuquerque Office of the U.S. Bureau of Reclamation (Reclamation) contributed the 2012 LiDAR data of the overbank areas. Vincient Benoit and Nathan Holste assisted with topography measurements upstream of the diversion dam. Tetra Tech Inc. (Walt Kuhn, of the Tetra Tech Inc. Albuquerque, NM Office) provided cross section data, design topography for the downstream island lowering and channel widening and their HEC-RAS model. Yong Lai, of the Sedimentation and River Hydraulics group (Reclamation) provided technical support for the use of the SRH-2D model. Cody Walker of the Isleta Pueblo, and David Gensler, Kevin Lente, and Jim Russell of the Middle Rio Grande Conservancy District provided their observations of flow patterns for various historic gate operations. Jennifer Bountry of the Sedimentation and River Hydraulics group (Reclamation) provided helpful experience for project planning and reviewed this manuscript. These contributions are gratefully acknowledged.

Abstract A pulse of water was released from Morelos Dam into the dry streambed of the Colorado River in its former delta on March 23, 2014. Although small in relation to delta floods of a century ago, this was the first flow to reach the sea in nearly two decades. The pulse flow was significant in that it resulted from an international agreement, Minute 319, which allowed Colorado River water to be used for environmental restoration. Here we present a historical perspective of channel change and the results of geomorphic and sediment transport monitoring during the pulse flow between Yuma, Arizona and San Luis Rio Colorado, Sonora. This reach is known as the Limitrophe, because the river channel is the legal border between the United States and Mexico. Peak discharge of the pulse flow was 120 m^3/s at Morelos Dam, but decreased to 71 m^3/s at the southern border because of infiltration losses to the dry streambed. In contrast, flood flows in the 1980s and 1990s peaked above 600 m^3/s at the southern border, and high flows above 200 m^3/s were common. The sustained high flows in the 1980s caused widening and reworking of the river channel downstream through the delta. In the Limitrophe, flooding in 1993 from the Gila River basin dissected the 1980s flood surfaces, and smaller floods in the late 1990s incised the modern "active" channel within these higher surfaces. Field observations show that most geomorphic change during the pulse flow was confined to this pre-pulse, active channel. Relatively little bank erosion was evident, particularly in upstream reaches where vegetation is most dense, but new sandbars formed in areas of flow expansion. Farther downstream, localized bed scour and deposition ranged from 10s of centimeters to more than a meter, and fluvial dunes aggraded the bed in several locations. Measurable suspended-sediment transport occurred throughout the Limitrophe. Sediment concentrations peaked during the rising limb, and suspended sand concentrations suggest deposition in the lower 7 km of the Limitrophe as the channel gradient decreases by an order of magnitude. The pulse flow was small compared to historic floods, and flood magnitudes greater than the 2014 pulse flow are therefore necessary to significantly rework stable geomorphic surfaces or induce channel widening.

INTRODUCTION

The Colorado River delta is a completely transformed landscape. The Colorado River in much of its former delta is now an intermittent stream and includes long segments that are persistently

dry. Historically, the delta extended from a point approximately 21 km upstream from the Gila River confluence near Yuma, Arizona, downstream to the Gulf of California, and includes the closed basins of the Salton Sink in the United States and Laguna Salada in Mexico. Sykes (1937) estimated the delta covered approximately 8600 km^2. Prior to the construction of large dams and diversions, the flow of the Colorado River in its delta fluctuated annually with high flows from snowmelt in the Rocky Mountains and periodic widespread rain or rain-on-snow events in the lower basin. Discharge recorded at the Yuma stream gage exceeded 5000 m^3/s several times in the early 20^{th} century, and, occasionally, during periods of extended low flow, no water reached the estuary in the pre-dam period (Sykes, 1937). In its natural state, the Colorado River delta was characterized by shifting channels and high sand, silt, and clay loads. Meade et al. (1980) estimated that the Colorado River delivered more than 10^8 tons of sediment per year to the delta prior to significant human activity in the watershed. The completion of diversions to the Imperial and Mexicali valleys in the early 1900s initiated the period of major regulation of streamflow and sediment to the delta, which became increasingly dramatic following the construction of large dams such as Hoover Dam (1935) and Glen Canyon Dam (1963). Today, the Colorado River is normally dry throughout the year along large segments of its former delta in the United States and Mexico and essentially no sediment reaches the Gulf of California.

High flows of the 1980s and 1990s rejuvenated portions of the riparian and wetland ecosystems of the delta that had been lost during the filling of upstream reservoirs. The ecological impact of these flows created significant bi-national interest in using intentional flow releases to rehabilitate parts of the delta ecosystem (Tiegs et al., 2005; Glenn et al., 2008; Flessa et al., 2013). Following more than a decade of international negotiations, Minute 319 of the International Boundary and Water Commission (IBWC) established the political foundation for one experimental flow release. The release of intentional flows into the delta is extremely controversial in a fully utilized river system faced with protracted drought. Thus, the science that underlies this pulse flow and the monitoring of its consequences is crucial to deciding if future environmental flows will occur. Here we present an overview of historical geomorphic change and effects of the spring 2014 pulse flow release in the Limitrophe. The Limitrophe, or border, reach of the river lies between Morelos Dam, the last dam on the river, and the Southern International Boundary (SIB) (Fig. 1). The Limitrophe is a critical segment of the Colorado River in the delta because it is the only segment that is a shared border of the U.S. and Mexico, it is relatively rich in native riparian and marsh habitat in its upstream half (Glenn et al., 2008), and it is almost always dry in its downstream half. This zone was potentially an area of significant loss of flow into the bed and ground water system, and the losses here may greatly decrease the magnitude of flows in Mexico where the potential for rehabilitation is greater.

POST-DAM HYDROLOGY OF THE COLORADO RIVER DELTA The construction of Hoover and Glen Canyon Dams, and the subsequent filling of the reservoirs they impound, resulted in progressively decreasing flows and drastically reduced sediment loads to the lower Colorado River. Stream gaging at SIB serves as a measure of flows to the Mexican portion of the delta from 1950 to the present, and represents the minimum discharge in the Limitrophe because of infiltration losses to the streambed in the downstream half of the Limitrophe. We present the following hydrologic analysis based solely on this stream gage. From 1950 to 1963, Hoover Dam modulated flood flows from the upper Colorado River basin, but the river often flowed to the

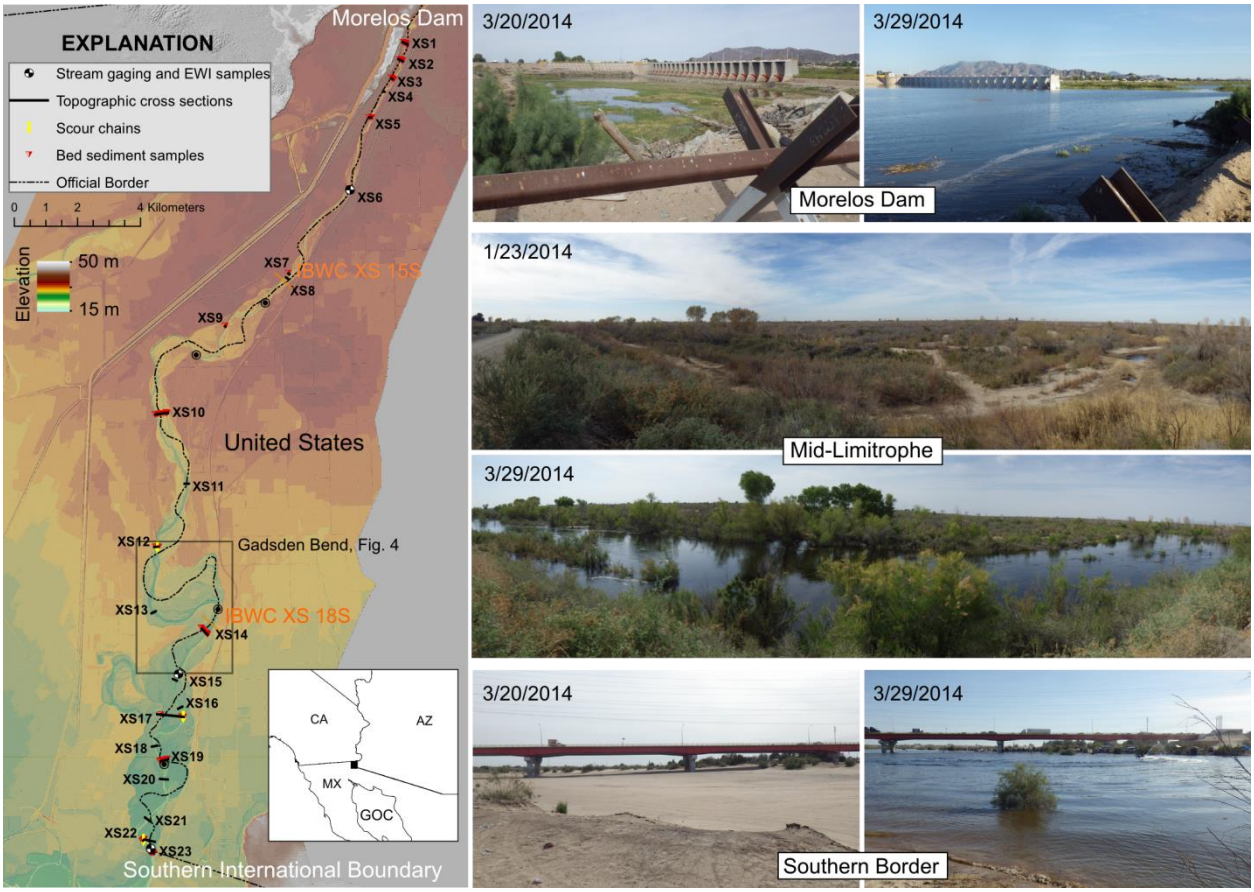

Figure 1 The Limitrophe reach study area (left); inset map shows the location of the Limitrophe as a black square; GOC: Gulf of California. Photos before and during the pulse flow (right).

Gulf of California. During that time the peak daily discharge was 581 m^3/s, the average daily discharge was 93 m^3/s, and zero flow was recorded on only 14 days. From 1963 to 1981, the filling of Lake Powell upstream from Glen Canyon Dam and other reservoirs in the upper basin greatly reduced flows; the peak daily discharge was 268 m^3/s, the average daily discharge was 15 m^3/s, and no flow was recorded 18 percent of the time.

POST-DAM DELTA FLOODS In the 1980s, successive years of extremely high snowmelt runoff from the upper Colorado River basin resulted in a period of high flow releases from Glen Canyon and Hoover Dams (Fig. 2). As a result, flood flows in the delta region were the greatest since the completion of Hoover Dam and caused considerable channel adjustment (McCleary, 1986; Tiegs and Pohl, 2005). Peak daily discharge at SIB reached 934 m^3/s on August 20, 1983, andremained above 500 m^3/s for more than 250 consecutive days. From 1983 to 1987, mean daily discharge remained above 150 m^3/s for nearly four consecutive years. Since that time, flows with magnitudes of 150 m^3/s have occurred less than 3% of the time (Fig. 2). Following the 1980s floods, periods of zero discharge at SIB became increasingly common. From 1989 to 1992, there was no flow recorded at SIB 92% of the time. This dry period was punctuated by flood flows from the Gila River in 1993 that peaked at 646 m^3/s on March 7th and 8th (Fig. 2). The 1993 flooding was caused by a series of winter storms that produced widespread rain and

rain-on- snow in the upper Gila River watershed (House and Hirschboeck, 1997). Discharge at SIB remained relatively high throughout much of 1993 because of continued upstream water releases from reservoirs on the Gila River. Following extended periods of zero discharge in the middle 1990s, a series of moderately high flows occurred in the late 1990s. These high flows peaked above 200 m^3/s and followed releases from Hoover Dam that resulted in over-deliveries to Mexico. Progressively decreasing flows have been recorded at SIB since 2000 (Fig. 2).

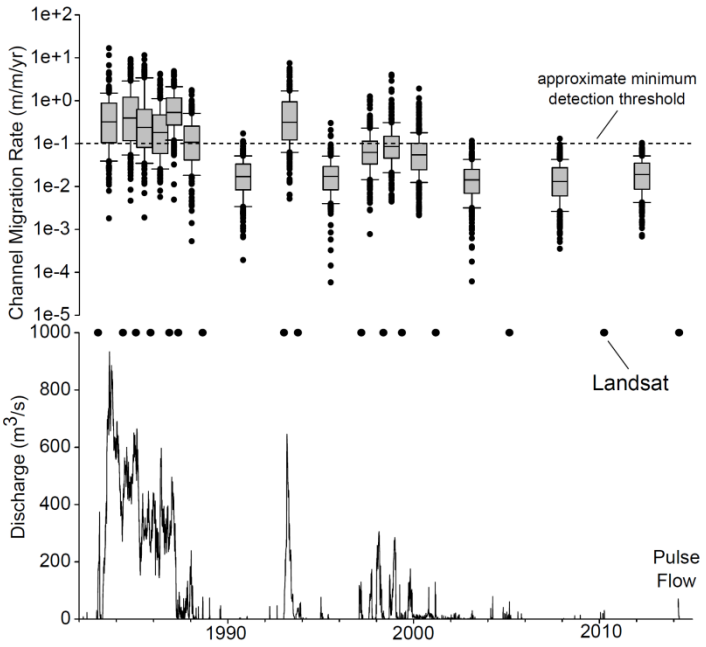

Figure 2 Box plots (top) showing channel migration rates of the Colorado River in the 50 km reach downstream from Morelos Dam; rates are bracketed by the Landsat imagery dates shown. Boxes represent the 25th, 50th, and 75th percentiles; whiskers represent the 5th and 95th percentiles, with outliers as dots. Daily mean discharge (bottom) recorded at SIB, 1980 to present.

THE PULSE FLOW The periodic floods of the 1980s and 1990s created bare sediment surfaces for native seedling recruitment, and made water more available to maturing trees during subsequent periods of low or no flow. But since 2000, drought conditions in much of the Colorado River basin have greatly reduced flows past Morelos Dam. Typically, the upstream half of the Limitrophe has some baseflow because of a higher water table and irrigation return flows. Periods of no flow at SIB have occurred more than 60% of the time since 2000, and the channel bed is usually dry in most of the downstream half of the Limitrophe where the groundwater table is meters below the streambed. This contributed to losses of native riparian vegetation, such as cottonwood and willow, which had established in the prior two decades. The maximum daily discharge measured at SIB since 2000 was 129 m^3/s (on March 1st, 2001). The last measured discharge at SIB prior to the pulse flow peaked at 30.5 m^3/s (in April, 2010) following several winter and spring storms in the lower basin (Ramírez-Hernández et al., 2013).

On March 23rd, 2014, an experimental pulse of water bypassed Morelos Dam and flowed into the dry river channel. The maximum peak discharge released past Morelos Dam was 120 m^3/s on March 29th, which decreased to 71 m^3/s at SIB (Fig. 2) because of infiltration losses to the dry

streambed (discussed further in the results). The peak release occurred during a three-day period, and the flow was reduced to zero during a period of approximately three weeks after which flow from Morelos Dam ceased. Additional water was supplied to the river from irrigation canals downstream from SIB in order to supplement the losing flow of the river. The pulse flow reached the Gulf of California on May 15th, by which time the discharge was approximately 0.6 m^3/s.

GEOMORPHOLOGY In the Limitrophe, the Colorado River follows approximately the same path as reported in some of the earliest accounts of river navigation (Sykes, 1937). The river delta was essentially natural until 1900, when large-scale diversions and levees began to be constructed. The period 1900-1930 saw the river channel avulse several times in the delta, with most of the sediment load deposited internally downstream from the Limitrophe, but not flowing to the sea (Sykes, 1937). Closure of Hoover Dam muted flood peaks and greatly decreased the sediment load. Nevertheless, aerial photographs from 1949 show the Colorado River as a dynamic meandering channel with many active bars and bounded by floodplains and terraces that show evidence of recent occupation (Fig. 3). Olmstead and others (1973) report that the Colorado River incised from 3-6 meters from north of Yuma to SIB following the construction of Hoover Dam, but they provide no supporting data. Cross-sections surveyed by the IBWC, spaced approximately 2-3 km apart in the Limitrophe, show 2 to 3 m of bed incision during high flows in the early 1940s. Following this degradation, the bed remained vertically stable or aggraded slightly until the early 1980s (IBWC data, unpublished). There was significant channel widening in the 1980s (Tiegs and Pohl, 2005), and bed elevations in 1989 remained similar to those in 1982, but were still lower than those observed in the early 1940s (Tetra Tech, 2004; NCD/FPC, 2006). The flood of 1993 reworked much of the river corridor that was inundated in the 1980s, and dissected finer channel threads into the 1980s deposits (Tiegs and Pohl, 2005). By 1999, vegetation encroachment, dominated by tamarisk, had created a narrower channel (Tiegs and Pohl, 2005; Tiegs et al., 2005), and the thalweg of most of the IBWC cross-sections reached their minimum elevations (Tetra Tech, 2004; NCD/FPC, 2006).

THE MODERN COLORADO RIVER IN THE LIMITROPHE The Limitrophe can be divided into two major geomorphic segments that have a gradational boundary. The river channel in the upstream segment is more confined within levees, and irrigation return flow results in a wetted channel with dense bank vegetation. In the downstream segment, the river channel is dry, bank vegetation is less dense, and the channel is less confined by levees (Fig. 1). The width of the alluvial corridor between the levees ranges from approximately 0.5 km immediately downstream from Morelos Dam, to more than 4 km in the downstream part of the Limitrophe. The average channel gradient is 0.00022 m/m along the modern thalweg, but reach-scale (5-10 km) gradient ranges from 0.000044 to 0.00040. Sediments range in grain size from silt and clay to gravel, with the active channel composed dominantly of fine to medium sand and finer sediments on higher abandoned surfaces.

METHODS

In this paper, we present results from two related elements to characterize the geomorphic response of the Colorado River in the Limitrophe to the 2014 pulse flow. First, we build on the analysis of historic channel changes from 1983 to 2014 that shaped the configuration of the pre-pulse channel and set the boundary conditions for surface water flow and sediment transport

during the pulse. Second, we report results from geomorphologic and sediment transport monitoring of the pulse flow.

CHANGES IN CHANNEL MORPHOLOGY, 1983-2014 We used 30 m Landsat imagery to map changes in the channel thalweg or centerline using 16 image sets that bracketed major flow events. We purposefully chose periods of relatively low flow to more accurately digitize the channel thalweg. During the periods of sustained high discharge in the 1980s, flows were often too high to define the thalweg, and we used the channel centerline instead. After digitizing the channel thalweg/centerline, we used the Planform Statistics Toolbox from the National Center for Earth Surface Dynamics (Lauer, 2006) to calculate channel migration in 100-300 m segments. The exact length of individual segments depended on the degree of channel sinuosity, and thus point spacing, in the digitizing process. In order to account for different segment distances and time intervals, we report the results in meters of lateral change per meter of streamwise distance per year. We approximate the error in thalweg location as plus or minus 30 m, or one pixel width, as a conservative estimate of a minimum detection threshold. Our analysis builds on that of Tiegs and Pohl (2005), extending it through 2014, and establishes the magnitude of those flows that are sufficient to cause significant lateral channel migration.

We also developed a geomorphic base map of portions of the Limitrophe reach to better understand the spatial and temporal evolution of geomorphic change. We used high-resolution aerial photography and a 1-m bare earth lidar digital elevation model acquired from an airborne scanner in March 2014 prior to the pulse flow. Aerial photography dating back to 1949 was available for the entire Limitrophe reach (earthexplorer.usgs.gov). Imagery from 1949 and 1963 is sub-meter resolution, imagery from 1976, 1981, and 1989 has a resolution ranging from 5 to 6 m per pixel, and data sets from 1992 to present (1992, 1996, 2003, 2007, and 2013) are 1-m resolution. These aerial photo dates include images of the river corridor prior to construction of Glen Canyon Dam, which caused major reductions in flow as discussed above. These photo dates also bracket the major floods of the 1980s and 1990s, allowing for documentation of channel change in response to these events. In addition to these aerial photos, we compared historic IBWC cross-sections to the pre-pulse flow lidar to document changes since 1999, and to provide a quantification of changes in bed elevation. Here we present data for two IBWC cross-sections that we could most reliably match to the lidar data (Fig 1).

GEOMORPHOLOGY AND SEDIMENT TRANSPORT DURING THE PULSE FLOW We used repeat cross-sections, scour chains, and suspended sediment transport measurements at multiple locations to document the geomorphic response to the pulse flow. We established 23 cross-sections within the Limitrophe reach (Fig. 1) to document changes in bed elevation and installed scour chains at three of these cross-sections (12, 17, and 22, Fig. 1) to analyze scour and fill. We spaced cross-sections 1 to 4 km apart and focused on areas likely to be inundated by the flood. Cross-sections were more concentrated immediately downstream from Morelos Dam, and in the dry reach in the downstream portion of the Limitrophe (Fig. 1). We collected 3 to 15 sediment samples on representative surfaces at 14 of the cross-sections before and after the pulse flow. Lidar data were obtained for the entire Colorado River delta in March and August 2014, and will be used to provide a broader spatial picture of channel change resulting from the pulse flow (as of the time of writing, the second lidar data set was still being processed). Suspended sediment measurements were made at three locations in the Limitrophe to provide a record of

sand and silt and clay concentrations. Daily equal width increment (EWI) samples were collected on six occasions at three sites during the period of peak discharge of the pulse flow. Here we report results from the two downstream sites located near cross section 15 (Colorado River near Gadsden, Arizona) and at SIB (Colorado River at the Southern International Boundary) (Fig. 1).

RESULTS AND DISCUSSION

CHANGES IN CHANNEL MORPHOLOGY, 1983-2014 Channel migration rates during the three decades since 1983 were greatest during the large floods of the 1980s. Landsat imagery bracketing individual hydrograph peaks during this time shows that between 50 and 75% of the channel had migration rates above the minimum detection threshold, and as much as 25% of the river channel migrated at rates exceeding 1 m/m/yr (Fig. 2). Channel change was particularly pronounced in the downstream portion of the Limitrophe, and substantial portions of higher pre-dam terraces eroded 500 to 1000 m laterally, effectively increasing the size of the lower elevation channel (Fig. 3). There was little channel activity in the late 1980s and early 1990s during a period of very little flow (Fig. 2). The Gila River floods of 1993 caused a similar proportion of the channel to migrate as during floods in the 1980s (Fig. 2). Yet most geomorphic change was confined to the part of the channel affected by the 1980s floods, rather than eroding older and higher terraces (Fig. 3). The 1993 flood dissected much of the 1980s flood surfaces, resulting in a braided appearance on many of these surfaces (Tiegs and Pohl, 2005). Measureable channel migration occurred along approximately 25% of the channel for three periods analyzed during moderately high flows in the late 1990s and early 2000s (Fig. 2). Channel migration rates were 2-10 times less than during the larger 1980s and 1993 floods, and confined to a narrower zone in the river corridor. No measureable channel migration, within the resolution of the Landsat data, has occurred since 2001 (Fig. 2).

Our analysis of aerial photography and the historic IBWC cross-sections suggest that bed incision occurred during high flows in the late 1990s that peaked above 200 m^3/s. While the exact positioning of cross-sections has changed over time, decreasing confidence in smaller scale changes, it is clear that the modern cross-sections derived from lidar are similar to the form measured in 1999 (Fig. 4). The 1980s floods caused significant channel change between 1982 and 1989, but relatively little change in bed elevation (Fig. 4; Tetra Tech, 2004; NCD/FPC 2006). By 1999, the thalweg of the channel had incised below the 1989 thalweg, and the 2014 lidar indicates that the channel configuration is very similar to that observed in 1999. Prior to the 1980s floods, the IBWC data suggest that the most significant channel changes occurred in the early 1940s when there was roughly 2 and 3 m of bed degradation (IBWC unpublished data). The resulting geomorphology of the river corridor in the Limitrophe thus benches down from higher terraces that were active in the pre-dam period, to intermediate terraces representing portions of the active channel and floodplain in 1949 that were largely stable by 1963, and finally to more recent surfaces of the 1980s and 1990s (Fig. 3). Aerial photos and lidar suggest that, in the downstream part of the Limitrophe, the floods of the early 1980s deposited a higher alluvial surface (Fig. 3), and smaller flood peaks in the late 1980s formed an inset channel within this surface (Fig. 3). The 1993 flood reworked this lower 1980s surface considerably, but also caused a more defined thalweg to become incised. The floods in the late 1990s mostly modified this inset channel, which became further incised, and forms the modern "active" channel (Fig. 3). The bed of this inset active channel is 2 to 3 m below those surfaces reworked in 1993, and has a

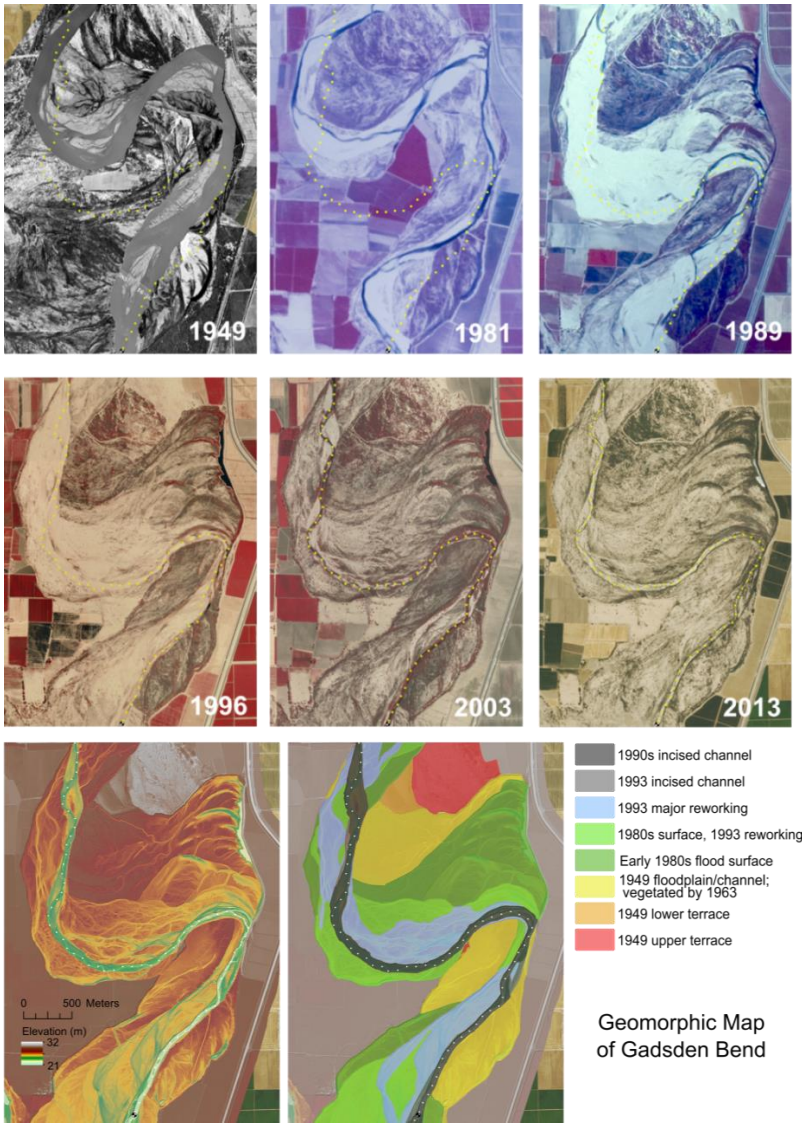

Figure 3 Aerial photos showing geomorphic change for six years from 1949 to 2013; yellow dots indicate modern thalweg. Pre-pulse flow lidar (bottom left) and geomorphic surfaces (bottom center), showing modern thalweg in modern "active" channel incised in the late 1990s.

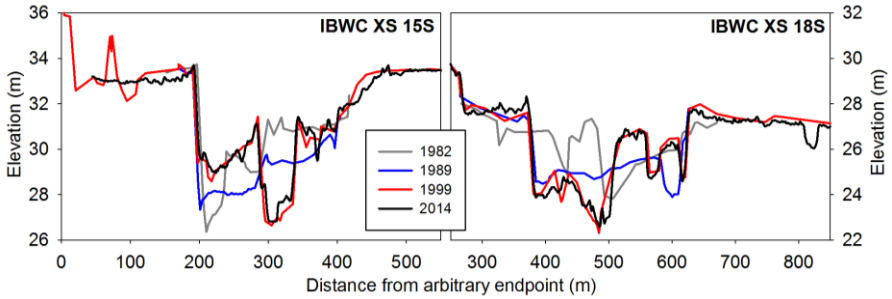

Figure 4 Historic cross-section changes at two locations shown in Figure 1 in the Limitrophe from 1982 to present. 1982, 1989, and 1999 surveys from the U.S. IBWC (data from TetraTech, 2004 and provided by NCD/FPC, 2006), and 2014 data from pre-pulse flow lidar.

typical width of 50-200 m in the Limitrophe. This incised part of the channel contained the majority of the pulse flow, but it did inundate higher surfaces with shallow, low-velocity flow.

GEOMORPHOLOGY AND SEDIMENT TRANSPORT DURING THE PULSE FLOW

The hydrograph of daily flow from Morelos Dam shows a 3-day period of maximum releases, a second discharge spike three days after the peak, and several other fluctuations during the falling limb (Fig. 5). Attributes of the hydrograph observed in the Morelos Dam releases are preserved downstream, but discharge decreased by 30 to 40% because of flood attenuation and, primarily, by infiltration losses to the dry streambed. Further, because of increased groundwater levels during the preceding week, the second peak was of similar magnitude to the first peak in the downstream reaches that were initially dry. The pulse flow tended to inundate a wider area upstream, resulting from a combination of higher discharge upstream and greater channel roughness from dense bank vegetation (Fig. 6).

Suspended sediment concentrations were somewhat greater at the beginning of the pulse and decreased over time, and there is evidence of discharge-concentration hysteresis as measured at our two sampling locations in the downstream part of the Limitrophe (Fig. 5). The decrease in sand concentration at SIB during the pulse may coincide with the formation of dunes that increased drag, because both the grain size and concentration of suspended sand decreased as flow increased. Alternatively, suspended sand coarsened slightly with discharge at our measurement site 7 km upstream (near Gadsden). Sand concentrations were two to three times greater at this upstream site, but silt and clay concentrations were similar between the two sites. Thus, silt and clay likely behaved as wash load and moved downstream to Mexico, whereas sand deposition is likely to have occurred in the downstream 7 km of the reach. Channel gradient is an order of magnitude less between the Gadsden gage and SIB, compared to the reach immediately upstream, and may be a factor in decreasing downstream sand concentrations.

Geomorphic change in response to the pulse flow was limited to the incised active channel that formed during the progressively decreasing flows of the late 1990s and early 2000s. Cross-sections show that the pulse flow inundated most areas to an elevation equal to or slightly greater than the bank top elevation of the previously incised active channel (Fig. 5). In the upstream part of the Limitrophe, thick bank vegetation focused channel change on the narrow, ~20 to 50 m wide, part of the channel that was within, or immediately adjacent to, the wetted portion of the pre-pulse channel. There was little evidence of bank erosion, but sandbars locally buried vegetation and the main channel bed was reworked (Fig. 6, top photo). Because of the negligible upstream sediment contributions and the confined nature of the active channel, we expected that bed incision would occur in these upstream reaches (XS1-XS6, Fig. 1). Instead, our repeat surveys show little evidence of bed incision in these reaches, and, in fact, slight (~0.25 m) aggradation at several cross-sections. A potential sediment source immediately downstream of Morelos Dam was the erosion of dredged material composed of sand and gravel along the Mexican side of the river corridor, but outside of the primary active channel. Much of the channel bed that had been composed of sand overlain by finer sediments bound by an organic mud was composed of sand and gravels following the pulse. Sandbars formed in zones of flow expansion, and the bed of the river developed pool-riffle topography in several locations. Riffles were characterized by coarser bed material and active bed load transport at baseflow discharges (~1-2 m^3/s) following the pulse flow.

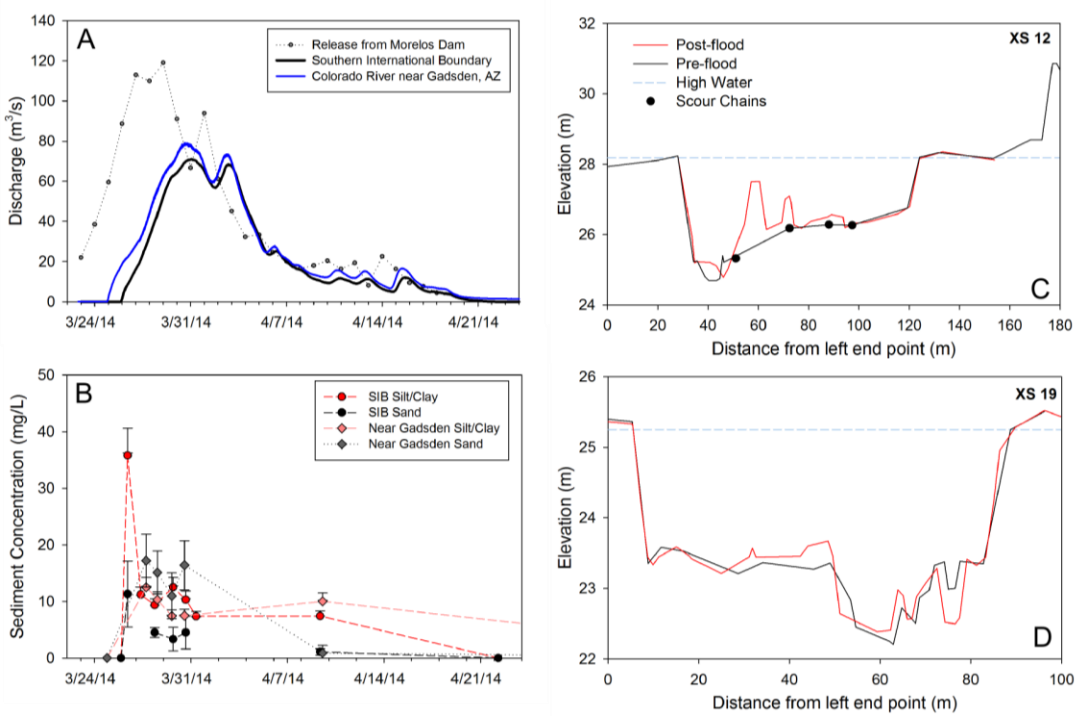

Figure 5 Hydrograph of the pulse flow released at Morelos Dam and measured near Gadsden, Arizona and at SIB (A). Measured sediment concentrations at the Gadsden and SIB gages (B). Two example cross-sections showing topographic change during the pulse flow (C and D).

Downstream where the channel widens, areas of localized bed scour and deposition ranged from tenths of meters to more than a meter and fluvial dunes provided evidence of widespread bed mobilization (Figs. 5 and 6). In the middle portion of the Limitrophe, the main thalweg usually has some baseflow that has allowed dense riparian vegetation to flourish, which protected the stream banks from erosion during the pulse flow. However, there are also remnants of the old 1990s channel that are dry and barren of vegetation. These open sand areas (tens of meters by hundreds of meters) were zones of active dune transport despite relatively shallow flow. The dunes had wavelengths of order 5-15 m, and amplitudes of 0.2 to 0.4 m. Alternatively, the wetted part of the channel in the middle Limitrophe generally showed bedforms associated with topographic steering in a more confined and sinuous channel. Five scour chains placed across the active channel in the mid-Limitrophe show no evidence of bed scour, but as much as a meter of deposition (XS-12, Fig. 5). Immediately upstream from the scour chains there was obvious bed scour and the repeat cross-section shows areas of erosion and deposition in the thalweg.

In the farthest downstream section of the Limitrophe, where the channel was dry and the channel bed was largely devoid of vegetation, evidence of dune migration was obvious throughout the reach. Localized lobate forms (1-10 m) and larger-scale dune fields (>100 m) were common in many places (Fig. 6). Cross-sections in this reach show evidence of both scour and deposition (XS-19, Fig. 5), with little change in grain size. Of our scour chains, and those of our Mexican colleagues, only two locations show evidence of significant scour (>0.1 m) prior to deposition, whereas most show simply scour or deposition. Scour chains at our site just upstream of SIB did show 0.05-0.15 m of scour followed by up to 0.3 m of deposition. Dunes are clearly visible from

Figure 6 Landsat image from 3/31/2014 during the peak of the pulse flow and examples of sediment deposition and bed forms because of the pulse flow. Backpack (circled), 2 m rod in foreground, and person (circled) for scale. Width of channel is approximately 300 m in the Worldview panchromatic image at right.

aerial photos at this site during the waning stage of the pulse flow (Fig. 5). As stated above, the lower 7 km of the Limitrophe was likely a depositional reach, and the short duration of the pulse likely limited downstream transport distances. Any sediment transported past the border must have been deposited on the channel bed far upstream from the estuary as flow rapidly decreased.

Sediment transport and geomorphic change in the Limitrophe during the pulse flow was concentrated in the recent active channel where flow depths were several meters. Higher surfaces were only marginally inundated, and there was no noticeable geomorphic change. Thus, these surfaces served as a pseudo-floodplain for flows similar to the 2014 pulse flow, which flowed through a channel roughly sized to convey that discharge. Ongoing studies will provide quantification of sediment concentrations in the upstream part of the Limitrophe measured at XS-6 (Fig. 1), and allow us to construct sediment budgets between the three gaging stations. We also anticipate that our future analysis of repeat lidar measurements will provide a more spatially robust link between the flux-based sediment budgets and morphologic change, and document the fate of sediment transported to reaches farther downstream in Mexico.

CONCLUSIONS

The Colorado River in its delta is now an intermittent sand-bedded stream for much of its course. Decreasing peak flows during the last two decades shaped the active channel in the Limitrophe reach, and the active channel is sized to convey flows of roughly 100 m^3/s. Terraces formed during the 1980s floods and dissected by the 1993 flood served as a pseudo-floodplain during the 2014 pulse flow. Geomorphic change and sediment redistribution during the pulse flow was limited to reworking of the channel bed and topographic changes of order 1 m or less within the active channel. Channel widening or widespread scouring or burial of vegetation that may affect

native vegetation recruitment is only likely to occur with higher discharges. This presents a dilemma for future planning of environmental flows to the delta, because higher river flows correspond to a greater cost in terms of volume of water lost to the subsurface and may cause further channel incision. Furthermore, long-term restoration outcomes will also be contingent on larger floods that will occur periodically from widespread and persistent precipitation in the Gila River basin, and monitoring strategies should consider these unplanned floods.

INTRODUCTION

Understanding the basin-scale geomorphology and dominant sediment transport processes active in any river system is an important first step when evaluating the potential impacts of large civil works projects. This paper focuses on the study of the Mouse/Souris River watershed in north-central North Dakota, conducted as part of the Mouse River Enhanced Flood Protection Plan. The work was conducted following the Mouse/Souris River flood of record in 2011 when the peak flow was more than five times the estimated 100-year peak flow for which existing channels and levees (constructed by USACE in the 1970's and 1990's) had been designed. In response to this catastrophic event, a plan to reduce the risk of flooding and flood-related damages was developed, including 21.6 miles of levees, 2.8 miles of floodwalls, two high-flow diversions, several transportation closure structures, and stormwater pump stations, among other measures.

This paper presents a framework for understanding how sediment is mobilized through the watershed and riverine system that is based on relating the geologic history of the basin to key present-day watershed (e.g., topography, soils, land use) and river (e.g., channel cross section, stream slope, planform) characteristics. The present day characteristics of the Mouse/Souris River are highly constrained by the area's glacial history, resulting in distinct river segments delineated by major geomorphologic features. Stream classification using basin-scale data affords a foundational understanding of the natural tendencies of the river that is essential in order to adequately evaluate the potential impacts on the morphodynamics (erosion and/or sedimentation) of the Mouse/Souris River associated with the proposed project.

GEOLOGIC SETTING

The configuration of today's Mouse/Souris River Basin is the result of the area's glacial history. The basin's origins can be traced to a catastrophic outburst of glacial melt water in Canada about 11,000 years ago (Lord (1991), Kehew and Teller (1994)). Floodwaters from this outburst carved what are now known as the Des Lacs and Mouse/Souris River valleys (Figure 1, Kehew and Clayton (1983)). The meltwater eventually flowed into glacial Lake Souris, which extended from Verendrye to the Canadian border, creating two distinct Mouse/Souris River reaches in North Dakota (upstream and downstream of Verendrye), each with its own behavior and structure.

Geologic events shaped not only the landscape but the paths the Mouse/Souris River now takes, affecting in particular its ability to convey water and sediment during extreme flood events. Signatures of the ancient glacial flood, such as shape and size of the Des Lacs and Mouse/Souris

River valleys and the lack of a confining valley downstream of Verendrye, still influence certain aspects of water and sediment movement (Figure 2). Of note for this study is that the highest potential for erosion will continue to exist in the river reaches upstream of Verendrye, while the downstream reaches will be more likely to experience sediment deposition in future floods.

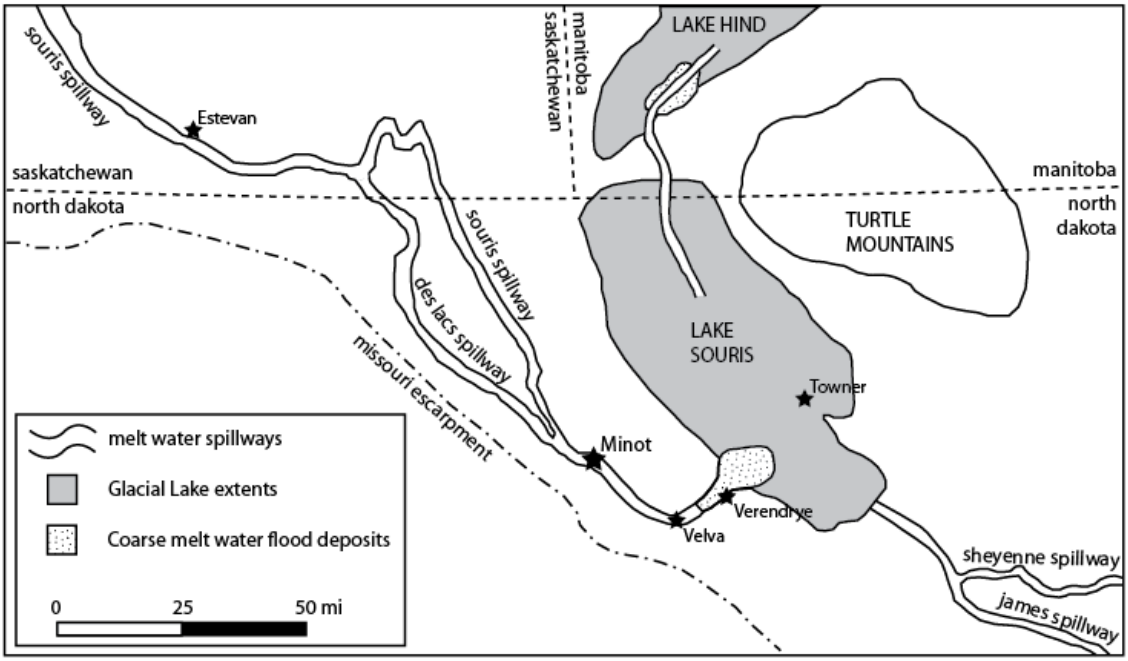

Figure 1 Schematic map of significant glacial landforms in the Mouse/Souris River watershed, after Kehew and Clayton (1983).

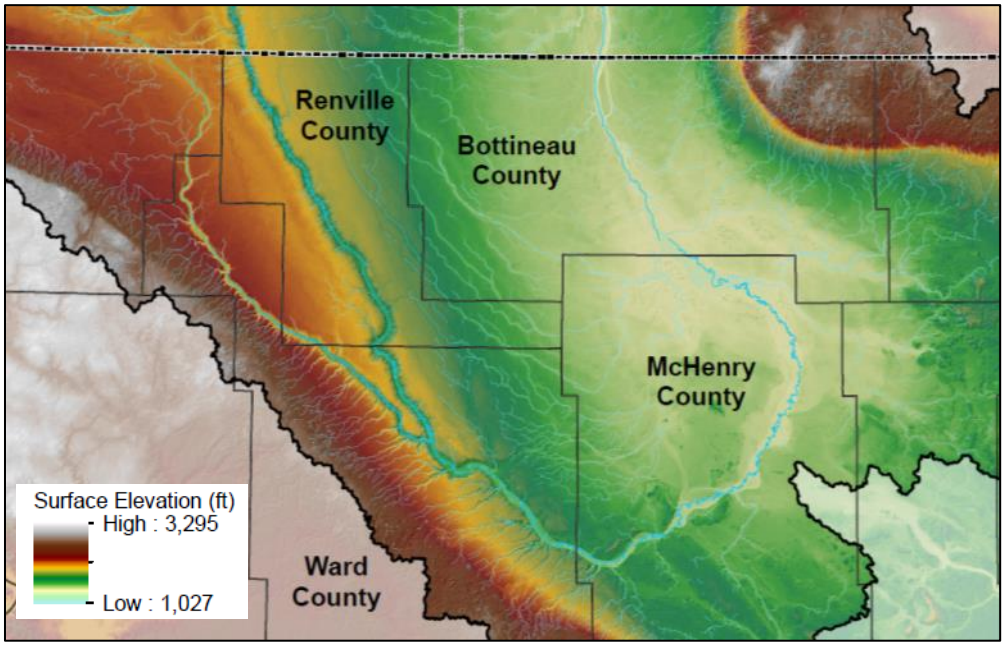

Figure 2 Mouse/Souris River watershed topography.

VALLEY AND STREAM CHARACTERISTICS AND CLASSIFICATION

The overall goal of stream classification is to organize and describe stream reaches based on shared attributes. The methods, metrics, and spatial and temporal scales used in stream classification systems vary widely, but such systems frequently use common characteristics such as river width, valley width, slope, sinuosity, and amplitude or radius of curvature (see for example Leopold et al. (1964), Montgomery and Buffington (1993), and Rosgen and Silvey (1996)). Grouping stream reaches based on quantitative characteristics presents the ability to look for patterns, identify commonalities and differences, and make inferences about the future behavior of the stream system. The emphasis of the analysis presented here is on developing an understanding of the processes at work in the Mouse River and its history rather than to take a point-in-time snapshot of the river under current conditions. For this study, streams were classified according to features of both the valley and the river channel.

Characteristics used in stream classification

- Valley width
- Valley slope (in direction of river flow)
- Valley sediment types (represented by % sand)
- Land use
- Channel width
- Channel cross-sectional area
- Channel slope (in direction of river flow)
- Channel length per unit valley length (sinuosity)
- Channel planform

The project team classified the Mouse/Souris River into nine reaches that vary in length and have been grouped according to similar valley, channel, and sediment characteristics (Figure 3). The nine reaches defined for the Mouse/Souris River can be broadly considered as three separate groups: upstream of Burlington (reaches G-H-I), between Burlington and Verendrye (reaches D-E-F), and downstream of Verendrye (reaches A-B-C). This grouping corresponds to the major geologic shifts along the Mouse/Souris River: the confluence with the Des Lacs River at Burlington and the entrance to the bed of glacial Lake Souris at Verendrye.

The reaches of the Mouse/Souris River between Burlington and Verendrye (reaches D-E-F) received the most attention in the study because 1) they are the areas with the steepest river gradient and contain soils most likely to be mobilized; 2) have been most affected by changes in the last several decades; and 3) will be the most directly affected by the proposed project. This section of the river is the most susceptible to erosion.

The reaches downstream of Verendrye (reaches A-B-C) may also be influenced by the proposed project because they lie downstream of the project features and receive sediment carried from upstream reaches. These reaches represent the portions of the river that have 1) the lowest river gradients; 2) soils typically finer than those in upstream reaches; 3) the most open water and wetlands; and 4) the lowest channel banks. This section of the river is the most likely to experience sediment deposition.

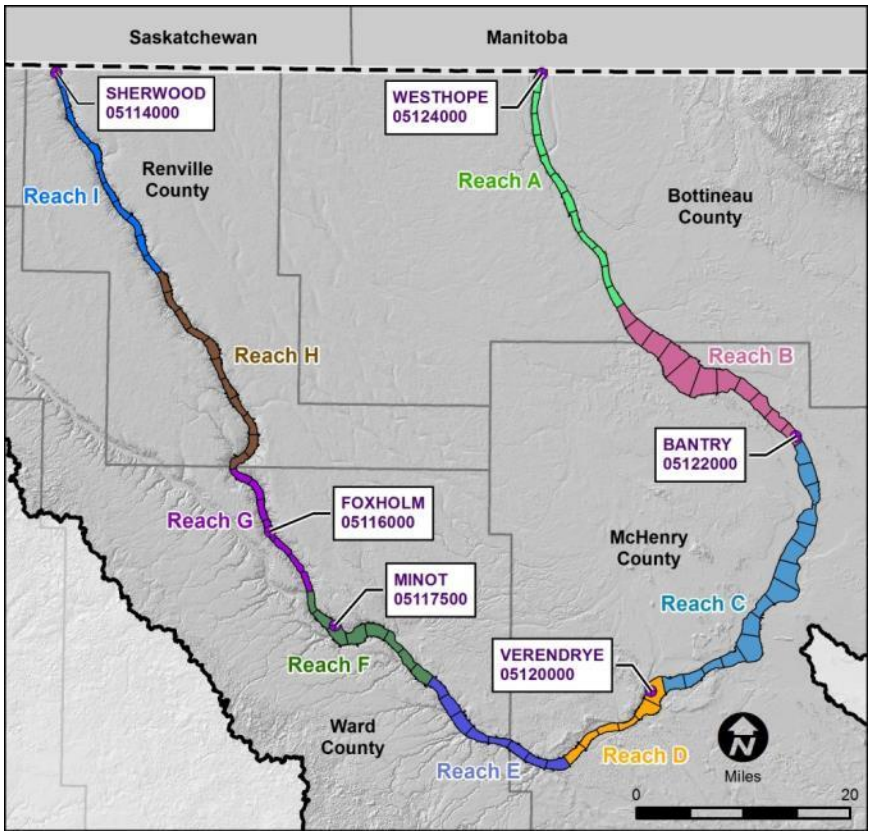

Figure 3 Mouse/Souris River valley geomorphic reaches.

The reaches upstream of Burlington (reaches G-H-I) will be less affected by the project partly because Lake Darling controls sediment movement in the system.

CHANGES IN RIVER SHAPE OVER TIME

The Mouse/Souris River valley has undergone significant anthropogenic changes in the past 150 years, including shifts in land use, increasing population, and construction of several federal flood-risk-reduction projects. The historical changes in the valley suggest how the river may adapt to future modifications of the channel and/or floodplain.

A key source of historic information about the Mouse/Souris River is aerial photography. The consulting team compared aerial photos taken in 1946 and 1969 with 2010 images and assessed the changes in the river's centerline. The 1969 photos show the river as it existed before the addition of flood-risk-reduction measures between Burlington and Velva. The 1946 images, although taken after the construction of Lake Darling, constitute the area's earliest full set of aerial photographs.

Comparing the images revealed that in areas not located near flood-risk-reduction works, changes in river alignment and in the river length (or sinuosity) over the past several decades have been minimal. While the Mouse/Souris River actively meanders, the observed rate of

channel migration—the slow but constant reshaping of a sinuous river—is not high for a river with its characteristics.

In contrast, pronounced changes in river length have occurred in reaches subject to the channel straightening and cutoff of bends that were part of federal projects (Figure 4). For the 10-mile-long section of river valley near Minot, these projects caused a reduction in stream length of more than 40% (9 river miles) between 1969 and 2010. The sinuosity (ratio of river length to valley length) for this section of the valley is now markedly different from that in the rest of the Mouse/Souris River valley, a condition that can cause excessive erosion and "unraveling" as the river attempts to compensate for the imposed reduction in length. Although no observable major changes in other river characteristics have occurred since the federal projects were completed, there is a limit to how much straightening can be performed without increasing erosion.

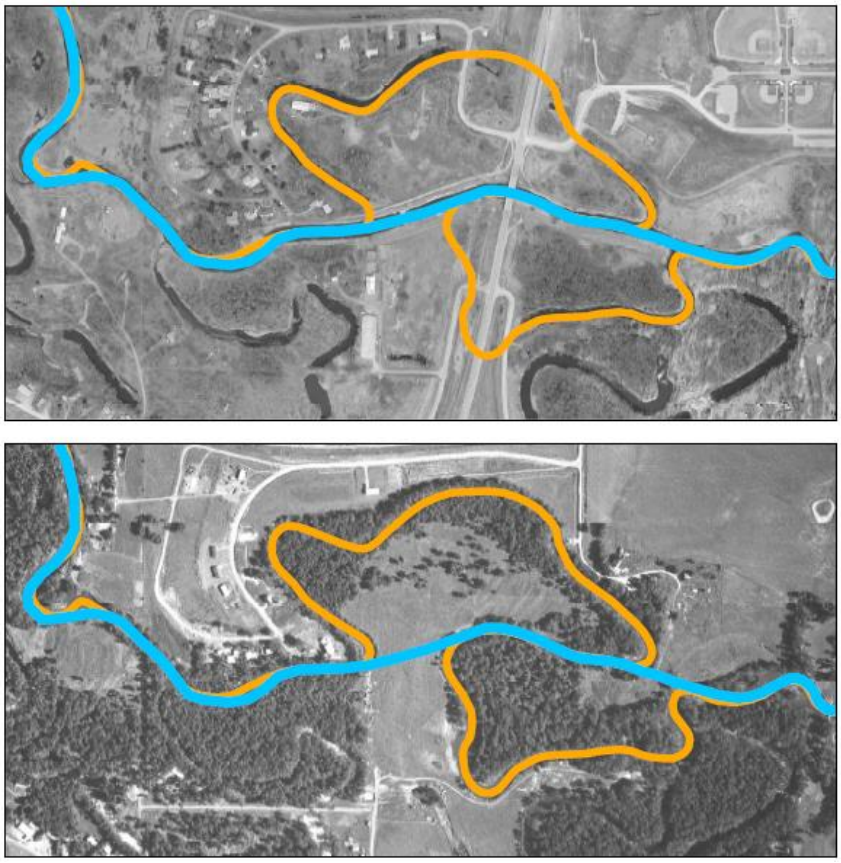

Figure 4 Aerial photographs from 1969 (bottom) and 2010 (top) showing a meander cut off by a federal flood risk reduction project.

SEDIMENT CHARACTERISTICS

Another important source of historic information is sediment transport data, including measurements of the type and quantity of sediment that is transported in the river system. Measurements of the channel-bed material size are especially important, because different types of soil particles interact differently with flowing water.

The available sediment-transport data for the Mouse/Souris River was collected mostly by the U.S. Geological Survey in the 1970s. Because the data is very limited in the most sensitive Burlington-to-Verendrye reach (especially with respect to channel-bed material and to sediment transport rates for a wide range of flows), the team could not quantify erosion or sedimentation potential. Based on the available data, the Mouse/Souris River in the vicinity of Minot appears to have bed material of primarily fine sand and relatively low suspended sediment concentrations (Figure 5).

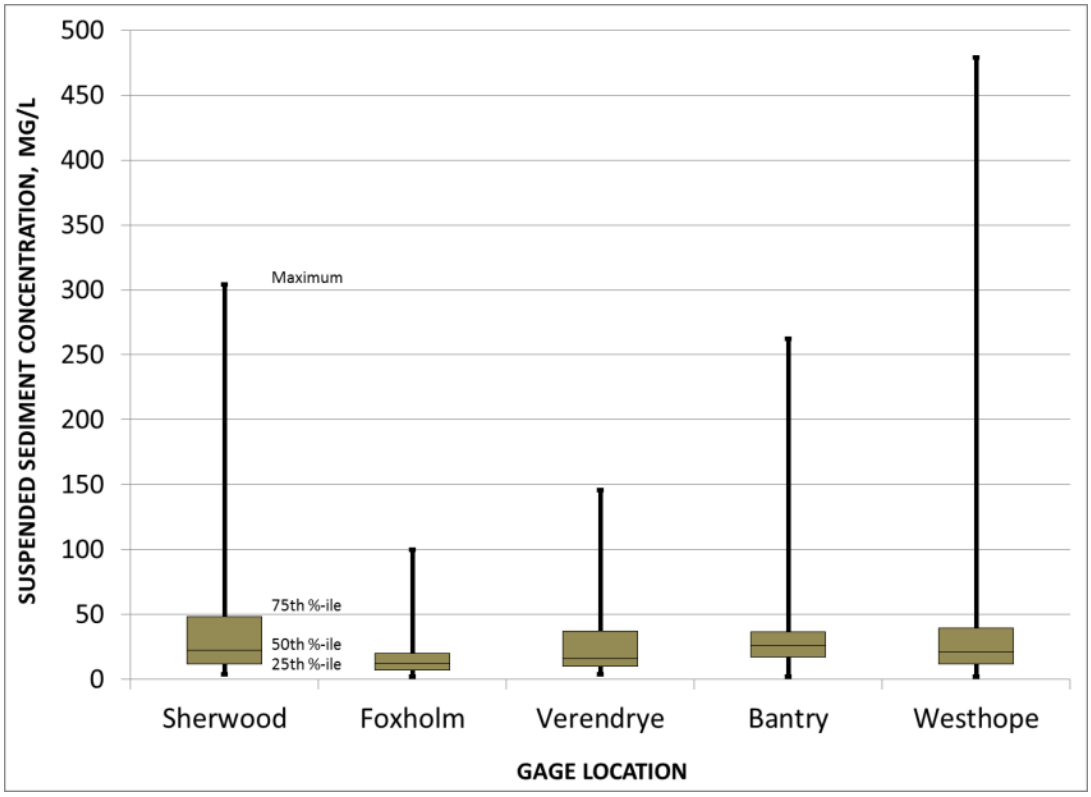

Figure 5 Mouse/Souris River suspended sediment concentration ranges.

PRELIMINARY EVALUATION OF POTENTIAL PROJECT IMPACTS

Based on the initial characterization of the processes of erosion, transport, and deposition of river sediment in the study area, it is possible to offer a preliminary qualitative assessment of erosion and sedimentation impacts that may occur in the Mouse/Souris River if the proposed flood-risk-reduction project is implemented.

As discussed above, the reaches of the Mouse/Souris River between Burlington and Verendrye are naturally more susceptible to erosion. Because the project will increase flow velocities in some locations during very high flow conditions, the project's most likely local impact is an increased risk of erosion. The design considerations of the preliminary project alignment are intended to reduce the potential for erosion by including areas of overbank excavation and widening many of the bridge openings and by providing scour protection near diversion

structures. However, current plans call for some bridge crossings to significantly constrict flood flows—a situation that may lead to erosion in extreme flood events.

In addition, there is a risk of increased erosion (both bank erosion and channel scour) where the river channel is constricted by levees occupying a significant portion of the floodplain. This is particularly true in areas where the river is restricted to a very narrow region between a levee on one side and a valley wall on the other. At these locations, flow convergence may result in increased erosion (Figure 6).

Figure 6 Significant erosion and channel migration after the 2011 flood opposite the existing levee at Velva.

The Souris Valley Golf Course in Minot (Figure 7) will continue to be an area within the proposed project limits that is subject to sediment deposition. In the preliminary alignment created for this project, the golf course is the only area within Minot where the river has an appreciable floodplain, which reduces flow velocity even during very large floods and allows sediment deposition to occur. Similar deposition is also likely just downstream of Minot where the river will leave the protected area and return to its natural floodplain.

Judging by the characteristics of the Mouse/Souris River's valley and channel and by observations from the 2011 flood, it is unlikely that erosion and sedimentation impacts from the project will extend beyond the most sensitive reaches between Burlington and Verendrye. However, additional field investigations and numerical modeling are warranted to validate this

initial conclusion, particularly as it relates to the development of river management alternatives in the rural areas.

Figure 7 Sand deposition after the 2011 flood at the Souris Valley Golf Course.

There is not sufficient information available (especially for sediment characteristics) to numerically quantify the magnitude of the erosion and sedimentation impacts discussed above. These impacts can be quantified by modeling the most sensitive reaches of the river—modeling that accounts for driving forces (e.g., shear stress) and sediment characteristics (especially of the bed material) and sediment loading.

CONCLUSIONS

Present day characteristics of the Mouse/Souris River are highly constrained by the area's glacial history, resulting in distinct river segments delineated by major geomorphologic features. Stream classification using basin-scale data affords a foundational understanding of the natural tendencies of the river that is essential in order to adequately evaluate the potential impacts on the morphodynamics (erosion and/or sedimentation) of the Mouse/Souris River associated with the proposed project.

The primary objective of this study was to characterize the river morphology and sediment transport processes in the study area and to use this characterization to conduct a preliminary evaluation of the proposed project's potential to result in undesirable erosion and sedimentation

impacts. The evaluation was qualitative due to the limited available historic information on sediment-related variables. The qualitative evaluation has served the purpose of identifying data gaps and additional analyses that will be required to determine the magnitude of the impacts and propose measures to lessen these impacts.

One of the preliminary conclusions of this study is that despite the significant existing alteration of some Mouse/Souris River reaches (such as channel straightening and levee construction), only isolated erosion and sedimentation impacts were observed in a very extreme event (the 2011 flood of record). Additional river alignment alterations associated with the proposed project or alterations in the rural areas could translate into a different outcome.

The main outstanding questions in this report that may be addressed in a future phase of study are 1) how will the project change sediment transport upstream and downstream of project features, and 2) what will be the magnitude of the associated erosion or sedimentation responses to such changes?

SUSPENDED-SEDIMENT TRANSPORT THROUGH A LARGE FLUVIAL-TIDAL CHANNEL NETWORK

Scott A. Wright, Research Hydrologist, U.S. Geological Survey, Sacramento, CA, sawright@usgs.gov; Tara L. Morgan, Hydrologist, U.S. Geological Survey, Sacramento, CA, tamorgan@usgs.gov

INTRODUCTION

The Sacramento – San Joaquin River Delta (the Delta) is formed at the confluence of the Sacramento River and San Joaquin River, the two main watersheds draining California's Central Valley (Figure 1). Once an extensive tidal marsh system, the Delta has been subject to an array of changes since the discovery of gold and subsequent development of California in the mid-1800s. These changes include the following: construction of channel levees and draining of tidal marshes for agriculture; hardening (rip-rap) of existing channels and construction of new channels/canals to support water conveyance; hydraulic gold mining activities which introduced large quantities of fine sediment to the Delta in the late 1800s; construction of large dams in the watershed in the mid-1900s that trap sediment and reduce sediment loads to the Delta; construction and ongoing dredging to maintain shipping channels through the Sacramento River (upstream to Sacramento) and San Joaquin River (upstream to Stockton); and the construction of large pumping facilities in the south Delta that export water to the San Joaquin valley and southern California for agricultural and urban uses. These physical modifications have affected the hydrodynamics and sediment transport characteristics of the Delta (Lund et al., 2007, Whipple et al., 2012), which have in turn affected the aquatic ecosystem. In addition to the physical modifications, the ecosystem has been affected by direct biological modifications, in particular the introduction of non-native species.

Delta smelt, a fish species endemic to the Delta currently listed as Threatened under the Federal Endangered Species Act and Endangered under the California Endangered Species Act, is currently a major regulatory, management and scientific focus in the Delta. The Delta smelt, along with other native and non-native species, experienced abrupt population declines in the early 2000s, referred to locally as the Pelagic Organism Decline., or POD. While the POD is generally thought to be the result of multiple stressors, Delta smelt habitat and migration patterns have been linked with turbidity and temporal changes in turbidity such as "first flush" river runoff events (for a review of Delta smelt habitat studies refer to Sommer and Mejia, 2013). First flush refers to the first major runoff event in the watershed that produces substantial sediment loads and increases in turbidity in the Delta. Increases in turbidity in the southern Delta in the vicinity of the State Water Project and Central Valley Project pumping facilities (near Clifton Court Forebay, see Figure 1) have been linked to high entrainment of Delta smelt at the facilities (Grimaldo et al., 2009), which can lead to severe curtailments of water deliveries south of the

Delta on which 25 million people depend for at least part of their drinking water supply. Because turbidity in the Delta is caused by suspended sediments, studies of sediment transport dynamics are important for understanding Delta smelt habitat and informing Delta smelt management decisions.

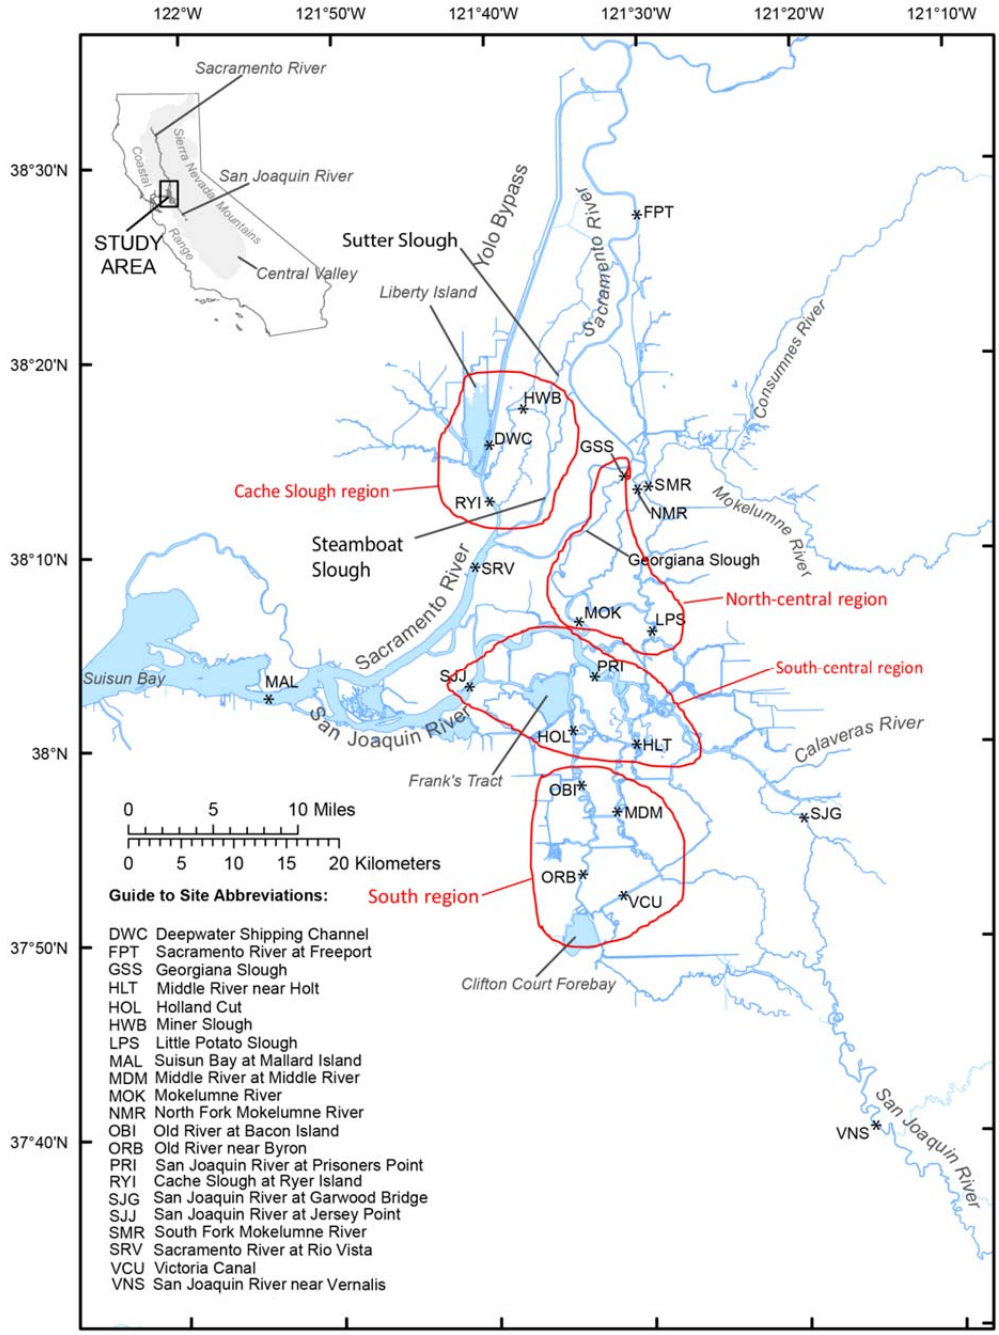

Figure 1 – Site map showing locations of gages and region outlines used in this study.

The objective of this paper is to describe the advection and dispersion of a first flush sediment pulse through the Delta. We focus on a single event that occurred in December 2012 (Figure 2, first pulse beginning around 1-Dec-2012) to illustrate these processes, because this event provided a very clean signal from the Sacramento River and throughout the Delta due to relatively low sediment flux from the San Joaquin and Mokelumne rivers (Figure 2). The Sacramento River is the dominant source of water and sediment to the Delta (Wright and Schoellhamer, 2005), such that events like the December 2012 first flush can be considered fairly typically in terms of influencing Delta turbidity. In addition, these first flush events are known to be a cue for Delta smelt migration upstream into the Delta (Sommer et al., 2011, Bennett and Burau, 2014) and potentially into the zone of influence of the south Delta export facilities, where they are subsequently salvaged at the export facility fish screens and ultimately resulting in export curtailments.

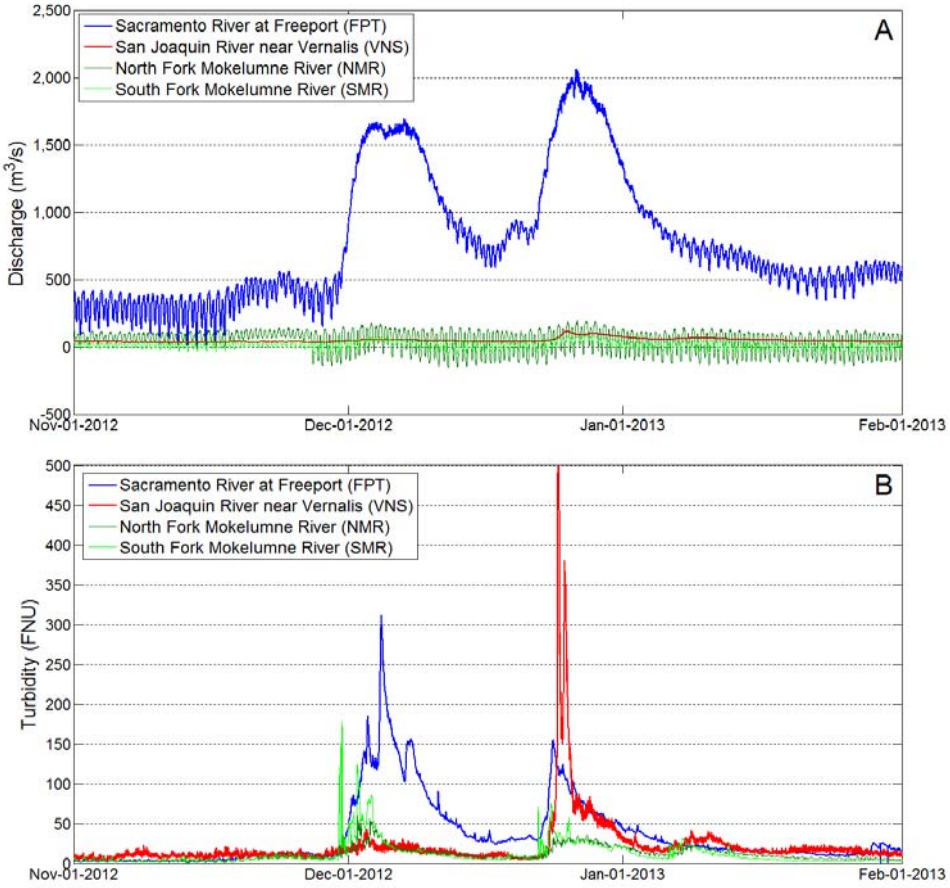

Figure 2 – Discharge (A) and turbidity (B) at upstream Delta boundaries.

METHODS

The U.S. Geological Survey (USGS), California Department of Water Resources (DWR), and Bureau of Reclamation (BoR) maintain an extensive flow and water quality monitoring network

in the Delta. Flow monitoring (USGS) is conducted using index velocity methods (Ruhl and Simpson, 2005, Levesque and Oberg, 2012). *In situ* continuous monitoring of turbidity, temperature, and conductivity (USGS, DWR, and BoR) is accomplished using multi-parameter sondes (Wagner et al., 2006). Suspended-sediment concentration (SSC) time series are generated through calibration of turbidity sensors (Rasmussen et al., 2009). In the analysis presented herein, we rely directly on the turbidity data (instead of SSC) because 1) turbidity is monitored at more sites than suspended sediment, and 2) the basic results of the analysis are the same whether turbidity or suspended sediment are used (we do not present sediment flux or sediment budgets). Figure 1 shows the gaging stations that were used in this study. Flow and velocity data were accessed from the USGS NWISweb database (http://waterdata.usgs.gov/ca/nwis/); turbidity data were accessed from NWISweb (for USGS data) and the California Data Exchange Center database (http://cdec.water.ca.gov/index.html) (for DWR and BoR data). The discharge at Mallard Island (downstream boundary of the Delta) and the discharge from the south Delta pumping facilities (daily water project exports from the vicinity of Clifton Court Forebay, Figure 1) were obtained from the DAYFLOW program (http://www.water.ca.gov/dayflow/).

Several metrics were computed from the time series data and used to evaluate transport processes during the event: 1) the pre-flood (base) and peak turbidity at each site; 2) the travel time of the turbidity peak to each gage from the upstream boundary (Sacramento River at Freeport); 3) the duration of the rising limb in turbidity at each site; and 4) the distance to each gage (along the most direct channel route) from the upstream boundary. These metrics were used to evaluate the transport pathways of the sediment pulse as well as the mechanisms controlling transport between sites.

RESULTS AND DISCUSSION

Time series of turbidity (panel A), tidally-averaged discharge (instantaneous discharge averaged over a tidal period, approximately 25 hours, panel B), and velocity (panel C) for all sites are shown in Figures 3-7. Each figure presents the conditions in a different region of the Delta, in the downstream direction from the source of the sediment pulse (the Sacramento River): Figure 3 shows conditions along the mainstem Sacramento River; Figure 4 shows conditions in the Cache Slough area; Figure 5 shows conditions in the north-central Delta; Figure 6 shows conditions in the south-central Delta; and Figure 7 shows conditions in the south Delta region. In each figure, the legend is organized from upstream to downstream. The conditions at the upstream boundary (Sacramento at Freeport) are shown in all figures; the y-axis scales are the same for Figures 3-5 but are condensed in Figures 6-7 (south-central and south Delta) in order to illustrate the dispersion of the sediment pulse as it moves southerly through the Delta. Refer to Figure 1 for the locations of the gaging stations identified in the time series figures.

The evolution of the sediment pulse as it travels down the mainstem Sacramento River (Figure 3) illustrates the processes of advection and tidal dispersion. At the upstream boundary (Freeport), flows are typically unidirectional (with some tidal influence) under low Sacramento River inflows (e.g. most of the year), but during the runoff event the tidal influence was washed out and the signal was entirely fluvial (Figure 3C). Further downstream at Rio Vista, the turbidity peak was reduced and the tidal signal is evident. At Mallard Island (downstream boundary of the Delta), the turbidity peak was further reduced and the signal was substantially broadened (increased time to peak). These features are the basic elements seen throughout the Delta as the sediment pulse moves through the fluvial-tidal transition.

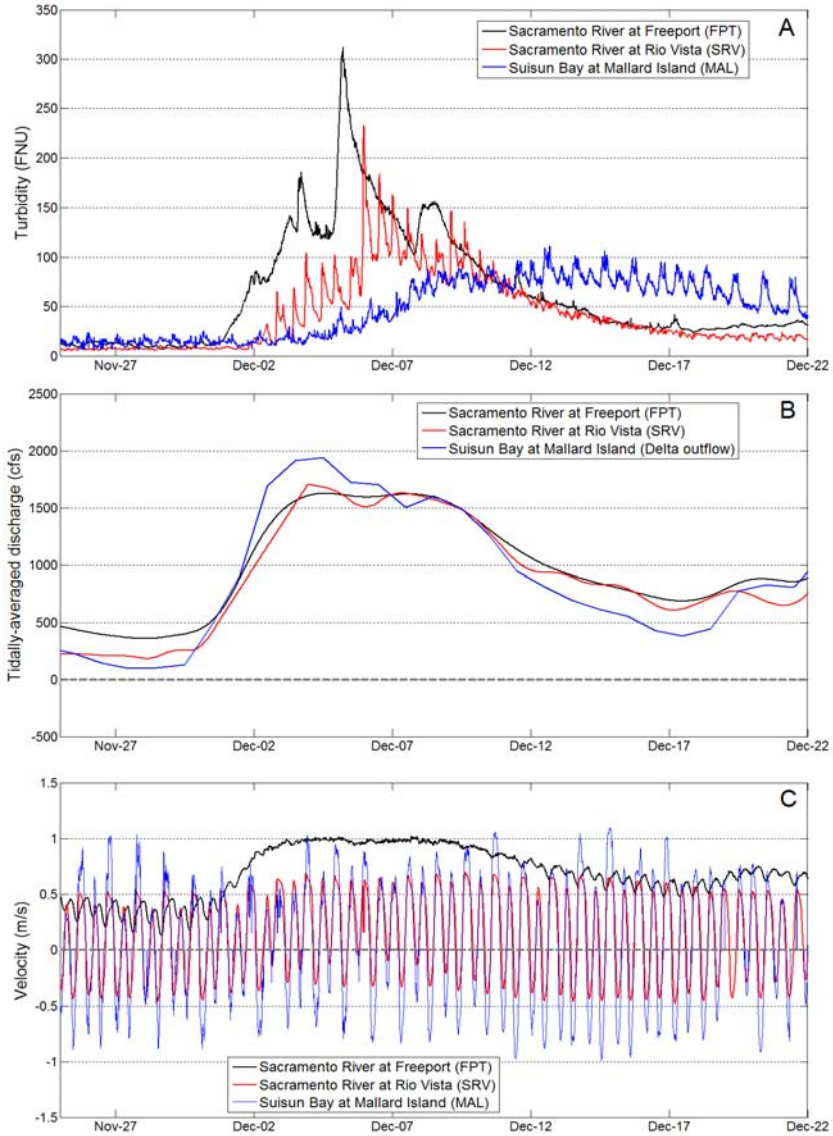

Figure 3 – Turbidity (A), tidally-averaged discharge (B), and velocity (C) along the mainstem Sacramento River.

Conditions in the Cache Slough and north-central Delta regions are shown in Figures 4 and 5, respectively, and illustrate the influence of the Sacramento River distributary channels. As the Sacramento River encounters tidal influence (around Freeport), it splits into several distributary channels (in downstream order: Sutter Slough, Steamboat Slough, Georgiana Slough, see Figure 1). During low flow, each of these distributary channels typically carries 10-20% of the upstream Sacramento River flow; during high flow, a combination of Sutter and Steamboat Sloughs can carry about 40% of the flow upstream at Freeport.

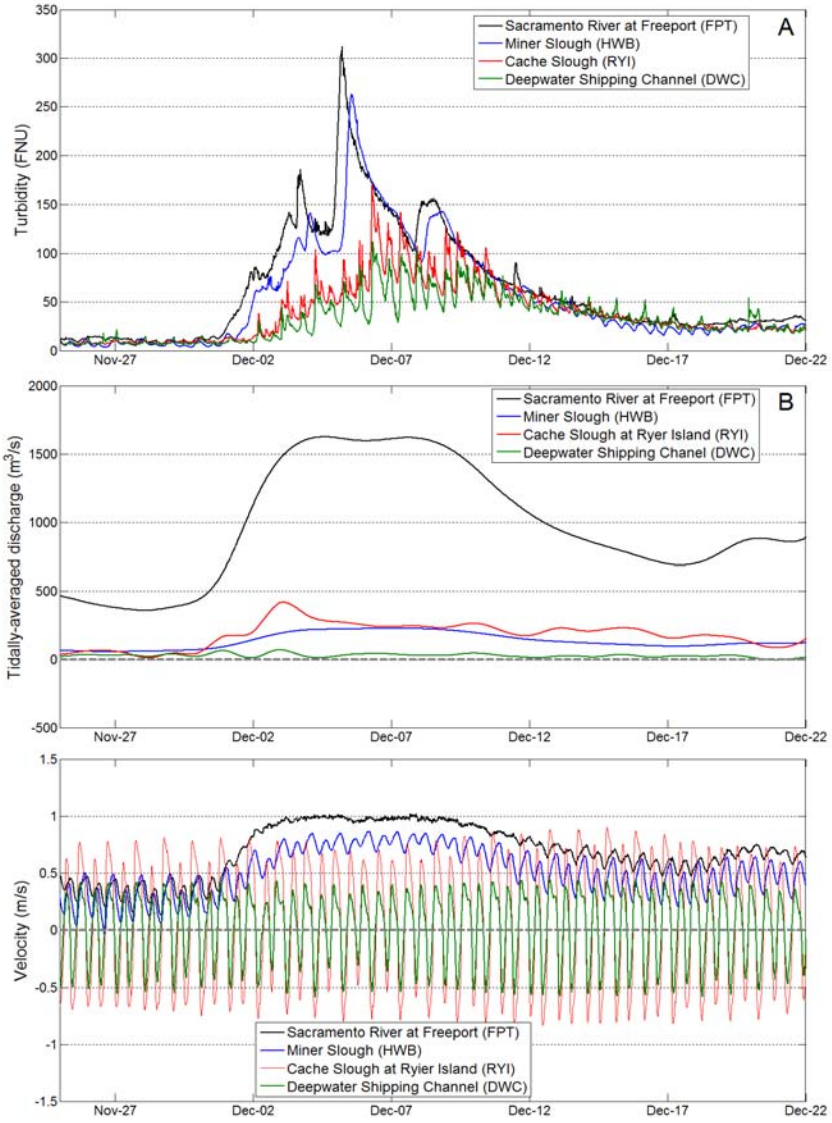

Figure 4 – Turbidity (A), tidally-averaged discharge (B), and velocity (C) in the Cache Slough region of the Delta.

Figure 4 shows that, based on the sampling stations we analyzed, Miner Slough is the primary pathway for sediment to reach the Cache Slough area; the turbidity signal in Miner Slough is nearly identical to that on the Sacramento at Freeport and the sites further downstream in the

Cache Slough area illustrate the effects of tidal dispersion and deposition (reduced turbidity peaks, increased tidal variability). Similarly, Figure 5 shows that Georgiana Slough is the pathway for sediment to reach the north-central Delta (the Delta Cross Channel is closed during high flow events); the turbidity signal in Georgiana is nearly identical to the Sacramento River at Freeport and the sites further downstream (Mokelumne River, Little Potato Slough) demonstrate the effects of tidal dispersion and deposition. This pathway also has particular importance for transport to the south Delta, as discussed below.

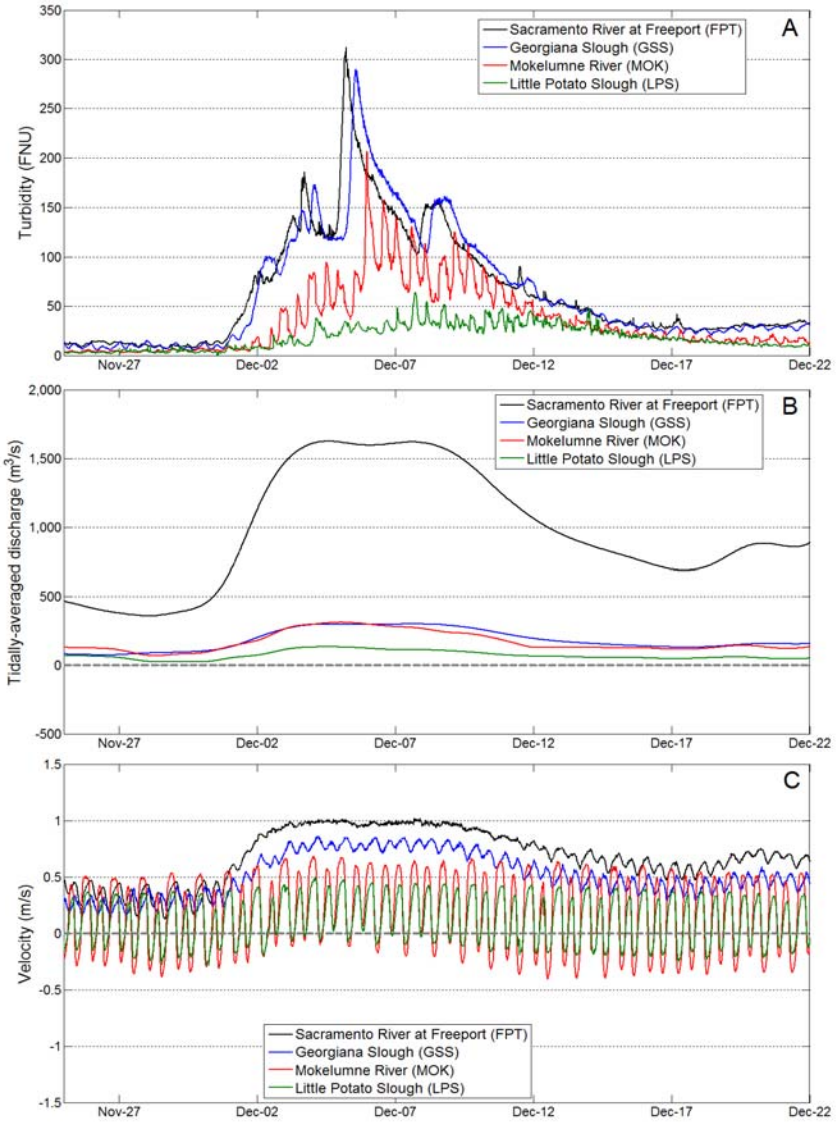

Figure 5 – Turbidity (A), tidally-averaged discharge (B), and velocity (C) in the north-central region of the Delta.

Conditions in the south-central Delta and south Delta regions are shown in Figures 6 and 7, respectively. The y-scale in the turbidity panels was reduced in order to better illustrate the signals, but the signal at Freeport was included for illustrative purposes. The sites in the south-

central Delta (Figure 6) include several along the San Joaquin River and have turbidity signals similar to other downstream tidal sites (such as Mallard Island), with reduced turbidity peaks and broader distributions. The sites in the south Delta (Figure 7) have even lower turbidity peaks and broader distributions due to tidal dispersion and deposition. An important aspect of transport processes in these regions is the direction of the tidally-averaged (net) flows (panel B) and the influence of the water export facilities. Negative net flows in these regions indicate "reverse" (landward) flows to the south toward the export facilities. In the absence of water exports, the net flows in these regions would be seaward and the mechanism for sediment transport into the south Delta (advection with the landward net flow) would not exist. Thus, the water export facilities play a key role in elevating turbidity in the south Delta during Sacramento River runoff events.

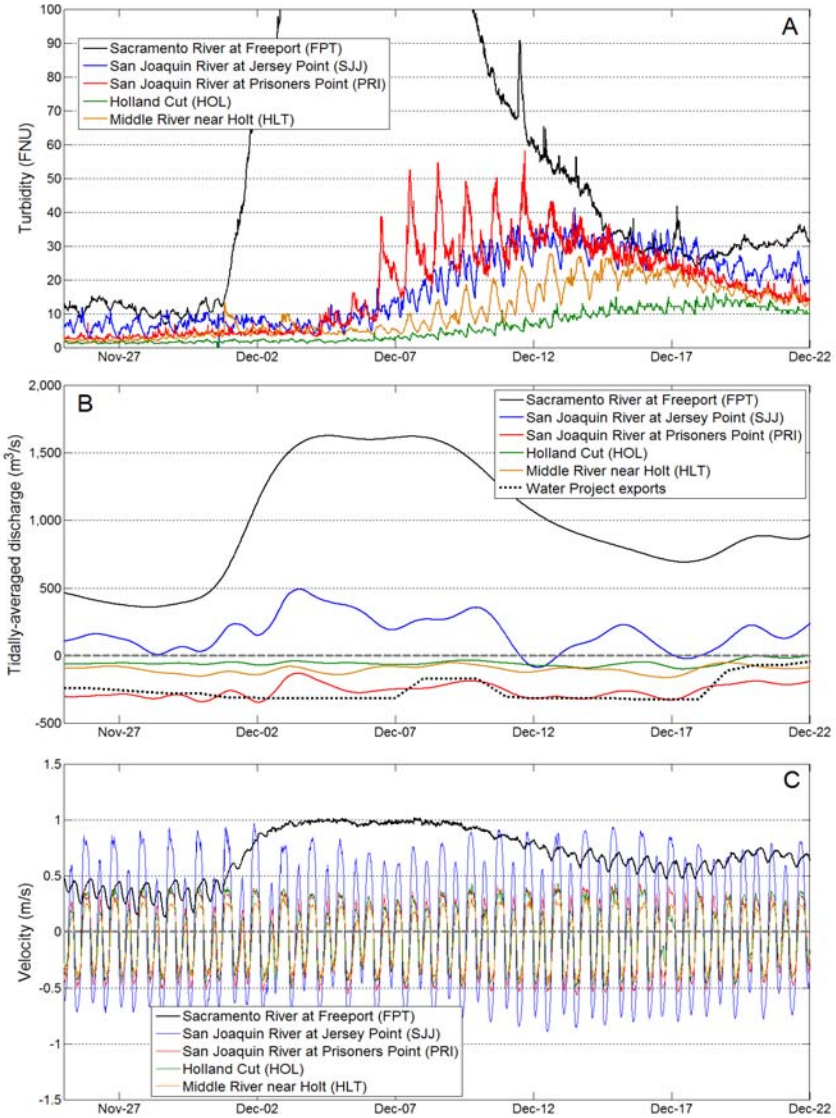

Figure 6 – Turbidity (A), tidally-averaged discharge (B), and velocity (C) in the south-central region of the Delta.

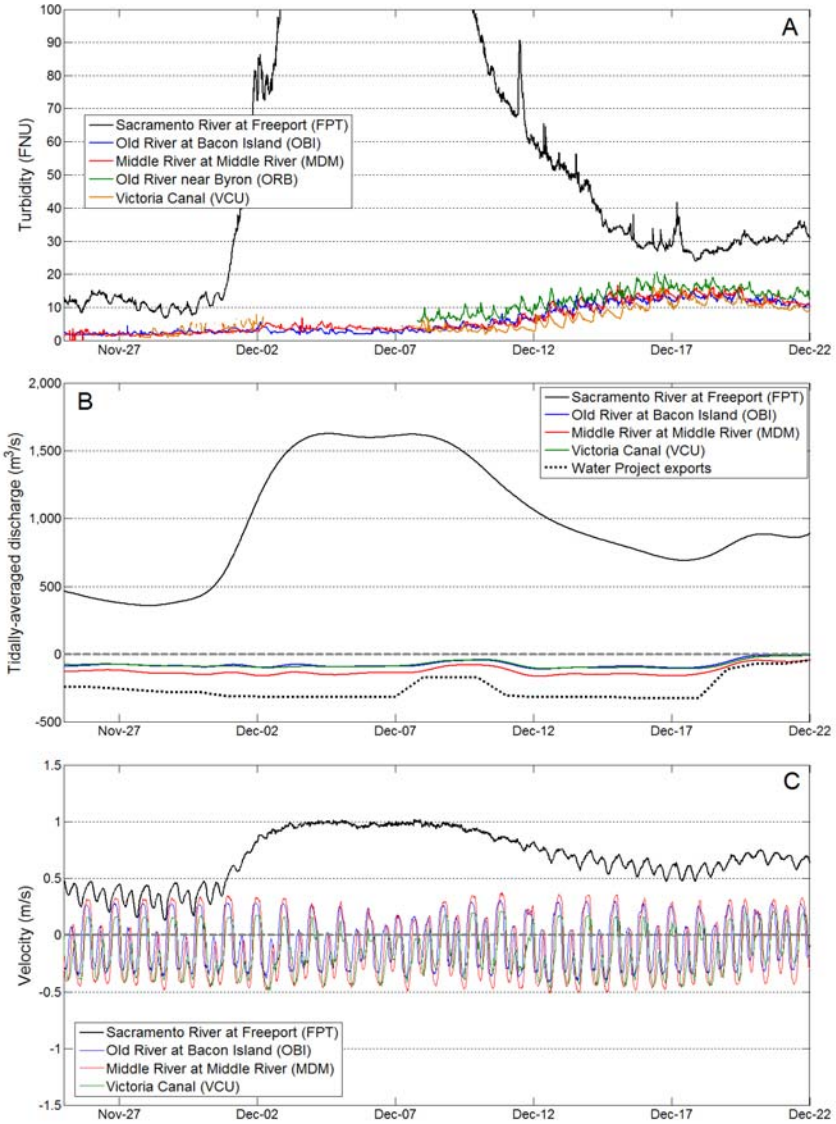

Figure 7 – Turbidity (A), tidally-averaged discharge (B), and velocity (C) in the south region of the Delta.

Figure 8 summarizes the pre-flood and peak turbidities for all of the sites, organized by region and in a downstream direction within each region. The decreases in peak turbidity in the downstream direction illustrate the processes of tidal dispersion and deposition that occurs through the fluvial-tidal transition. Figure 8 also shows the order of magnitude decrease in peak turbidity that occurs from the upstream boundary to the furthest downstream sites (south Delta).

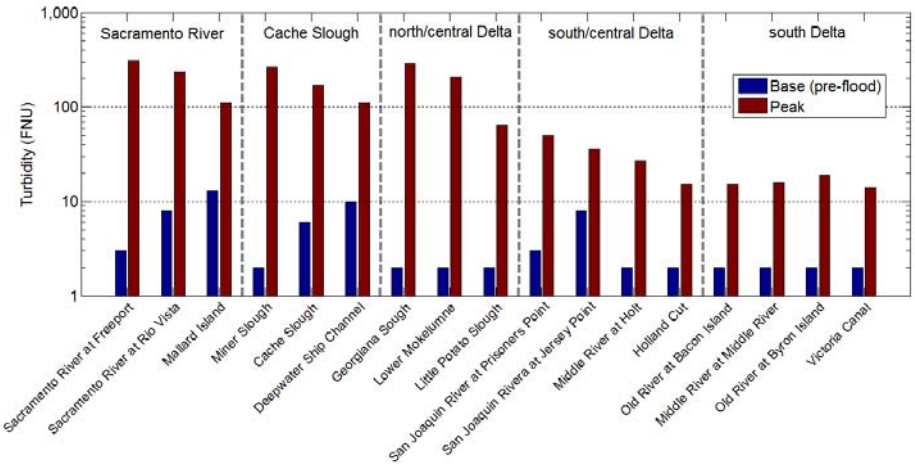

Figure 8 – Pre-flood (base) and peak turbidity at the sites identified in figure 1.

The change in several metrics of the sediment pulse as it moves through the Delta and the fluvial-tidal transition is shown in Figure 9. Three metrics were used: the peak turbidity (panel A); the travel time of the turbidity peak (measured from the Sacramento River at Freeport, panel B); and the duration of the rising limb of the turbidity signal (panel C). These metrics are indicative of the advection and dispersion processes between a given site and the source of the sediment pulse, and are plotted in Figure 9 as a function of distance downstream from the Sacramento River at Freeport. For all metrics, a relatively abrupt transition is apparent at 50-60 km downstream from Freeport. This is roughly the distance along the north Delta distributary channels to Cache Slough, as well as the distance along the Georgiana/Mokelumne pathway to the San Joaquin River. At these locations, there is an abrupt increase in the channel capacity and therefore an increase in tidal forcing and concomitant reduction in the net flow velocity. Thus, sites upstream of these junctions illustrate primarily fluvial responses with a weaker tidal influence, and sites downstream illustrate reduced fluvial influence with much greater tidal influence. Figure 9B demonstrates an order of magnitude reduction in the velocity of the sediment pulse through this transition, from about 0.6 m/s in the fluvial region to about 0.04 m/s in the tidal region. This is accompanied by about a two-fold increase in the duration of the rising limb of the pulse (Figure 9C), from about 4 days in the fluvial region to about 8-10 days in the tidal region. Finally, elevated pre-flood (base) turbidities at Mallard Island, Rio Vista and the Deepwater Ship Channel are given as one of the reasons Delta smelt are found at these location under pre-first-flush conditions (Sommer and Mejia, 2013).

SUMMARY OF MAIN FINDINGS

Herein we have examined the evolution of a sediment pulse, originating from the Sacramento River, as it moved through the fluvial-tidal transition in the Sacramento-San Joaquin Delta. This examination revealed the following main findings related to transport processes:

- Sacramento River distributary channels convey sediment to different regions of the Delta, resulting in elevated turbidity in these regions. In particular, Georgiana Slough is the primary pathway for sediment from the Sacramento River to the south Delta region.
- Sediment transport in the northern region of the Delta, near the upstream source, is dominated by fluvial processes. Tidal influence increases dramatically at about 50-60 km from the Sacramento River at Freeport, where the north Delta distributary channels encounter Cache Slough and the Mokelumne River system encounters the San Joaquin River
- Water export facilities in the south Delta result in negative (landward) net flows in this region and contribute to the landward transport of sediment and elevated turbidity in the south Delta.

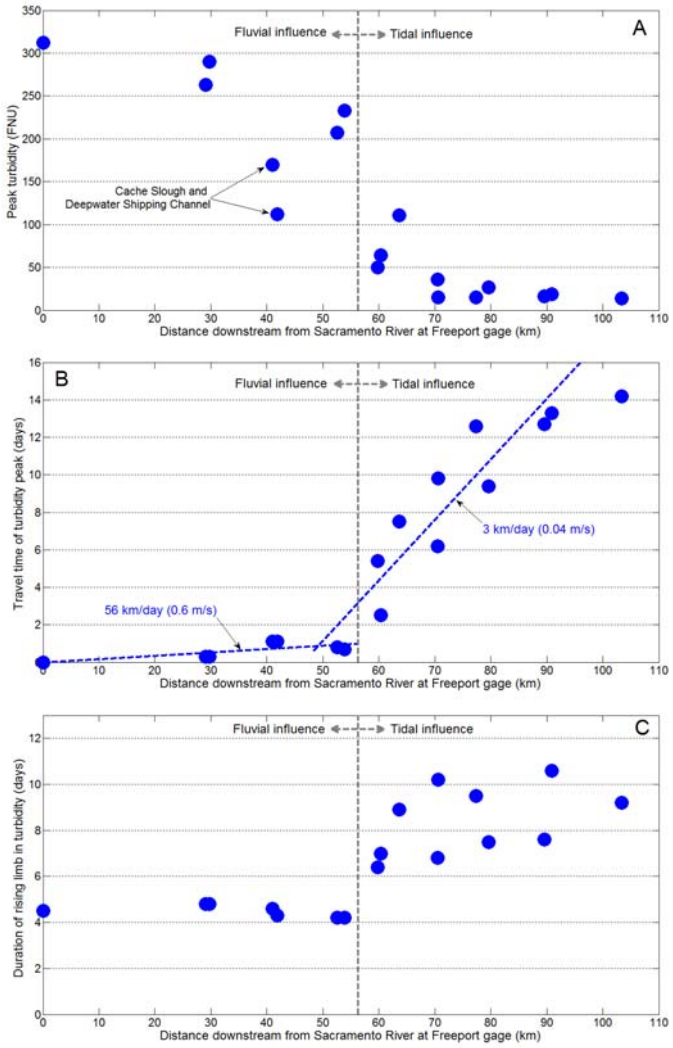

Figure 9 – Peak turbidity (A), travel time of turbidity peak (B), and duration of the rising limb in turbidity (C) versus distance downstream from the upstream sediment pulse source.

Abstract: This topic will be of interest for two reasons: (1) we make available to all interested parties thousands of high-quality bedload transport measurements that can be used in research and applications, and (2) we tested two empirical bedload transport equations using data from the database. We compiled the most comprehensive database to date containing high quality and well-documented bedload sediment transport measurements. We used a subset of the database to test the performance of the Barry et. al 2004 formula and Rosgen's Pagosa Good/Fair (FlowSed) formula. Each method used a single measurement at or near bankfull to calibrate the formula. The ability of each method to predict bedload transport was determined using the Root Mean Square Error of the logarithms of predicted and measured values of bedload. The Pagosa curve provided the greatest accuracy. The varying exponent of the Barry formula approximated the static exponent of the Pagosa formula. By improving bedload transport prediction, stream restoration professionals will have greater confidence in the competency of restored streams and reduce the potential for aggradation or degradation through improved channel design.

INTRODUCTION

Bedload transport formulae for gravel bed streams are used for stream restoration and urban stream design, sediment budget calculations, fish habitat assessment, and mitigating downstream effects of dams [Wilcock et al., 2009]. Unfortunately, despite widespread use, these formulae fail to consistently and accurately predict bedload transport across a wide range of natural conditions [Gomez and Church, 1989; Wong and Parker, 2006]. Due partly to inaccuracies and uncertainties, field measurements are often collected to calibrate formulae. However, bedload sampling is both expensive and difficult, which leads some practitioners to simply apply bedload formulae without calibration [Doyle et al., 2007]. While calibration of bedload formulae is known to improve accuracy [Wilcock, 2001], previous studies have not compared the relative performance of calibrated formulae. Additionally, previous studies have only focused on semi-empirical formulae, which are based on theoretical considerations and then adjusted using flume or field data.

Therefore, the objective of this research was to evaluate and compare the performance of two calibrated bedload transport formulae. Both of the selected formulae were empirical, essentially created by fitting a best-fit curve to large quantities of data. This research employed more measurements than previous comparison studies and used one field measurement near bankfull discharge for calibration. This analysis evaluates the advantage of calibrating a formula with a single measurement. It also evaluates the predictive performance of two formulae not previously examined.

LITERATURE REVIEW

The comparison of bedload transport formulae is not a new idea. Numerous comparison studies of total sediment load (including suspended load and bedload) have been conducted. While many studies

studies favor sand bed channels, some also include elements pertinent to coarse bed channels [Karamisheva et al., 2006; Molinas and Wu, 2001; Pacheco-Ceballos, 1989; Wu et al., 2000]. For example, Yang and Huang [2001] used a large flume data to test a series of formulae that included mostly total load equations with a few interspersed bedload transport equations. They also referenced an additional twelve total load comparison studies largely dealing with total load formulae and sand bed channels.

McLean [1980] reported that very little effort had been made to test bedload predictive formulae on gravel bed streams up until that time. Since that time, a number of comparisons of bedload transport formulae have been conducted. McLean used field data from five rivers (Vedder River near Yarrow, Canada; Elbow River near Bragg Creek, Canada; North Saskatchewan River at Nordegg, Canada; Snake River near Anatone, WA; and Clearwater River near Spalding, FL) to compare bedload predictive formulae. Gomez and Church [1989] used 358 measurements, 90 of which came from flume experiments and the rest from field sampling, to test twelve predictive equations on gravel bed streams. Reid et al. [1996] used data from Nahal Yatir, an ephemeral stream located within the Negev Desert, Israel, to perform a comparison study of six equations. Almadeij & Diplas [2003] used 174 measurements from three gravel-bed streams to test four equations. Bravo-Espinosa et al. [2003] used 1,020 measurements from 22 gravel-bed streams to test seven equations. Martin [2003] used data from the Vedder River in Canada to test four formulae. Barry et al. [2004] used 2,104 measurements from 24 gravel bed rivers in Idaho to test eight different variations of four bed load transport equations. In addition to the equations evaluated in this study, they proposed a new empirical formula calibrated using sub-basin characteristics. Duan et al. [2006] using three formulae tested 14 bedload samples on the Las Vegas Wash, a desert, gravel-bed stream in Las Vegas that conveys effluent wastewater and drainage.

In summary, although there have been many tests evaluating bedload formulae, this present study is warranted for several reasons. First, there are still a significant number of formulae that have not been tested; this study includes two such equations which, uniquely, are empirical. Second, testing of bedload equations has been performed often in the past using increasing numbers of observations with each iteration. The present study improves on past efforts in that it uses a sub-set of a database with more than 8,000 high-quality observations from 160 field sampling datasets (Hinton, 2012).

BEDLOAD TRANSPORT FORMULAE

This study compared the Barry and Pagos bedload transport formulae as summarized in Table 1. The Barry formulae was selected because, first, it is an empirical formula and, second, because of a reference outlining the calibration process [Barry et al., 2004]. The Pagosa formula was selected because it is perhaps the most well-known empirical bedload predictive formula [Lave, 2008; Rosgen et al., 2006; Simon et al., 2007; Simon et al., 2005]. Both formulae used the same sampling methodology for data collection. The following section describes each formula in greater detail.

Table 1 Summary of selected bedload transport formulae

Formula Name	D_{50} Range for Formula Development	Collection Location	Collection Method	Stream Slope
Barry	23 mm – 204 mm	Idaho Streams	Helley-Smith	0.0005 < S < 0.0718
Pagosa	~76 mm[1]	Colorado Streams	Helley-Smith	0.0117

Barry et al. [2004] developed an empirical power relationship between flow and bedload transport derived from Snake River Adjudication data. The Barry et al. general power formula (Barry) was derived for channels with coarse-grained surfaces and takes the form (refer to Table 2 for formula notation):

$$q_b = 257\, A^{-3.41} Q^{(-2.45q^* + 3.56)} \quad (1)$$

$$q^* = \left(\frac{\tau_{Q_2} - \tau_{D_{50S}}}{\tau_{Q_2} - \tau_{D_{50ss}}}\right)^{\frac{3}{2}} \quad (2)$$

The Barry formula is essentially a rating curve in which the coefficient is related to the tributary drainage area and the exponent is related to the channel armoring of the site relative to its transport capacity and sediment supply. As such, it may be considered an "off-the-shelf" formula that does not require direct calibration. However, the drainage area coefficient may be calibrated to match measured bedload data. The exponent is not adjusted and is calculated using the average cross-sectional shear stress at bankfull with the critical shear stress required to mobilize the surface and subsurface layers.

Barry et al. [2004] reported there were three streams in their study for which the exponent could not be calculated. This is due to a weakness in how the relative armoring coefficient is calculated. If the total cross-sectional average shear stress at the 2-year return discharge is less than the critical shear stress required to mobilize the D_{50} of either the surface or subsurface, the exponent becomes undefined and can no longer be calculated. It should also be noted that this formula is unable to predict sediment transport by sediment size class or the effects of changing velocity and shear stress.

The Pagosa Good/Fair and Poor (Pagosa) methods were developed by David Rosgen with Helley-Smith data collected from six streams near Pagosa Springs in Colorado [Rosgen et al., 2006]. The data were non-dimensionalized using a measurement of discharge and bedload transport at bankfull and then fit with a power relationship for each stability class [Rosgen et al., 2006]. The two power fit relationships are (refer to Table 2 for formula notation):

$$G_* = -0.0113 + 1.0139 Q_*^{2.1929} \quad \text{[Good/Fair]} \quad (3)$$

$$G_* = 0.07176 + 1.0217 Q_*^{2.3772} \quad \text{[Poor]} \quad (4)$$

The Good/Fair curve represented three streams exhibiting good/fair stabilities while the Poor curve represented three streams with significant degradation or aggradation. Only the Good/Fair curve is used in this analysis. A disadvantage of the Pagosa formula is that it must always be calibrated using field measurements at bankfull discharge that are difficult to obtain or may not occur during the study period. It also is unable to directly predict sediment transport by sediment size class or the effects of changing velocity and shear stress.

Table 2 Formula notation

Notation	Description	Units
A	drainage area	km^2
G*	bedload transport term equal to the ratio of the given transport rate with the transport rate at bankfull	-
Q	discharge	m^3/s
q_b	unit bedload transport rate	kg/s/m
Q_b	bedload transport rate	kg/s
q*	relative armoring term	-
Q*	discharge term equal to the ratio of the given discharge with bankfull discharge	-
$\tau_{D_{50s}}$	critical shear stress required to mobilize the surface layer	N/m^2
$\tau_{D_{50ss}}$	critical shear stress for the subsurface layer	N/m^2

STUDY METHODOLOGY

The study first commenced with collecting the necessary data. Prior to the bedload comparison effort, a bedload database of more than 8,000 bedload field measurements was compiled as described in Hinton [2012]. Quality bedload measurements from around the world were gathered from sources including published journal articles, direct physical measurements of bedload by the authors, and other researchers' unpublished data. Following data selection, the formulae were calibrated and then statistically analyzed. These three phases are described in more detail in the following paragraphs.

Data selection

Data were selected based on appropriateness and availability of information required to solve the formulae. Sites that produced negative or unrealistic exponents for the Barry formula were not selected. All bedload data selected for the study were collected with Helley-Smith pressure differential samplers.

Nearly 2,300 distinct bedload measurements obtained from 23 sites were included in this comparison. The data represent varying geologic compositions and drainage areas ranging from 3 to 360 square kilometers. Because very few sites included measurements of the bottom channel width, the top width was used instead. Some sites reported bankfull discharge derived from field-based parameters while others approximated bankfull using the 1.5-year discharge calculated using a Log-Pearson Type III analysis of historical stream gage data.

The sites included in this study were coarse bed channels with surface median diameters ranging from 10 to 160 mm. Surface grain size distributions were measured using standard pebble count methodology while subsurface grain size distributions were measured by collecting bulk core

samples on site and then analyzing the composition in the laboratory. Water surface slopes ranged from 0.001 to 0.055. Additional information regarding the sites can be found in the references provided in Table .

Formulae Calibration

Using the methods listed earlier within the Bedload Transport Formulae section, two formulae calibrated with one bedload measurement were compared. The calibration point was used to match predicted values to measured values by adjusting the leading coefficient of the Barry power relationship. The predicted rates were then compared with the actual measurements of transport rate. The Idaho data was used to derive the Barry formulae; however, the calibration process adjusted the coefficient from its standard "off-the-shelf" form.

Statistical Analyses

The root means square error (RMSE) has previously been used [Gomez and Church, 1989] as a statistical comparison between predicted and measured values of bedload transport. The root mean square error can be computed according to Equation 5:

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}\left(x_{p,i}-x_{m,i}\right)^2}{n}} \qquad (5)$$

where:

x_p = predicted bedload transport (kg/s)
x_m = measured bedload transport (kg/s)
n = number of samples

Because the RMSE accounts for the differences between predicted and measured values, errors associated with higher discharges will be emphasized. In other words, the same percent difference will produce much higher errors for high discharges than for low discharges. To remove this bias, a log transformation was applied to the predicted and measured values by adding 1 to each value and then calculating the base-10 logarithm. The RMSE was then calculated for the transformed values. The transformation and resulting RMSE equation is summarized in Equation 6, referred to as the root mean square error of the logarithmic values (RMSEL).

$$\mathrm{RMSEL} = \sqrt{\frac{\sum_{i=1}^{n}\left(\log_{10} x_{p,i}-\log_{10} x_{m,i}\right)^2}{n}} \qquad (6)$$

RESULTS AND ANALYSIS

The RMSEL values comparing the logarithms of the predicted and measured rates are reported in Table 4 which include errors for each individual stream. Also included in Table 4 was the exponent calculated for the Barry formula. Figure Figure 1 shows the predicted versus measured transport rate and includes a 1:1 relationship line for comparison. If the predicted values perfectly matched the measured values, they would match the 1:1 relationship line. Both the Barry and Pagosa formulae shown in Figure Figure 1 approximate a 1:1 correlation between measured and predicted values.

The Pagosa formula was most successful at predicting bedload transport with RMSEL values ranging from 0.002 to 0.114. The Barry provided slightly less accurate results with RMSEL values ranging from 0.002 to 0.228. However, both results were comparable as shown in Figure 1. During the data selection process it became evident that the Pagosa formula was easier to apply to various sites because the exponent of the Barry formula becomes undefined if the critical shear stress calculated for the surface and subsurface D_{50} grain size is greater than the average shear stress at the predicted bankfull discharge. On the other hand, it was noted that for very small measured bedload rates the Pagosa formula occasionally erroneously predicted negative transport rates.

As was mentioned previously, the exponent for the Barry formula was calculated using bankfull characteristic and gradations of the channel surface and subsurface. In this analysis, the calculated exponent ranged from 1.24 to 3.53 with a weighted average of 2.47. A rating curve

relating bedload transport to discharge for any given site has been shown to vary between 2 and 5 for Helley-Smith sampling data [Pitlick et al., 2004].

In comparison, the Pagosa formula exponent remains at a static value of 2.19. The Pagosa formula differs from typical rating curves as it relates bedload transport rate to the percent of bankfull discharge, not discharge itself.

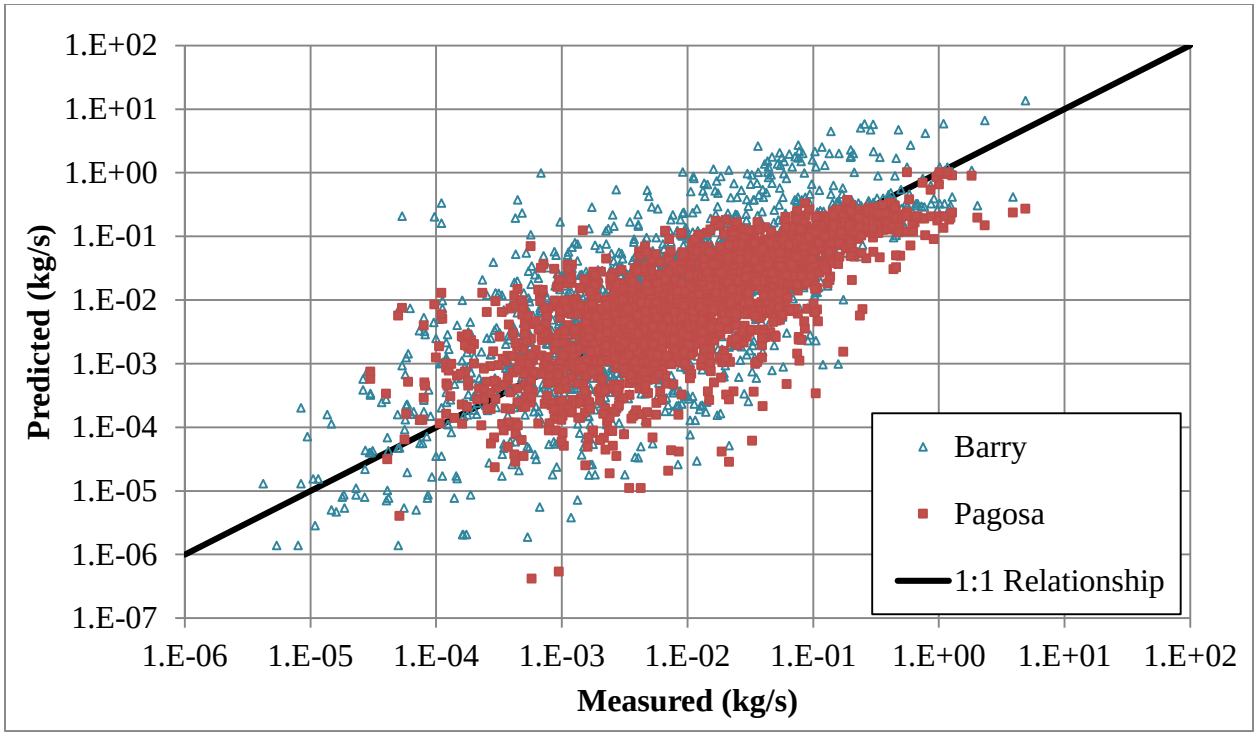

Figure 1 Barry and Pagosa predicted versus measured bedload transport values

CONCLUSION AND RECOMMENDATIONS

Two bedload transport prediction formulae were compared using nearly 2,300 Helley-Smith measurements from 22 different streams in the western United States using calculated RMSEL values. The sites included in this study had water surface slopes, median diameters, and drainage areas between 0.001 and 0.055, 10 and 160 mm, and 3 and 360 km^2, respectively. The performance of these formulae in this study have not previously been compared. Of the formulae compared, the Pagosa Good/Fair equation was the best predictor of bedload transport rates.

The exponent calculated for the Barry formula for the 22 sites varied between 1.2 and 3.5; however, the average value for all data was 2.5. This is compared to the 2.2 exponent of the Pagosa formula.

Abstract: Snow water equivalent (SWE) is an important quantity contributing to the spring water level rise on each of the Great Lakes. This study analyzed modeled and satellite SWE data available for the Great Lakes basin from three primary sources: (1) the SNOw Data Assimilation System (SNODAS) created by NWS National Operational Hydrologic Remote Sensing Center (NOHRSC), (2) the Defense Meteorological Satellite Program (DMSP) Special Sensor Microwave/Imager (SSM/I), and (3) the Large Basin Runoff Model (LBRM) developed by NOAA Great Lakes Environmental Research Laboratory (GLERL). SWE data were evaluated for ability to estimate the absolute and relative magnitudes of annual SWE as well as the timing of snow accumulation and melt. The comparison shows that the satellite SSM/I data severely underestimates Great Lakes SWE and seems to be heavily affected by vegetation cover. Although the SNODAS SWE estimates appear reasonable, it has limited availability for the Great Lakes, with complete binational coverage dating back only to 2011. One challenge for the U.S. Army Corps of Engineers is incorporating near real-time SWE estimates into the water level forecasts for the coming months. In particular, when SWE estimates are very high or very low, the magnitude of influence on the lake's forecasted water level is poorly understood given that the water level is also influenced by other hydrologic components. Since SWE primarily enters the lake through runoff, historical runoff estimates based on measured stream discharges are also analyzed along with historical precipitation data. A useful relationship is found between observed runoff to Lake Superior and the combined total of precipitation and melted SWE across the Lake Superior watershed. A methodology is presented for how current SWE can be used to improve forecasted runoff and forecasted water levels.

INTRODUCTION

Mission: The Detroit District (LRE) of the U.S. Army Corps of Engineers (USACE) under the auspices of the International Joint Commission (IJC) and the Coordinating Committee on Basic Great Lakes Hydraulic and Hydrologic Data (CCBGLHHD) has a crucial role in water management decisions on the Great Lakes. Hydrologists and others interested in the hydrologic budget of the Great Lakes require estimates of snow water equivalent (SWE), and knowledge of the SWE statistics at various times throughout the winter. USACE has been forecasting the Great Lakes water levels as part of its operational mission since 1952. Near the beginning of each month, LRE releases the "Monthly Bulletin of Water Levels for the Great Lakes" which

includes the six-month forecast of Great Lakes water levels. An improved knowledge of SWE would enable the forecasters to determine whether the current values are above or below normal and improve the accuracy of the water level forecasts. The objective of this study is to improve Great Lakes water level forecasting based on an analysis of the available modeled and satellite SWE data for the Great Lakes Basin.

Background: The seasonal snowfall of the Great Lakes Basin is an important feature of the hydrometeorology of the region and snowmelt an important contribution to the runoff entering the Great Lakes (Norton and Bolsenga, 1993). Snowfall occurs in the Great Lakes watershed as a result of the northern latitude and "continental" climate. The Great Lakes themselves also create "lake-effect zones" where air and water temperature differentials drive enhanced snowfall downwind of the lakes. Figure 1 shows the Great Lakes and their respective basin delineations by country.

Figure 1 Binational delineation of the Great Lakes basins

The volume of water stored in the seasonal snow cover can be a significant fraction of the total annual runoff entering the lakes. For example, the volume of the annual maximum SWE in the Lake Superior watershed for the period 1979-2004 (Daly et al., 2007) ranged from 28% to 58% of the total estimated annual runoff entering the lake. The ability to estimate the volume of SWE contained in the Great Lakes watershed can lead to improvements in the forecasts of the Great Lakes water surface elevations. However, estimation of SWE volume contained in the watersheds of the Great Lakes in real or near real time is fraught with difficulties. There are three basic approaches: using ground-based and aerial observations, modeling, and satellite remote sensing.

Ground and aerial observations (CRREL): Geospatial interpolation of ground and aerial observations of SWE can be used to estimate the SWE volume contained in the entire watershed. Daly et al. (2007) used ground observations to estimate the time series of SWE volume for the Lake Superior basin for the period 1979-2004. This study, referred to as CRREL data from this point forward, relied exclusively on National Weather Service (NWS) first-order and cooperative stations for data in the United States and daily and weekly snow depth observations taken by the Meteorological Service of Canada and 20 other agencies for Canada. Unfortunately, the NWS changed its observation procedure in the 1990's through deployment of the Automated Surface Observing System (ASOS) at most first-order stations. ASOS does not measure snowfall or snow depth and remains ineffective for measuring SWE (Doeskin and McKee, 2000). Almost all cooperative stations snow observations are limited to snow depth. The result is that at the present time there are almost no regular observations made of SWE by the NWS throughout the Great Lakes Basin. The number of Canadian SWE observations made each winter has declined continuously starting in the 1980's (Daly et al 2007).

Satellite-based observations (SSM/I): Satellite observations of SWE are based on measuring the passive microwave signal naturally emitted from the Earth. Passive microwave signals at frequencies greater than 25 GHz are scattered as they pass through the snowpack; lower frequencies are not scattered to the same degree. The estimated SWE is proportional to the difference between the emitted signals at a low frequency that is not scattered by snow and a high frequency that is scattered. A singular advantage of satellite observations of emitted passive microwave signals is that they can be observed through cloud cover and at night.

In practice, the accuracy of SWE estimation using passive microwave signals is limited by factors that impact the emitted passive microwave signal. Sources of error in microwave SWE retrievals stem from the dynamic nature of snow and the static assumptions made in the empirical formulations concerning snow properties. Several studies have shown a significant impact of vegetation on the passive microwave signal (Chang et al 1996, Foster et al 2005, Derksen et al. 2005). Other factors that can cause errors include excessive snow depth (Dong et al., 2005, Foster et al., 2005, Clifford, 2010), liquid water in the snowpack (Matzler, 1987, Hallikainen et al., 1986, Walker and Goodison, 1993), changes in snow density and grain size (Foster et al., 1999, Hall et al., 1986; Josberger and Mognard, 2002) and topology of the ground (Matzler and Standley 2000, Dong et al., 2005, Vuyovich and Jacobs, 2011). Ongoing research, which has attempted to account for these errors and to improve results regionally and seasonally, has had varied success (Farmer et al. 2010, Tedesco and Narvekar 2010, Mizukami and Perica 2012).

Daily passive microwave SWE data from the Special Sensor Microwave/Imager (SSM/I) were used for this investigation. The SSM/I sensor was launched in 1987 on board the Defense Meteorological Satellite Program (DMSP) satellites. These data are available near real-time and have the advantage of a relatively long historical record. SWE estimates are derived from the SSM/I brightness temperatures measured at wavelengths 19 and 37 GHz, and have a spatial resolution of 69x43km (19.4 GHz) and 37x29km (37 GHz) (Armstrong and Brodzik 1995). Data are available from the National Snow and Ice Data Center (NSIDC) in an Equal-Area Scalable Earth Grid (EASE-Grid) projection at a 25 km resolution. To avoid gaps at the basin boundaries,

the passive microwave data were re-sampled to 1 km^2 grid cells using the nearest neighbor method which assigns the same value to the pixel as the data layer in that location without any interpolation. SSM/I SWE products are available twice daily; ascending passes which occur in the afternoon and descending passes which occur in the early morning. For this study, only descending SWE data was used to reduce the potential wet snow impacts in the afternoon. A gap in the satellite swath coverage can occur every 3 to 4 days, depending on the latitude of the region.

SNODAS Model: Modeled estimates of SWE throughout the Great Lakes watershed are provided by the NWS National Operational Hydrologic Remote Sensing Center (NOHRSC). It offers a near real-time estimate of SWE and other snow properties for the U.S. through its SNOw Data Assimilation System (SNODAS). SNODAS is physically based, spatially distributed, energy-balance and mass-balance snow accumulation and ablation model run at a 1-km^2 resolution. SNODAS ingests data from the Rapid Update Cycle numerical weather prediction model and downscales it from 13 to 1 km^2. Multiple sources of available satellite, airborne, and ground-based snow observations are assimilated into the model and used to adjust model output by using a Newtonian nudging technique. The objective of using all of the available snow data is to produce a 'best estimate' of near real-time snow conditions for the conterminous USA and to minimize error associated with any individual method (Carroll et al., 2006). Though these data are also subject to errors, this product provides the best spatially distributed estimate of snowpack conditions throughout the U.S. and is used operationally in a number of locations. The snow model within SNODAS has been evaluated and generally shown to provide good results at a point scale (Rutter et al., 2008, Frankenstein et al., 2008, Clow et al., 2012), though over a larger scale, particularly where ground observations are sparse, additional error is introduced. The SNODAS model provides 1-km^2 estimates of snow cover and associated parameters near real-time on a 3-hourly and daily basis. SNODAS data are available from 01 October 2003 through the present from the National Snow and Ice Data Center (NSIDC). The data for Canada begins in approximately 2011. Due to this discrepancy in period of record, this study analyzed the SWE estimates of the US portion with the respective historical results, along with the watershed totals for the recent period.

Large Basin Runoff Model: Developed by NOAA's Great Lakes Environmental Research Laboratory (GLERL), the Large Basin Runoff Model (LBRM) is a lumped-parameter model of runoff for the Great Lakes Basin (Croley and He 2002). Within the LBRM framework, the daily snow pack is calculated from the previous day's snow pack, precipitation, air temperature, and a snowmelt rate parameter. In general, it is more simplified than the SNODAS model, since it only computes daily time steps and does not include any observational SWE data. However, it has the advantage of being able to simulate daily snow pack as far back as 1950, which is the available range of reliable meteorological data.

METHODOLOGY

This study analyzed time series for each of the Great Lakes watersheds of the SSM/I, SNODAS, and LBRM data over their periods of record. The evaluation compared the SSM/I and SNODAS data sets for each watershed using the estimated annual maximum SWE and the weekly maximum SWE values. The results for the Lake Superior watershed were compared to the

results of an independent study that was conducted earlier (Daly et al. 2007). The SWE statistics for each day of the year were determined.

Average basin SWE estimates from passive microwave and SNODAS SWE products were compared over the contributing watersheds to each of the Great Lakes in the north-central U.S. (Figure 1). Weekly time series of SWE and annual maximum values were evaluated over 10 years from 2004 through 2013. SNODAS data is available in the Canadian portion of the Great Lakes basins only since 2011, so the historical comparison was done only in the U.S. portions of the basins.

In order to improve the understanding of how SWE influences Great Lakes water levels, the historical record of LBRM SWE estimates were analyzed, beginning with the Lake Superior basin. Other basins could be analyzed in the future using the framework presented in this study. Statistics for the monthly LBRM SWE data were computed and compared with other historical hydrologic datasets. For the runoff component of the hydrologic cycle, the GLERL Area Ratio Method (ARM) is the most reliable historical data set. ARM includes stream flow observations within the basin, extrapolating from gauged areas to ungauged areas using an area-weighted approach. For precipitation data, the internationally coordinated over-basin precipitation data set is used. This precipitation data set begins with NOAA GLERL's Thiessen Method, is reviewed by NOAA Center for Operational Oceanographic Products and Services (CO-OPS), and is agreed upon between USACE and Environment Canada. Currently, the coordinated precipitation data set spans 1900 through 2010.

RESULTS

Gridded daily SWE data from SSM/I and SNODAS were obtained for ten water years when both datasets were available, 2004 – 2013. For both datasets, the gridded data were aggregated by basin region to produce a daily time series of average-basin SWE. Weekly time series were also developed for each basin using the maximum weekly values in order to accommodate the satellite overpass cycle which results in some days without satellite observations. Annual maximum SWE values for each of the ten water years were extracted from the weekly time series. Daily maximums, minimums, and averages were calculated from the daily time series. Data for the Superior, Michigan, Erie, and Ontario basins are shown in Figure 2 through Figure 5.

The SSM/I data is clearly underestimating the SWE in the Great Lakes. The passive microwave results seem to be heavily affected by the significant vegetation in the region considering the U.S. portion of the Lake Erie basin has a 14.9% forest fraction while the Superior, Michigan, Huron, and Ontario basins all have greater than 30% forest fraction according to the Vegetation Continuous Field collection from the University of Maryland (Hansen et al. 2006). Azar et al (2008) evaluated the SSM/I SWE products in the Great Lakes region using the SNODAS data and found poor results using the original passive microwave algorithm. They were able to improve the SSM/I results around the Great Lakes by developing an algorithm that uses a Normalized Difference Vegetation Index (NDVI) to classify the mixed use forest in the region. Figure 6 shows the SWE for the U.S. portion of the Lake Superior basin during the winter of 2003-2004, the only winter in common between the SSM/I, SNODAS, and CRREL data sets. In

the winter of 2003-2004, the SNODAS and CRREL data are well correlated ($R^2 = 0.91$) as might be expected since both the SNODAS and CRREL estimates likely use the same ground observations. This provides some confidence in the SNODAS SWE.

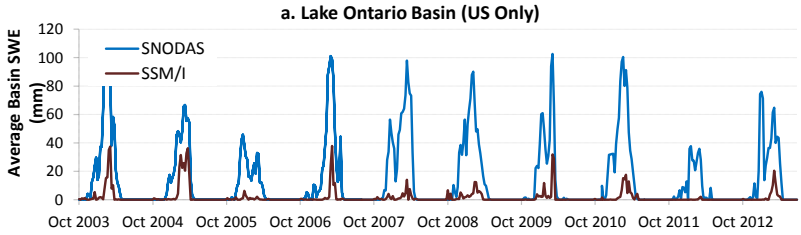

Figure 5 Lake Ontario basin (US only) SWE estimates since 2003

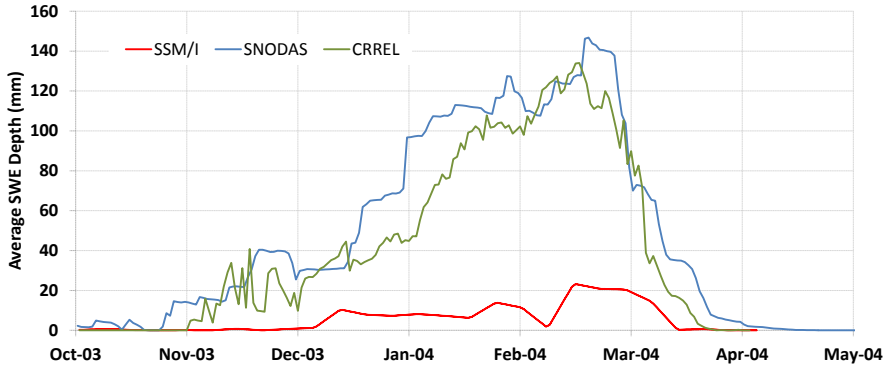

Figure 6 CRREL (daily), SNODAS (daily), and SSM/I (weekly) SWE estimation for Lake Superior (US only) for the winter of 2003-04

The LBRM Lake Superior SWE statistics were calculated using end-of-month data and are shown in the box and whisker plot of Figure 7. For Lake Superior, the snow pack generally begins to develop in November, peaks in March, and lasts until May. A further analysis is to look at the decline of SWE through each month, as shown in Figure 8, which shows the amount of water which is made available to runoff (when positive) or the amount of precipitation which enters snow pack (when negative). This figure clearly shows that SWE typically gives a boost to runoff, and hence the Lake Superior water level, during the months of April and May.

To further understand the influence of SWE within Lake Superior's hydrology, the statistics for historical runoff and historical precipitation were also analyzed, as shown in Figure 9 and Figure 10, respectively. The runoff component has been converted to depth units of mm over land, in order to match the units of SWE. The precipitation data set represents units of mm averaged over the entire basin, and this study will assume that the depth is constant over each part (land area and lake area). When comparing Figure 8 with Figure 9, one can clearly see an influence of SWE on runoff. However, Figure 10 shows that there is also an increase in precipitation at this time of the year as well.

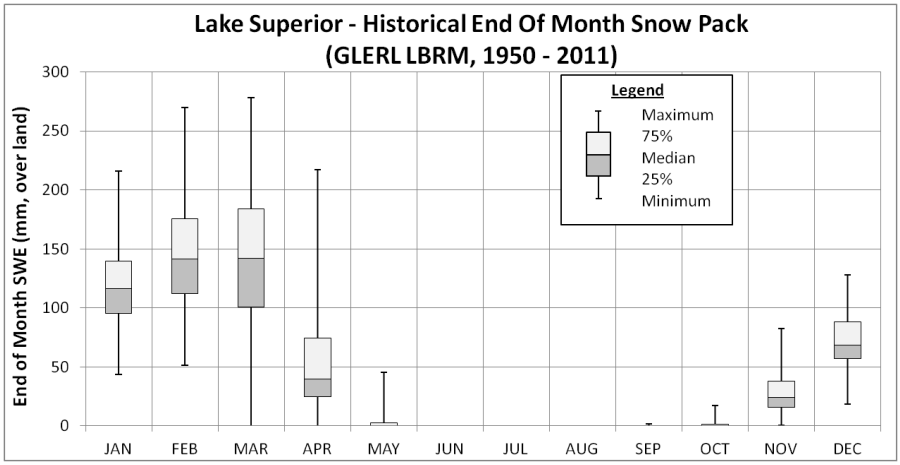

Figure 7 Lake Superior LBRM historical snow pack

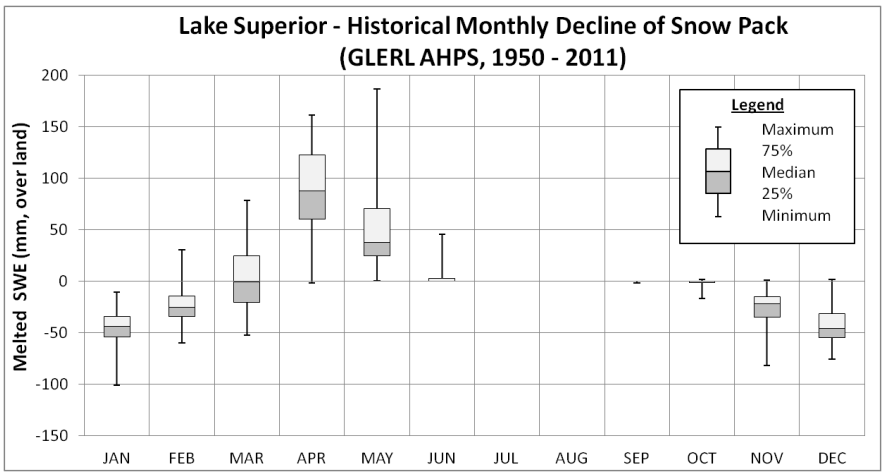

Figure 8 Lake Superior LBRM historical average decline of snow pack

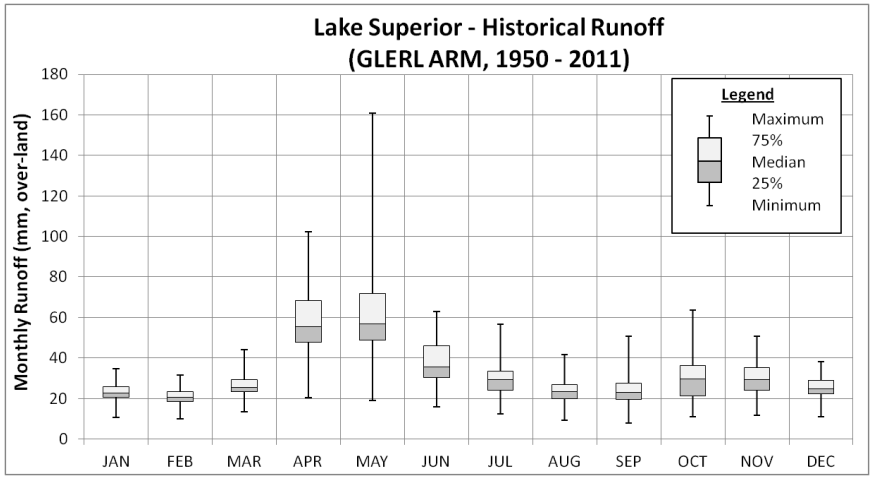

Figure 9 Lake Superior ARM historical runoff

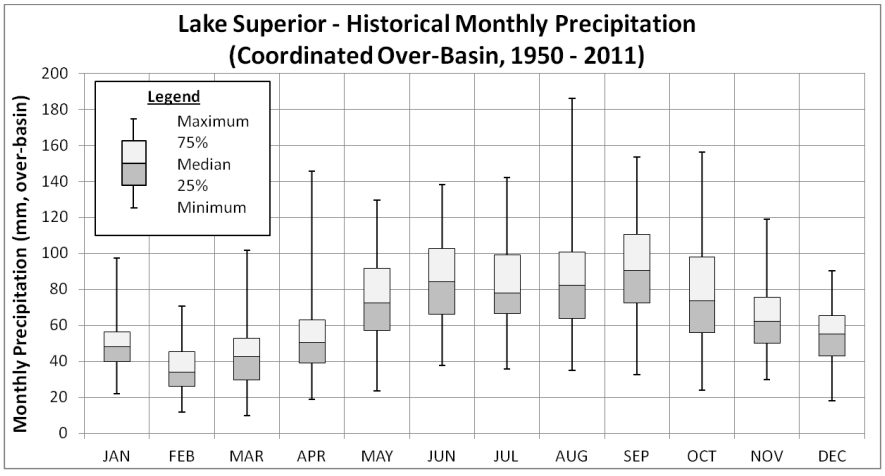

Figure 10 Lake Superior historical coordinated precipitation

Water which is available for spring's seasonal runoff to Lake Superior comes from two sources: melted SWE and spring over-land precipitation. This study found that developing a relationship

between only one of these components and runoff was not as strong as including both components. Figure 11a shows the historical data for Lake Superior during April of runoff on the vertical axis and the combined total of melted SWE and over-land precipitation on the horizontal axis. Figure 11b shows the historical data for the month of May. Other months exhibited much weaker relationships.

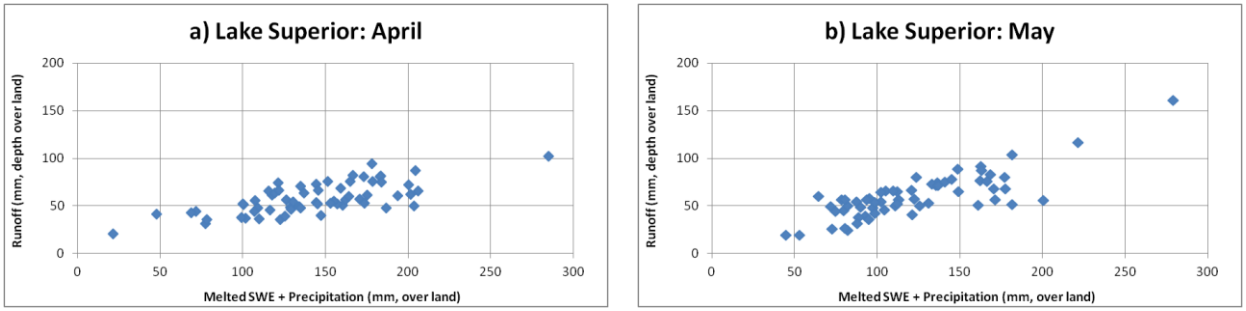

Figure 11 Relationship between Lake Superior runoff and the combined total of melted SWE and over-land precipitation for the months of (a) April and (b) May

As shown in the above figures, the total amount of available water is significantly greater than what arrives to the lake since much of the water infiltrates into the ground or is taken up by vegetation. For example, during the month of April the historical average amount of melted SWE in the Lake Superior drainage basin is 11.24 km^3 and the average over-land precipitation is 6.91 km^3 for a total of 18.15 km^3, while the average runoff during April is only 7.41 km^3. Assuming the two sources of water behave equally, 62% of Lake Superior's April runoff typically comes from melted SWE and 38% comes from over-land precipitation. For the month of May, 39% of Lake Superior's runoff typically comes from melted SWE while 61% comes from over-land precipitation.

APPLICATION: WATER LEVEL FORECASTING

A challenge in forecasting the Great Lakes water levels is determining how much of an adjustment to implement in the predicted water supply when viewing the near real-time SWE estimates within the basin. The analysis in the previous section demonstrated a clear relationship between the April and May runoff and the available water from melted SWE and over-land precipitation during each month. These relationships can be used in the water level forecast for the months of April and May.

Implementing the relationships of Figure 11 into operational forecasting is suggested in two basic steps: assess the current SWE and then adjust the forecasted runoff. First, the near real-time SWE estimates are compared with the average SWE for that time of the year. For example, a current end-of-March SNODAS SWE estimate is divided by the historical average end-of-March LBRM SWE. At the current time, this comparison has uncertainty since the best SWE estimates are from the SNODAS model while the relationships developed in the previous section used the LBRM data set. The SNODAS model only has full basin coverage since 2011, and although the two model results seem to agree relatively well in the recent overlapping years, this method should improve as more years of data become available.

Once the current relative SWE is determined, as a percentage of the typical SWE, the forecasted runoff can be adjusted using the typical proportion of melted SWE for that month. For the month of April, the average runoff volume for Lake Superior is 7.41 km^3, 62% of which (or 4.59 km^3) comes from melted SWE and the rest (2.82 km^3) from over-land precipitation. Since the relationship between runoff and available water was linear in Figure 11, the runoff adjustment is made by directly multiplying the SWE portion of runoff (4.59 km^3) by the current relative SWE. This text explained the connection in terms of water volume, but in general the USACE forecasts use units of flow rate for the runoff component. For runoff in units of flow rate, the same logic can apply by calculating the proportion (62%) of the flow coming from melted SWE and adjusting it based on the current relative SWE. As an example, if the current end-of-March SWE was 150% of average and the typical runoff for April was 2,560 m^3/s, the adjusted runoff for the forecast would be 3,350 m^3/s. An improvement to the forecasted runoff will also improve the Great Lakes water level forecast.

CONCLUSION

Available historic SWE data from passive microwave SSM/I and NOAA NOHRSC SNODAS were compared for the Great Lakes basin. Since the Canadian coverage of the SNODAS model is only available since 2011, figures present the 10 available years (since 2003) of U.S. coverage of SWE. Results indicate that SSM/I data severely underestimates Great Lakes SWE, likely due to the significant forest fraction within the basin. Historical LBRM snow pack, ARM runoff, and coordinated precipitation were analyzed for the Lake Superior basin in order to quantify the influence of SWE on the Lake Superior water level. A linear relationship was found between runoff and the combined total of melted SWE and over-land precipitation during the months of April and May. A method of adjusting the forecasted April and May runoff is suggested which uses near real-time SWE and the historical proportions of runoff which originate from melted SWE and over-land precipitation. As more years of SNODAS become available, the understanding of SWE behavior and its incorporation into the Great Lakes water level forecasts will continue to improve, as will the uncertainty in the proposed method.

Kay, P.E., Hydraulic Engineer, U.S. Army Corps of Engineers, Omaha, NE, roger.l.kay@usace.army.mil

Abstract: Hydraulic modeling was performed in support of the Yellowstone River Corridor Cumulative Effects Assessment (CEA). The CEA is a joint effort of the Yellowstone River Conservation Districts Council and the U.S. Army Corps of Engineers, Omaha District (Omaha District). The interdisciplinary study examines hydrologic, hydraulic, geomorphic, biologic and socioeconomic characteristics of and impacts on the Yellowstone River and adjacent floodplain in a 565-mile reach from Gardiner, Montana, to the confluence with the Missouri River in western North Dakota. The purpose of the study is to perform an assessment of the cumulative impacts for the entire river corridor and develop a comprehensive plan that provides for sustainable use of the river and its floodplain for both economic and environmental needs.

The hydraulic analysis is intended to detect changes associated with two potential drivers of cumulative effects: altered (regulated) hydrology due to water resources development within the Yellowstone River basin and physical alteration (development) of the Yellowstone River floodplain. One facet of the cumulative impacts assessment is to characterize the impacts of human development including man-made structures, encroachments, storage, diversions, and depletions on the Yellowstone River hydraulic profiles and flood boundaries, by comparing current and “pre-historic” conditions.

The hydraulic analysis utilized the modeling software HEC-RAS and geospatial software ArcGIS and the Geo-RAS extension for model geometry development and floodplain mapping. Flow information was obtained from an intensive hydrology study of the basin performed jointly by Montana U.S. Geological Survey (USGS) and Omaha District. The hydraulic model was developed to evaluate human impacts by generating two geometry files and two flow files. The geometry files include “Developed” conditions (i.e., the file represents current conditions with existing bridges, embankments, diversion dams, etc.) and “Undeveloped” conditions (i.e., human made structures are manually removed from the geometry file.) The flow files include “Regulated” conditions (i.e., hydrologic discharges representing current conditions resulting from human-controlled reservoirs, irrigation canals, etc.) and “Unregulated” conditions (i.e., hydrologic discharges represent natural conditions). Four scenarios were modeled using these input files.

Comparison of the results from modeling and mapping the combinations of the geometric and hydrologic conditions provided valuable information for a range of flow frequencies that will

assist the CEA and restoration planning process. Results critical to the cumulative effects assessment include the extent of inundated floodplain under differing scenarios, hydraulic characteristics (e.g., river stages, velocities, flow depths) and the differences between each scenario. Of particular interest to cumulative effects assessment and restoration planning is the frequency of side channel and floodplain inundation and how that frequency may have changed over time due to channel modifications and water resourcing.

INTRODUCTION

The Yellowstone River is one of the longest free-flowing rivers in the lower 48 states (USGS, 2013). The river corridor provides for various sized communities; supports agricultural (range and crop), industrial, commercial and recreational uses; and is home to abundant wildlife. The river crossings in the study reach are limited to bridges and low-head weirs, and channel modifications consist of bank stabilization, flow deflectors and side channel cutoffs. Floodplain development includes urbanization; transportation routes; Federal, community and agricultural levees; and irrigated and dryland farming. The width of the 100-yr floodplain ranges from 0.12-miles to 2-miles within the study reach. Narrow floodplain widths are due to both natural and man-made flow constrictions.

The study area for the Yellowstone River hydraulic analysis extends from the Park-Sweet Grass County line at River Mile 478.2 to the confluence of the Missouri River floodplain at River Mile 2.8 (Figure 1). Within the study reach, the Yellowstone River and its corridor are described by its alluvial system characterized by its meandering flow path, anabranching side channels, vegetated islands and dynamic gravel bars (DTM Consulting, 2009).

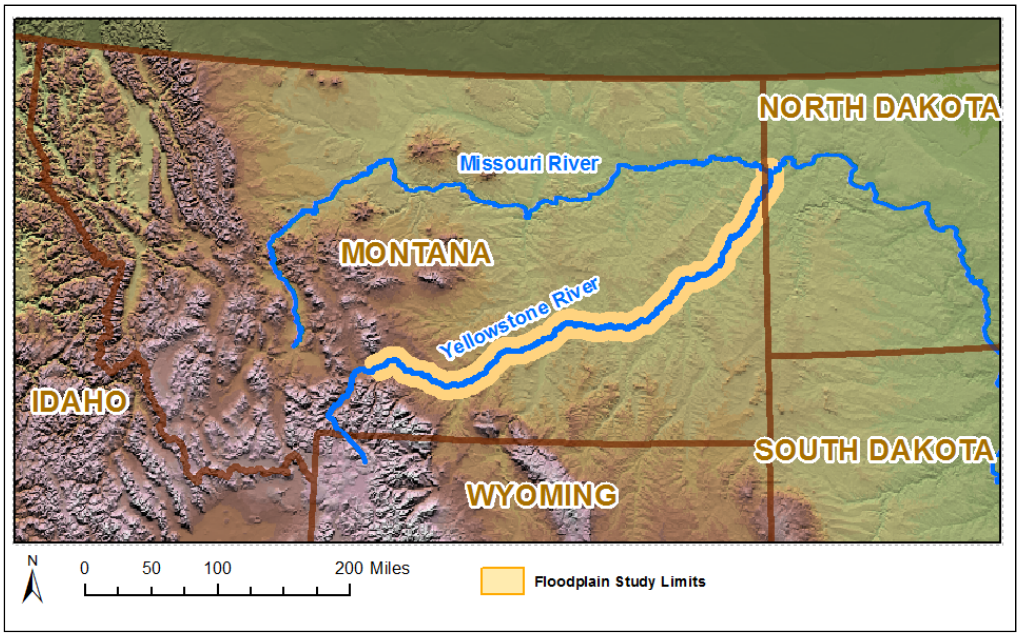

Figure 1 Hydraulic Study Location and Extents

MODELING APPROACH

Water surface profile models of the Yellowstone River were developed using the U.S. Army Corps of Engineers Hydrologic Engineering Center-River Analysis System (HEC-RAS) backwater computer program Version 4.1 (USACE, 2010) utilizing steady-state and subcritical flow computations to calculate water surface profiles and associated hydraulic parameters. The main computational procedure, generally known as the standard step method, is based on the solution of the one-dimensional energy equation with energy loss from friction evaluated with Manning's equation and from flow constrictions and expansions. The model requires terrain and flow inputs to characterize the floodplain and hydrology, respectively.

Hydrologic Data: The hydrologic analysis was conducted as two studies. The hydrology for the reach upstream of the Big Horn River was conducted by the Omaha District (USACE, 2011). The study downstream of the Big Horn River was conducted by the USGS (USGS, 2013). The same methodology was utilized to develop the Regulated and Unregulated discharges in both studies. Daily stream flow data were collected from gauging stations throughout the Yellowstone River Basin for the 1928-2002 study period. Missing periods were synthesized from monthly mean flows. Once an entire dataset of observed flows was developed for the period of record, historical depletions (including reservoir holdouts) recorded by the Bureau of Reclamation were added to the observed flow dataset, and Bulletin 17B methodology was used to generate the Unregulated peak-flow frequency data. Then, the depletions recorded in 2002 were subtracted from the Unregulated dataset to generate the Regulated peak-flow data. The discharges selected for the hydraulic analysis include the 67-, 50-, 20-, 10-, 5-, 2-, 1-, 0.5- and 0.2-% annual chance exceedance (ACE) events and the 5% by duration event. These discharges were identified as beneficial for the cumulative effects assessment, and hydraulic results are intended to support concurrent studies including aquatic, riparian, avian, socioeconomics and water quality.

Topographic Data: Topographic data was collected in 2004 and in 2007 as Light Detection and Ranging (LiDaR) data and supplied as Triangulated Irregular Network (TIN) data file. The data were provided in Montana State Plane Coordinates, NAD83, suitable for generation of 1-meter contours. Accuracy was evaluated with ground truthing and surveyed spot elevations, meeting National Map Accuracy Standards. Bathymetric data was collected in 2004 for select study reaches. Floodplain and bathymetric data were merged and provided in TIN format and 2.5-meter Digital Elevation Models (DEMs). All elevations are referenced to the North American Vertical Datum of 1988 (NAVD88) unit meters. Aerial imagery was collected in 2004 and 2007.

Hydraulic Model: Nine individual HEC-RAS projects were created covering the ten counties included within the study. The hydraulic model geometry was created utilizing the ESRI ArcGIS software and HEC-GeoRAS, a GIS extension specifically designed to process geospatial data for use with HEC-RAS. The HEC-GeoRAS extension allows the creation of an HEC-RAS import file containing geometric attribute data from an existing digital terrain and complementary data sets. The corresponding ArcGIS software extensions 3D Analyst and Spatial Analyst were also utilized for geometry development.

In HEC-GeoRAS, an import file was created containing river, reach and station identifiers by generating GeoRAS layers consisting of a stream centerline, cross-sectional cut lines, bank

stations, overbank flowpaths, and cross-sectional roughness coefficients. These GeoRAS layers were combined with the terrain elevation files, and the software calculated the downstream reach lengths for overbanks and channel, extracted cross-sectional station and elevations points, and generated the HEC-RAS input file.

Cross sectional cutlines were spaced approximately 500 to 1000 feet apart, with closer spacing near structures and areas of specific interest to adequately represent the hydraulic impacts of the structure. Spacing exceeded 1000 feet in areas of sharp channel bends to prevent the cutlines from overlapping in the overbanks and in areas of inadequate survey data. Cutlines were drawn perpendicular to both channel and overbank flow and often dog-legged to adequately represent the overbanks and sinuous channel as a one-dimensional system. Cross sections were extended to high ground to ensure capture of elevation data for the 0.2% ACE.

Additional GeoRAS layers were incorporated. A vegetative cover shapefile was provided by the Montana Natural Resource Conservation Service (NRCS) for the entire study area as a 2006 vegetative cover map. Corresponding Manning's Roughness Values were assigned based on available reference data and engineering judgment. The overbank flow paths were drawn based on the anticipated flow path of the 1% ACE. Once the GeoRAS layers were compiled, the HEC-RAS import file was generated and brought into the program.

In HEC-RAS, the structures such as bridges, levees and diversion dams were characterized, channel bank locations were edited and river mileage was included. The roughness values imported from GeoRAS were verified for the channel and overbanks and adjusted where appropriate. Expansion and contraction coefficients were 0.3 and 0.1, respectively, for typical channel cross sections. The coefficients of 0.5 and 0.3, respectively, were used to characterize all bridges and the diversion dam. Bank stations were placed at locations defining the main channel and typically assigned elevations between the 67% ACE and 0.2% ACE profiles.

In areas where bathymetric data was not collected, a low-flow trapezoidal channel was incorporated into the model geometry. The channel flows at the time the LiDaR surveys and aerial photographs were collected were used to approximate the channel width and depth and applied to the entire county reach. The modeled low flow water surface was compared and calibrated to the LiDaR water surface and the wetted channel shown in the aerials. Adjustments to the low flow channel dimensions were made to individual cross sections. The calibration of the low-flow channel was generally within one foot of the LiDaR surveyed water surface.

Developed Model Geometry: The developed model geometry represents current conditions and includes terrain alterations due to human development. Structures incorporated into the model include transportation embankments, Federal and agricultural levees, canals and ditches, wastewater treatment lagoons, and designed depressions and pilings (e.g., quarries and electrical tower pilings). Yellowstone River structures requiring manually-entered descriptions in HEC-RAS include bridges and low head dams. Bridge surveys were performed by the Montana USGS between 2005 and 2009 and included bridge dimensions, chord elevations, and pier and channel descriptions. A total of 39 bridges were modeled, and one low head dam was modeled at Intake, MT in Dawson County. Surveys of Intake Diversion Dam were obtained from the Intake Fish Passage Study (USACE, 2009).

Ineffective flow areas and levees were coded into the HEC-RAS model by inspecting cross sections, contours, aerial photographs and structure descriptions to determine applicability, location and elevation. The locations of Federal levees were verified and natural and agricultural levees were identified based on the terrain elevation and flow characteristics between adjacent cross sections. Ineffective flow restraints were also added manually to the geometry to follow conveyance expansion and contraction guidelines. The ineffective flow area and levee options were set with the attempt to represent all stream flows; however the 1% ACE was used as the basis for calibration.

An in-depth Physical Feature Inventory was generated as part of the CEA study. This database includes locations and descriptions of various structures including bridges, embankments, low-head dams, canals, irrigation returns, and bank stabilization. The inventory and geo-database was useful in determining structures location, type and applicability to the hydraulic modeling.

Undeveloped Model Geometry: The Developed model geometry was used as a base for the Undeveloped model geometry. The Undeveloped geometry was generated by manually adjusting each cross section's station elevation points from the Developed geometry file that represent man-made features such as railroad embankments, levees, elevated roads, etc. Elevations of natural land adjacent to the structures were used to estimate natural elevations at the structure. Bridges and inline structures and the immediate downstream bounding cross section were also removed within the HEC-RAS model. Manning's Roughness Values for urban areas, decreased expansion and contraction coefficients which define bridges, ineffective flow areas representing flow restriction due to man-made structures, and other associated geometric components attributed to human impacts were also adjusted or eliminated to reflect natural conditions.

Figure 2 shows a cross section in Billings, MT at River Mile 366.2. The cross section, high-lighted in red on the top image, is depicted in the bottom image. The station elevation points shown in pink represent the man-made structures captured in the LiDAR surveys. These points were manually removed and the final undeveloped geometry is shown in black. Similarly, the ineffective flow areas were widened due to the removal of the man-made structures allowing more of the overbanks to convey flow.

The channel geometry, including the approximated low flow channel, was not adjusted as part of the Undeveloped geometry characterization. Although locations of bank stabilization (e.g., riprap protection, flow deflectors, etc.) have been identified through the CEA, it is difficult to predict the spatial and vertical degradation and aggradation potential and the extent of channel migration under completely natural terrain and flow conditions.

Flowpaths were not adjusted as part of the Undeveloped geometry adjustments. The 1% ACE flowpath was used to describe channel and overbank flow distances between cross sections for the Developed geometry. Structures such as embankments and levees may cause significant flow restrictions and affect the flow path and distance. Removing a flow-restricting structure would widen the conveyance area resulting in a shorter flowpath.

Most structures are apparent on the recent aerial photographs and terrain surveys and were listed in the physical feature inventory. In some areas with significant or questionable development, the 1950 historic aerial photographs (DTM Consulting, 2006) were used as a guide to estimate the extent and contours of the natural system. However, significant engineering judgment was used to create the Undeveloped geometry files due to the limited historic information and the use of current terrain data to estimate undeveloped terrain.

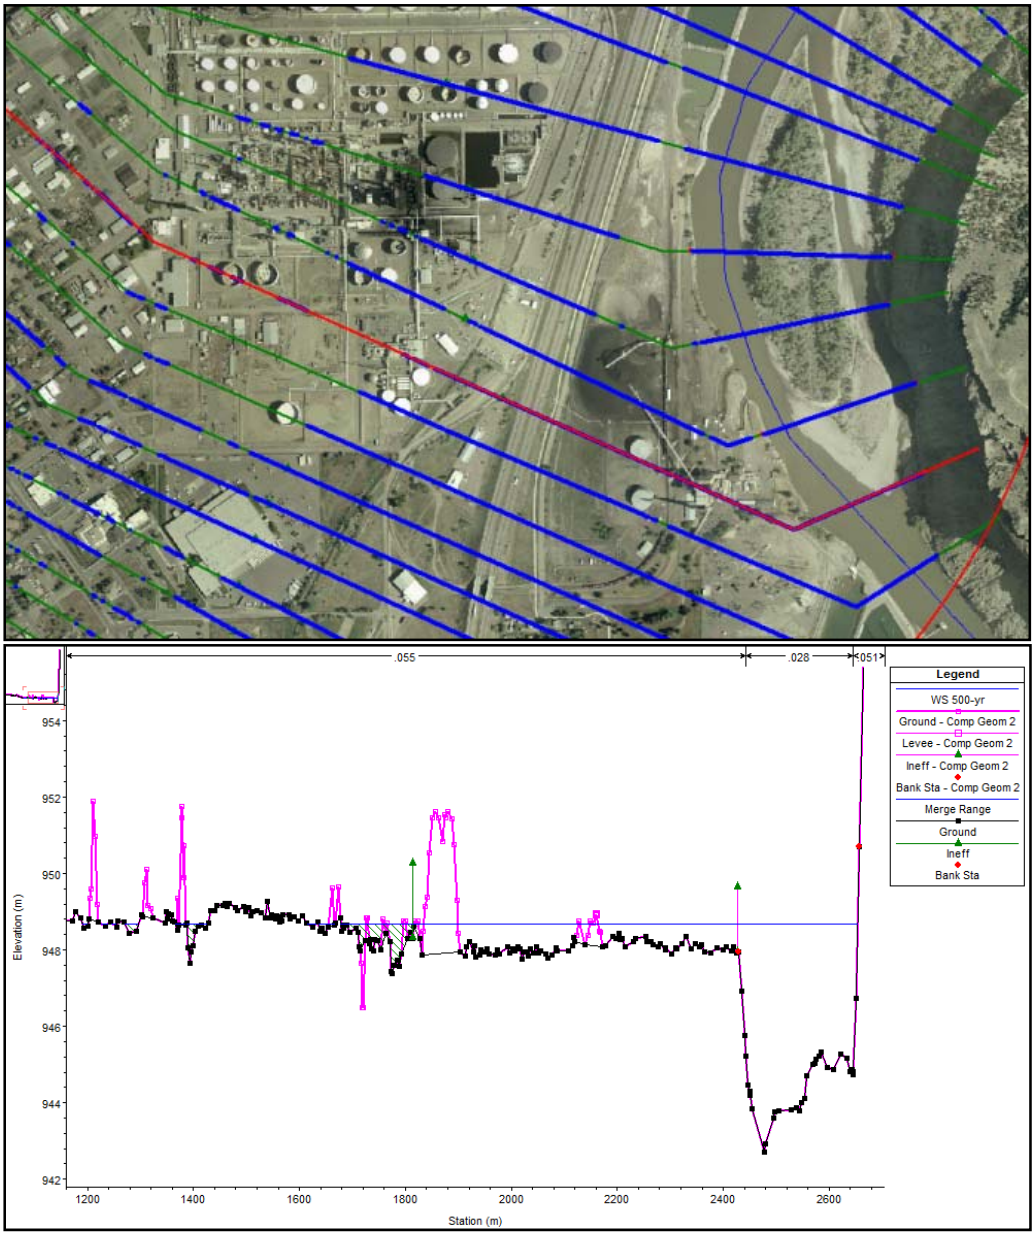

Figure 2 Removed Man-Made Structures in Undeveloped Geometry File, Billings, MT

In several instances, human modification was apparent, but the level and extent was uncertain as comparison of adjacent terrain and current and historic aerials did not always offer an indication of historic conditions. For example, much of the floodplain consists of irrigated cropland that has

been terraced and sloped in an effort to maximize irrigation efforts. However, it is difficult to discern if soil was added, removed, or both, in order to obtain the gentle slope. A potential example of this is shown in Figure 3 and highlighted in green for River Mile 68.1 in Dawson County. In areas of uncertainty, the Undeveloped terrain was not adjusted, and the Developed geometry obtained from the LiDAR surveys was used.

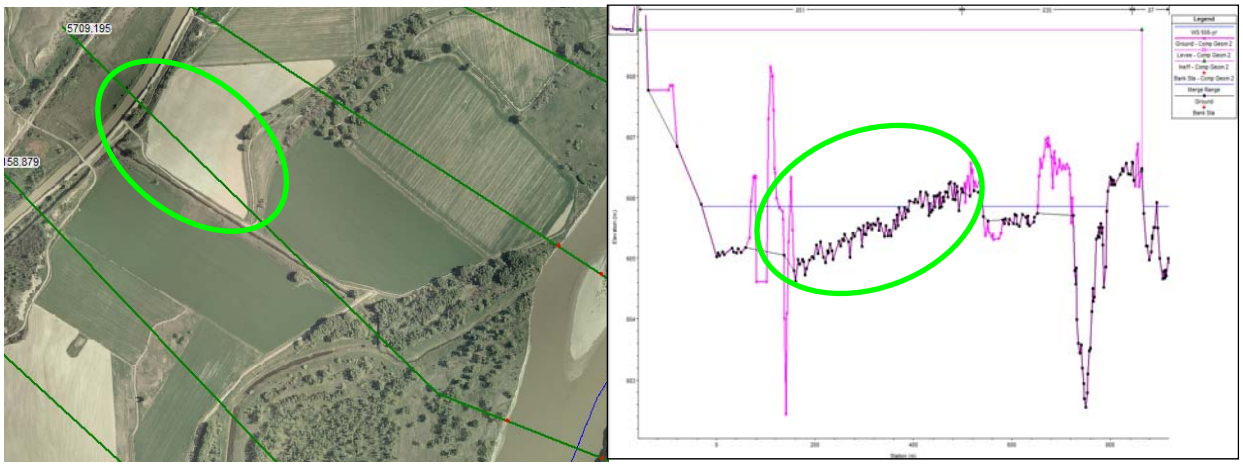

Figure 3 Undeveloped Terrain Uncertainty

Model Plans: A starting water surface for each profile was either computed by HEC-RAS using the normal depth calculation based on the energy slope for subcritical flow or was defined by water surface results from adjacent models. Results were incorporated between adjacent models to ensure continuity throughout the study reach.

Four modeling scenarios were executed as individual HEC-RAS plans for each model. By modeling a combination of the Developed and Undeveloped geometries with the Regulated and Unregulated flows, the individual components of human impacts on the terrain and flow regulations, can be evaluated. The scenarios modeled are listed in Table 1.

Table 1 Scenarios Modeled

Scenario	Geometry File	Flow File	Characterization Intent
Developed Floodplain Conditions A	Developed	Regulated	Current conditions
Developed Floodplain Conditions B	Developed	Unregulated	Storage reservoirs and irrigation diversions impacts
Undeveloped Floodplain Conditions A	Undeveloped	Regulated	Man-made structures impacts
Undeveloped Floodplain Conditions B	Undeveloped	Unregulated	Natural conditions

By comparing results from the four modeled scenarios, it is possible to characterize the impacts of human influence on the system. Table 2 lists the water surface elevation computed for the 5% ACE

at selected locations upstream and downstream of structures. By comparing the resulting elevations of the four scenarios, the impacts of the structures and flow regulations on the river stages are apparent. Similarly, Figure 4 depicts the resulting water surface profiles for the four scenarios at the railroad bridge in Glendive, MT.

Table 2 Water Surface Results (elevation meters), 5% ACE (20-yr), Dawson County

Location	River Mile	Develop A	Develop B	Undevelop A	Undevelop B
Five miles upstream of Glendive	99.68	632.77	633.13	632.77	633.13
Upstream of the BNSF RR Bridge in Glendive	94.57	628.46	628.90	628.07	628.38
Upstream of the I-90 Bridge in Glendive	92.18	625.62	626.03	625.35	625.70
Five miles downstream of Glendive	87.17	620.65	620.99	620.65	620.99
Upstream of the Intake Diversion	73.07	609.25	609.52	608.94	609.23
Downstream of the Intake Diversion	72.83	608.60	608.92	608.60	608.92

MAPPING APPROACH

Inundation maps were generated for select water surface profiles and scenarios to the extent of the survey data and as shapefile polygons, depth grids and 0.2-meter depth interval polygons. All mapping products have a projection of NAD 1983 Montana State Plane and NAVD 88 datum, unit meters. Due to ArcMap constraints, all inundation mapping was performed utilizing the 2.5-meter DEMs generated from the LiDaR surveys.

Mapping was performed for each county model utilizing the HEC-GeoRAS ArcMap extension, and inundations extend to the county lines to ensure continuity within the study reach. Once initially mapped, backwater areas were identified. Backwater areas connect to the inundated system at one location resulting in a single water surface elevation for the backwater area. Since

HEC-GeoRAS mapping is performed using a sloping water surface TIN for the entire river reach, proper mapping of backwater areas required additional efforts. For Undeveloped conditions, only backwater areas that occurred due to the natural terrain were remapped. Due to the additional level of effort, only backwater areas that affect large areas and several flood profiles were considered and remapped.

Backwater modeling efforts included one of two approaches, depending on the number and locations of backwater areas. If several backwater locations were identified in a county reach, a new water surface TIN was generated that incorporated the sloping profile of the main channel and the single elevation of each backwater, and the entire reach was remapped with the GeoRAS extension. If only a couple backwater areas were identified, these locations were remapped individually. The original, sloping backwater was clipped out and the revised backwater elevation was merged with the main channel. This was done for both the inundation shapefiles and the inundation depth grids.

An example of the backwater mapping result is shown in Figure 5. The image shows the right bank of the Yellowstone River just downstream of the Highway 310 Bridge in Laurel, MT at the Clarks Fork confluence for the Developed Floodplain Conditions A 1% ACE. Traditional GeoRAS mapping extends the calculated water surface profile from the main channel across the entire cross sections (shown as green lines) and results in an inundation boundary shown in orange. Upon close examination, the inundated area only connects to the main channel at one downstream location. The elevation at the connecting point was used to reprocess the water surface and the resulting main channel and backwater inundation area is shown in blue. Tributaries to the Yellowstone River were not part of this study; therefore the final backwater inundation only represents the impacts from the Yellowstone River flood event.

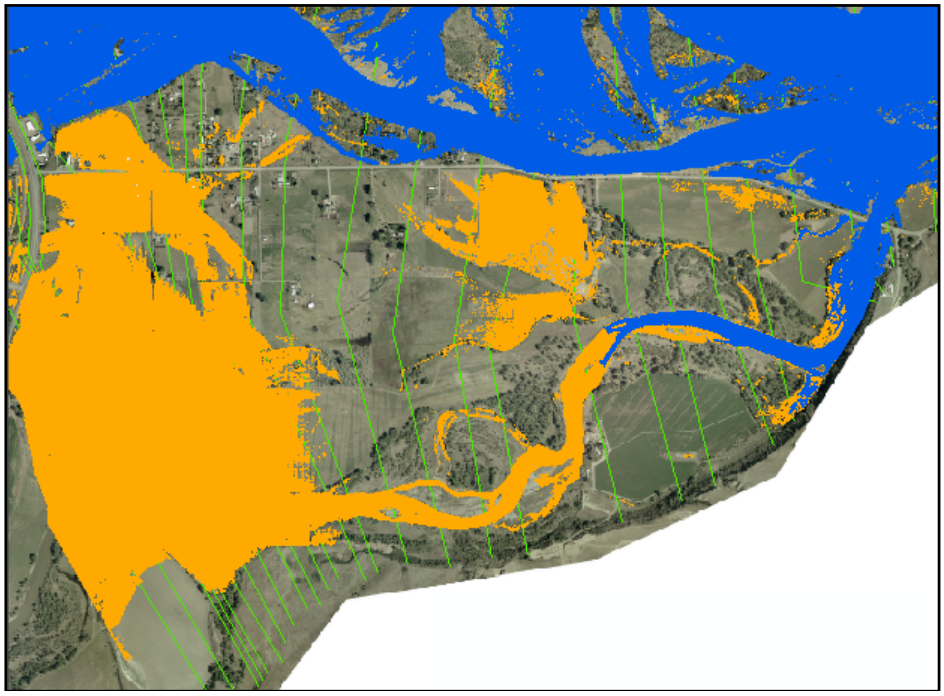

Figure 5 Backwater Inundation Remapped at Clarks Fork Confluence

During mapping editing, excess ponding areas and disconnected floodplains were removed if they were not directly connected to the main channel. Some areas appeared connected through a culvert or a bridge that was not removed in the survey data. If a culvert, bridge or other connection point is evident in the aerials or survey data then the area was considered connected and mapped as inundated. If a connection was uncertain, then the inundated area was considered disconnected and removed.

Undeveloped geometry mapping required additional efforts. Although the structures and station-elevation points were removed in the HEC-RAS models, the man-made features were not modified in the terrain data files. Therefore, manual adjustments were made to the inundation shapefiles in areas where man-made structures are present. For example, the presence of a road embankment may detach an inundated area of the floodplain from the main channel, and these areas were manually connected to reflect the Undeveloped inundation extent. Only disconnected areas or backwater locations due to the natural terrain were removed or remapped, respectively. Similarly, inundations boundaries were smoothed where any structure (e.g., bridge embankment, fishing access point, etc.) causes an unnatural boundary. Although the inundation shapefiles were edited, the depth grids reflect the depths with respect to structures since they were generated from the DEMs.

Figure 6 shows the mapping results for the Undeveloped conditions at Forsyth, MT. The image on the left compares the edited inundation boundary of the Developed condition in blue to the Undeveloped condition in orange for the 1% ACE Regulated flow. The Federal Levee is located on the south overbank and significantly restricts floodplain conveyance, apparent in the image on the left. The image on the right depicts the same area as a depth grid for the Undeveloped condition. The structures captured in the LiDAR survey are apparent and were not adjusted for the final depth grid. However, these features were edited for the inundation shapefile to show the areas spanning the structures as flooded.

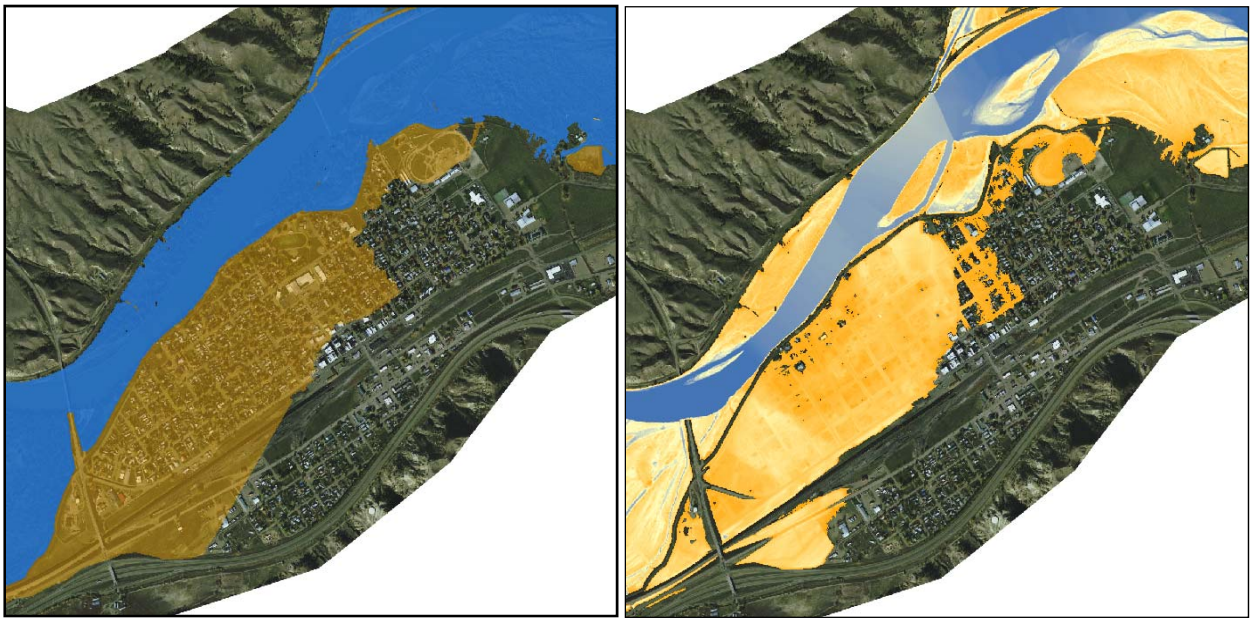

Figure 6 Undeveloped Conditions Shapefile and Depth Grid

DIFFICULTIES AND ASSUMPTIONS

Topographic data was provided as TINs and DEMs. When performing the hydraulic analyses, utilization of the TINs are preferred due to the slight increased level of accuracy over the generated DEMs. However, several of the TINs supplied contained errors and could not be read by the ArcMap software. For consistency throughout the study, the DEMs were used for the majority of the modeling and all of the mapping products. The DEMs were created using 2.5-meter pixels. This high resolution resulted in minimal added error.

Portions of the floodplain terrain were not fully captured or were incomplete. In areas of incomplete data, cross sections were spaced further than the desired 1,000 feet, were modeled by manual adjustments within HEC-RAS using USGS topology maps, or the DEMs were patched with USGS digital terrain data.

In some mapping products, the edges of the floodplain shapefiles and depth grids do not line up exactly with the source DEMs. This was observed between the shapefiles and corresponding depth grids, between individual profiles and between scenarios. The error varies between products and is less than one pixel (2.5-meter). The source of the error appears to occur during the extraction of the shapefiles and depth grids from the HEC-GeoRAS geodatabase. Although the error is small, caution should be used when comparing mapping products.

The HEC-RAS program is a one-dimensional model that was used to represent a wide floodplain and a range of stream flows. The one-dimensional computations assume a constant water surface elevation across the entire cross section. In reaches with large islands, this assumption may not be accurate and would warrant a split flow analyses. Similarly, ineffective flow area locations may be unique to each stream flow based on water surface elevations and terrain conditions. Therefore, the single or dual geometry files used in this analysis may not accurately characterize all flow conditions and results should be considered a general representation of the system.

The Undeveloped geometry created for this study is a generalized representation of the natural topography of the floodplain. The use of the developed terrain to generate the undeveloped conditions is a significant limitation to the hydraulic analysis. Although manmade structures were removed within the model and maps, some components such as inhibited channel migration and floodplain aggradation and degradation, which may have occurred extensively under natural conditions, could not be represented without significant further analysis and was beyond the scope of this study.

CUMULATIVE EFFECTS ASSESSMENT

Comparison of the results from modeling and mapping the combinations of the geometric and hydrologic conditions will provide valuable information for a range of flow frequencies that will assist the cumulative effects assessment and restoration planning process. Results critical to the cumulative effects assessment include the extent of inundated floodplain under differing scenarios, resulting hydraulic characteristics (e.g., river stages, velocities, flow depths) and the differences between each scenario. Of particular interest to cumulative effects assessment and

restoration planning is the frequency of side channel and floodplain inundation and how that frequency may have changed due to channel modifications and water resourcing.

Inundation shapefiles have been generated for select locations, scenarios and profiles. From these mapping results, comparisons can be made to characterize the impacts that man-made structures, flow regulation, or both have on the Yellowstone River Corridor. Isolated floodplains due to 1) flow regulation, 2) physical structures, and 3) both flow regulation and physical structures were evaluated as part of the CEA to characterize the impacts humans have had on the floodplain for the 50%-, 20%- and 1%-ACE. An example of Historic Floodplain Isolation is depicted in Figure 7 at the Rosebud-Custer County Line for the 1% ACE. The orange polygon represents the area of natural floodplain that is no longer inundated due to human development and flow regulation, and the blue polygon represents the current floodplain inundation.

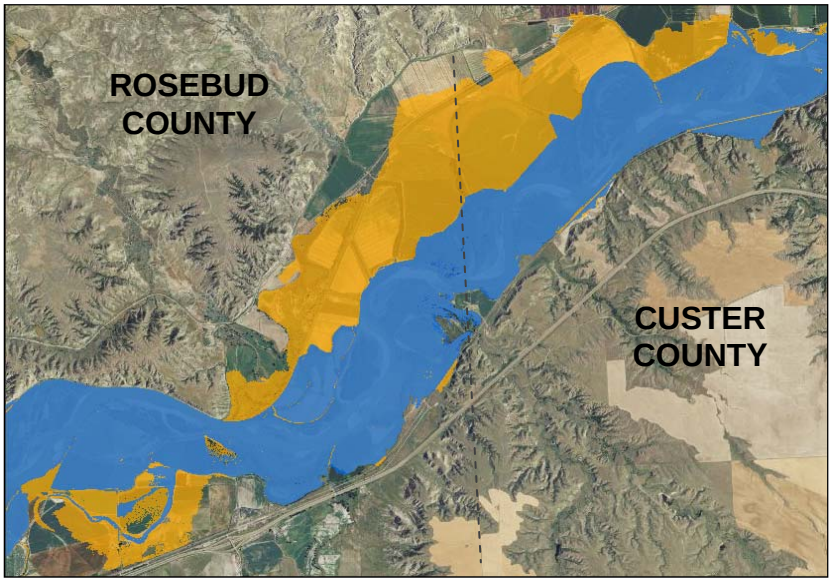

Figure 7 Historic 1% ACE Floodplain Isolation Example at the Rosebud-Custer County Line

BACKGROUND

The Colorado River provides drinking water to nearly 40 million people and supplies water to irrigate over five million acres of farmland across seven western states and is vital to agricultural and municipal needs within the United Mexican States. The Colorado River also supports numerous ecological and recreational resources, provides water for hydropower generation, and is the lifeblood for 22 federally recognized tribes within the Colorado River Basin (Basin) (Bureau of Reclamation, 2012). The Basin is depicted in Figure 1.

As part of the Bureau of Reclamation's (Reclamation) WaterSMART program, the Colorado River Basin Water Supply and Demand Study (Basin Study) was conducted by Reclamation and the seven Colorado River Basin States in collaboration with stakeholders throughout the Basin. The Study's objectives were to assess future water supply and demand imbalances in the Basin over the next 50 years and develop and evaluate options and strategies to resolve the imbalances. To address the considerable amount of uncertainty in projecting the future state of the Colorado River system, the Study adopted a scenario planning approach that resulted in four water supply scenarios (each with over 100 future realizations), six water demand scenarios, and two reservoir operation scenarios. The combination of all of these scenarios is referred to as the baseline in the Basin Study. The Basin Study shows that by 2060, the median supply and demand imbalance in the baseline is approximately 3.2 million acre-ft, though it can range from 0 to over 7 million acre-ft. Though these estimates ignore both the effectiveness of using reservoirs to help meet demands in times of drought and the geographic disparity of supply and demand, it indicates that in the absence of any actions, there is potential for large imbalances in the future (Bureau of Reclamation, 2012).

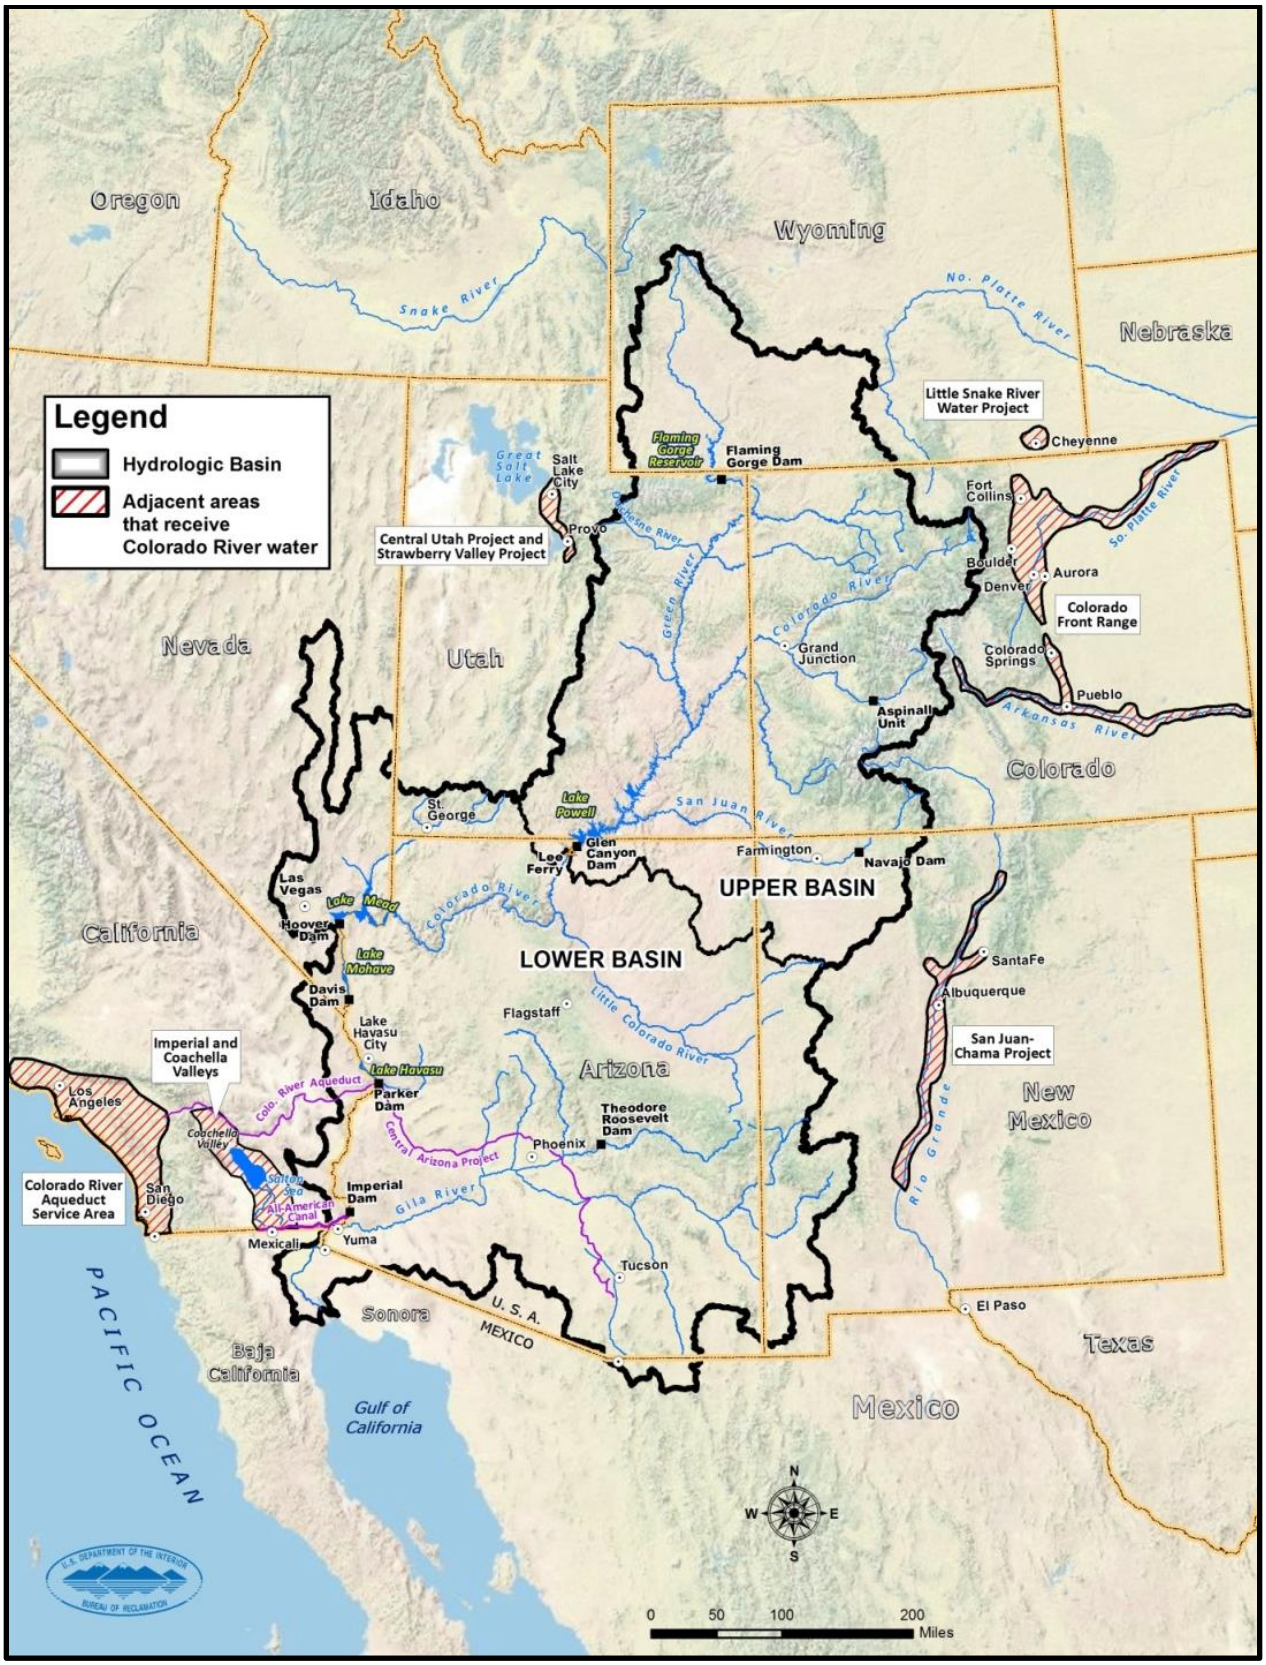

Figure 1 The Colorado River Basin

Options to help address the projected imbalances were solicited from the public. 160 options ranging from increasing the supply through importations or desalination to decreasing demand through various conservation efforts were submitted during the Study. Four unique portfolios, or strategies combining various options, were then developed from the many options as examples of different strategies for resolving system imbalances. The combination of each portfolio combined with all baseline scenarios to analyze the performance of the portfolios across a wide range of plausible future scenarios. The tradeoffs between price, yield, and ability to improve system performance were compared across portfolios using a robust decision making framework. System performance was indicated through reliability metrics that were developed for water delivery, electrical power, water quality, flood control, recreational, and ecological resource categories. The metrics were evaluated to understand how resource vulnerabilities changed through time, geography, and across resources, and the extent to which vulnerabilities could be mitigated through actions.

The Study concluded that the Basin faces an uncertain future with a range of potential imbalances between supply and demand, and that all resources within the Basin are increasingly vulnerable through time, due to both increasing demands and the potential for decreasing supply due to climate change. However, the Basin Study's portfolios demonstrated that actions do help meet the imbalances and reduce vulnerabilities. Actions and diligent planning are necessary at the local, state, regional, and Basin-wide levels, as there is no single solution. Rather, as demonstrated by the many options comprising the portfolios, a wide-range of solutions are necessary and it is imperative to begin work to further some of the concepts in the near future. Though there was no decision made in the Basin Study, the modeling tools and methods employed during the Study provide a common technical foundation for future actions. A suite of modeling tools forms the basis of this technical foundation and was necessary to conduct the Basin Study.

MODELING TOOLS

In order to carry out the scenario planning approach employed by the Basin Study, a suite of modeling tools was necessary. The foundation of the suite was an existing model, though some enhancements were necessary, and several new tools were developed to both help meet the needs of the Study and provide for generalized tools with application beyond the Basin Study.

The Colorado River Simulation System (CRSS): The Colorado River Simulation System (CRSS) has been Reclamation's long-term planning model since the 1980's. Originally developed in Fortran, CRSS was converted to RiverWare®, a generalized reservoir operations modeling platform (Zagona et al., 2001), in 1996. CRSS models the entire Basin, from headwaters in the Upper Basin, e.g., Green, San Juan, and Gunnison, down to the northerly international boundary with Mexico. The operations of nine Upper Basin Reservoirs and three Lower Basin reservoirs, including Lakes Powell and Mead, are represented in CRSS while deliveries are simulated to hundreds of users throughout the Basin. The basis of the simulation is a mass balance (or water budget) calculation that accounts for water entering the system, water leaving the system (e.g., from consumptive use of water, trans-basin diversions, evaporation),

and water moving through the system (i.e., either stored in reservoirs or flowing in river reaches). The model is used to simulate the future conditions of the Colorado River system on a monthly time-step for decades into the future (2012-2060 in the Basin Study). See Reclamation (2012) for more details on CRSS.

CRSS was used as the modeling tool in the Basin Study to simulate all 240 scenarios (the combination of all four supply scenarios, six demand scenarios, two reservoir operating options, and four portfolios). As each scenario contains over 100 future realizations, all together over 110,000 unique 50-year simulations were made. Studies such as the Basin Study or the modeling to support the Colorado River Interim Guidelines for Lower Basin Shortages and Coordinated Operations for Lake Powell and Lake Mead EIS (Reclamation, 2007) that utilize CRSS take advantage of RiverWare's features and policy language to perform efficient "what-if" analysis. Features in RiverWare make it easy to import different data to perform such analyses; however, until recent development, this was a manual step. In the case of the Basin Study, which simulated 240 total scenarios, this would require many human hours to complete. Additionally, manually launching each scenario increases the total run time for such an effort.

RiverSMART: To help alleviate these issues while supporting the Basin Study and other similar scale studies, development of the RiverWare Study Manager and Research Tool (RiverSMART) was undertaken. The RiverSMART facilitates the creation, execution and archiving of planning studies that compare the results of many scenarios, all steps one must manually take when using RiverWare to simulate multiple scenarios. RiverSMART provides a user friendly interface as shown in Figure 2. For construction of a study, this also provides a graphical representation of the study to help conceptualize all of the components and their interactions.

RiverSMART is built on a plug-in architecture and provides the framework for communication amongst the various plugins. In general, the plugins generate hydrologic ensembles, specify alternative input data to the RiverWare model, define alternative model configurations and policy, and post process desired outputs. Each individual instance of a plugin is called an event. Each event has settings that are configured by the user. Following is a description of some of the plugins available in RiverSMART (input side) and utilized in the Basin Study:

- Hydrology Simulator and Disaggregation Plugins: The Hydrology Simulator plugin synthesizes an ensemble of streamflows from reference values, usually observed historical or paleo reconstructed values. There are various methodologies available including K Nearest Neighbor resampling, Paleo Conditioned Homogenous Markov Chains, and Paleo Conditioned Non-homogenous Markov Chains. There is also a Spatial Disagg plugin to disaggregate the flows from one site to a number of sites according to correlations of the reference data. The Temporal Disagg plugin disaggregates annual ensemble data to a monthly timestep.
- RiverWare Model: The RiverWare Model plugin instructs which RiverWare model to use. This allows the user to develop alternative facilities or model configuration as a component in the study.
- RiverWare DMI: The Data Management Interface (DMI) plugin instructs which RiverWare DMIs in the model should be run to bring in alternative data. DMI events are grouped into user-named categories that contain input alternatives. For example there might be a category of DMI events named "Supplies" that contains several ensembles of

hydrologic inflows, and a category of DMI events named "Demands" that includes different demand schedules. DMI events instruct RiverWare to bring in data from specified sources such as a database, text files, or excel spreadsheet. In addition, the Demand Input Tool (DIT) can be used to develop the sets of demands. This Excel-based tool generates the detailed demands for water in the entire basin and allows easy modification of demand projections and automatic loading of the new demands into a RiverWare model. The DIT enables users to enter baseline demand data, create and enter alternative demand scenarios and plot the baseline and scenario data to visualize changes.

- RiverWare Policy: The RiverWare Policy plugin specifies the RiverWare ruleset to use. This allows the user to develop alternative operations as one of the scenario components.

Once the study network has been defined and all of the events have been configured, the user instructs RiverSMART to generate the list of scenarios. Scenarios are specific combinations of input data, policy sets, models, and run configurations. RiverSMART first creates a list of all possible combinations of alternatives and then the user can then look through the list of scenarios and deactivate those that are not of interest. Figure 2 illustrates the different supply and demand scenarios in the Basin Study organized in RiverSMART.

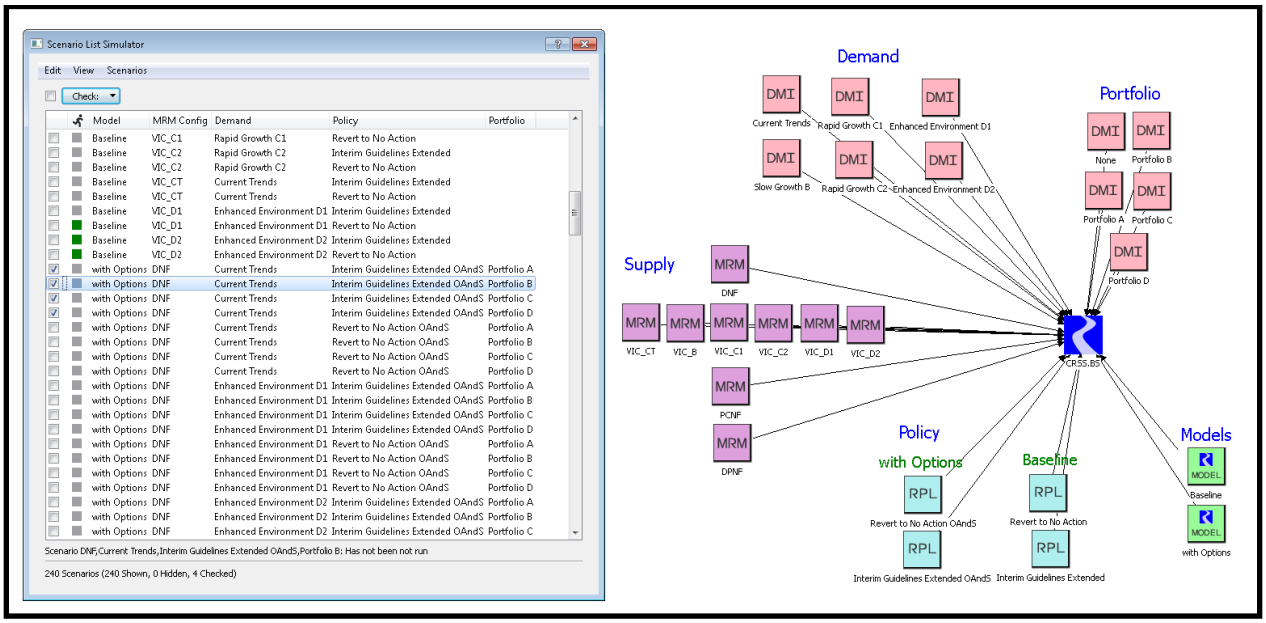

Figure 2 Screenshot of Basin Study in RiverSMART

The user then runs the specified scenarios with RiverSMART managing the data archiving, importing data for new scenarios, and starting the next scenario. The runs utilize RiverWare's distributed Multiple Run Management where individual runs are spread over available computer processors.

Once the scenarios are simulated, the user instructs RiverSMART to post process the scenarios by executing events that act on each scenario or on sets of scenarios. The plugins for post processing scenarios include plugins to convert files from RiverWare's Data Format (RDF) to Excel and annualize monthly data to an annual timestep. Plugins can generate plots using an R

Script plugin or generate graphs in Excel using the Graphical Policy Analysis tool, GPAT. This Excel tool allows users to visualize and analyze RiverWare model outputs as well as other data sets. This tool is designed to allow statistical comparisons and graphing of multiple modeling runs that may vary with respect to hydrology, operational policy, or other parameters.

The Basin Study utilized the R programming language to process results from all scenarios simultaneously, evaluate the reliability metrics, and prepare the data for plotting. For the Basin Study, the post-processing step was critical to distill the results of 240 scenarios into understandable and meaningful figures. R was used to process the data and prepare it for use within Tableau, software for interactive data visualization and analytics. Figure 3 is taken from the Basin Study and shows the percent of future simulations in which Lake Mead drops below 1,000 feet, a critical elevation for water deliveries to Las Vegas. This figure distills the results from over 20,000 simulations and 48 scenarios into 144 points. This type of visualization allows one to understand how the results for the particular variable vary with supply scenario, demand scenario, operational option, and through time. Additionally, Tableau helped the modelers understand and verify model results during the Basin Study by utilizing its interactive features, a step that is critical in any modeling exercise.

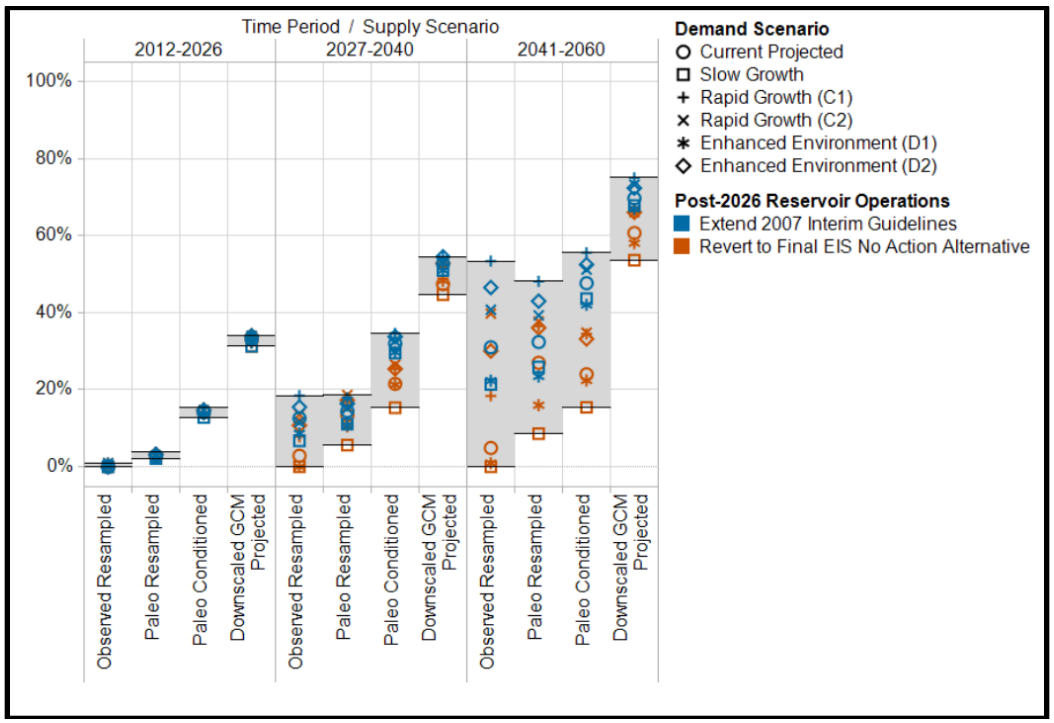

Figure 3 Percent of Baseline Future Simulations Resulting in Lake Mead Less than 1,000 feet

Even with the efficiency of RiverWare, RiverSMART and R, the total computing time for simulating and processing the scenarios was on the order of 4-6 weeks. To help decrease the computing time and based on other lessons learned during the Basin Study, Reclamation has continued to support targeted development for RiverWare and RiverSMART components. An R plugin was added to RiverSMART and RiverWare now supports exporting data in a format directly readable by Tableau, which will expedite the analysis process and cutout one of the post-

processing steps. Additional work is underway to support exporting data from RiverWare to NetCDF files; a step that could help make modeling results machine readable, and could decrease the total storage size of results. The RiverSMART tool has also become part of Reclamation's widely relied upon modeling tools utilized in many different studies. As RiverWare helped CRSS evolve in 1996, RiverSMART is the next step in this evolution of Reclamation's modeling tools.

SUMMARY

The Basin Study helped quantify the potential supply and demand imbalance on the Colorado River Basin over the next 50 years, while analyzing potential options for alleviating such imbalances. A scenario planning approach led the Basin Study to use many scenarios to quantify a wide range of plausible future outcomes. All together 240 scenarios were simulated using CRSS—the Basin-wide model developed in RiverWare.

The suite of tools employed in the Basin Study, i.e., RiverWare, RiverSMART, R, and Tableau, was critical to the development and management of the numerous simulations necessary for the robust decision making framework utilized in the Basin Study. This suite of tools can be used to support any planning study or "what-if" analyses that require many iterations of input or assumptions. Since the completion of the Basin Study, the tools have become part of Reclamation's standard suite of modeling tools, and development has continued to enhance their capabilities.

TRUCKEE-CARSON RIVERWARE© PLANNING MODEL DESCRIPTION AND APPLICATIONS

Heather Gacek, Project Manager, Precision Water Resources Engineering, Loveland, CO, heather@precisionwre.com; Thomas Scott, Hydrologic Engineer, Bureau of Reclamation, Carson City, NV, tscott@usbr.gov; Shane Coors, Principal, Precision Water Resources Engineering, Loveland, CO shane@precisionwre.com

Abstract: The Bureau of Reclamation's (Reclamation) Lahontan Basin Area Office has developed a long-term RiverWare© model of the Truckee River Basin (Basin) including the Newlands Project area. The Truckee River basin contains seven upstream storage reservoirs, including Lake Tahoe, and terminates in the Great Basin at Pyramid Lake. The basin's seven upstream storage reservoirs are operated to meet the demands of downstream agricultural, environmental, industrial, and municipal water users along the Truckee River, as well as the agricultural demands of the Newlands Project in the Carson River Basin. Supplying the Newlands Project requires an inter-basin diversion from the Truckee River to the Carson Basin through the Truckee Canal.

The RiverWare© model, known as the Truckee-Carson Planning Model (Planning Model), was developed through a collaborative effort between several of the significant basin stakeholders, often with competing interests. Participating entities include the Bureau of Reclamation, Federal Watermaster, Truckee Meadows Water Authority, Pyramid Lake Paiute Tribe, the state of California, and the state of Nevada. The model represents the entire river system, and simulates each of the stakeholders' current operational policy. The model also allows users to adjust many operational criteria and variables to analyze proposed policy, hydrology, and water use changes for up to 100 years.

This unique collaboration has both facilitated wide acceptance of the model and driven the model development to be amenable to a wide range of applications. The model is designed to assist water managers and stakeholders in making long-term planning and management decisions. Applications include the Newlands Project Planning Study, the Truckee Basin Study, and policy revision studies.

An overview of the collaborative development process, a review of the primary model components, and a description of past, current, and proposed applications of the model will be presented.

INTRODUCTION

The Truckee River system is approximately 100 miles long, flowing from Lake Tahoe in the Sierra Nevada mountain range to Pyramid Lake in Nevada. There are seven upstream reservoirs, including Lake Tahoe, that regulate approximately 70% of the basin's water supply. The majority of the Basin water supply originates in California, while the majority of the water usage takes place along the Truckee River in Nevada.

In addition to water users along the Truckee River, water is diverted through the Truckee Canal as part of an inter-basin water transfer to supplement supply to agricultural water users in the Newlands Project within the Carson River Basin. The inter-basin diversion takes place at Derby Dam and delivers water to water users along the Truckee Canal and supplements the storage at

Lahontan Reservoir. Construction of the Truckee Canal was the first Reclamation project in 1903. A map displaying the combined Truckee and Carson River basin is shown in figure 1.

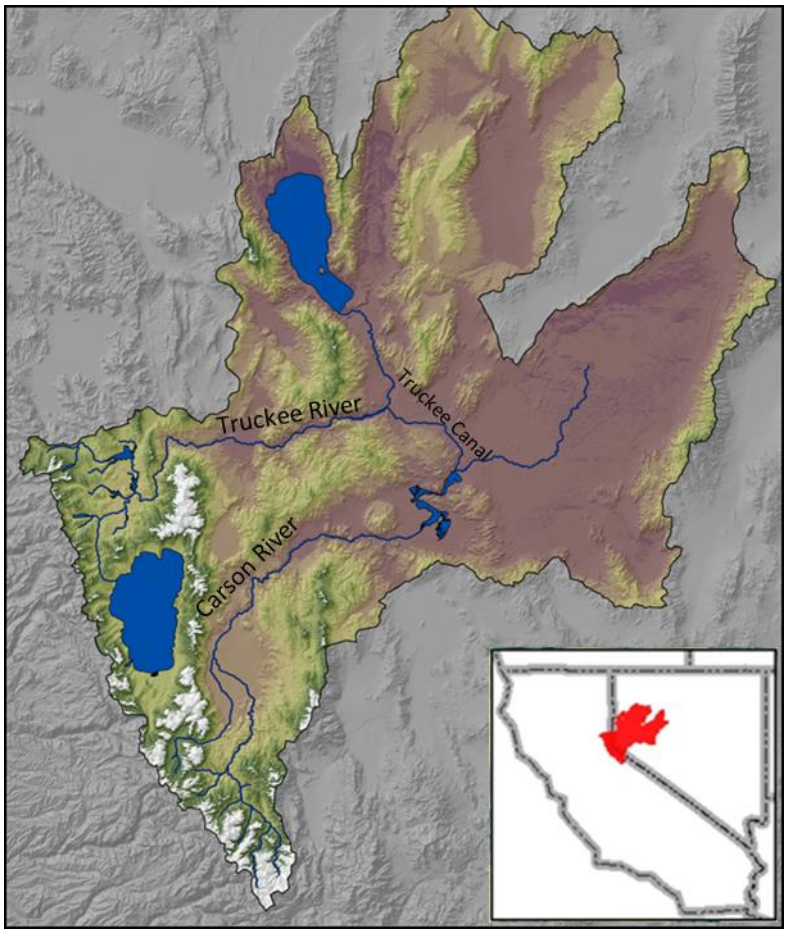

Figure 1 Map of the Truckee and Carson River Systems

A daily timestep RiverWare model has been developed by Reclamation to simulate the Truckee River System, including the Truckee Canal, for up to 100-year model runs. The Planning Model simulates the entire system's operations and performs complete daily water accounting of the water rights within the system. The model, its development process, and its uses are discussed in more detail in the following sections.

MODEL DEVELOPMENT PROCESS

The Truckee River Basin has a suite of modeling tools developed and maintained by Reclamation and the Federal Watermaster. This paper discusses the long-term Planning Model tools which were developed as part of a collaborative effort by many of the key basin stakeholders and government agencies.

Model Development Team: The Planning model was developed by a collaborative effort among many of the significant basin stakeholders, often with competing interests. Participating entities include the Bureau of Reclamation, Federal Watermaster, Truckee Meadows Water Authority, Pyramid Lake Paiute Tribe, the state of California, and the state of Nevada. In late 2009, the

formation of the Planning Model development group and the start of the development of the Planning Model began. Participating parties have met every 6 to 10 weeks in-person and/or video conference meetings to discuss development of the model and review the progress.

Pre-TROA Planning Model: At the start of the Planning Model development effort, the Truckee River Operating Agreement (TROA) had been approved and signed by the parties, but was still being contested in the courts. The existing basin policies, now known as the Pre-TROA operating policies, were still in effect. The model was therefore initially constructed to model the current, Pre-TROA, operating policy.

In addition to simulating the current operating policy, the model is designed to be a long-term planning and management tool. Unlike the existing and more mature Operations model, the Planning model cannot be overly dependent upon the user to control operations on a daily or even an annual time frame. This required an increased level of detail and more comprehensive operational logic than in the short-term daily operations model, which was already being used within the basin. The participating members of the Planning Model development team were tasked with providing detailed operational polices for their individual systems sufficient enough to allow the model to operate under all operational and hydrologic conditions without requiring additional input from the user.

Although the Planning Model will continue to be developed as basin policies change and stakeholders' operational policies evolve, the Pre-TROA version of the Planning Model was largely completed in 2014. The Pre-TROA version of the model was the foundation for the TROA Planning Model.

TROA Planning Model: Under the 1990 Settlement Act, the Secretary of the Interior was directed to negotiate an operating agreement for the Truckee River Reservoirs. The purpose of the policy is to improve operational flexibility and efficiency of Truckee River Reservoirs while satisfying water rights in conformance with existing decrees. TROA was officially signed into law in 2008, but court challenges have delayed its implementation. TROA is currently expected to be implemented in 2015.

As the TROA operating policy came closer to being implemented, the Planning Model development group began the process of incorporating the new operating policy within the framework of the existing Planning Model. In 2013 the Planning Model development team began the implementation of TROA within the Planning Model with the goal of using the model to support the Truckee River Basin Study in 2014. The Truckee River Basin Study was a Bureau of Reclamation study that identified and quantified potential impacts to the Truckee Basin due to climate change. An updated version of the Planning Model referred to as TROA-Lite was completed in mid-2014 for use in the Truckee Basin Study. This model simulated the most fundamental elements of TROA for water and supply. Model development work is ongoing to incorporate additional, more flexible operating policies such as complex water exchanges

involving instream flows below reservoirs in California, and voluntary exchanges between parties under a variety of conditions.

TROA operating policy allows parties to hold back unneeded, but entitled flows to establish credit water in the reservoirs. It also allows for a multitude of possible exchanges between the water right holders. Along with the increased flexibility and efficiency, TROA adds a lot of complexity to the system which needs to be captured by the modeling tools. The basin stakeholders are continuing to refine policies for their individual operations under the operating agreement as part of the model development

MODEL COMPONENTS

A RiverWare model workspace consists of objects, each representing a specific component of the modeled system, linked together to simulate the storage, flow, diversion and consumption of water in a system. The primary model components in the Planning Model include the seven upper Truckee River reservoirs, the Truckee Meadows section of the river between Farad gage and Derby Dam, the Truckee Canal and Lahontan Reservoir, and the lower Truckee River below Derby Dam and including Pyramid Lake. These four sections are each discussed in more detail below. A schematic diagram of the model components is provided as Figure 2.

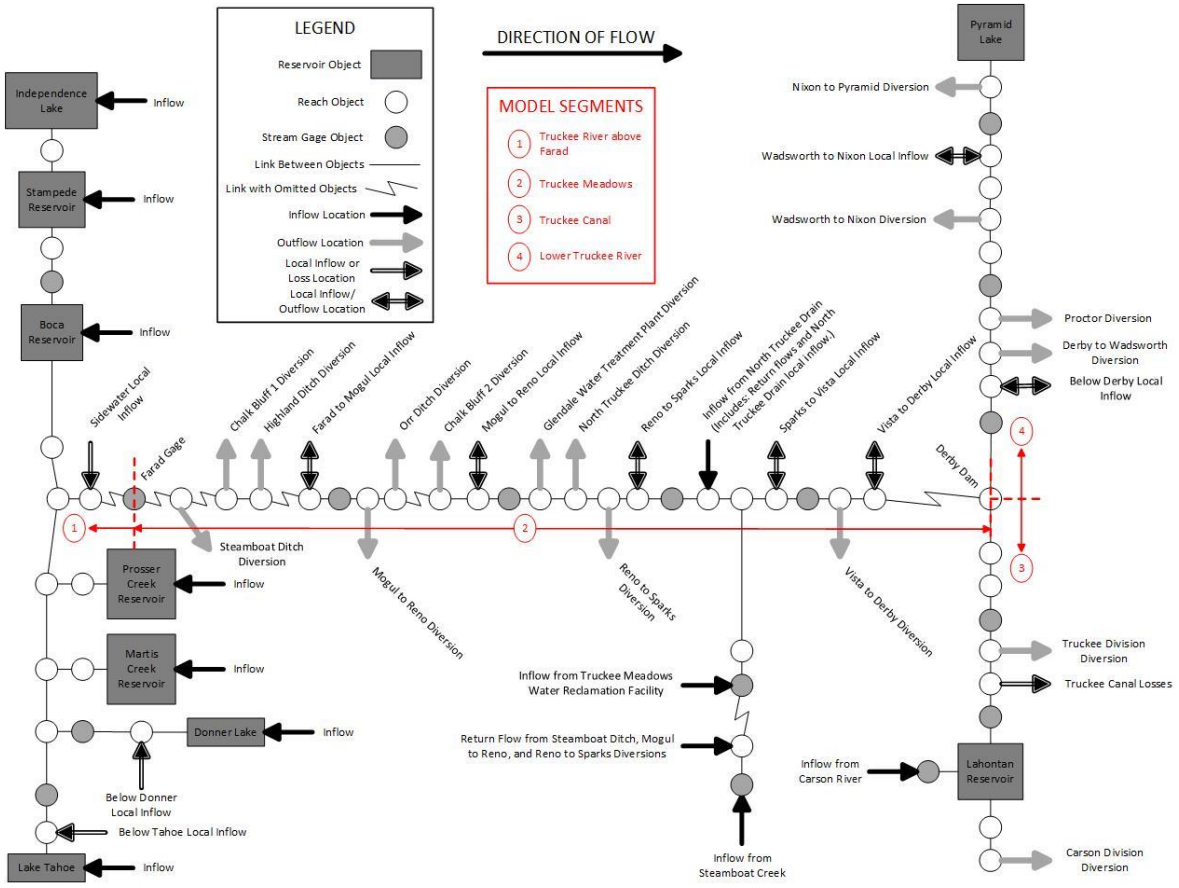

Figure 2 Schematic showing the reservoirs, reaches, outflows, and inflows for the Pre-TROA Truckee-Carson RiverWare Planning Model

Truckee River above Farad (1): The Truckee River above Farad section of the model is everything upstream of the gage at Farad. This section contains seven reservoirs: Lake Tahoe, Donner Lake, Martis Creek Reservoir, Prosser Creek Reservoir, Boca Reservoir, Stampede Reservoir, and Independence Lake. The majority of the water in the Basin originates within this section of the basin. The reservoirs regulate the flow of the water in the river. The system is operated to meet flow targets at Farad Gage, referred to as the Floriston Rate target flows.

Truckee Meadows (2): The Truckee Meadows represents the reach of the Truckee River between the gage at Farad and Derby Dam. This portion of the model contains: agricultural diversions, municipal diversions, industrial diversions, return flows from the Truckee Meadows Water Reclamation Facility, inflows from tributaries, and system losses.

Truckee Canal (3): The Truckee Canal portion of the model represents diversions at Derby Dam through the Truckee Canal to Lahontan Reservoir and its downstream water users. This portion of the model also includes an inflow point representing the inflow to Lahontan Reservoir from the Carson River. This portion of the model represents the entire Newlands Project. The Newlands Project includes agricultural diversions taken directly from the Truckee Canal as well as agricultural diversions taken downstream of Lahontan Reservoir.

Lower Truckee River (4): The lower Truckee River represents everything below Derby Dam flowing to the terminus at Pyramid Lake. For this reach of the river the model currently contains: agricultural diversions, environmental flow targets, and system losses. In the future, conditions in this reach are expected to include municipal diversions as well as the before mentioned demands.

MODEL APPLICATIONS

The following section includes descriptions of past and future model uses. The Planning model is intended for use by system operators to analyze existing Basin policies and to develop future operational strategies and Basin policies. It is also intended for use by individual stakeholders to develop their own operational strategies and perform reliability testing on their water supply and current policies. The following examples are just a handful of the possible applications of the Planning Model tools.

Newlands Project Planning Study: The Newlands Project Planning Study (Study) was conducted by Reclamation to formulate, develop, and evaluate a range of alternatives to reliably deliver water to Newlands Project water rights holders while also reducing risk to local communities from operating the Truckee Canal. Reclamation describes the impetus for and purpose of the Study in the report, *Newlands Project Planning Study Special Report,* as:

> The Newlands Project is one of Reclamation's first irrigation projects and nearly as old as the agency itself. Reclamation began the Project in 1903 to provide irrigation water to the Lahontan Valley, near Fallon, Nevada, and to lands in the Truckee Basin near Fernley, Nevada.

In the early morning of January 5, 2008, a 50-foot portion of the Truckee Canal embankment failed about 12 miles downstream from Derby Dam, releasing water that inundated a residential development in the City of Fernley, flooding 590 properties. No fatalities occurred, but more than $1 billion in tort claims were filed against the Federal government, local governments, and the Truckee-Carson Irrigation District (TCID), and have now been consolidated into class action lawsuits.

Although the damaged portion of the canal embankment was soon repaired, evaluations of the canal revealed a high potential for future failure. In response, Reclamation imposed restrictions on the water surface elevation allowed in the canal and the amount of water allowed to flow through the canal. The flow restrictions were reinforced by the Federal District Court for Nevada. If not lifted, these restrictions could complicate the long-term ability of Reclamation to provide Newlands Project water rights holders with reliable supplies.

Federal authorization for the Study was provided in the Omnibus Appropriations Act of 2009 (Public Law 111-8, 123 Statute 609), which directed Reclamation to determine the actions necessary to rehabilitate the Truckee Canal so restrictions on its operation can be removed.

The modeling effort for the Newlands Project Planning Study included the modeling of 24 preliminary alternatives, a no action alternative, and a desired reliability alternative. After thorough review of the modeling results, environmental and regulatory review, engineering and cost estimates, and financial and benefits analysis were performed, seven final alternatives were identified. These seven alternatives were then modeled using the Planning Model and reviewed to develop the study's key findings.

Truckee River Basin Study: The Truckee River Basin Study (Basin Study) is a part of Reclamation's response to the Department of the Interior's WaterSMART Program to enact the SECURE Water Act of 2009. The Basin Study was kicked off in late 2012. The RiverWare modeling effort was performed in 2014. The Basin Study is part of a program "to evaluate and report on risks and impacts from a changing climate and identify appropriate adaptation and mitigation strategies in conjunction with stakeholders." (Bureau of Reclamation Mid-Pacific Region Lahontan Basin Area Office, October 2013)

The Basin Study Team worked with key Basin stakeholders as part of the Project Steering Team and Technical Advisory Group to develop the study components and analyze the potential impacts of the Basin Study's hydrology and demand scenarios on the Truckee Basin water users and environment. The Basin Study Team engaged the community at multiple public meetings throughout the process.

The Basin Study Team developed a broad range of potential climate change hydrology scenarios to capture the possible effects of climate change on the region. The Team also developed three

demand scenarios to encompass possible future development within the Basin. The Planning Model was used to perform model runs combining these various hydrology and demand scenarios. The results from these model runs were analyzed collectively to identify system vulnerabilities due to climate and demand changes. Once the vulnerabilities in the system were identified, the Basin Study team were able to evaluate tradeoffs between different mitigation strategies and develop robust operational strategies for the future. These strategies were modeled using the Planning Model and the improvements were quantified and reported in the Basin Study.

Boca Reservoir Study: As part of a larger study, an alternative was performed to analyze the impacts of introducing a reduced water surface elevation limit on Boca Reservoir. Six runs of the Planning Model were performed to model three reservoir storage limit scenarios with two different demand scenarios. The purpose of the study was to determine the impacts on the remainder of the Truckee Basin as a result of altering the storage limits at Boca. The demand scenarios were meant to provide a range for the impacts given that basin demand levels remain near current levels or demand levels are increased to represent future water use.

Future Model Uses: Future use of the Planning Model will include the Truckee Canal Environment Impact Statement, and subsequent policy revision studies. Additionally, it is expected that individual Basin stakeholders will use the model to perform their own private studies. The implementation of TROA will necessitate these private studies as parties work to determine the most efficient and robust operating policies with the framework of the new flexible operating system.

SUMMARY

The Truckee-Carson Planning Model was developed through a collaborative effort between several of the significant basin stakeholders. Currently there are two versions of the Planning Model, one containing only the Pre-TROA operating policies and one under development which contains both the Pre-TROA and TROA operating policies. The Planning Model has been used by several federally funding planning studies to date, including the Newlands Project Planning Study and the Truckee River Basin Study. The model is slated for use in future federally funded planning studies as well as private studies to be performed by individual Basin stakeholders.

UTILIZING PROBABILISTIC FORECASTS FOR COLORADO RIVER RESERVOIR OPERATIONS USING A MID-TERM PROBABILISTIC OPERATIONS MODEL FOR DECISION MAKING AND RISK MANAGEMENT

Anthony Powell, Project Engineer, Precision Water Resources Engineering, Loveland, CO, tony@precisionwre.com; Daniel Bunk, Bureau of Reclamation, River Operations Group, Boulder City, NV, DBunk@usbr.gov; Shana Tighi, Bureau of Reclamation, River Operations Group, Boulder City, NV, STighi@usbr.gov; Katrina Grantz, Hydrologic Engineer, Bureau of Reclamation, Salt Lake City, UT, KGrantz@usbr.gov; Shane Coors, Principal, Precision Water Resources Engineering, Loveland, CO shane@precisionwre.com

Abstract: The Bureau of Reclamation (Reclamation) manages reservoirs on the Colorado River Basin (Basin) from the headwater sub-basins down to the border with Mexico. Ensemble inflow forecasts are utilized to develop probabilistic information that supports decision-making at various temporal scales, from daily operations and spring runoff routing to annual operations and multi-year planning. The Upper Basin reservoirs, from the headwaters to Lake Powell, are supply driven and their operations depend heavily on forecasted inflows. Risk management in the Upper Basin balances water supply, hydropower, flood control, endangered species, fish and wildlife, and recreation. Operations of Lower Basin reservoirs, from Lake Mead to the border with Mexico, utilize Upper Basin probabilistic operational scenarios to manage risk by identifying a range of future Lake Mead elevations and potential impacts on water delivery in the Lower Basin. Probabilistic risk management helps to inform decision making for Basin stakeholders concerned with flood control, hydropower, recreation, environment, water supply, and water delivery in the Lower Basin.

Reclamation has developed a suite of RiverWare™ operations and planning models to aid with different aspects of decision making and risk management in both the Lower and Upper Basins. The Mid-Term Probabilistic Operations Model (MTOM) is the newest model utilized by both basins to support decision making by Reclamation and other Basin stakeholders. The MTOM System provides 5-year probabilistic projections for the Basin's major reservoirs and critical reaches at a monthly time step. The MTOM system is comprised of several components that include an ensemble forecast from the Colorado Basin River Forecast Center, a RiverWare™ operations model of the major reservoirs of the Colorado River System, and probabilistic output with an analysis and visualization tool. The system is currently being used to generate a 5-year probabilistic operational outlook for the Basin that is distributed monthly to stakeholders and decision makers.

This paper will present an overview of key components of the MTOM System and also highlight sample results and applications of the system for particular Basin operations.

INTRODUCTION

Current climate and hydrologic conditions in the Southwestern United States and predictions of increased climatic variability in the future give rise to the need for improved predictive tools for managing water resources in the region. The Bureau of Reclamation (Reclamation) is responsible for the operation of the infrastructure that provides water, hydropower, and flood control to the Colorado River Basin (Basin) states of Arizona, California, Colorado, Nevada,

New Mexico, Utah, and Wyoming. Historically, Reclamation has used two primary Basin-wide modeling and decision support tools. These are (1) the 24-Month Study and (2) the Colorado River Simulation System (CRSS). The 24-Month Study, which is used in the Annual Operating Plan (AOP) process, is an operational model with a 2-year outlook that uses most a probable inflow forecast (updated monthly) provided by the National Weather Service's Colorado Basin River Forecast Center (CBRFC). The 24-Month Study is limited in its ability to incorporate hydrologic uncertainty because it is designed to simulate only one hydrologic and operational scenario and future reservoir operations must be input manually. CRSS, which is used in long-term planning studies (e.g., the Colorado River Basin Water Supply and Demand Study and development of the 2007 Interim Guidelines for the Coordinated Operations of Lake Powell and Lake Mead), is a planning model that simulates Basin conditions decades into the future. Although CRSS accounts for hydrologic uncertainty in its ability to simulate hundreds of future hydrologic scenarios, it is limited in its ability to incorporate real-time forecasts and operations. Reclamation and Basin stakeholders have desired a decision support tool that blends the probabilistic strength of CRSS with the operational knowledge of the 24-Month Study. The Mid-Term Probabilistic Operations Model (MTOM) System was developed to meet this need. It provides probabilistic information about risk and uncertainty associated with Basin reservoir operations in the 1- to 5-year timeframe. The MTOM System consists of a RiverWare™ model and supporting components that enable the model to access input and produce output in an efficient manner. The MTOM System uses an ensemble of hydrologic forecasts to produce probabilistic 5-year operational projections for the major reservoirs in the Basin. The model results are then analyzed collectively to quantify the likelihood of significant future system conditions.

ENSEMBLE FORECASTS

The primary input, and main driver of operations, for the MTOM System is an ensemble of unregulated inflow forecasts at various forecast points in the Upper Basin. Unregulated flow is the forecasted flow that would arrive at a specific point if there were no dams located upstream of that point. The CBRFC provides thirty 60-month traces for 12 forecast points in the Upper Basin (locations of Upper Basin inflow points are provided in Figure 1). Each inflow forecast is derived from historical sequential climatology (temperature and precipitation based on the period from 1981 to 2010) that is applied to the current Basin conditions (e.g. soil moisture, antecedent streamflow, snowpack). The CBRFC utilizes the data to develop 30 traces of hydrologic inflow forecasts.

The CBRFC methods of producing the forecasts involve the use of the Ensemble Streamflow Prediction (ESP) System which is part of the National Weather Service Forecast System (NWSFS). A continuous hydrologic model comprised of two main sub models, the Sacramento Soil Moisture Accounting Model (SAC-SMA) and the SNOW-17 snow model, are used to simulate the soil moisture and snow states throughout the Basin, which determine the initial conditions for the ESP System, Brandon (2005).

The ESP System then generates multiple scenarios of forecast streamflow time series from which probability functions for water supply volume can be computed. The future scenarios are based on a combination of the current soil moisture and snow states mentioned above and the historical sequences of precipitation and temperature to produce the ensemble of streamflow forecasts. Each year of historical climatology data is assumed to be a possible representation of future

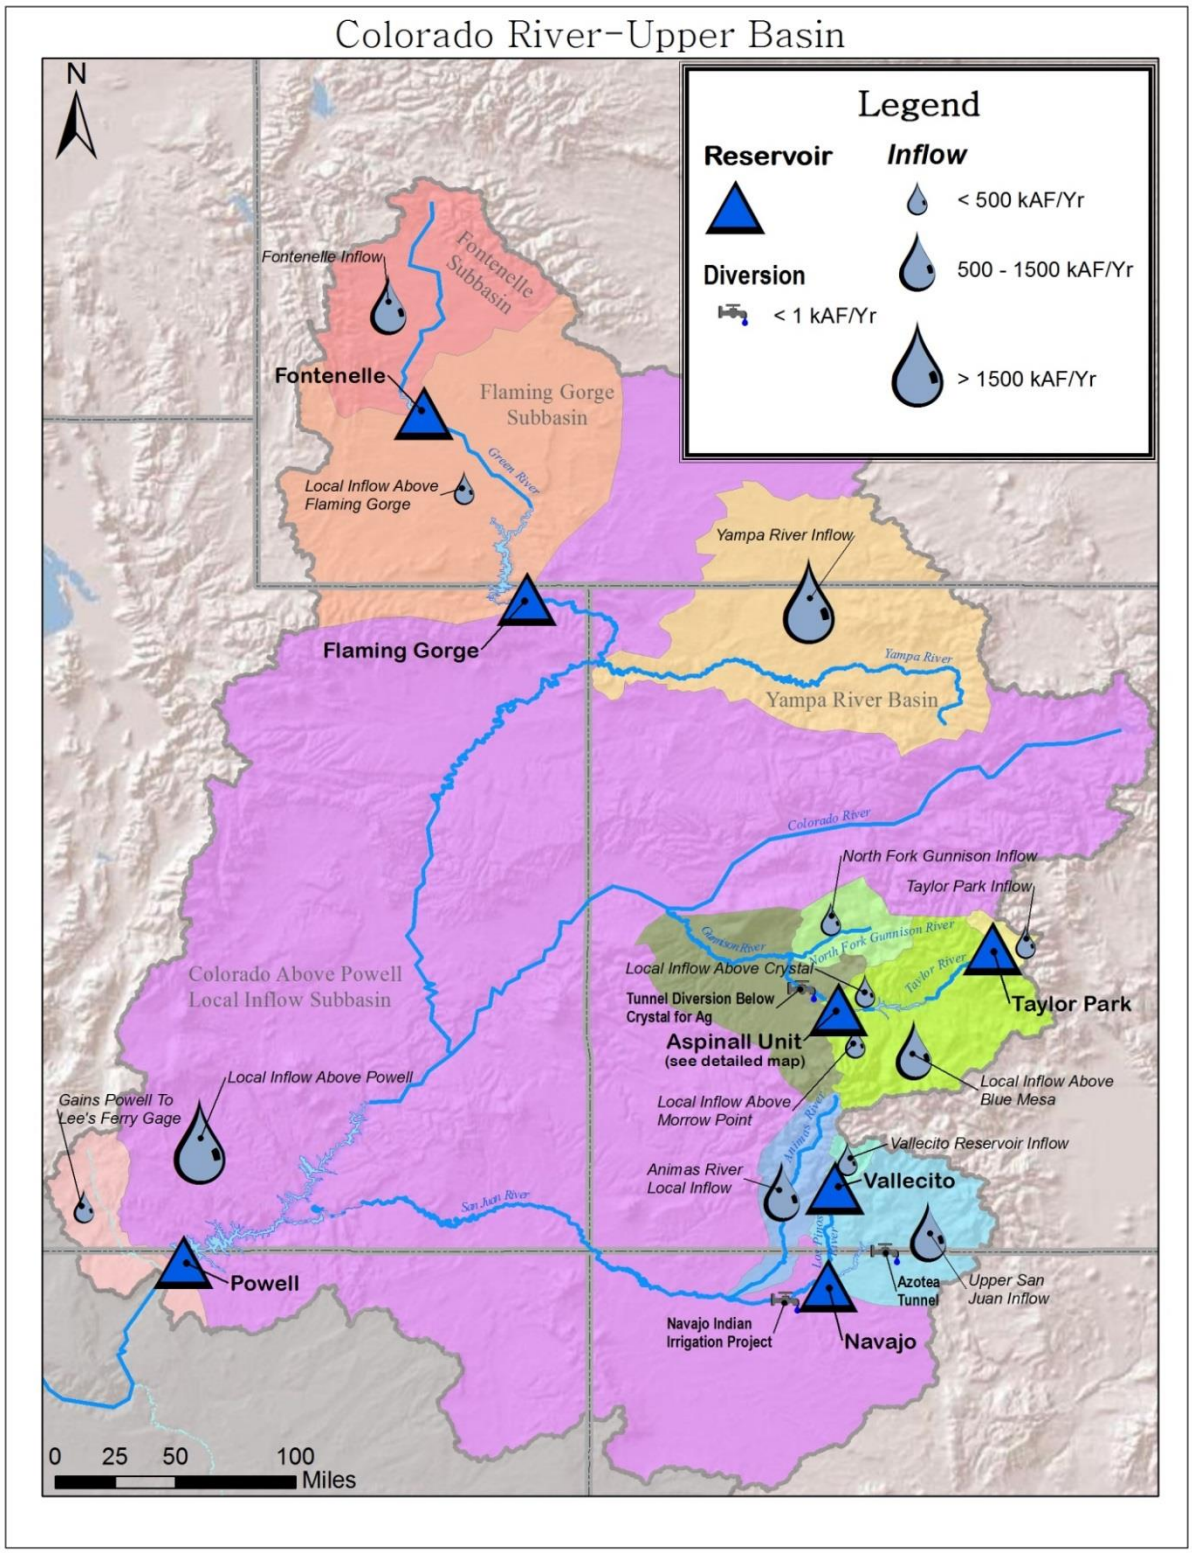

Figure 1 Upper Colorado River Basin as Represented in the MTOM System Model

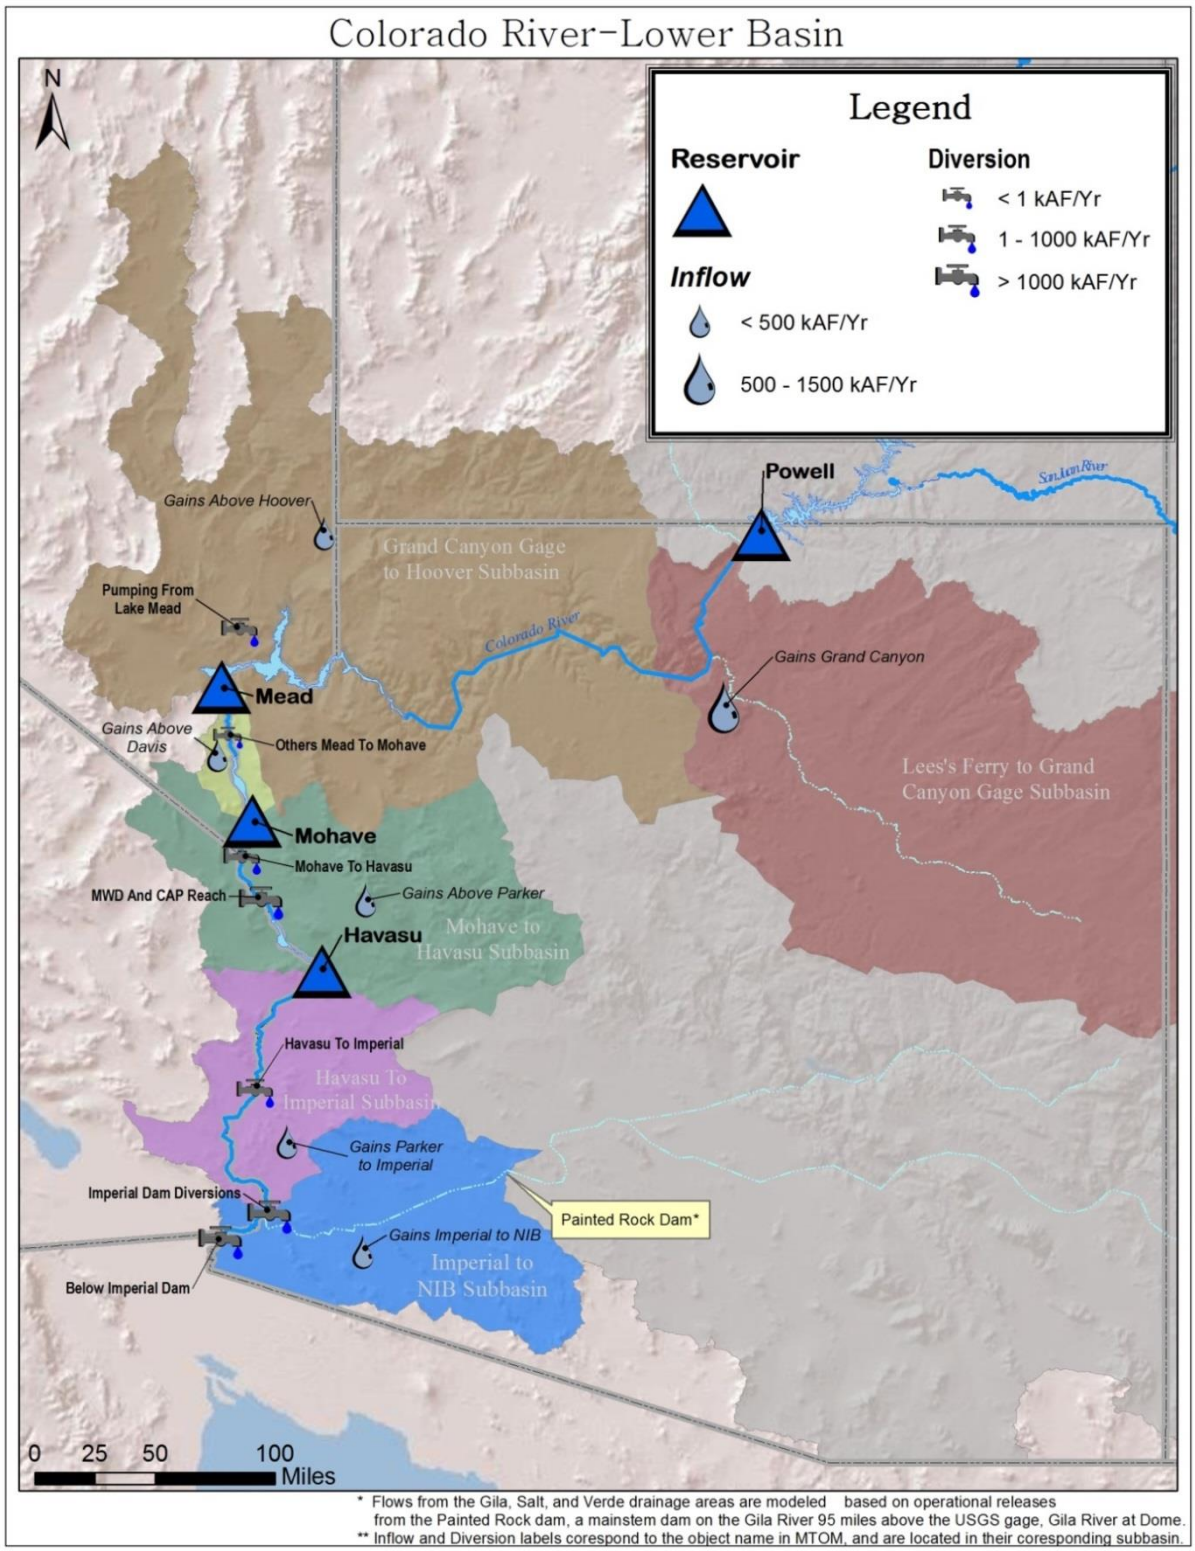

Figure 2 Lower Colorado River Basin as Represented in the MTOM System Model

streamflows in the Basin and each forecast trace produced by the ESP System is treated as equally likely to occur

The ensemble of 30 equally likely unregulated inflow forecasts is run through MTOM to produce an ensemble of potential operations and system conditions. The results can then be analyzed collectively to project potential future conditions within the Basin, and quantify the uncertainty in those projections.

Lower Basin intervening inflow projections are based on a resampling of historical data over the period from 1981 through 2010 in the reaches above Lake Mead and on statistics (median, 10th percentile, and 90th percentile) from the same 30-year period for reaches below Lake Mead (locations of Lower Basin inflow points are provided in Figure 2).

MID-TERM PROBABILISTIC OPERATIONS MODELING SYSTEM

The MTOM System consists of a RiverWare™ model and supporting components that enable the model to access input and produce output in an efficient manner. The modeling system as a whole is comprised of six components that allow for MTOM to function either as (1) a single run (deterministic) simulation model, which allows the users to compare the results of the MTOM run to those from the 24-Month Study model; or (2) as an ensemble, or probabilistic, modeling tool that can be used to estimate the probability of outcomes given an ensemble of inflow forecasts as demonstrated in Figure 3. This paper focuses on MTOM's strength as a probabilistic operations modeling system.

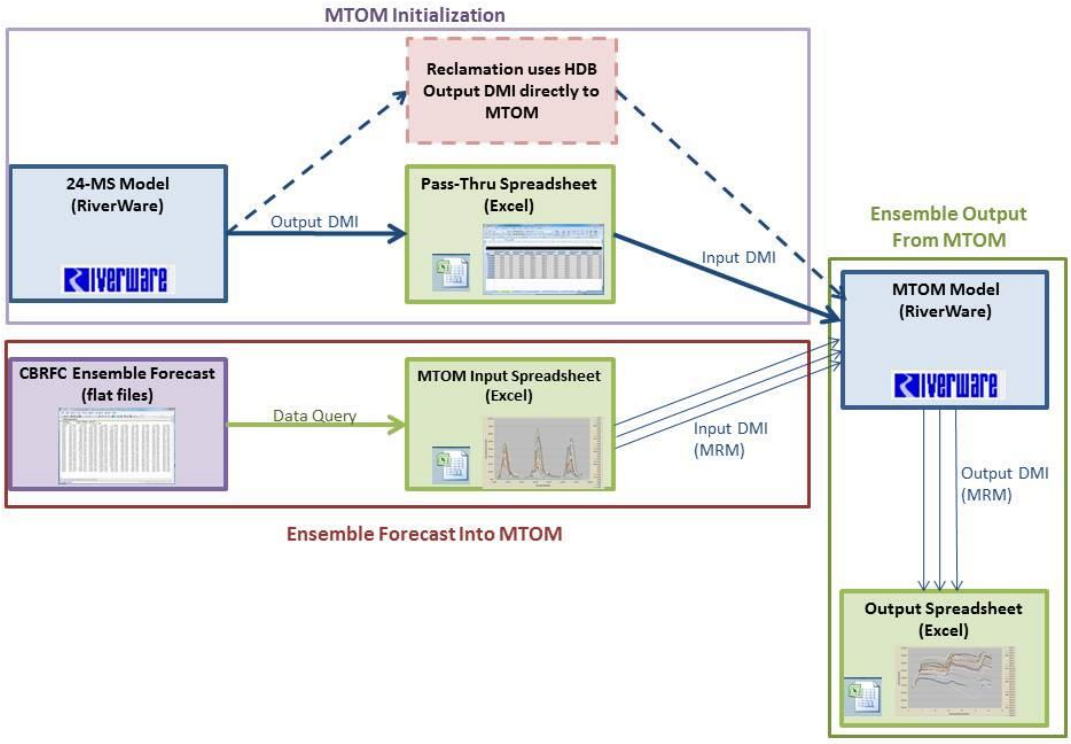

Figure 3 MTOM System Schematic

The MTOM Input Spreadsheet is a Microsoft Excel spreadsheet application designed to import the CBRFC forecast ensembles from data files and provide a platform for MTOM to access those data. The spreadsheet includes forecasts for each of the 12 forecast points in the Upper Basin as well as intervening flows (derived from the historical record) for reaches between Glen Canyon Dam and Hoover Dam. The spreadsheet provides users the capability to view the ensemble of forecasts for each forecast point, and formats the data for import into the RiverWare™ model.

MTOM is a basin-wide RiverWare™ model which simulates reservoir operations at a monthly time step. MTOM uses two RiverWare™ components to correctly model the Basin. The first is a workspace which represents Basin. This allows for the setup of reservoirs, reaches, diversions, and data objects to describe the physical characteristics of the Basin.

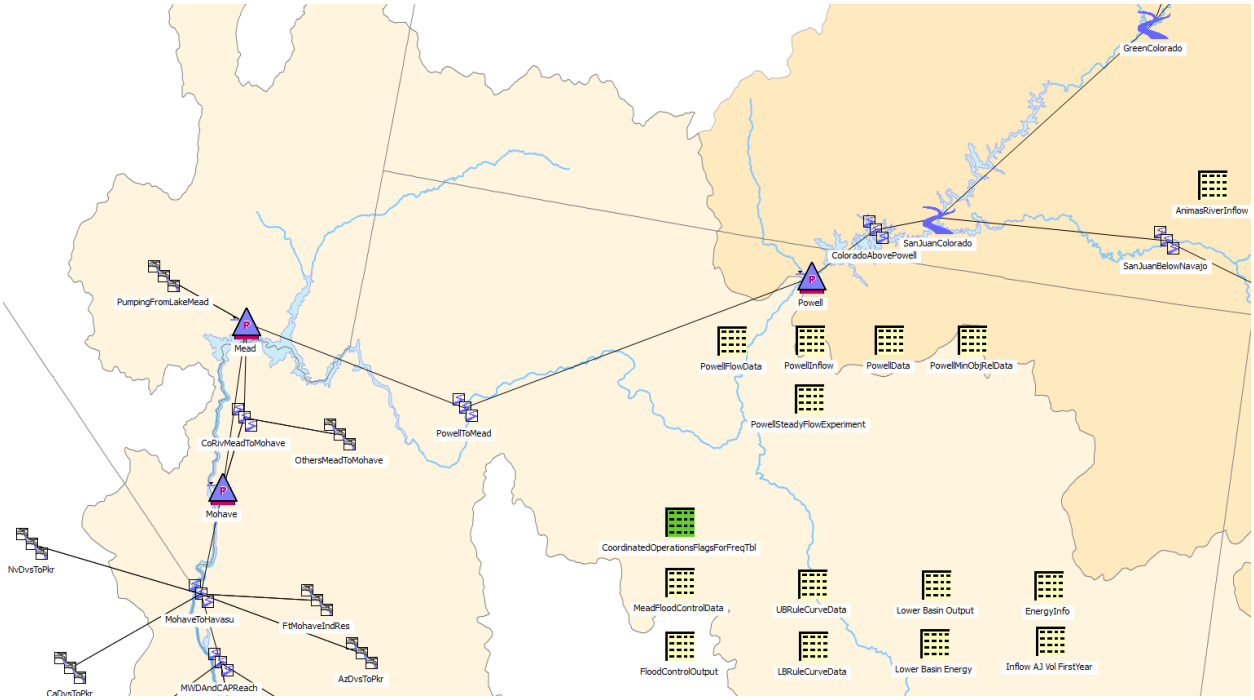

Figure 4 MTOM Workspace above Lake Powell to Below Davis Dam

The second component is a unique programming language known as the RiverWare™ Policy Language or RPL. This language allows users to code operational policy into MTOM. RiverWare™ then uses this policy to determine the various physical components within the model to solve the mass balance equations in place of user inputs for operations in MTOM. The RPL policy is developed in separate components called rules. Rules are written to contain a specific piece of policy language, such as a guide curve for simulating releases from a reservoir, or implementation of flood control operations under high inflow conditions. The individual rule format, as opposed to a single script containing all of the policy coding, is used to order policy components by priority. The rules guide the simulation of the Basin and are based on the law that governs the operations of the reservoirs in the Basin as well as operational guidance provided by reservoir operators.

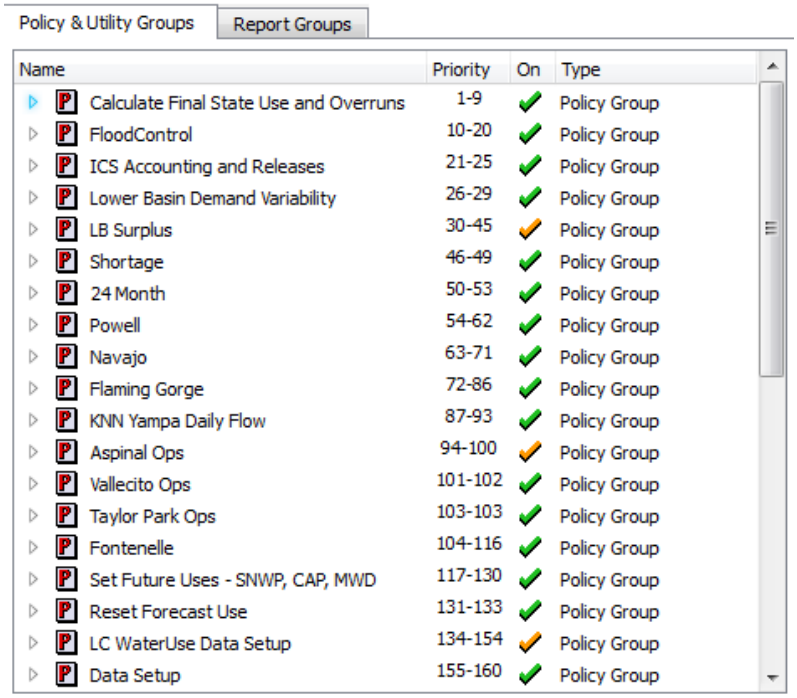

Figure 5 MTOM RiverWare™ Policy Language Interface

In addition to the physical workspace and the rules that that drive reservoir operations in the model, MTOM uses a unique capability in RiverWare™ called run cycles. Run cycles allow the model to solve the entire system in pieces using select portions of RPL logic to solve a portion of the system in each run cycle. This is useful because it allows the model to provide needed information from one piece of the reservoir system to the next. In MTOM, once operations are set for the most upstream reservoirs, operations for the next downstream reservoirs can be simulated. Information about upstream reservoir operations is required before operations can be set for the downstream reservoirs because a full year of projected inflow is required for planning reservoir releases at those downstream reservoirs (in accordance with the distinct RODs that govern operations of those reservoirs). Additionally, operations for Lake Powell and Lake Mead are frequently set in an iterative manner, as Lake Powell and Lake Mead operations are coordinated based on their respective releases and resulting elevations. Four run cycles are utilized in the MTOM RiverWare™ model. The upstream reservoirs in the headwaters of the system (Fontenelle Reservoir, Vallecito Reservoir, and Taylor Park Reservoir) are solved in the first run cycle, the remainder of the Upper Basin reservoirs (Flaming Gorge Reservoir, Navajo Reservoir, and the Aspinall Unit) down to Lake Powell are solved in the second run cycle, Lake Powell and the Lower Basin are solved in the third run cycle, and any operations at Lake Powell or Lake Mead that need to be fine-tuned in an iterative manner solve in the fourth run cycle. The run cycles allow the MTOM model to solve the basin according to the Law of the River and various operational guidelines throughout the Basin.

The Output Spreadsheet is a Microsoft Excel spreadsheet application that stores and processes the results of each simulation of a multi-trace model run. The spreadsheet is used to process the model's output so that information can be disseminated in a way that is useful for stakeholders and decision makers within the Basin. Data can be viewed in the raw output form for a given

output variable of interest, or data can be viewed post-processing to give an in-depth look at the frequency of occurrence for certain conditions within the Basin. The Output Spreadsheet is a tool that summarizes the probabilistic analysis and risk assessment that is provided through the MTOM System.

OUTPUT FOR DECISION MAKING AND RISK MANAGEMENT

The output from the MTOM System model is an ensemble of results throughout the Basin that includes inflow, outflow, and content for reservoirs; diversions for water users; and indicators of specific operational conditions such as lower Basin shortage, surplus and flood control. The Output Spreadsheet compiles the output data into useful plots and tables that can be used by Reclamation to disseminate information to stakeholders throughout the Basin. Using an ensemble of equally likely forecasts to drive multiple runs of the model and then collecting and analyzing the ensemble of results provides stakeholders and water managers with an estimate of uncertainty at any point in the time range of the model run. Because the MTOM System provides a more complete characterization of what the future condition of the Colorado River Basin might be, it enables decision-makers to more effectively manage their water supplies.

The most informative and standard product of the MTOM System process is a table that gives the percent of traces showing the occurrence of system conditions at Lake Mead and Lake Powell. Table 1 displays a template of this frequency table, where the system conditions are defined in the Interim Guidelines for Lower Basin Shortages and the Coordinated Operations of Lake Powell and Lake Mead (2007). Events that are categorized in this table include the annual release tier at Lake Powell and the annual release volume (if the volume is categorized further). In the Lower Basin the water supply conditions Shortage, Surplus, or Normal are categorized.

Table 1 Example of Percent of Occurrence of System Conditions Produced by the MTOM System

	Event or System Condition	WY1	WY2	WY3	WY4	WY5
Upper Basin - Lake Powell	**Equalization Tier**					
	Equalization - annual release > 8.23 maf					
	Equalization - annual release = 8.23 maf					
	Upper Elevation Balancing Tier					
	Upper Elevation Balancing - annual release > 8.23 maf					
	Upper Elevation Balancing - annual release = 8.23 maf					
	Upper Elevation Balancing - annual release < 8.23 maf					
	Mid-Elevation Release Tier					
	Mid-Elevation Balancing - annual release = 8.23 maf					
	Mid-Elevation Balancing - annual release = 7.48 maf

	Surplus Condition - any amount (Mead >= 1,145 ft)					
	Surplus - Flood Control					
	Normal or ICS Surplus Condition					

The output spreadsheet also provides a tool to view any number of the output traces for any of the mass balance components of the reservoirs included in MTOM. The graphics produced from this tool, sometimes referred to as spaghetti plots, give a visual representation of the probabilistic outcome of an MTOM System run. Figure 6 shows an example of results for the Lake Mead pool elevation.

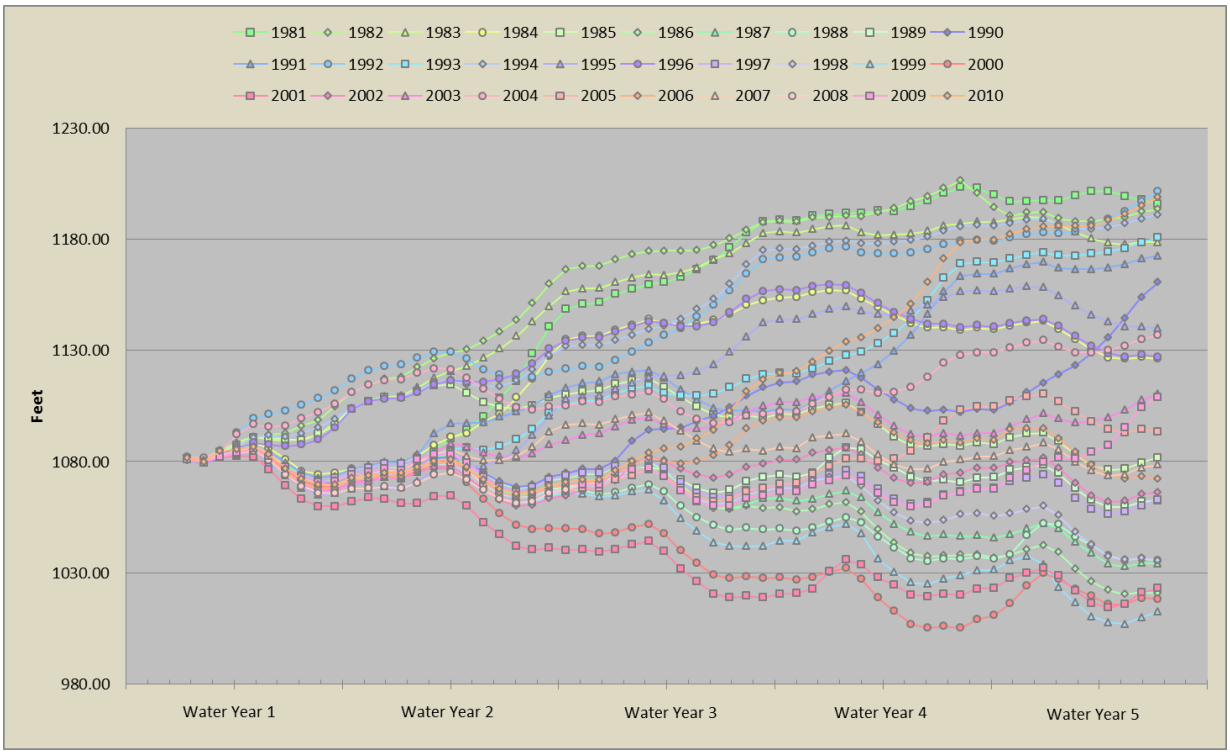

Figure 6 Example of Raw Lake Mead Pool Elevation Output from the MTOM System

The raw output traces are further processed using a month by month exceedance algorithm that can provide further analysis of the ensemble output. This month by month exceedance analysis can provide a possibly more informative view of the MTOM System output as demonstrated in Figure 7. It is important to note, however, that the exceedance algorithm produces traces that could be outside of the bounds of any given ensemble forecast; meaning that the driest (90 percent) trace may be drier than any one of the 30 output traces and the wettest (10 percent) trace may be wetter than any one of the 30 traces. This is due to the monthly exceedance analysis performed on the data which calculates an exceedance value for each month based on the raw data. The exceedance analysis is performed month-by-month such that the 90 percent trace is the 90 percent value for each individual month appended together into a single trace. Each exceedance trace is actually a compilation of the driest 90 percent value of each month in the run. This makes a very dry trace and this effect is more pronounced at the extremes than the raw ensemble output. The month by month exceedance value calculation is demonstrated with Table 2 and Equation 1 to obtain the 35 percent exceedance value for Lake Mead Pool Elevation using linear interpolation; which solves to a value of 1,081.50 feet for Month 1.

Table 2 Ranking of Lake Mead Pool Elevation (PE) for Exceedance Calculation Algorithm

Rank	8	9	10	11	12	13
Rank/n observations	25.81%	29.03%	32.26%	35.48%	38.71%	41.94%
Month 1 Ranked Mead PE Values	1,081.51	1,081.51	1,081.48	1,081.43	1,081.41	1,081.36
Month 2 Ranked Mead PE Values	1,080.49	1,080.48	1,080.46	1,080.41	1,080.30	1,080.23
Month 3 Ranked Mead PE Values	1,083.44	1,083.40	1,083.29	1,083.19	1,083.14	1,083.06

$$LakeMeadPE_{30\%,Month1} = \mathrm{PE}_9 + (\mathrm{PE}_{10} - \mathrm{PE}_9) * \frac{(30\% - \%_9)}{(\%_{10} - \%_9)} \quad (1)$$

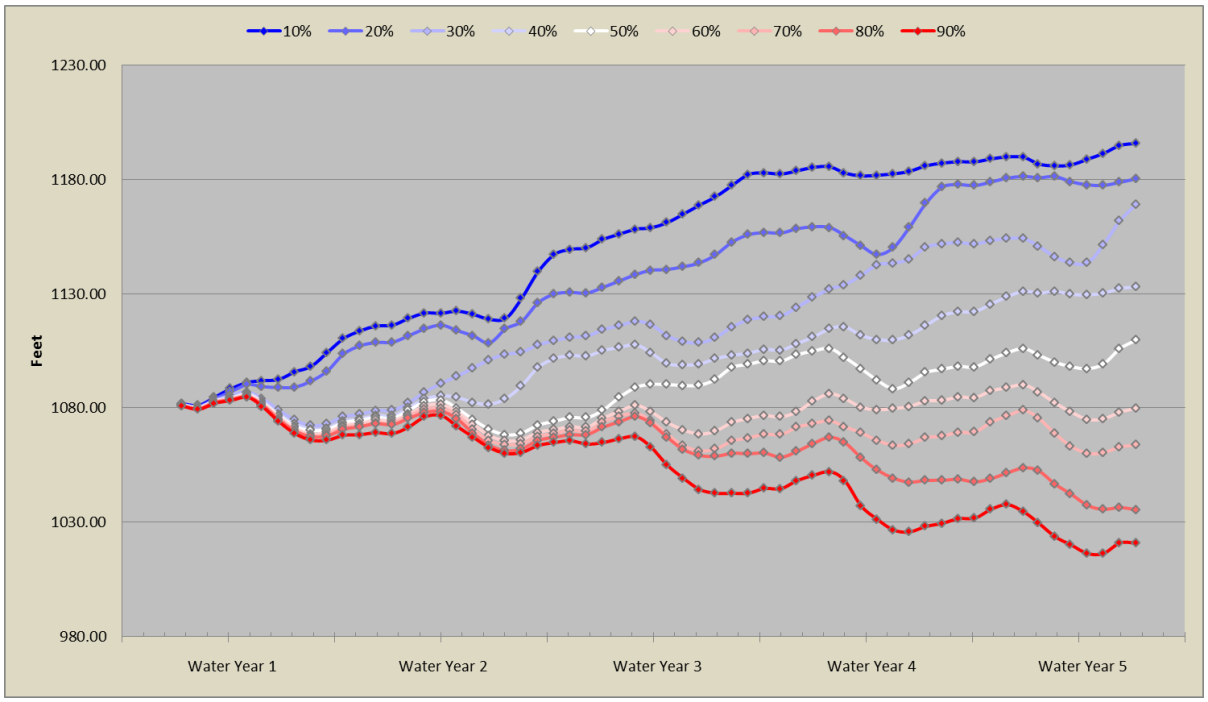

Figure 7 Example of Monthly Exceedance Processing of Lake Mead Pool Elevation Output

SUMMARY

MTOM has been developed to compliment two established and well-used models of the Colorado River Basin. It builds on the operations-specific strength of the 24-Month Study and the probabilistic strength of the Colorado River Simulation System to provide a probabilistic 60-month outlook for reservoir operations throughout the Basin. MTOM is a RiverWare™ model that uses RiverWare™ Policy Language and run cycles so that the specific operational policy and guidelines in the Basin can be modeled correctly at a monthly time step. The MTOM System includes the use of Colorado Basin River Forecast Center ensemble forecasts as the probabilistic input for the model. The System includes input and output spreadsheets as components that allow users to interact with the input and output data easily. The MTOM System outputs probabilistic data for reservoir operations and specific Basin conditions that aid in the understanding of risk and uncertainty in future conditions within the Basin. With MTOM

and the other modeling tools used in the Basin, Reclamation and Basin stakeholders obtain greater information for decision-making through ensemble forecasting and probabilistic analysis.

PIPELINE STREAM CROSSINGS – A RISK-BASED APPROACH TO MINIMIZE AQUATIC IMPACTS

Janine Castro, Geomorphologist, US Fish & Wildlife Service, Portland, Oregon, Janine_M_Castro@fws.gov; Anne MacDonald, Principal, Rivergrove Environmental Consulting, Lake Oswego, Oregon, rivergrove.environmental@frontier.com; Erin Lynch, Hydrogeologist, Ecology & Environment, Portland, Oregon, elynch@ene.com; Colin Thorne, Professor, University of Nottingham, Nottingham, UK, colin.thorne@nottingham.ac.uk.

INTRODUCTION

The global increase in the supply and demand of natural gas and oil has resulted in many new proposals for pipeline delivery systems throughout North America, which will result in thousands of new stream crossings if constructed. These pipes will cross a wide spectrum of stream, floodplains, and aquatic ecosystems – from arid, headwater streams, to perennial, mainstem channels – that vary greatly in their response to natural and anthropogenic disturbance. Even without additional new pipelines, the current distribution of pipelines throughout North America is quite extensive (Figure 1), and poses varying levels of risk to ecosystems.

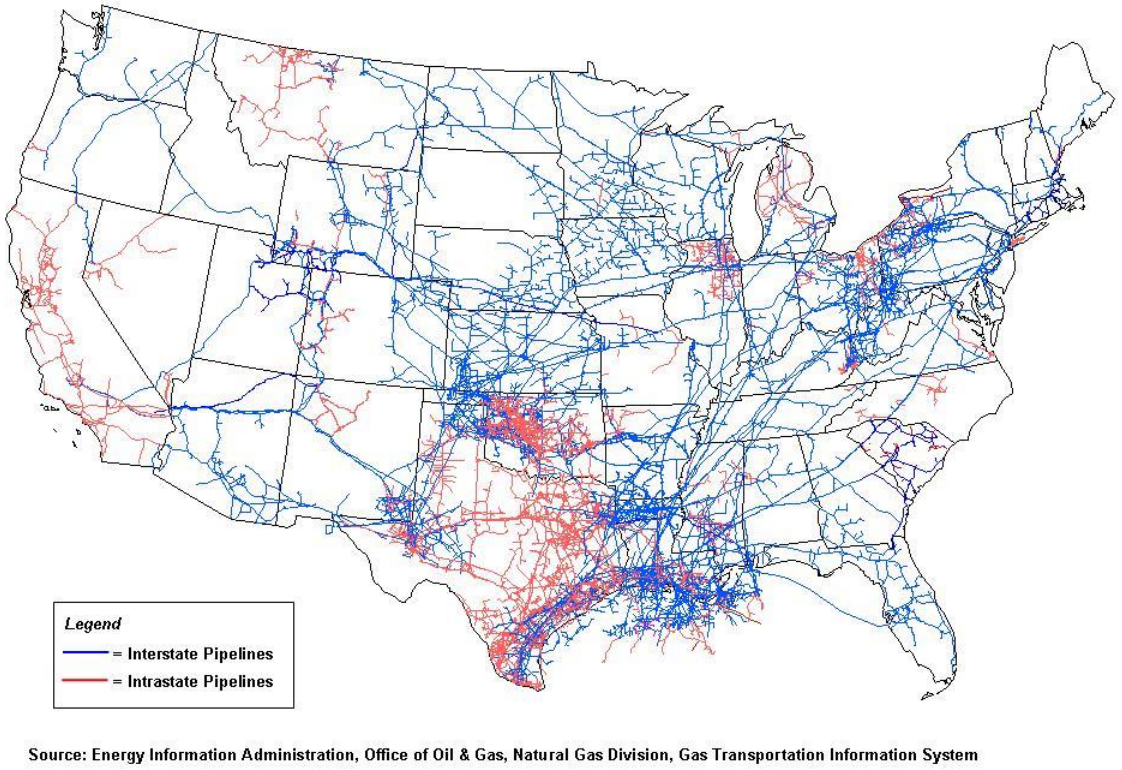

Figure 1 US natural gas pipeline network in 2009, not including the recently completed Ruby Pipeline from: http://www.eia.gov/pub/oil_gas/natural_gas/analysis_publications/ngpipeline/ngpipelines_map.html.

RISK ASSESSMENT

Because of the static nature of pipes and the dynamic nature of many streams, there are inherent risks at many of these crossing locations to aquatic species and habitats. To assess these risks, the US Fish and Wildlife Service in collaboration with the Ruby Pipeline, LLC, have developed a pipeline crossing framework (Figure 2) and linked risk assessment screening matrix (Figure 3) for project applicants and reviewers.

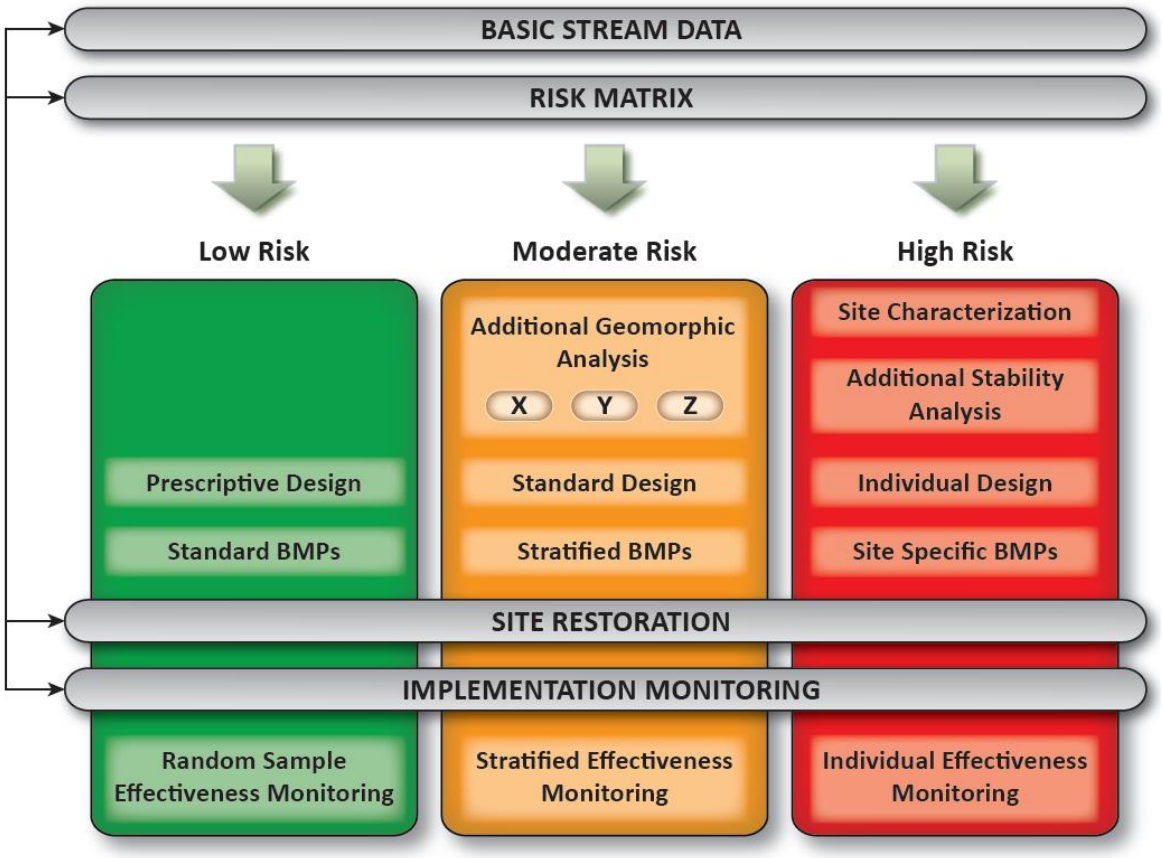

Figure 2 Generic waterbody crossing framework developed by the FWS

The crossing framework provides a robust justification for baseline data collection that is linked to a risk analysis, project design, site restoration, and implementation and effectiveness monitoring. Baseline data include floodplain and stream characteristics, such as valley width, riparian corridor, floodplain dimensions, stream type, stream slope, sinuosity, and bed and bank materials that allow application of the risk screening matrix.

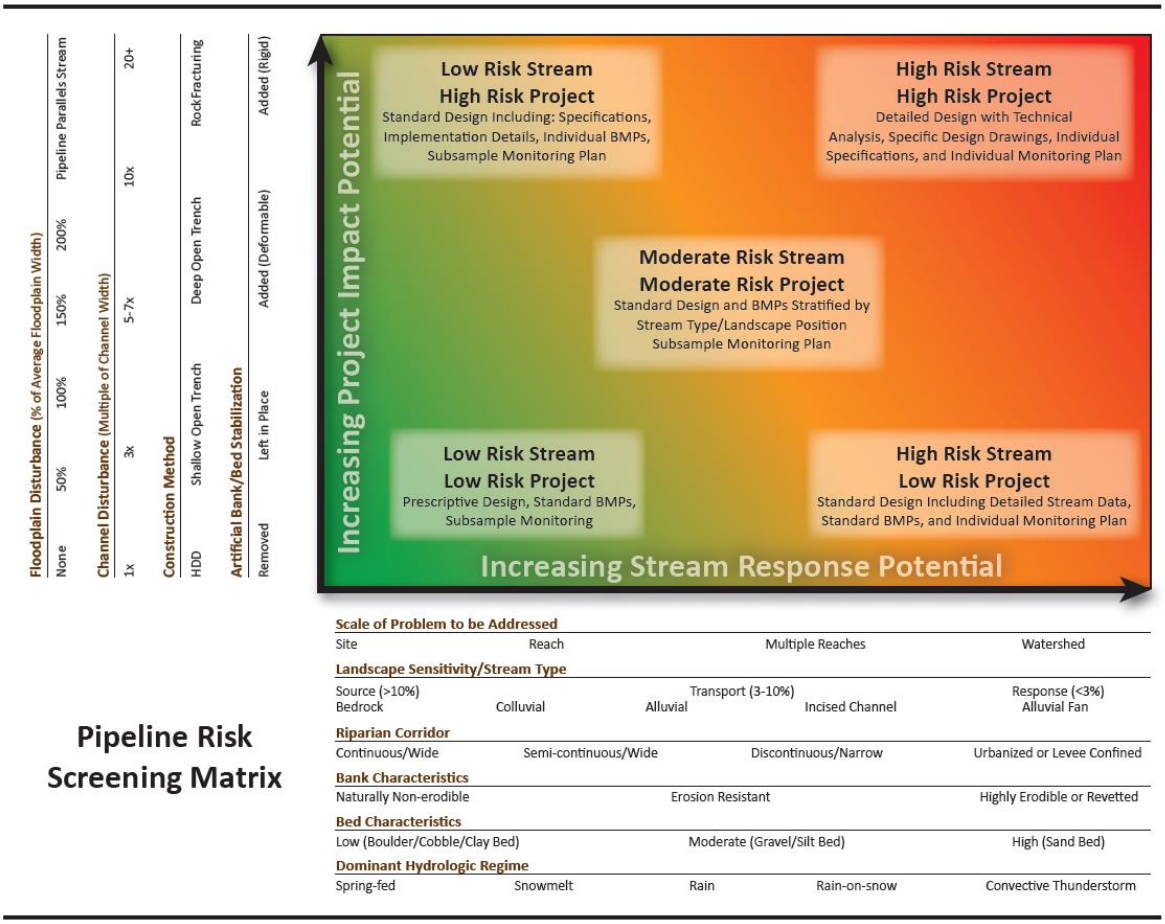

Figure 3 Pipeline Risk Screening Matrix

The risk matrix, embedded within the framework, is based on potential stream responsiveness to disturbance utilizing physical characteristics of the stream system. Because the x-axis relates to physical characteristics, reduction of risk generally requires relocation of the stream crossing. The y-axis describes potential impacts due to the degree of disturbance, construction methods, and extent of artificial stabilization, so risk on this axis can be reduced through both design and relocation. Using this geomorphology baseline, combined with the qualitative evaluation of relative risk, potential effects to aquatic habitat and species can be inferred.

CASE STUDY

The framework and matrix were tested on the Ruby Pipeline which traverses Wyoming, Utah, Nevada, and Oregon and crosses 1200 water bodies (Figure 4).

Figure 4 Ruby Pipeline Route

The process was highly effective in screening out low risk crossings, which received prescriptive designs and standard Best Management Practices, from higher risk crossings that were individually designed and monitored. This framework and risk matrix approach allows project developers and reviewers to focus resources and monitoring on the crossings that present the highest risks to aquatic habitat and species, while expediting design and construction, and minimizing the monitoring of low risk crossings.

SUMMARY

While primarily intended for new pipeline projects, the framework and matrix are also well-suited to the evaluation of existing pipelines to identify crossings that are at a high risk of pipeline exposure and rupture. The framework and risk matrix are easily adaptable to any linear transmission and/or transportation projects, such as power lines and highways.

The approach described in this extended abstract is provided in detail in the following publication:

MULTI-OBJECTIVE MODELING IN RIVERWARE FOR USACE-SWD

John Daylor, Hydraulic Engineer, USACE, Tulsa, OK, John.Daylor@usace.army.mil; David Neumann, Water Resource Engineer, Center for Advanced Decision Support for Water and Environmental Systems, University of Colorado, Boulder, CO, David.Neumann@Colorado.edu; Edith Zagona, Director, Center for Advanced Decision Support for Water and Environmental Systems, University of Colorado, Boulder, CO. Edith.Zagona@Colorado.edu; Jennifer Steffen, Hydraulic Engineer, USACE, Tulsa, OK, Jennifer.Steffen@usace.army.mil

Abstract: The U.S. Army Corps of Engineers Southwestern Division (USACE-SWD) and associated Districts operate numerous multipurpose reservoirs for flood control, water supply, hydropower, navigation, recreation, and water quality. They have developed several models in RiverWare for planning studies. This paper describes the methods and functions in RiverWare, how they are applied in the context of the rulebased simulation solver to perform these studies, and some additional utilities in RiverWare developed in collaboration with SWD to strengthen their usability and analysis capabilities. The SWD methods include: surcharge release from reservoirs, regulation discharge computations to determine the available space at downstream control points, system-wide flood control algorithm that computes flood control releases at all reservoirs while maintaining balanced storages and releasing flood storage over a forecast period without flooding downstream control points, water supply and stream diversions, minimum flow releases to meet targets while balancing reservoir storage, and hydropower releases to meet system load. The integration of the SWD algorithms brings together RiverWare's object-oriented modeling features and the power and flexibility of the priority rulebased simulation. The algorithms are thus implemented in modular, object-specific contexts for ease of maintenance and extension, as well as flexibility of use through user-selectable methods. In addition to these multi-objective planning studies, the capability to perform single or multiple reservoir yield studies was developed by enhancing RiverWare's Multiple Run Manager using a user-define logic to make iterative runs that converge on the demand that empties the conservation pool during a specified hydrologic sequence. RiverWare includes statistical post-processing and a direct data connection to the Corps' Data Storage System (DSS). Numerous studies arise that involve requests for proposed reservoir and system operational changes and associated affects to the existing operating plan. Typical studies include reallocation of authorized purposes, dam safety concerns, navigation enhancement, dependable yield determination, changes in target pool elevations, and downstream channel constraints. Period of record modeling with RiverWare provides tools for evaluating these proposed alternative operating management plans. This paper will also present examples of RiverWare modeling of case studies in SWD Tulsa District. RiverWare was developed by the University of Colorado Center for Advanced Decision Support for Water and Environmental Systems (CU-CADSWES) under sponsorship of the Tennessee Valley Authority (TVA), the U.S. Bureau of Reclamation (USBR), and the USACE.

INTRODUCTION

The Corps of Engineers, Tulsa District is responsible for managing 45 multipurpose reservoirs plus five run of river lock and dams. Major river systems in Tulsa District include the Arkansas and Red Rivers with contributing runoff areas extending from central Kansas, southwest

Missouri, all of Oklahoma, northern Texas, Texas panhandle, and western Arkansas, as shown in Figure 1. These reservoirs and river systems have series and tandem configurations with common downstream focus points for operational management, as well as individual reservoir requirements. Management follows existing reservoir and system operating guidance that has been adopted and accepted by the Corps, other Federal and state agencies, and numerous stakeholders. An authorized operating management plan is in place, however public and political interests exist that often conflict with the authorized plan. Examples of authorized purposes for the reservoirs include flood storage, navigation, water supply, water quality, irrigation, recreation, and hydropower. On a regular basis, there are requests for the Corps to investigate proposed changes to the authorized reservoir and system management plan. Some examples include different seasonal guide curves, additional water withdrawals, water quality variations, hydropower loading, and navigation enhancements. Due to the complexity of the reservoir and river system, a modeling approach is needed to investigate impacts of these requested operational changes. The RiverWare program provides a modeling tool for such analyses.

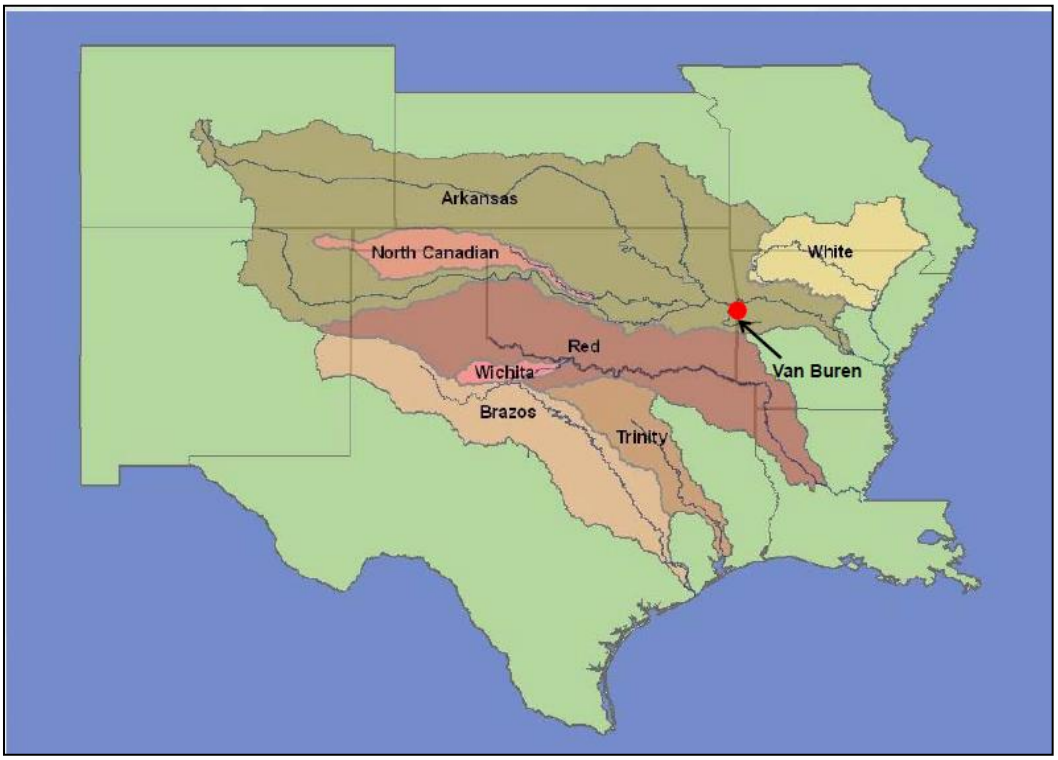

Figure 1 Corps of Engineers SWD-Districts RiverWare modeled basins.

RIVERWARE PROGRAM: TULSA DISTRICT APPLICATION

The reservoirs in Tulsa District were constructed and became operational over a period of time spanning from the late 1930's into mid-1980's. To investigate proposed changes in the reservoir and river system, a period of record planning model with rulebased simulation in RiverWare is used. The RiverWare model configuration for the Arkansas River, as shown in Figure 2 has 21 reservoirs, 48 regulation stream control points, and numerous routing reaches. All reservoirs are

configured in the model as being operational during the entire period of record simulation time frame, thus depicting a present day system condition analysis approach. For the Arkansas River model the period of record spans from January 1, 1940 through December 31, 2008 with daily time step computations. Historic surface water hydrology records are used to obtain local intervening area flow into headwater reservoirs and downstream control points. Historic precipitation and evaporation are applied to reservoir surface areas. During this 69-year timeframe of daily historic hydrology, significant extremes have occurred that provide wide variation of basin hydrologic conditions. Therefore, flood, drought, and average operations can reasonably be investigated.

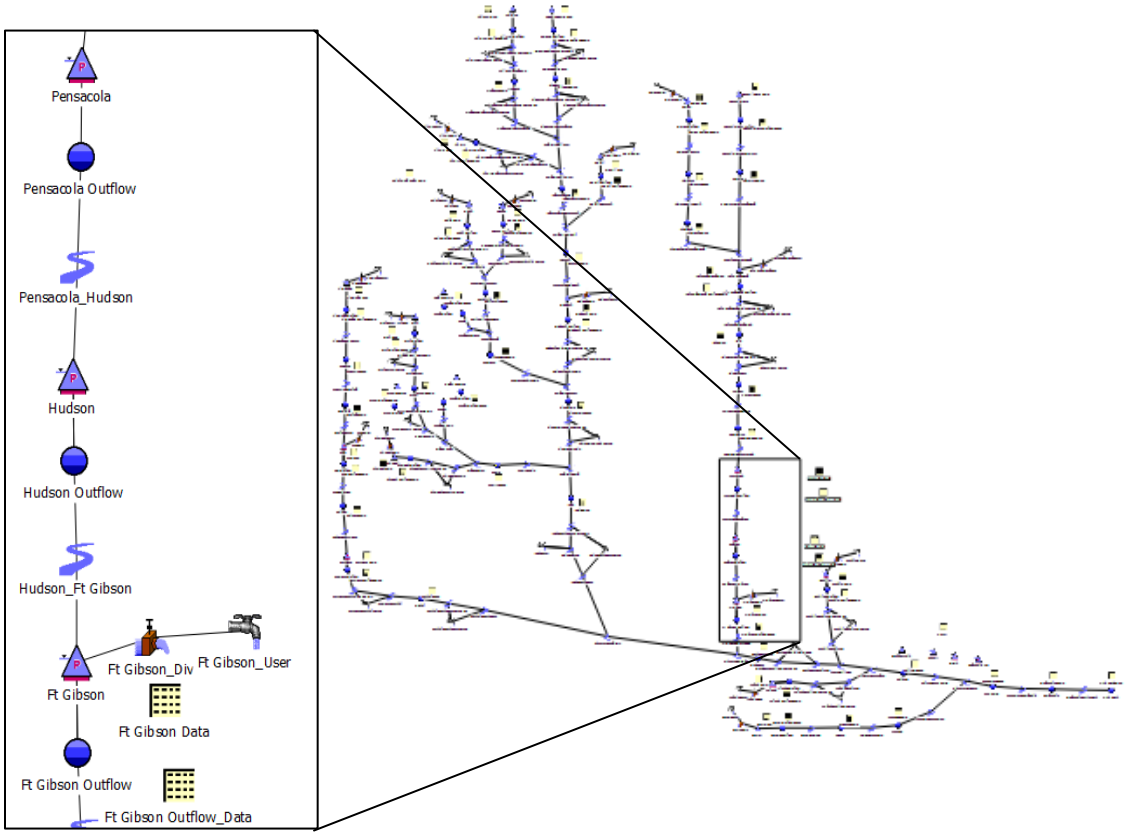

Figure 2 Arkansas River RiverWare model object configuration.

RiverWare's rulebased simulation approach is used by Tulsa District to replicate the reservoir and river system operating criteria. RiverWare is rich with rule development potential, both with pre-configured functions and user developed logic. One of the pre-configured sets of logic involves the Corps of Engineers Southwestern Division (SWD) flood control method which is a system approach to flood storage evacuation. This approach includes predefined functions, user selectable methods on individual objects, and methods that apply across a group of objects called a subbasin. The rules typically execute the methods or do the computation on the objects and subbasin. Data and user configuration options on the objects allow the different calculation approaches for different objects. The results of the computations are values for the decision

variables, usually reservoir releases and/or diversions. A sample ruleset that includes the SWD method for the Arkansas River model is shown in Figure 3.

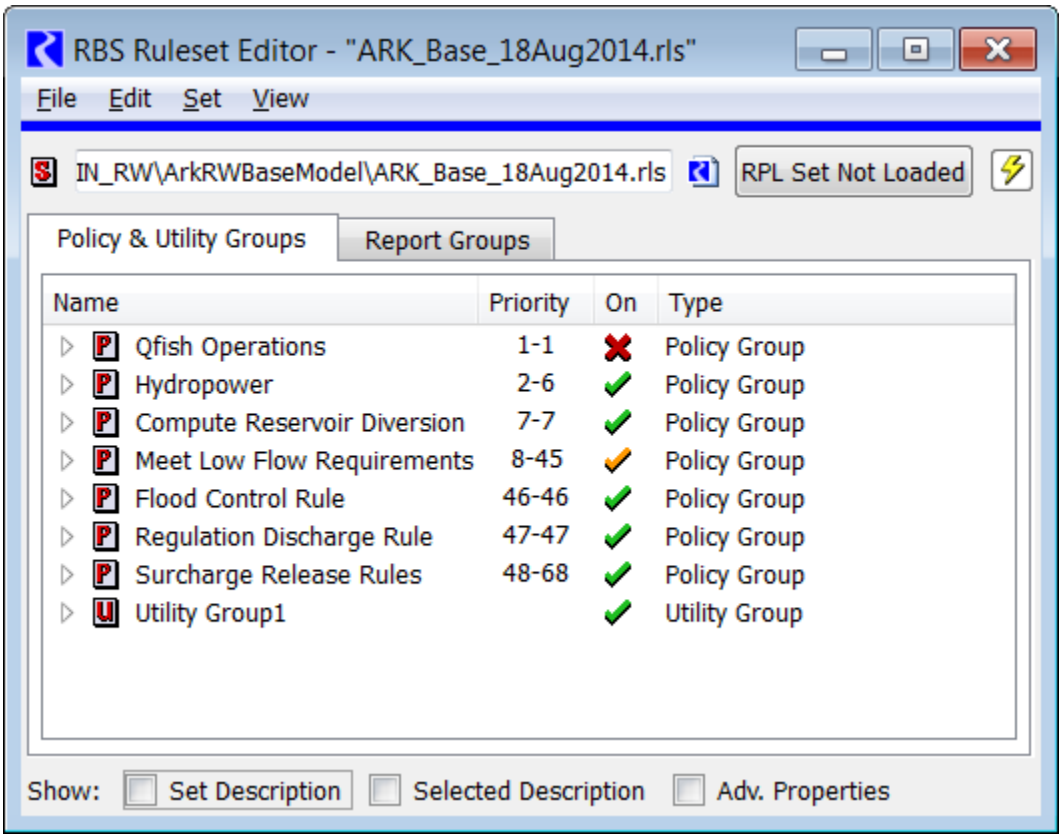

Figure 3 RiverWare ruleset for the Arkansas River basin.

Surcharge Release Rule: The surcharge release rule evaluates if inflow into each reservoir is sufficient to exceed flood storage and enter into surcharge conditions. If so, a release schedule is determined regardless of downstream conditions. The headwater reservoirs are evaluated first, such that any upstream reservoirs' surcharge release becomes part of a downstream reservoir's inflow. All reservoirs are evaluated in this upstream to downstream order to determine these mandatory surcharge releases.

Regulation Discharge Rule: The regulation discharge rule considers available channel space at each downstream regulation control point. The space hydrograph is the difference between the flow limit and actual flow that is a combination of local intervening area runoff flow plus prior time steps routed flow from upstream reservoirs releases. For each control point, a multi-time step space hydrograph is computed for upstream reservoir release potential. There are four general methods for configuring a control point's regulation criteria as used by the SWD:

- channel maximum flow method: The channel method usually involves a single maximum flow limit.
- current level regulation method: The current level regulation method considers an upstream reservoir's fullness at current time.

- future regulation method: The future level regulation method considers an upstream reservoir's fullness over the next several time steps.
- system method: The system percent method considers several upstream reservoirs' collective fullness. A key control point configuration and designation is used in the SWD flood control method to identify those control points that usually govern reservoir releases over other control points.

In the Arkansas River model, the main constraint for reservoir releases on the Arkansas River is Van Buren, Arkansas regulation control point. This location, as shown in Figure 1, has flow limitations based on the fullness of 13 reservoirs that have influence on this location. Flood damage flow is a consideration as well as flow benches for navigation. Flood storage evacuation must also follow a tapering plan for navigation. The Van Buren control point is designated as a key control Point.

Flood Control Rule: The flood control rule evaluates if any reservoir is in the flood storage zone; if so, a multi-day release schedule is developed based on downstream control points' available space as well as its fullness compared to other reservoirs in the system. If several reservoirs are competing for channel space, a priority scheme is used in the SWD flood control method. Each reservoir is configured with a balance level verses percent full of flood storage, Figure 4, which is used to determine priorities for flood storage releases as per the system manual operating criteria. In this way, the flood control logic computes reservoir releases to prevent downstream flooding. When the inflows to the system are reduced, the reservoir releases are computed to recover the flood control space in a balanced manner while not exceeding the downstream flow targets.

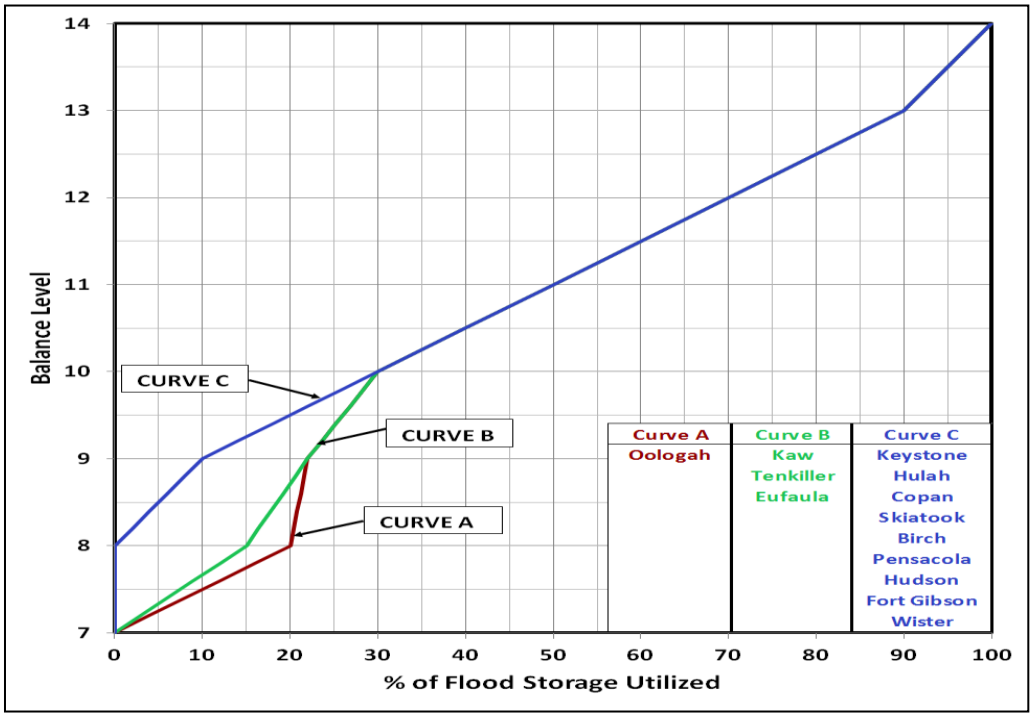

Figure 4 Balance level vs. percent of flood storage for reservoirs.

Low Flow Rule: The meet low flow requirements rule tries to meet low flow targets at several downstream locations from one or more upstream reservoirs. Low flow requirements can be a constant rate or can vary by season, as well as a function of the supplying reservoir's fullness. For example, as the providing reservoir's conservation storage is being depleted, the downstream minimum flow requirement can be reduced. The rules compute the releases to meet the low target based on the fullness of the supplying reservoirs. Releases are made from the fullest reservoir first up to its maximum specified release and then releases are made from the next fullest reservoir, and so on until either the low flow requirement is met or there is no more water to meet low flows.

Reservoir Diversion Rule: The compute reservoir diversions rule evaluates reservoir withdrawals, typically for municipal and industrial (M&I) demands. A monthly request for diversion is input and can be configured with return fraction. Actual withdrawals are based on the reservoir's available storage and the withdrawal can be reduced with depleting storage. The rules compute the available water and compute the flow necessary to meet the demand. Stream withdrawal points can also be configured with dependencies on reservoir conditions in the system.

Hydropower Rule: Any releases made for other purposes are automatically sent through the turbines to the extent possible, but additional power demands may exist that require additional turbine releases. The hydropower rule computes the power load requirements and then makes releases to meet that load. The load can be input several ways in RiverWare. Examples include period of record firm loadings, reservoir guide curve, and system energy in storage. Weekday and weekend loading ratios are available. Downstream channel space availability is considered when making hydropower. A hydropower release is proposed and then the system is solved downstream to ensure that the proposed release does not cause additional downstream flooding. If it does, the hydropower release is cut back. Thermal purchase (power deficiency) and dump energy (power surplus) computations are made in conjunction to input firm power requirements. RiverWare period of record modeling computations for Tulsa District is a daily time step and the computed daily average turbine release for the day may meet a required low flow release for the day on a daily average basis. In reality there are a few hours during the day where this low flow requirement is not being met with turbine release, therefore RiverWare includes functions to consider and account for the partial day of turbine release and resultant low flow release needed for the remaining hours of the day.

Post-Run Analysis: RiverWare has many tools for viewing and analyzing post simulation results. RiverWare's statistical functions on the data object are a common use for Tulsa District, as well as graphical and tabular features. Unique computations of interests can be developed with the expression slot tool. The output manager provides features for configuring and saving outputs. RiverWare's model report tool can be used to develop HTML report files with user selected input for study specific areas of interests. RiverWare's data management interface (DMI) can be used to transfer datasets into and out of the RiverWare interface, such as the Corps of Engineers' DSS file format, commonly used by Tulsa District. An example of the output manager's graphical capabilities is the pie chart shown in Figure 5. This pie chart shows the percentage of flood control storage for a single example time step at 10 reservoirs in the lower

Arkansas River basin. Each wedge represents that reservoir's fraction of the total flood control space. The colored portion of the wedge represents the flood control storage percentage at that time step. Labels and numeric data provide specific information on the flood storage volume and percentage. RiverWare's pie chart function has animation capability that allows viewing over several time steps.

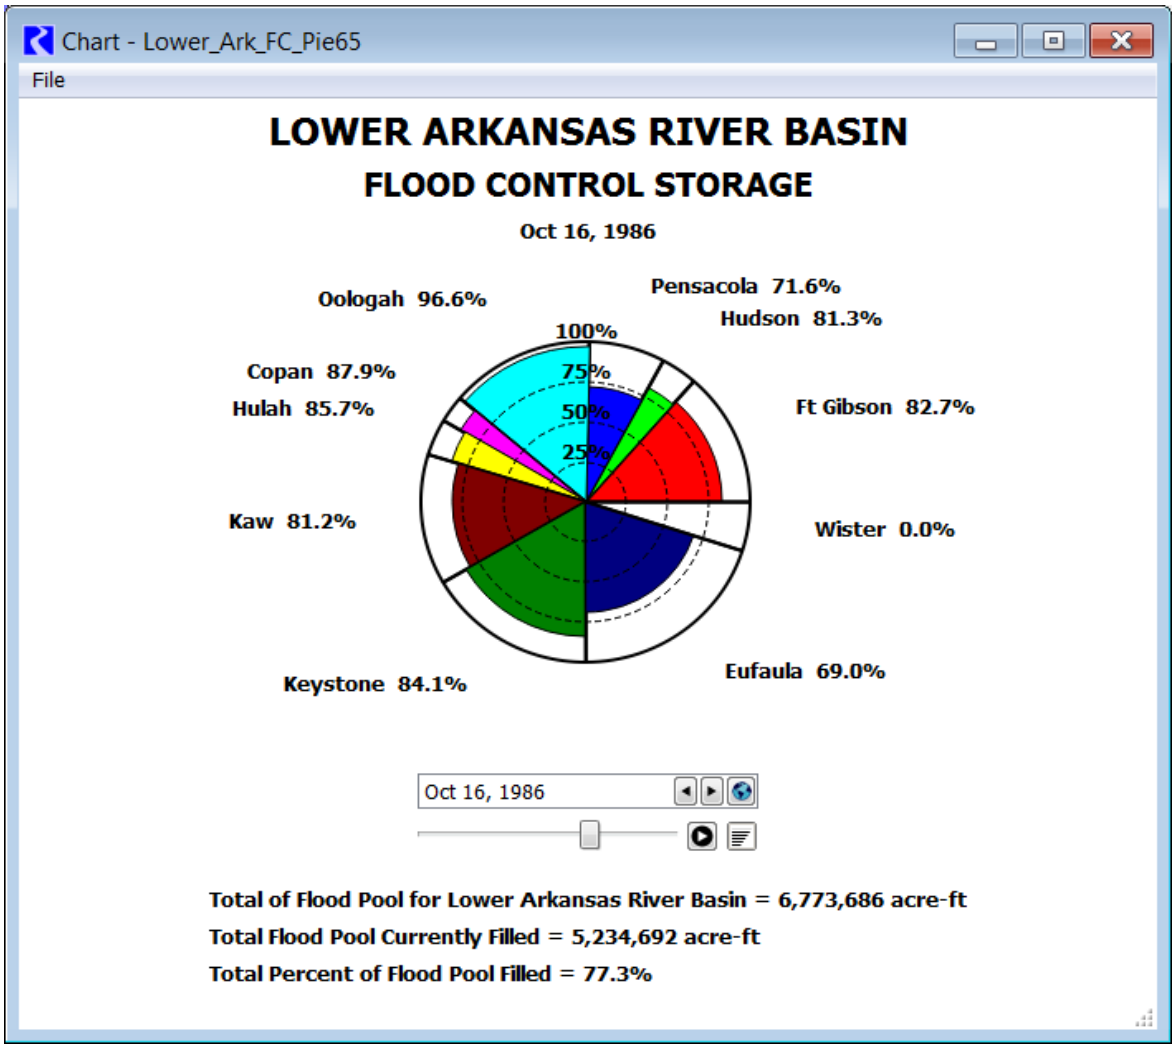

Figure 5 Pie Chart for reservoirs with flood storage.

CASE STUDY: FIRM YIELD ANALYSIS

Tulsa District Corps determines dependable reservoir yield by examining the period of record hydrology and determining the reservoir withdrawal that can be sustained during the most severe drought of record. In other words, what yield (firm yield) can be maintained while exhausting the conservation pool storage without going below the bottom of conservation pool zone. To accomplish this analysis, Tulsa District uses RiverWare's iterative multiple run manager tool to cycle through the period of record to converge on this firm yield value. The iterative MRM makes a run through the period of record and then executes logic to determine if another run is

needed and if so, the variables that should be changed. Using this tool, the period of record can be run many, many times with different inputs to search for the desired solution. For the yield study, an initial estimate for yield is either input or the program uses average annual inflow on the first passes to get bounding conditions. The iterative MRM rules then converge on the yield using a modified bisection algorithm to find the withdrawals that exactly exhausts the storage at some point in the period. The user specifies a tolerance target for convergence limits. RiverWare's system control table (SCT) is used to show the iterative and final values, as shown in Figure 6. This example provides results from a single reservoir yield determination in the Red River multi-reservoir system. This firm yield analysis approach with RiverWare's MRM can also be configured sequentially to compute firm yield for several or all reservoirs in the system.

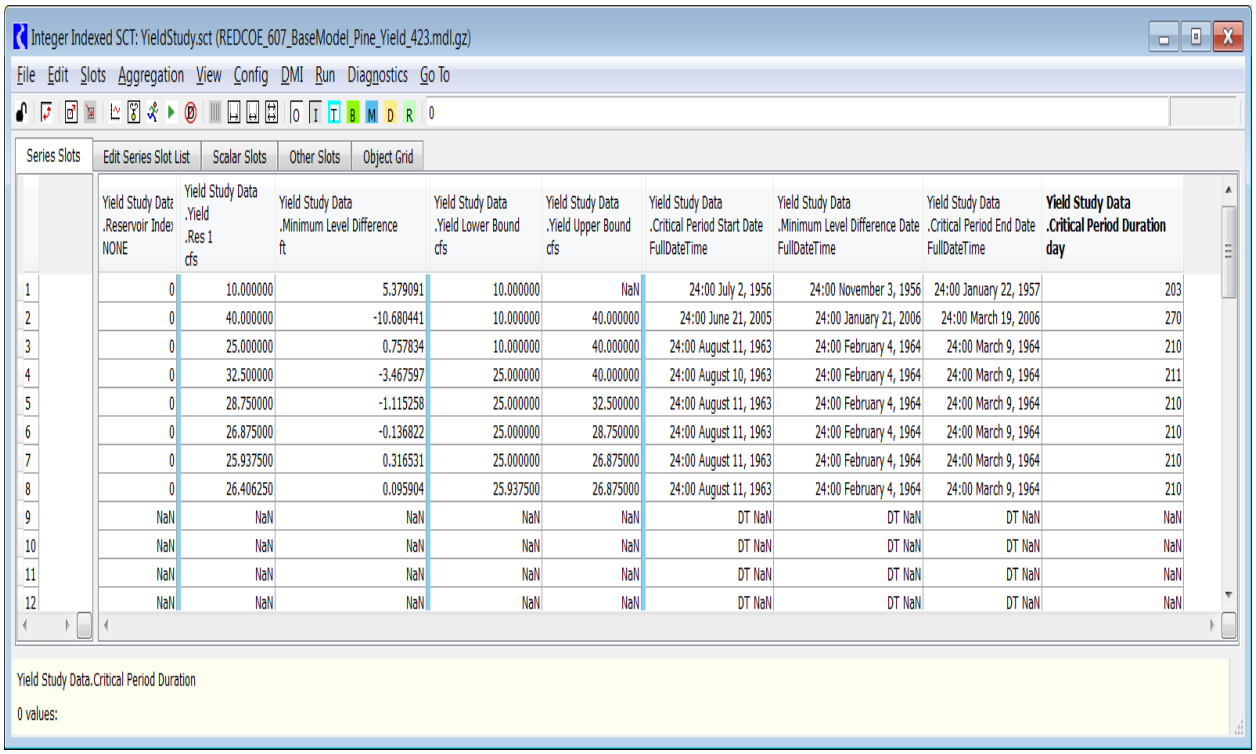

Figure 6 System Control Table with Iterative Multiple Run Manager for firm yield analysis.

CASE STUDY: PINE CREEK LAKE DAM SAFETY

Pine Creek Lake is a headwater reservoir on the Little River in southeastern Oklahoma that is a major tributary to the Red River. Embankment seepage around the gated conduit has been discovered at Pine Creek Dam. The Corps' dam safety team is currently evaluating corrective measures. For precautionary measures the dam safety team has requested a lower operating level for the top of conservation pool elevation. Pine Creek is a multipurpose reservoir with flood control storage, water supply and low flow requirements, and recreation interests. Pine Creek is one of 15 reservoirs in the Red River system that collectively operate for the common downstream regulation point at Shreveport, LA. A RiverWare model was used to investigate various proposed alternative operating levels for Pine Creek in conjunction with the Red River system operating plan. Impacts of reducing the conservation storage needed to be investigated

and mitigated. Figure 7 shows the elevation duration relationship of the normal operating level at elevation 438.0 ft and the reduced operating level at elevation 433.0 ft. The selected interim operating level provides minimal impacts to the system while providing reduced risk of embankment concerns.

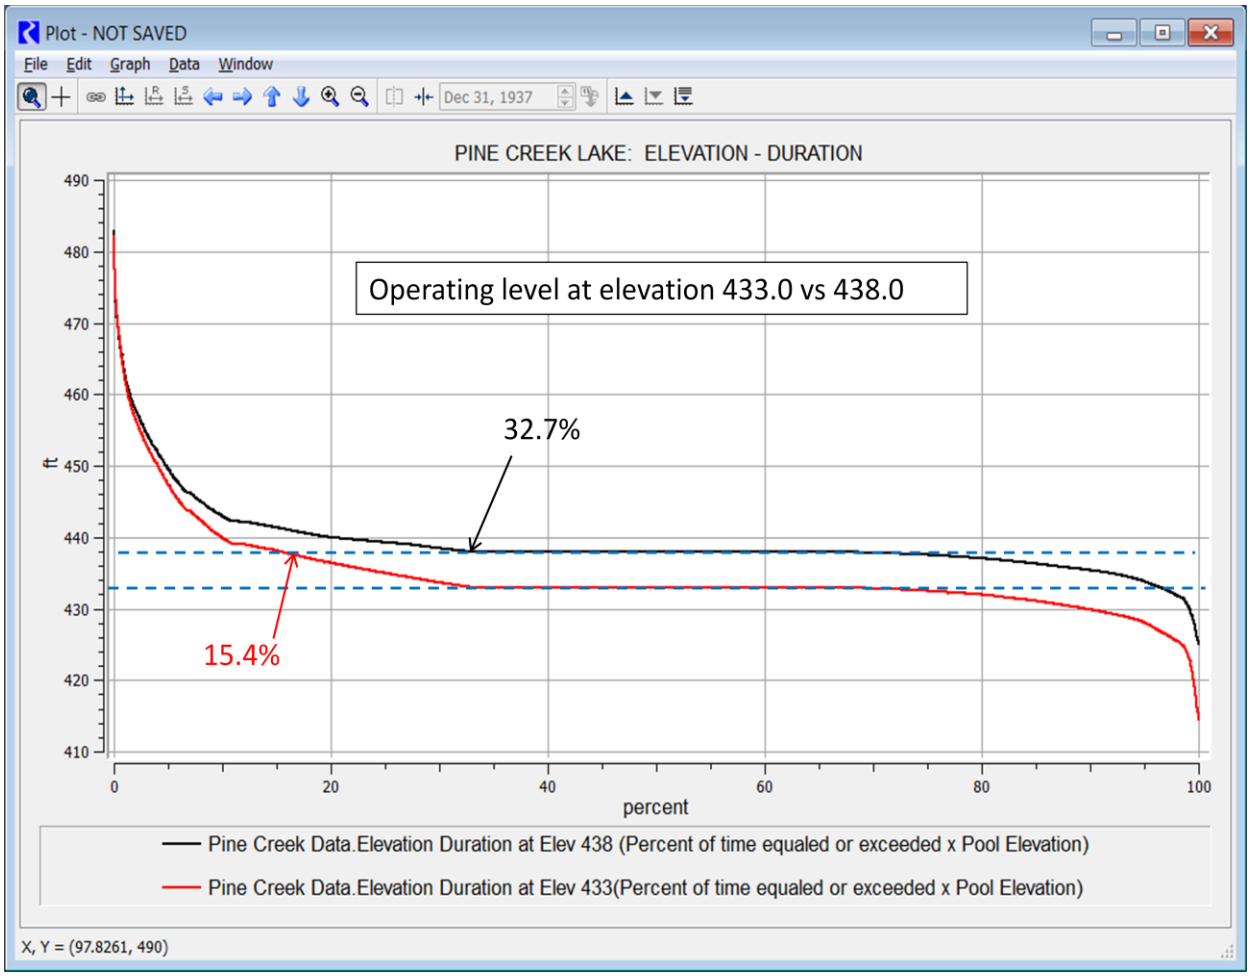

Figure 7 Pine Creek Lake elevation - duration for alternative top of conservation pools.

TYPICAL MISCELLANEOUS APPLICATIONS BY TULSA DISTRICT

On a periodic basis the District's Reservoir Operating Manuals and System Manuals are updated. The period of record hydrology and any operating changes are updated in RiverWare to provide simulated data for these manual updates. The Corps is currently involved with dam safety evaluations, periodic assessments of structures, and levee certifications, hence numerous requests are made of RiverWare's reservoir and system modeling output. RiverWare modeling provides for a rapid and easy tool to investigate potential deviations to operational management. The impoundments in Tulsa District are aging and experiencing depleting storage due to sediment deposition. Figure 8 showing Keystone Lake on the Arkansas River main stem provides an example of reduced storage as measured with periodic resurveys. The effects of depleted capacities can be investigated.

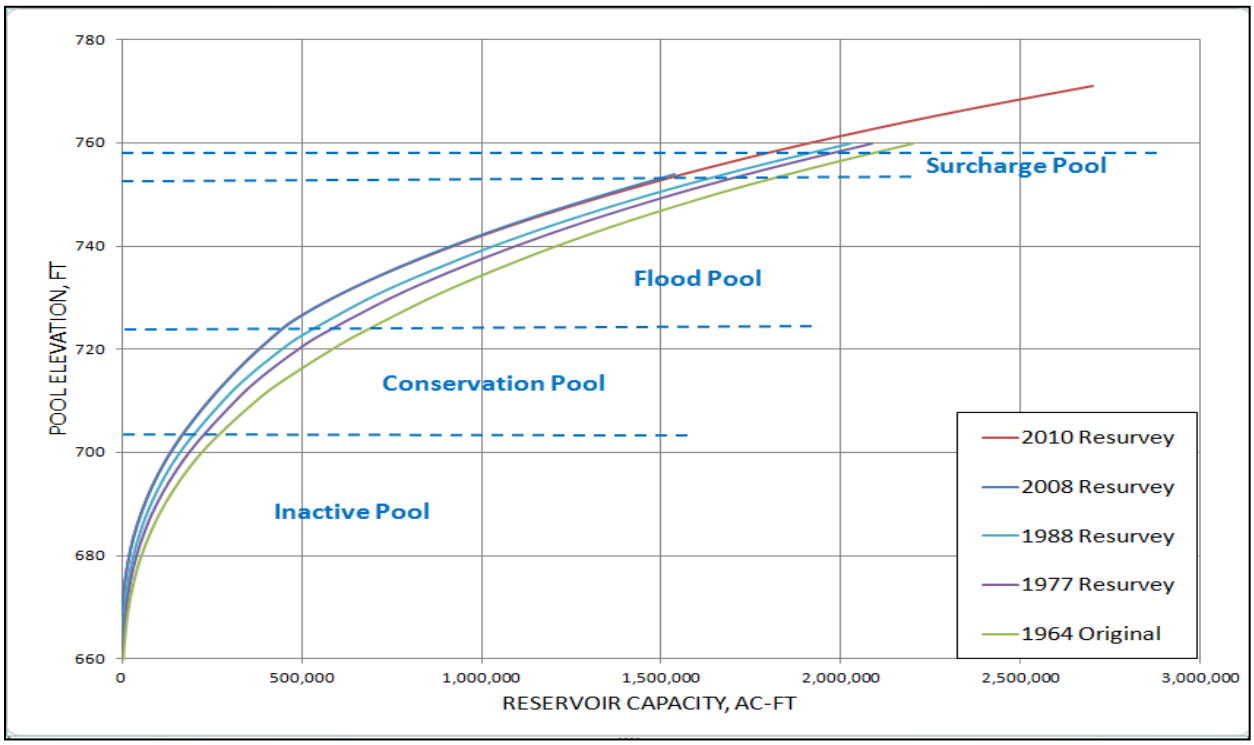

Figure 8 Capacity reduction with sediment deposition for Keystone Lake.

CLIMATE CHANGE ANALYSIS

RiverWare modeling has potential to investigate climate change concerns. In Tulsa District's period of record rulebased modeling, the historic surface water hydrology, precipitation, and evaporation can be adjusted for climate change scenarios. Operational rule logic can be configured to analyze responses to basin conditions and trends. In Tulsa District watershed, most precipitation and resultant runoff typically occurs in the spring months and another inflow season in the fall. Summer and winter seasons typically have less experienced runoff. One example of conditional operation with RiverWare rule simulation that can be applied for climate change effects involves evaluating the inflow into a reservoir during a specified time frame, say the spring months and comparing to a selected threshold. If the threshold is not met an alternative reservoir target operational guide curve is used in an attempt to maintain some additional pool storage in late spring for upcoming dry summer months. In the future, the RiverWare models of the basins will be used to perform this type of studies.

CONCLUSION

Tulsa and other Districts in the Southwestern Division of the Corps have numerous reservoirs that must be operated individually and as a system for existing authorized purposes as well as the many interests competing for finite resources. RiverWare's rulebased simulation modeling provides a study approach for evaluation and decision tools to manage the system as well as compare the effects of proposed alternative operating scenarios.

CHANNEL AND BANK STABILITY OF THE BURNETT RIVER IN THE AFTERMATH OF THE 2011 AND 2013 FLOODS: IMPLICATIONS FOR SEDIMENT DELIVERY TO THE GREAT BARRIER REEF

Andrew Simon, Senior Consultant/Geomorphologist, Cardno, P.O. Box 1236, Oxford, Mississippi 38655, USA, andrew.simon@cardno.com; Natasha Bankhead, Senior Project Scientist, Cardno, P.O. Box 1236, Oxford, Mississippi 38655, USA, natasha.bankhead@cardno.com and Peter Wilson, Soil Scientist, Burnett-Mary Regional Group, Bundaberg, QLD, Australia, peter.wilson@bmrg.org.au

Abstract The Burnett River, QLD Australia, experienced severe flooding in early 2011 and 2013, with the latter flood breaking all historical records. As a result, damage to infrastructure and the loss of agricultural land from bank erosion was considerable. Exacerbated by the floods is concern about sediment delivered to downstream locations including dams/weirs, and ultimately to the Coral Sea and the Great Barrier Reef (GBR). The primary objectives of this work were to: (1) provide strategies for cost-effective protection of local assets and (2) determine the relative contributions of bank sediment (particularly fine-grained material) to overall sediment loads to the GBR.

Analysis of aerial imagery between 2009 and 2013 revealed that a total of about 27.8 million m^3 (47.3 Mt) of materials were eroded from the banks of the lower 300 km of the Burnett River main stem (about 6.1 million m^3/y or 10.4 Mt/y). An equal volume is not delivered to the Coral Sea, as an unknown proportion is deposited on low-bank surfaces, beds, bars and floodplains. It can be assumed that the majority of the fine-grained materials is transported through the system Approximately 21 million m^3 (35.6 Mt) or about two thirds of these sediments were eroded from banks downstream of Paradise Dam while much of the hydraulically-controlled bank sediment eroded from reaches upstream of rkm 170 was trapped behind the dam (7.0 million m^3).

Long-term simulations (42 years) were conducted using the Bank Stability and Toe Erosion Model (BSTEM), to compare longer term averages with the 2009-2013 rates calculated from aerial imagery. Over this longer time period, annual bank-erosion rates are about 3.1 million Mt/y; about 18 times greater than the value predicted by the catchment model SedNet. Bank-erosion rates below Paradise Dam (rkm 131) are 2.4 million t/y. Assuming 100 years of simulation and using an empirical relation between the period of BSTEM simulations and calculated erosion rates, a conservative value for the average, annual rate of bank erosion is 2.0 Mt/y. Bank erosion, instead of being a minor source of sediment representing 8% of the total, was found to be the single largest contributor of sediment in the Burnett River Catchment, representing at least 44% of the total, annual sediment budget.

The implications of these findings are considered in the context of erosion sources and rates in Brodie et al., (2003) who report that on average, 2.75 Mt/y are eroded from the catchment. By replacing their 0.175 Mt/y from the banks with the 2.0 Mt/y calculated in this study, a new total of 4.6 Mt/y is obtained. Given these significant differences in both the relative importance and absolute rates of bank erosion than was earlier reported, sediment management should be re-focused to include this important source. Doing so would not only protect local assets by limiting land loss and bank retreat, but would help maintain reservoir and harbour capacity, minimize downstream flooding, and protect marine resources.

INTRODUCTION AND BACKGROUND

The Burnett River is one of the Reef Catchments flowing through the city of Bundaberg in its downstream reaches before exiting to the Coral Sea. The Burnett River experienced severe flooding in early 2011 and 2013, with the latter flood breaking all historical records. As a result of these floods, damage to assets, infrastructure and the loss of agricultural land from bank erosion was considerable. Massive amounts of sediment were transported to the Coral Sea (Figure 1). In an effort to develop a strategy for prioritizing and determining resilient and cost-effective protection measures, an understanding of both site-specific and system-wide stability conditions is essential. For site- and reach-specific solutions, this is accomplished by quantifying the driving (flow and gravitational) forces and resisting (shear strength) forces operating on the channel banks, and testing how alternative stabilization measures would perform over a range of flows. System-wide analysis then provides the spatial and temporal context of

channel instability to determine the suitability of conducting various types of channel works (i.e. energy dissipation, bank stabilization, etc.) to protect assets and to aid in prioritization of those works.

The geographic scope of this study extends from the mouth of the Burnett River east of Bundaberg, upstream about 300 km to Eidsvold (Figure 2). Results of this study will also be germane to managing sediment delivery from the catchment to the Coral Sea and the Great Barrier Reef by providing data on sediment contributions from streambank erosion.

Figure 1 Sediment plume from the Burnett River entering the Coral Sea, January 2013. Image provided by D. Honor (Bundaberg Regional Council; 2013).

FLOWS

This study was undertaken in the context of flood recovery following the record flows of January 2013. It is important, therefore, to put the magnitude and frequency of these kinds of devastating events in the perspective of the long-term flow record. Fortunately, the Burnett River has flow records extending back for more than a century. Annual-maximum peak flows from 1910 to present are shown in Figure 3 for the gauge at Walla Weir (136001A). Over the period, the flow of January 2013 represents the maximum recorded peak since 1910 and by definition, has a return period of at least 104 years. When viewed over the period of record, the 2013 peak is significantly greater (46%) than the previous maximum of 10,780 m^3/s recorded in 1942. In comparison, the 2013 peak was 157% greater than the peak flow in 2011. However, when the peak flows of 1890 and 1893 are considered, a slightly different picture emerges. Discharges for the large floods in 1890 and 1893 were estimated from stage data provided by Department of Natural Resources and Mines (DNRM; R. Maynard, written comm, 2013) and included in the peak-flow series. These flows represent the second and third largest flows since 1890, respectively, and demonstrate that the flood of January 2013 was (1) not that uncommon, and (2) only 17% greater than the estimated 1890 peak. By also considering the flood of February 1875 which had a peak 0.9 m below that of the 2013 peak at Bundaberg (DNRM, 2013), the return period for the 2013 flood reaches 139 years.

SYSTEM-WIDE STABILITY CONDITIONS

Analysis of current geomorphic conditions and dominant channel processes along the study reaches were conducted, in part through the use of Rapid Geomorphic Assessments (RGAs). RGAs utilize diagnostic criteria of channel form to infer dominant channel processes and the magnitude of channel instabilities through a series of nine, channel criteria. Inclusion of each criterion in the ranking scheme is founded on 30 years of research on the controlling forces and processes in unstable channels (Simon and Hupp, 1986; Simon, 1989; Simon and Downs 1995).

For each RGA, the dominant processes occurring along a reach were recorded using a Channel-Stability Ranking Scheme. Scoring for each criterion is such that a higher value indicates greater potential for erosion and instability. A maximum value of four (4) can be assigned to each, preventing subjective assumptions on the relative importance of each criterion. The nine criteria are directed at determining trends of recent channel adjustments through identification of the stage of channel evolution as impaired streams undergo a systematic adjustment (stages of channel evolution) as processes migrate through a channel network with time. To provide detail, the 2013 post-flood, aerial imagery of the reaches was analyzed over adjacent 2-km reaches to obtain information needed for the RGAs. The result is an almost continuous evaluation of channel conditions and dominant processes over 300 km of the Burnett River.

As hypothesized at the inception of this study, the effects of the impoundments on channel stability can be dramatic. The channel-stability index shows wave-like longitudinal variations, with peak values just downstream from the impoundments and other river-crossing structures. These effects attenuate (decrease) with distance downstream from each of the structures (Figure 4). The most unstable reaches are included in the orange fill (scores of 20-30) and are indicative of an incised channel with actively failing banks and limited vegetative cover over much of each of those 2-km reaches. Conversely, those reaches within the green fill (scores of 0-10) are generally stable with no active bank failures and generally good vegetative cover. The reaches with the most severe instabilities are located just downstream of Walla Weir and Paradise Dam where values of the channel-stability index are typically greater than 20 (Figure 4). Conversely, stable conditions extend upstream from these two impoundments; for 39 km above Paradise Dam (to rkm 170) and, for about 16 km above Walla Weir (to rkm 90). The stability imparted through the hydraulic effects of the dam extends about 20 km upstream of the head of the impoundment at rkm 150.

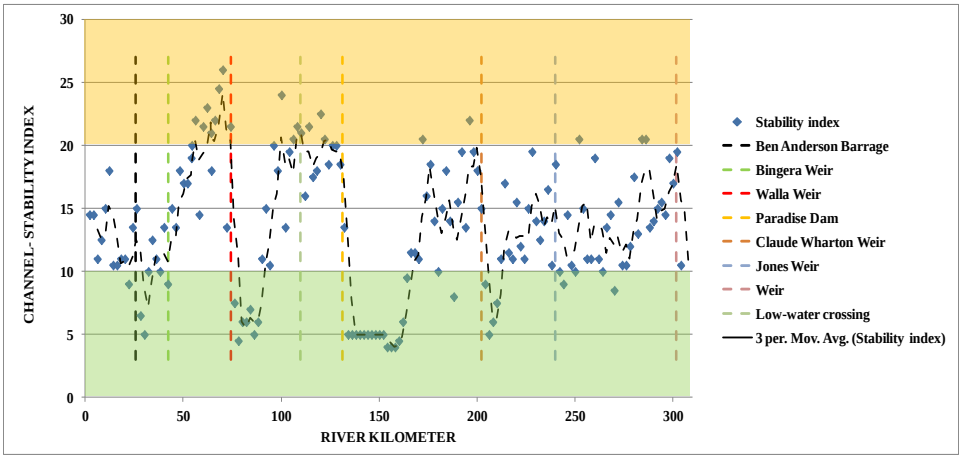

Figure 4 Longitudinal variation in the channel-stability index along the Burnett River main stem showing the effects of dams. Orange fill denotes very unstable conditions (20-30) while the green fill denotes very stable conditions (0-10).

Data on system-wide channel geometry (bank height, width, and slope) were obtained at 2-km increments from analysis of LiDAR data in those reaches where available. LiDAR coverages are not all from the same time, ranging from 2009 to early 2011. For the purposes of this study, it was assumed that they are all from one data set, representing the pre-flood condition of the channel. To determine the magnitude and extent of recent bank erosion, an analysis of the 2010 pre-flood and the 2013 post-flood, aerial photography was conducted. Fixed points on each bank were identified at 2-km increments in each paired image (2010 and 2013) to determine the distance from the

point to the top-bank edge. A comparison of the difference in these distances produced the amount of lateral retreat of the particular bank over the time period. Multiplying this value by the height of the bank provided the amount of material eroded per unit length of channel (in m^2/m). To then obtain an estimated value of the volume of sediment delivered to the channel by bank erosion, the average value between two adjacent reaches was then multiplied by the reach length (2,000 m).

BANK-DERIVED SEDIMENT LOADINGS

Unit bank-erosion rates provided information of the average amount of land lost to the river per unit length (m) of channel, but did not assume that each meter of a specific 2-km reach retreated at the same rate. This would only be the case if "percent reach failing" values obtained from the RGA analysis were 100%. Unit bank-erosion rates shown in Figure 5 again display the typical wave-like functions with peaks on the downstream sides of the impoundments.

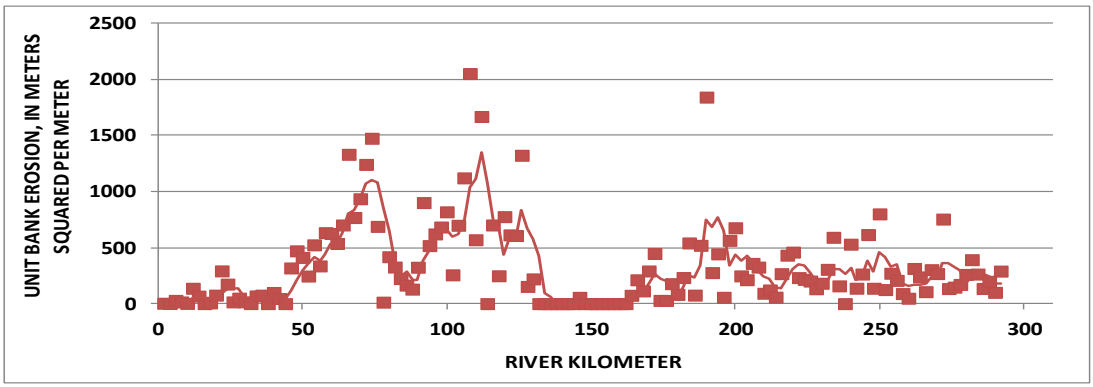

Figure 5 Unit bank-erosion rates, representing land loss (in m2/m) along the Burnett River main stem

To calculate total volumes of bank material eroded from the margins of the Burnett River, the unit bank-erosion rates for each bank, along each 2 km reach were multiplied by the "percent reach failing" (from the RGA data set) and by the reach length (2,000 m) (Figure 6).

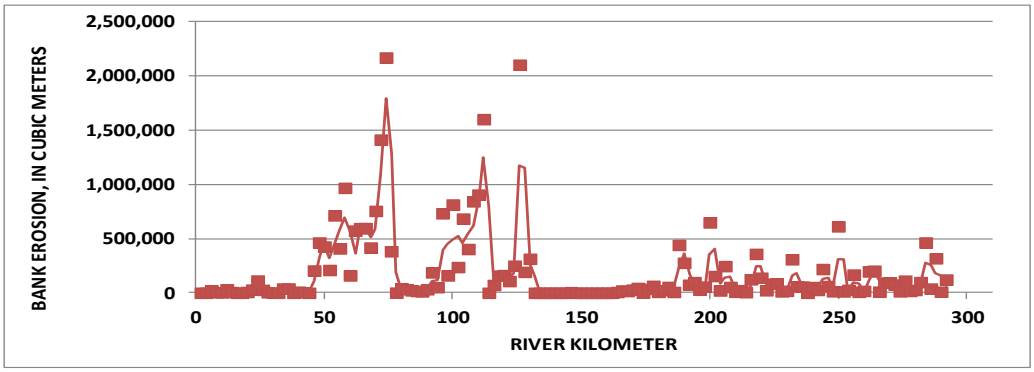

Figure 6 Volume of bank material eroded from floodplains and terraces along the Burnett River mainstem.

Summing the eroded-volume data along the entire 292 km reach of the Burnett River main stem gives a total volume of material eroded by bank processes of about 27.8 million m^3 (47.3 million t) or, about 6.1 million m^3/y (10.4 million t/y) over the 4.58-year modelling period. Erosion of these bank materials does not equate to an equal volume being delivered to the river mouth and the Coral Sea, as an unknown proportion is deposited on low-bank surfaces, beds, bars and floodplains. It can be assumed, however, that the majority of the fine-grained materials (silts and clays) are transported through the system and out to sea. Approximately 21 million m^3 (35.6 million t) or about two thirds of these sediments were eroded from banks downstream of Paradise Dam. One can assume that much of the

hydraulically-controlled bank sediment (less than 7 million m^3) eroded from reaches upstream of rkm 170 was trapped behind Paradise Dam. Erosion volumes are shown mapped in Figure 7.

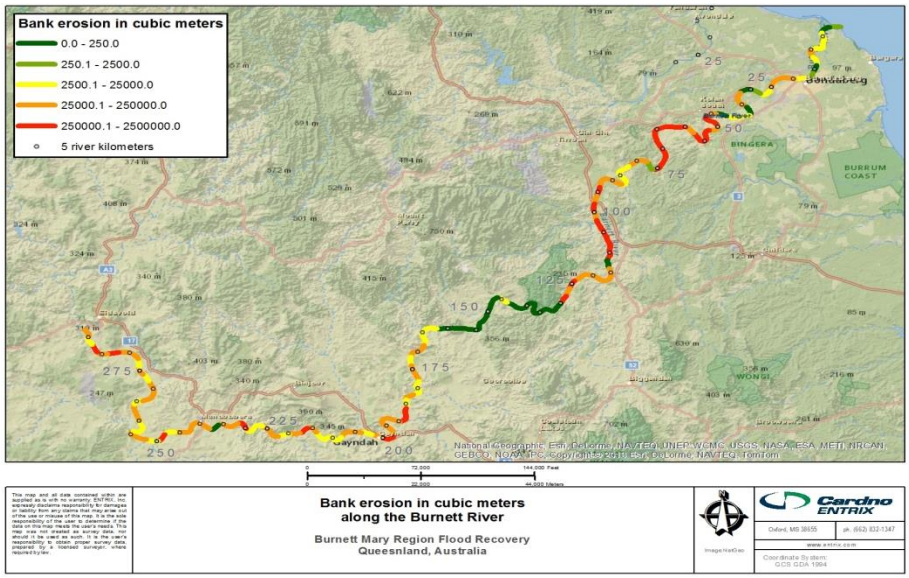

Figure 7 - Volumes of bank erosion over the period 2010-2013 along the Burnett River main stem.

Given these very high rates of bank erosion over the 2009-2013 period, it is important to place them in the context of longer-termed erosion rates and their implications for the management of sediment being delivered to the Coral Sea and the Great Barrier Reef (GBR). This is particularly germane to: (1) the Reef Rescue Program where conservation measures to reduce sediment delivery to the GBR are presently focused on upland and agricultural sources of sediment and not on streambanks, and (2) plans to dredge the lower Burnett River to reduce flood risks in Bundaberg.

Results of SedNet modelling in the Burnett River Catchment predict that on average, 175,000 t/y of sediment are eroded from banks of the Burnett River and its tributaries (Brodie et al., 2003). This represents about 8% of the predicted total amount of sediment erosion, with hillslope (1.6 million t/y) and gully (0.93 million t/y) sources making up the bulk of the total. Although it is unclear as to the length of the SedNet simulation period, we assumed that mean-annual flow was used to generate results expressed as "average annual" values. As a result of this large discrepancy between the SedNet results and those provided above, and its implications for sediment management, average, annual bank-erosion data were required for purposes of comparison.

AVERAGE ANNUAL RATES OF BANK EROSION: BSTEM MODELING

To obtain average, annual rates of bank erosion, values over a sufficiently long period of time were required. This was accomplished using numerical modelling. Geotechnical and hydraulic resistance of the bank and bank-toe materials were determined *in situ* at eight sites using conventional techniques (Iowa Borehole Shear Tester: Lohnes and Handy, 1968; Lutenegger and Hallberg, 1981, and the Submerged Jet-Test Device, Hanson, 1990; Hanson and Cook, 1997). Bank surveys and observations of stratigraphic layering for the tested banks were also obtained in the field. The field data were used with mean-daily flow data from gauges along the Burnett River to populate the Bank Stability and Toe Erosion Model (BSTEM-Dynamic 2.0; Simon et al., 2000) for the purpose of simulating bank-erosion rates over time periods ranging from about 4.5 to 42.5 years.

To obtain erosion results in units similar to those reported in Brodie et al., (2003), an average bulk unit weight of 1.7 kN/m^3 was used to convert m^3 to tonnes (t), resulting in a value of 47.3 million t of eroded bank sediment over the 2009-2013 period. This gives an average-annual rate of 10.3 million t over the 4.58-year simulation period. It is important to recall that this value represents 292 km of the Burnett River main stem and does not include bank erosion in the tributaries. Of course, it is unrealistic to use this average bank-erosion value because it represents a

short time period and a period of high and record flows. In order to make more direct and robust comparisons to the SedNet bank-erosion estimates, two steps were required.

First, bank erosion was calculated for the 292 km of main-stem channel using the BSTEM results from the mainstem sites over the 2009 to 2013 period. This necessitated the interpolation of erosion rates at the simulated sites to adjacent reaches and then summing them for the entire river. We then compared these results to the 47.3 million t that was calculated empirically to provide confidence in the methodology. Second, BSTEM was used again at the six sites to predict bank erosion over a longer time period. These results were then used to interpolate bank-erosion rates to adjacent reaches and to sum the values again. An average, annual bank-erosion rate was then obtained by dividing the result by the number of years used in the simulations. The resulting value was then compared directly with the results from SedNet. Unit bank-erosion rates were obtained for each of the six main-stem sites by modelling daily bank erosion over three periods:

- Calibration period (2009-2013) using 2009 as the starting geometry;
- Existing period (2003-2013) using 2013 as the starting geometry; and
- Long-term period (1971-2013) using 2013 as the starting geometry.

Overall, unit-erosion volumes for the 2009-2013 calibration period (in m^3 per length of channel) ranged from 40.5 m^3/m at the Gayndah (BMRG-06) site, to a maximum of 360 m^3/m at the Shalom College (BMRG-03) site. Bank-top retreat in the BSTEM calibration runs ranged from 4.70 m at the Eidsvold (BMRG-08) site, to 23.9 m at the Shalom College (BMRG-03) site (Table 1). It should be noted here that unit-erosion volumes are a function not only of bank-top retreat, but also of bank height.

In general, modeled bank retreat in the calibration runs corresponded reasonably well with the aerial- photography analysis and site-specific notes made in the field. Modeled rates of retreat during the calibration period were between -29% and 114% of those measured from the aerial photographs, with an average difference of 12%. In the case of BMRG-05, where the percent difference between measured and modeled bank retreat showed the highest percent difference (114 %). When the actual retreat values are compared, it can be seen that we are comparing bank retreat values of 2.94 and 6.29 m. Comparison of the aerial photographs from 2009 and 2013 for the entire reach showed however, that there is considerable variation in bank erosion along the reach, and a four meter difference between the two values could simply be a slight variation in field testing location versus digital measurement on the photographs. This percent difference at BMRG-05 is, therefore, not considered to be of concern and the calibration run is within a reasonable range for the reach.

Table 1 Unit erosion volumes for each site from BSTEM 2009-2013 simulations, and comparison with bank retreat measured from aerial photography.

Site	Unit Erosion Volumes from BSTEM (2009 to 2013) (m^3/m)	Bank Retreat from Aerial Photography (2009 to 2013) (m)	Bank Retreat from BSTEM (2009 to 2013) (m)	% Difference Between Measured and Modeled Bank Retreat
BMRG-02- Rubyanna	161	18.0	20.2	12.0
BMRG-03- Shalom	360	23.0	23.9	3.96
BMRG-04- Kolan	110	13.9	11.7	-15.8
BMRG-05- Wallaville	213	2.94	6.29	114
BMRG-06- Gayndah	40.5	6.01	6.19	3.00
BMRG-07-Munduberra	345	8.67	6.17	-28.8

BMRG-08- Eidsvold	81.9	4.89	4.70	-3.89

BSTEM results for each time period are shown in Table 2 and were then multiplied by the "percent reach failing" (obtained from the RGA analysis of each 2- km segment of the channel) and the reach length to obtain a volume of material eroded in each 2-km reach. Summing these values over the entire 292 km provided the volume of eroded material over 292 km of the Burnett River main stem. Unit-erosion values obtained for each of the sites were assigned over a reach extending halfway upstream and downstream to the next modelled site (Table 3). Values for the downstream-most site (BMRG-02; Rubyanna) at rkm 20 were extended to the mouth. Values for the upstream-most site (BMRG-08; Eidsvold) were extended to the top of the reach at rkm 292.

Results for the calibration period using interpolation of the BSTEM results showed that 25.1 million m^3 (42.7 million t) of bank erosion occurred over the 292 km-long reach. This value is about 10% less than the value obtained from the detailed empirical analysis of each 2 km segment and, therefore, provides sufficient confidence in the approach to utilize the 10-year and 42-year simulation periods to interpret long-term rates of bank erosion.

As one might expect, the empirical analysis showed greater longitudinal variability owing to data analysis of topographic data every 2 km (Figure 8). Average, annual bank-erosion over this 4.58-year period comes to about 5.5 million m^3/y (9.3 million t/y). The 10-year simulations, used to determine future erosion rates under "existing" (no action) and mitigated conditions represent a relatively short timeframe by which to compute long-term erosion rates. In this case, interpolation of the 10-year simulations at the six sites over the 292 km reach resulted in 39.5 million m^3 (67.2 million t) of bank erosion, with an average, annual value of 3.7 million m^3/y (6.3 million t/y). Details of these simulations (which include an analysis of the relative contributions from equal durations (5 years) of "wet" and "dry" periods) are included in the discussions of modelling results for each site. The bulk (about 90%) of the bank-derived sediment is delivered to the channel during the wet periods. However, it is important to note that the dry periods can still be effective at hydraulically eroding bank-toe sediments, thus making the bank more susceptible to further undercutting and collapse both during and after high-flow events.

The long-term simulations were conducted using a period slightly greater than 42 years (January 21, 1971 to July 31, 2013). This period was selected because it represented a timeframe covered by all of the gauges that were ultimately used to generate daily-flow data along the main stem. In our view, this was a sufficiently long period to determine average, annual bank-erosion rates. BSTEM simulations were again conducted for the six sites using daily time steps for this period. Results for the individual sites are shown in Table 3. Summing these results for each 2-km reach gives a total volume of bank erosion of 77.1 million m^3 (131million t). Dividing by 42.52 years gives an average, annual bank-erosion rate of 1.8 million m^3/y. Converting to tonnes produces a long-term rate of 3.1 million t/y over the 42 years of simulation, almost 18 times greater than the value predicted by SedNet. A value of 2.4 million t/y is calculated by summing just those reaches below Paradise Dam.

With all of the simulation periods including the peak flows of 2011 and 2013, it is not surprising that the calculated average, annual erosion rates decrease with increasing length of the simulation period. Plotting the calculated erosion rates against the length of the simulation period (Figure 9) shows this tendency. Because episodes of accelerated erosion are closely linked to high-flow years, it is essential, therefore, to use as along a simulation period as possible to accurately determine long-term, average-annual rates. Extrapolating the regression shown in Figure 9 to assume a 100-year simulation period gives an average, annual bank-erosion rate of 2.0 million t/y (from just the main stem channel), still more than an order of magnitude greater than the previous catchment-wide estimates from this source.

Brodie et al., (2003) reports that on average, 2.75 Mt/y are eroded from the catchment. By replacing the 0.175 Mt/y from the banks with the 2.0 Mt/y calculated in this study, a new total of 4.6 Mt/y is obtained. Assuming that the estimates from gully (0.93 Mt/y) and hillslope (1.65 Mt/y) sources are accurate, bank erosion becomes the single largest contributor, delivering 44% of the total sediment load; and once again, this does not include contributions from the tributaries. Brodie et al., (2003) further reports that average, annual total export of sediment from the Burnett River to the Coral Sea is 0.47 Mt/y, implying that 83% of all eroded sediment is deposited behind dams and on floodplain surfaces. Although this is a critically important parameter in estimating sediment export, it is beyond the scope of this investigation to verify that only 17% of the sediment eroded in the Burnett River Catchment reaches the Coral Sea and the GBR. Comparison of capacity surveys beyond structures such as Paradise Dam and additional LiDAR information with which to calculate floodplain-deposition would be valuable data used to validate and refine this parameter value. If however, we use a sediment-delivery rate of 17% with the improved predictions of bank erosion calculated in this study, a 66% increase in the export of sediment (0.79 Mt/y) is obtained. We assume that if erosion of bank sediments from tributaries were included in this analysis, that this figure would be even higher.

Bank erosion, instead of being a minor source of sediment representing 8% of the total (Brodie et al., 2003), has been shown to be the single largest contributor of sediment in the Burnett River Catchment, representing at least 44% of the total, annual sediment budget. In absolute terms, this is an increase in the average, annual rate of bank erosion from 0.175 Mt/y to 2.0 Mt/y. Given these significant differences in both the relative importance and absolute

rates of bank erosion than was reported earlier, sediment management should be re-focused to include this important source. Doing so would not only protect local assets by limiting land loss and bank retreat, but would help maintain reservoir capacity, minimize downstream flooding, reduce dredging costs, and protect marine resources.

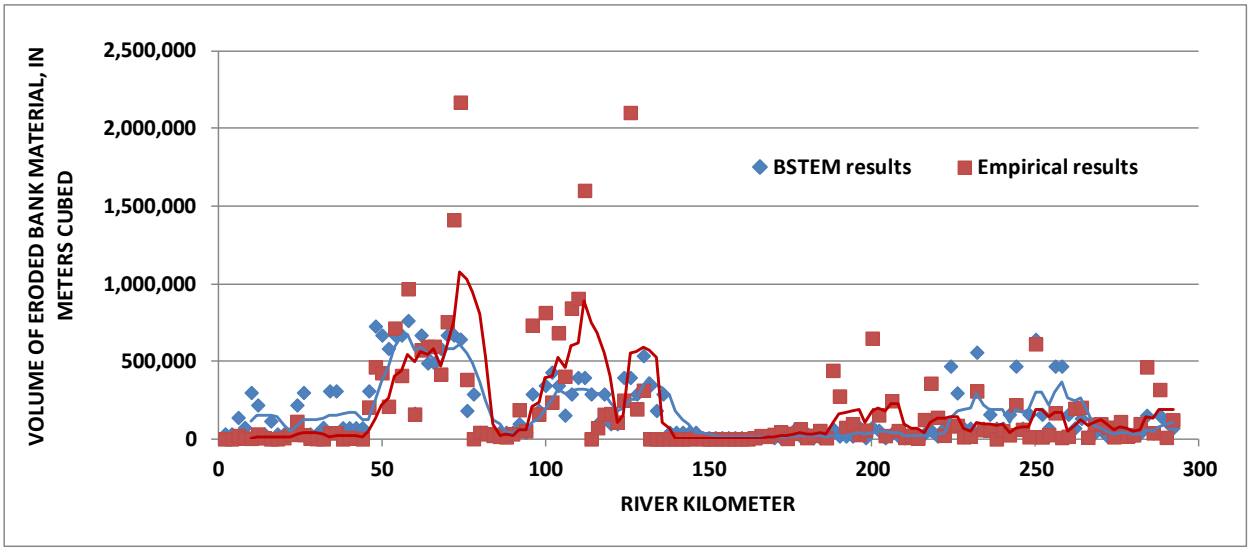

Figure 8 Comparison of bank-erosion volumes for each 2-km section of the Burnett River main stem as calculated from interpolation of BSTEM results and from analysis of LiDAR and air photo data over the 2009-2013 period.

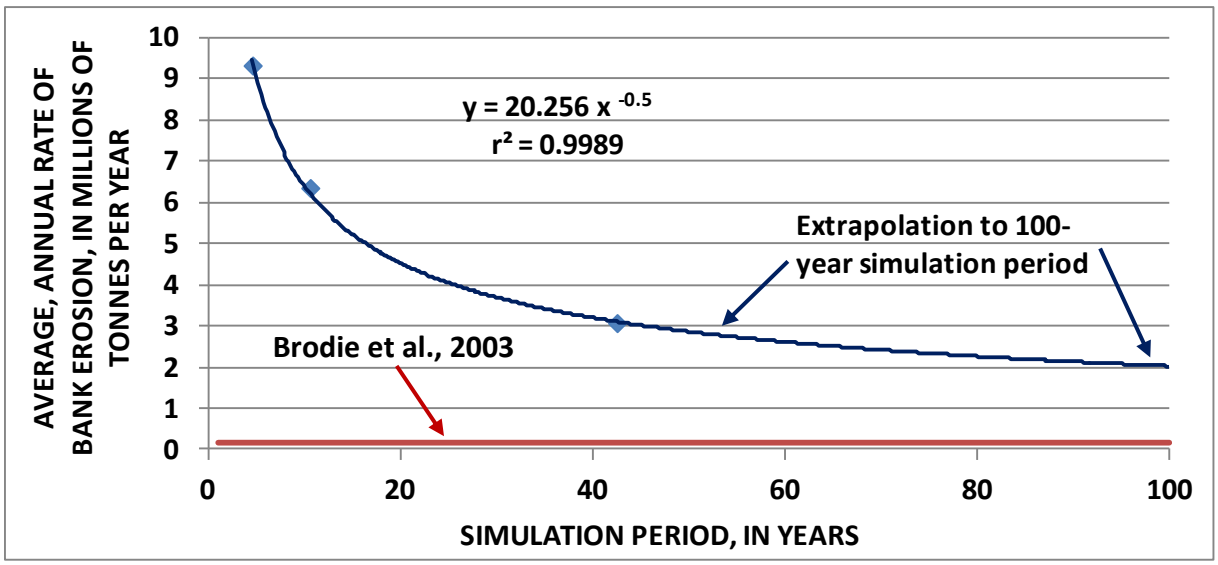

Figure 9 Comparison of average, annual bank-erosion rates (in millions of tonnes per year) for the Burnett River main stem derived from SedNet modelling (Brodie et al., 2003) and by interpolation of BSTEM results using different simulation periods.

SUMMARY AND CONCLUSIONS

Between 2009 and 2013 a total of about 27.8 million m^3 (47.3 Mt) of land were eroded from the banks of the lower 300 km of the Burnett River main stem. This translates into about 6.1 million m^3/y (10.4 Mt/y). Erosion of these bank materials does not equate to an equal volume being delivered to the river mouth and the Coral Sea, as an unknown proportion is deposited on low-bank surfaces, beds, bars and floodplains. It can be assumed, however, that the majority of the fine-grained materials (silts and clays) are transported through the system and out to sea.

Approximately 21 million m^3 (35.6 million t) or about two thirds of these sediments were eroded from banks downstream of Paradise Dam. One can assume that much of the hydraulically-controlled bank sediment eroded from reaches upstream of rkm 170 was trapped behind Paradise Dam (7.0 million m^3).
Long-term simulations (42 years) were conducted to determine average, annual rates of bank erosion. By again summing the results for each 2 km reach gives a total volume of bank erosion of 77.1 million m^3 (131 million t). Dividing by 42.52 years gives an average, annual bank-erosion rate of 3.1 million Mt/y, about 18 times greater than the value of 0.175 Mt/y predicted by SedNet. Bank-erosion rates below Paradise Dam are 2.4 million t/y. Assuming 100 years of simulation and using an empirical relation between the length of BSTEM simulations and calculated erosion rates, a conservative value for the average, annual rate of bank erosion is 2.0 Mt/y, and this does not include tributary contributions.

The implications of these findings are considered in the context of erosion sources and rates in Brodie et al. (2003) who report that on average, 2.75 Mt/y are eroded from the catchment. By replacing their 0.175 Mt/y from the banks with the 2.0 Mt/y calculated in this study, a new total of 4.6 Mt/y is obtained. Assuming that the estimates from gully (0.93 Mt/y) and hillslope (1.65 Mt/y) sources are accurate, bank erosion becomes the single largest contributor, delivering 44% of the total sediment load. Even using the 17% sediment-delivery rate reported in Brodie et al (2013), with the predictions of bank erosion calculated in this study, a 66% increase in the export of sediment (0.79 Mt/y) is obtained. We assume that if erosion of bank sediments from tributaries were included in this analysis, this figure would be even higher. Given these significant differences in both the relative importance and absolute rates of bank erosion then was earlier reported, sediment management should be re-focused to include this important source. Doing so would not only protect local assets by limiting land loss and bank retreat, but would help maintain reservoir and harbour capacity, minimize downstream flooding, reduce dredging costs, and protect marine resources.

SEDIMENT DIVERSION EFFICIENCY, LESSONS LEARNED FROM MISSISSIPPI RIVER MODELS

Ronnie Heath, Ronald.E.Heath@usace.army.mil, Gary Brown, Gary.L.Brown@usace.army.mil, and Jeremy Sharp, Jeremy.A.Sharp@usace.army.mil, Research Civil Engineers, U. S. Army Corps of Engineers, Engineer Research and Development Center, Coastal and Hydraulics Laboratory, Vicksburg, Mississippi.

ABSTRACT

Large scale diversions of sediment and water from the Mississippi River have been proposed as a means to restore valuable wetlands along the Louisiana coast (CRPA 2012). Successful design and operation of diversions requires that diverted water volumes and sediment loads be carefully balanced to maintain channel stability and to achieve restoration goals. In general, diversions reduce sediment transport capacity in the river downstream of the withdrawal, and disproportionally large diversions of bed material are required to balance this reduction. In the Mississippi River, deposition induced by insufficient sediment diversions may impact other authorized project purposes such as navigation and flood control.

Sediment diversions are defined in the HEC-6 one-dimensional sedimentation model by coefficients defining the fractions of water and sediment diverted from the river (USACE, 1993). The sediment diversion coefficient, k_{SD}, the ratio of the diverted sediment concentration, C, to the ambient concentration in the river (equation 1), describes the efficiency of the sediment diversion and is proposed as the basis for metrics suitable for comparing diversion alternatives and informing design and operation planning.[1] For computational purposes, the coefficient also may be defined in terms of water discharge, Q, and sediment load, Q_S. While the sediment diversion coefficient is conceptually simple, its application and estimation can be complex and challenging.

$$k_{SD} = \frac{C_{Diversion}}{C_{River}} = \frac{\left(Q_S/Q\right)_{Diversion}}{\left(Q_S/Q\right)_{River}} \quad (1)$$

The U. S. Army Engineer Research and Development Center's (ERDC) Coastal and Hydraulics Laboratory (CHL) has conducted model studies ranging from analytical models (Letter et al. 2008 and Brown et al. 2013) to estimate equilibrium sediment diversion efficiencies to multi-dimensional model studies of the West Bay Sediment Diversion (Sharp et al. 2013) and the Old River Control Complex to gain insight into the behavior and impacts of existing diversions. The CHL is currently working with the U. S. Army Corps of Engineers New Orleans District and the

ABSTRACT: The Price River contributes only one percent of the water but three percent of the total dissolved solids in the Colorado River. To investigate mechanisms driving salinity loads in the Price River Basin we are focusing on saline and sodic soils associated with the Mancos Shale formation. Rainfall simulations have been performed at study areas across a variety of slope angle and rainfall intensity to evaluate the effects vegetation has on salinity and sediment concentration in runoff. A 6x2 meter, computer-controlled Walnut Gulch rainfall simulator was ran with rainfall event intensities derived from the NOAA ATLAS 14 precipitation database: 2 year (5.08 cm/hour), 10 year (8.89 cm//hour), 25 year (11.43 cm/hour), and 50 year (13.97 cm/hour) and each intensity was replicated three times at each site. For each simulated rainfall event, we measured the time-varying concentration of major cations (Calcium, Magnesium, Sodium, Potassium, and Ammonium) and anions (Chlorine, Sulfate, Nitrite, and Nitrate) in runoff. We also compare depth-varying soil chemistry in soil cores at vegetated and un-vegetated areas to identify the effects of plants on soil chemistry distribution. Results of these simulations will be used to parameterize the dynamic Rangeland Hydrology and Erosion Model (RHEM) for saline and sodic soils of the Price rangeland areas and to assess the feasibility of mitigation strategies for reducing salinity loads to the Colorado River.

INTRODUCTION

The Bureau of Land Management, USDA Agricultural Research Service, Bureau of Reclamation, and Desert Research Institute are investigating salinity contributions to the

Colorado River from saline and sodic soils of rangelands in the Colorado Plateau. Field sites in Price and Ferron, Utah were selected to perform rainfall simulations to measure the response of salinity and sediment loads with respect to vegetation canopy cover (Figure 1). It is suspected that vegetation canopy cover has a large effect on water erosion and runoff processes primarily because of rainfall interception (Wischmeier and Smith, 1978). Interception of rainfall by vegetation is a function of precipitation and canopy characteristics (Hamilton and Row, 1949; Slatyer, 1965; Navar and Bryan, 1990; Domingo et al., 1994). Vegetation interception reduces runoff volumes, and stemflow may promote deep infiltration in the soil directly beneath the canopy (Branson et al., 1972). At the beginning of a rainfall event, canopies efficiently intercept almost all rainfall within the area they project over the ground until a maximum is reached when the cumulative interception (through-fall, foliar drip, and stemflow) is equal to the amount of precipitation. The amount of time to reach maximum cumulative interception is dependent upon the type of plant and the rainfall intensity (Wood et al., 1998). Proportionally, rainfall lost to vegetation interception is most prominent under conditions of lower rainfall intensities and may strongly influence erosion rates under such conditions (Simanton et al., 1991). Vegetation-driven spatial heterogeneity (VDSH) explains the relationship between soil development and evolution processes between vegetation and interspace areas (Puigdefabregas, 2005). VDSH influences sheet runoff and concentrated flow processes that in turn influence rill and channel development, and thereby affect salinity and sediment loading along those flow paths (Wilcox et al., 1996; Davenport et al., 1998; Urgeghe et al., 2010). Rills and gullies are considered erodible sediment conveyors, transporting detached sediment downslope depending on VDSH and the detachment and conveyance hydraulic factors (Puigdefabregas, 2005; Al-Hamdan et al., 2012).

There are two goals for this project: (1) improve the understanding of sources and transport mechanisms of salinity and sediment loads into streams from rainfall induced runoff within the Upper Colorado River Basin (UCRB) and specifically in the Price River Basin and (2) parameterize our findings for vegetation canopy cover so they can be implemented into the Rangeland Hydrology Erosion Model (RHEM). We hypothesize that the amount of vegetation canopy cover has a strong influence on the salinity and sediment loading in runoff during a rainfall event due to reduced splash erosion, increased infiltration, and reduced flow velocity. To accomplish these goals and test our hypotheses, we conducted rainfall experiments with the Walnut Gulch rainfall simulator (WGRS) (Paige et al., 2004) using four rainfall intensities replicated three times at two different field sites differing in slope, geology, and vegetation canopy cover. This rainfall simulator was chosen to perform these experiments because of the long history of successful use to measure how rainfall affects runoff and erosion, transportability, and its computer controlled interface. Using the WGRS, we may conduct experiments that accurately simulate specified rainfall intensities, and in turn, measure representative runoff and erosion processes occurring at the plot scale (6x2 m). Ultimately, our experiments will produce meaningful data to incorporate into the RHEM model so it can be used as a management tool by determining how vegetation affects the surface hydrology and controls salinity in the UCRB.

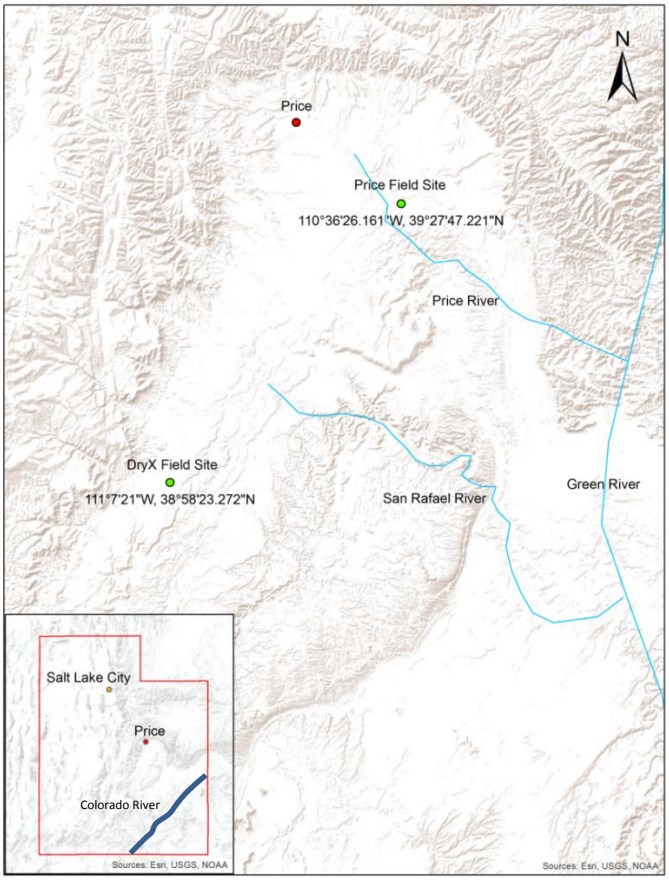

Figure 1 Map of field area in Price, Utah

MATERIALS AND METHODS

Location, Field Site Characteristics, and Experimental Design: The experimental sites were at Price (-110° 36' W, 39° 27' N) and Dry-X Ranch (-111° 7' 21" W, 38° 58' N) located in Utah. The Price field site contains well developed, light gray soil crusts surrounded by sparse vegetation on shallow grade slopes (0.6% - 10%). The vegetation at the site is comprised of halophytes that include a mixture of four shrubs (*Krascheninnikovia lanata*, *Chrysothamnus nauseosus, Atriplex gardneri, Ephedra viridis*), two subshrubs (*Eriogonum microthecum* & *Helianthella microcephala*), and three grass species (*Achnatherum hymenoides, Hilaria jamesii, Elymus elymoides*). The most predominant plant species were *Ephedra viridis, Atriplex gardneri*, and *Achnatherum hymenoides*. The Dry-X field site contains poorly developed, light-medium gray soil crusts surrounded by dense vegetation on steep grade slopes (11.4% - 24.5%). The vegetation at the site is solely comprised of salt tolerant shrub species *Atriplex Corrugata*. Both sites contained a marginal amount of cattle and antelope hoof impressions as they were a part of the natural landscape.

At both Price and Dry-X, 6x2 m rainfall simulation plots were installed and placed on the hillsides representative and NEPA approved for this study. The locations of each plot on the hillside were based upon where rills were already developed and would carry water down-gradient. Once the locations of each plot were determined, a Nikon NPR 352 total station was

used to make the borders square to one another. Metal stakes and construction string where then used to indicate where the 2x0.2 m steel plates are installed on the top and side borders. At the bottom of the plot, a flume was installed to channel runoff from the plot into the runoff collection pit. At each site, there were 5 types of plots: (1) control (no rainfall), (2) 2 year storm, (3) 10 year storm, (4) 25 year storm, and (5) 50 year storm. Each intensity, except for the controls, was replicated three times (Figure 2) resulting in 12 rainfall plots per site and 4 control plots per site.

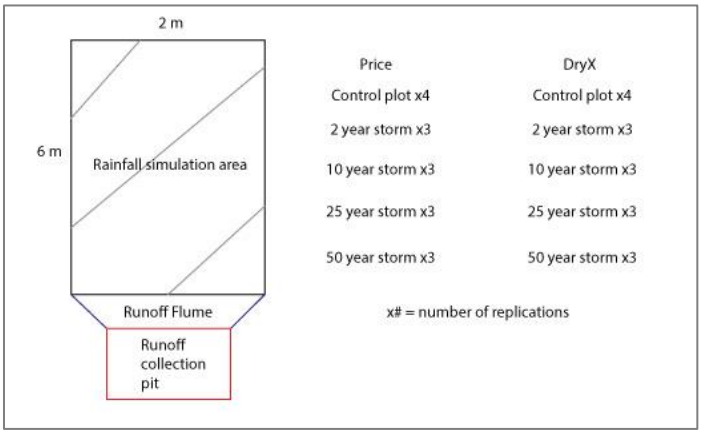

Figure 2 Rainfall plot design and types

Rainfall Simulations and Sampling Protocol: In this study, we used the WGRS that covers the 6x2 m plots. The WGRS was connected to a Husky 3785 L self-supporting onion tank using a series of water hoses and pumps. Intensities for our rainfall simulations were determined from 5 minute rainfall amounts reported in the NOAA Atlas14 point precipitation frequency estimates for the Price area.

Runoff was collected during each simulation using two different collection containers. The source water supply and runoff water quality samples were collected using VWR 50 mL centrifuge tubes. Runoff sediment samples were collected using 1 liter Nalgene bottles. Neither type of bottle was pretreated. The source water supply was sampled before each rainfall simulation was initiated. The same runoff sampling protocol was applied to each field site with the exception of the timing intervals. At Price, runoff was collected every 30 seconds for the first nine minutes and after the ninth minute, runoff was collected every minute until the end of the rainfall simulation. At Dry-X, runoff was collected every 30 seconds for the first three minutes and after the third minute, runoff was collected every 3 minutes until the end of the rainfall simulation. The timing interval was different at the two field sites because of the difference in vegetation cover and slope which influence runoff response timing. The runoff sediment samples were labeled and stored without refrigeration in plastic crates. The runoff water quality samples were para-filmed to reduce the chance of leakage and placed in large plastic Ziploc bags that were pre-labeled and stored inside coolers with dry ice in order to reduce subsequent bacterial reactions.

Samples of pre-rainfall soils were collected on the control plots using a standard hand shovel due to the lack of soil adhesion. Separate control plots were used to provide information on pre-simulation soil characteristics, since sampling in the rainfall plots prior to simulation would affect the flow and erosion. After rainfall simulations, soil samples were collected using an AMS

split soil core sampler with a 5 cm inside diameter. At each plot, soils were collected at three locations under the vegetation canopy and three interspace locations. Soil sample locations were quasi-randomly chosen by the field technician (Figure 3) in an area towards the middle portion of the plot to minimize the lateral flow affects that may occur near the plot borders. Soil samples were separated by depth increments into the surface crust (~0 cm), depth increment 1 (0-5 cm), and depth increment 2 (5-10 cm) (Figure 4). Finally, soil samples from each plot were aggregated by vegetation versus interspace for each depth increment, resulting in 6 composite samples per plot. The number of depth increments and the total depth to be collected was based on the wetting front from a test soil core taken from the first plot of each intensity. It was determined that two 5 cm depth increments were sufficient to capture the changes in soil moisture status during a rainfall event. We collected a total of 192 soil samples; 96 from Price and 96 from Dry-X.

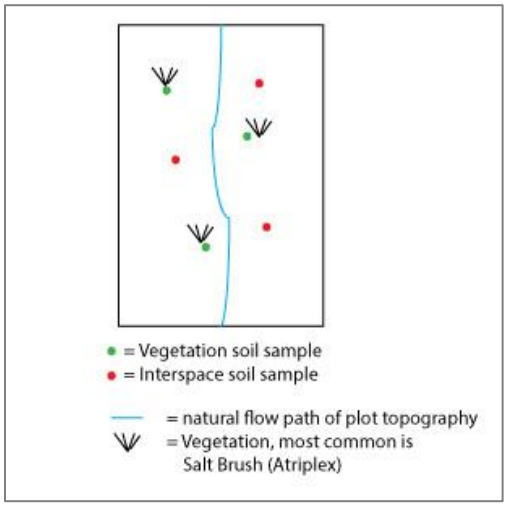

Figure 3 Aerial view of plot

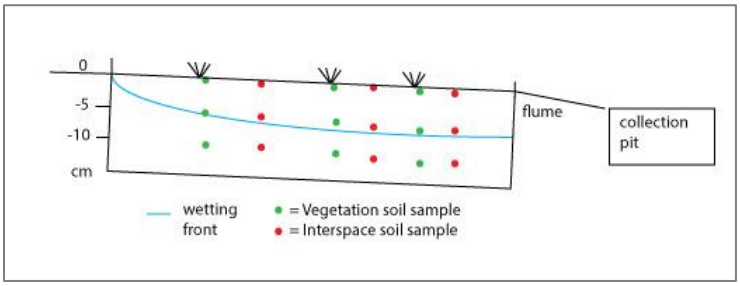

Figure 4 Profile view of plot

Vegetation Canopy Cover: A field technician took digital photographs spaced approximately 1 m apart all around the plot before and after the simulation. These digital images will be processed to planimetrically accurate orthophotographs and we will measure the distribution of canopy, litter, and bare soil. There was minimal detached litter, likely due to grazing on the site.

Laboratory Processing:

Water Chemistry

Runoff water quality samples were processed and measured at the USDA-ARS soils laboratory in Reno, NV. Price samples were centrifuged at 2000 rpm for three minutes to settle sediments and DryX samples were centrifuged at 5000 rpm for 5 minutes to settle sediments due to suspected high sodium concentrations. We measured the ions directly from the sample VWR 50 mL centrifuge tube. Major cations (Ca^{2+}, Mg^{2+}, K^{+}, Na^{+}) were measured using a Perkin Elmer Atomic Absorption (AA) Spectrometer. Ammonium ($NH4^{+}$) was measured using a Lachat Quickchem FIA+ instrument. Major anions (NO_2^{-}, NO_3^{-}, SO_4^{2-}, Cl^{-}) were measured using a Dionex Ion Chromatograph (IC). Water pH and EC were measured in the lab using an Oakton pH Meter 510 Series and VWR Scientific EC Meter Model 2052, respectively.

Soil Chemical Content and Texture

Soil samples were processed using several different methods. The total pool of soluble phase ions from the soils was processed by performing immiscible displacement (ID) (Mubarak and Olsen, 1977). To get the total pool of available exchangeable cations from the soils (mineral phase cations), we performed ammonium acetate ($NH_4C_2H_3O_2$) extractions (Thomas, 1982). Ammonium and nitrate were processed from the soils by performing KCl extractions (Bundy and Meisinger, 1994). Cation exchange capacity (CEC) was measured according to methods of Bower et al. (1952). Major cations were measured on the AA; major anions were measured on the IC, and ammonium and CEC on the Lachat. Soil soluble phase ion solution produced by ID was measured for pH and EC using an Oakton pH Meter 510 Series and VWR Scientific EC Meter Model 2052, respectively. Soil texture was measured using methods of Jackson and Barak (2005).

Data Analysis:

Principal Component Analysis, T-tests, and Regression Analysis

Data analysis is currently underway. Principal Component Analysis will be used as a data exploration tool that will aid us to determine sources of variability across different categories of interest. Data distributions will be normalized to correct for severe skewness and substantial outliers will be investigated. Two-sample T-tests with unequal variances will be performed on the runoff and soil data to ascertain whether or not the following hypotheses are true:

1. Is there a significant difference between Price soils (μ1) and DryX soils (μ2)?

    i. H_o: The Price and DryX soils mean difference = 0

    b. Is there a significant difference between Price soils SAR (μ1) and DryX soils SAR (μ2) (SAR = sodium absorption ratio)?

    i. H_o: The Price and DryX soils SAR mean difference = 0

    c. Is there a significant difference between Price soils CEC (μ1) and DryX soils CEC (μ2) (CEC = cation exchange capacity)?

    i. H_o: The Price and DryX soils CEC mean difference = 0

2. Is there a significant difference between Price runoff (μ1) and DryX runoff (μ2)?

    a. Is there a significant difference between Price sediment load in Runoff (μ1) and DryX sediment load in Runoff (μ2) (Sediment load units = g/L)?

    i. H_o: The Price and DryX soils sediment load mean difference = 0

    b. Is there a significant difference between Price salinity load in runoff (μ1) and DryX salinity load in runoff (μ2) (Salinity load = total dissolved solids (mg/L))?

    i. H_o: The Price and DryX soils Salinity Load mean difference = 0

3. Is there a significant difference between vegetation soils (μ1) and interspace soils (μ2) at each site?

   a. Is there a significant difference between vegetation soils sum of ions (μ1) and interspace soils sum of ions (μ2) at each site (Sum of ions (mg/L))?

      i. H_o: The vegetation and interspace soils sum of ions mean difference = 0

4. Is there a significant difference between vegetation (μ1) and interspace soils sum of ions (μ2) with depth at each site (Sum of ions (mg/L))?

   a. H_o: The vegetation and interspace soils mean difference = 0 at depth 1; 2; 3

We will conduct regression analyses of salinity concentration versus sediment concentration in runoff in order to evaluate if sediment concentration can be used as a proxy for salinity (TDS) when using the RHEM model.

1. By using sediment load (g/L) data, can sediment load be used as a proxy to reasonably estimate salinity load represented by TDS (mg/L)?

   a. H_o: Slope of salinity load against sediment load is zero; m = 0

PRELIMINARY RESULTS

Figures 5-7 present the mean sodium absorption ratio (SAR) values at Price and Dry-X for the pre- and post-rainfall soil samples and the mean runoff sediment load.

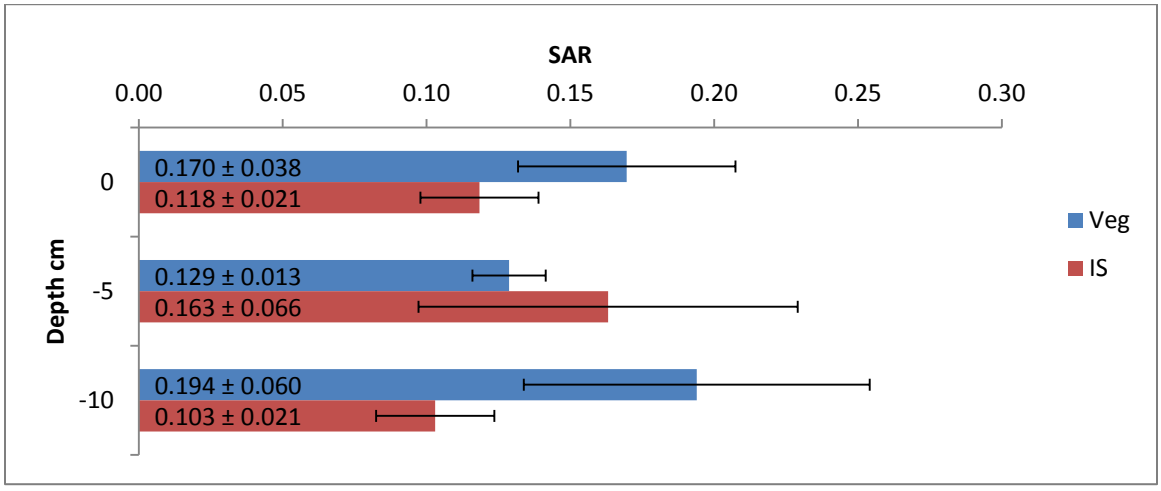

Figure 5 Price mean SAR ± standard error values with depth

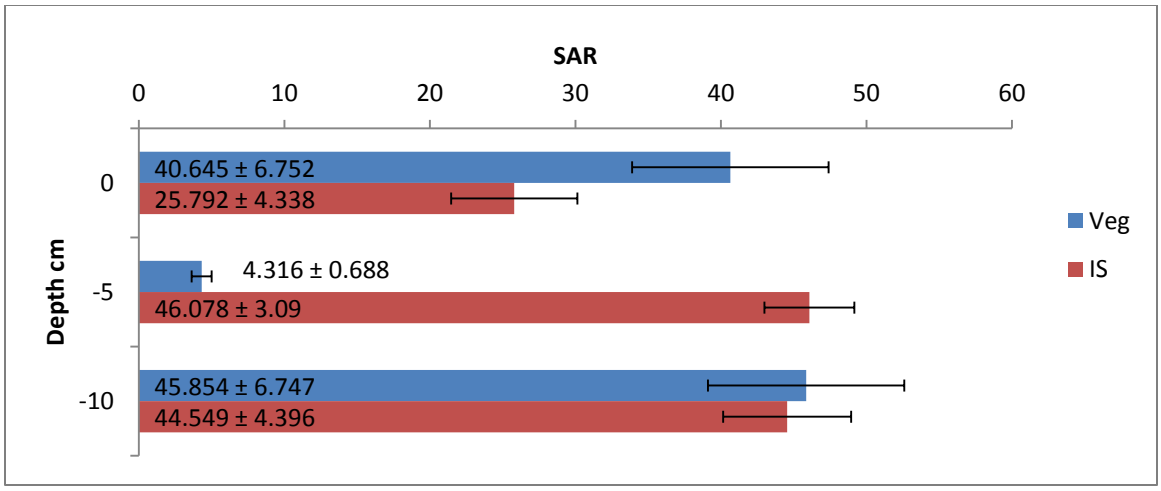

Figure 6 Dry-X mean SAR ± standard error values with depth

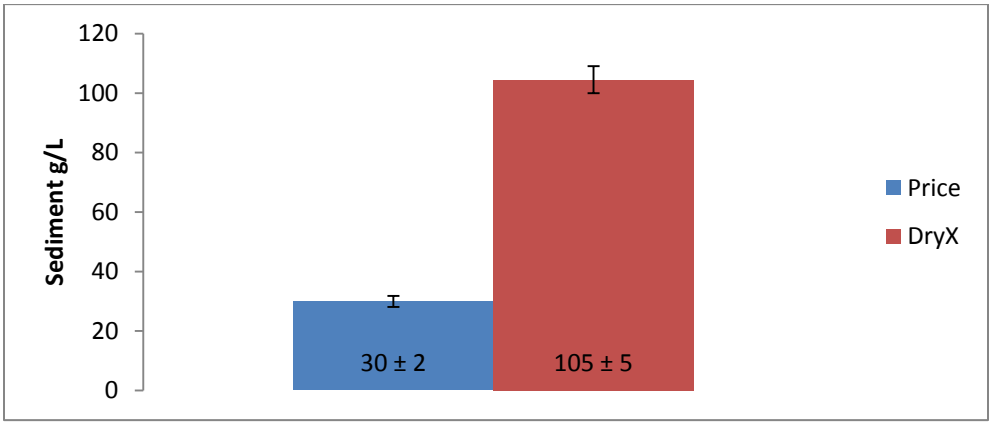

Figure 7 Mean sediment load ± standard error values at Price and Dry-X

The mean EC values at Price and Dry-X for the applied rainwater and runoff (Figure 8).

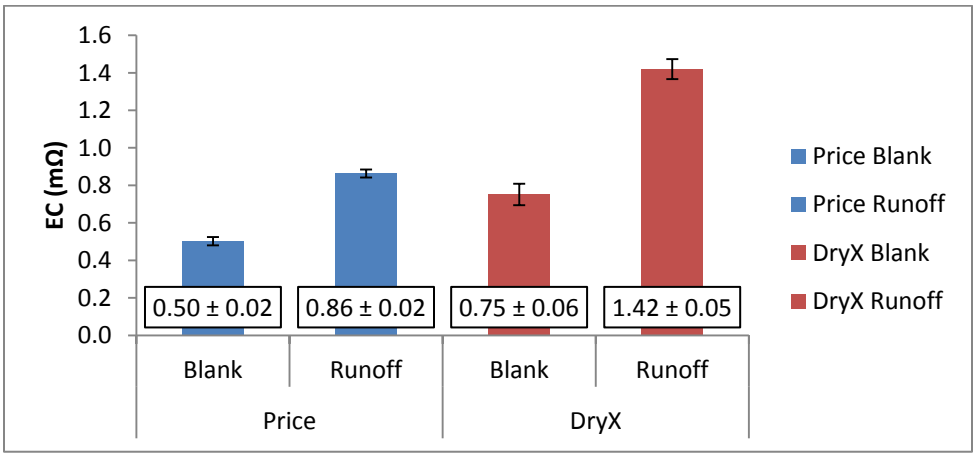

Figure 8 Mean EC ± standard error values for both Price and Dry-X

Price mean SAR values are < 1.0, indicating the soils have low dispersion (Figure 5). Almost all the Dry-X mean SAR values are substantially greater than 15.0 indicating the soils have high dispersion which indicates high erodibility (Figure 6). Price soils have substantially lower mean SAR values than Dry-X and indicate variation with depth, but there is no major difference between soil samples collected under the vegetation canopy (Veg) and those from the interspace soil (IS). Dry-X soils have substantially greater mean SAR values than Price and clearly present a decrease with depth at -5 cm for Veg. Dry-X mean sediment load and EC are much greater than Price (Figures 7 and 8). This may be a result of the level of soil dispersion and slope.

CONCLUSIONS

This study investigates vegetation canopy cover effects on salinity and sediment loading in runoff. Vegetation canopy cover may control salinity and sediment loads by rainfall interception and VDSH. Our data analysis will evaluate the complexity of interactions within our system and determine: 1) if sediment load may be used as a proxy for salinity load, 2) the sensitivity of vegetation canopy cover in RHEM, 3) the role of VSDH on salinity and sediment loading. Studies at these two sites which have substantial differences despite being from the same Mancos Shale formation will inform our understanding of the difficulties in applying the RHEM model to saline-sodic soils with variable vegetation canopy cover. Future results will help to prioritize improvements to the RHEM model and ultimately be used to assess mitigation strategies to reduce salinity loads into the Colorado River Basin.

CONTINUOUS VERTICAL SORTING MODEL IN SRH-1D

Sean Kimbrel, Hydraulic Engineer, Bureau of Reclamation, Denver, CO, skimbrel@usbr.gov; Blair Greimann, Hydraulic Engineer, Bureau of Reclamation, Denver, CO, bgreimann@usbr.gov; Victor Huang, Hydraulic Engineer, Bureau of Reclamation, Denver, CO, vhuang@usbr.gov

ABSTRACT

Reclamation's one-dimensional numerical hydraulics and sediment transport model, SRH-1D (Huang and Greimann, 2012), is used within Reclamation for its extensive capabilities, including the prediction of the routing of reservoir sediments as a result of dam removal. The development of SRH-1D over the past 15+ years has been important to the predictions of sediment-related impacts for several of Reclamation involved projects, which includes dam removal assessments for the Klamath River and Matilija Dam Removal studies, and continued monitoring of the removal of Glines Canyon and Elwha Dams on the Elwha River. Other studies include erosion downstream of Taiwan Dams, the Rio Grande River, and the San Joaquin River Restoration Project.

The current bed-material mixing algorithm in SRH-1D relies upon the active layer concept and this methodology has been observed to have difficulties simulating the change of the bed-material composition from a coarse, armored bed to a mixed bed of sand and gravel sized sediments. The current bed-material mixing algorithm requires the user-specified number of N layers, in which the bed is composed of one active layer and N-1 inactive layers. Most sediment models using the active layer concept simulating the release of finer sediments over a coarse armor layer are 'tricked' by making the initial armor immobile and giving the initial active layer an averaged grain size distribution of the reservoir sediments. This workaround keeps the pre- and post-dam release bed layers separate, thereby accurately simulating the transport of finer grained sediments, but neglects the potential mobility of the armor layer after finer-grained sediments are transported through the system.

Current research is developing and applying a continuous vertical sorting model in SRH-1D, with potential of incorporation into Reclamation's two-dimensional hydraulics and sediment transport model, SRH-2D (Lai, 2008). A continuous vertical sorting model was most recently proposed in Merkel and Kopmann (2012). This continuous vertical sorting model (or algorithm) has the ability to account for multiple sediment layers of varied thickness and gradation that are continuously depositing and eroding through time, thereby yielding a temporally and spatially varied stratigraphy of sediment layers. This method automatically keeps the coarse pre-dam removal armor layer separate from the finer sediment layers deposited and eroded from the channel. The research model is being tested against field and laboratory data.

BANKFULL WIDTH CONTROLS ON RIFFLE-POOL MORPHOLOGY UNDER CONDITIONS OF INCREASED SEDIMENT SUPPLY: FIELD OBSERVATIONS DURING THE ELWHA RIVER DAM REMOVAL PROJECT

Andrew K. Brew, River Engineer, Anchor QEA, Bellingham, WA, abrew@anchorqea.com; Jacob A. Morgan, PhD Student, Colorado State University, Fort Collins, CO, jamorgan@rams.colostate.edu; Peter A. Nelson, Assistant Professor, Colorado State University, Fort Collins, CO, peter.nelson@colostate.edu;

Abstract: Many gravel-bed rivers feature quasi-regular alternations of shallow and deep areas known as riffle-pool sequences, which in straight reaches are often forced by variations in channel width. The mechanisms responsible for the formation and maintenance of riffle-pool sequences are still poorly understood. There is also much uncertainty in the basic understanding of how fluvial systems respond and readjust to large sediment fluxes through time, as may occur during and after dam removal. Field observations have been made during a natural experiment on the Elwha River in Washington State, where the largest dam-removal project in history is providing riffle-pool sequences with greatly increased sediment supply. Analysis of aerial imagery and repeat bathymetric measurements indicate that prior to dam removal, pools on the Elwha were co-located with local decreases in bankfull width. During dam removal, a pulse of sediment temporarily filled in the pools, but eventually most of the pools reemerged at their prior location. During this time, the river did not experience large overbank flows. The persistence of the location of riffles and pools, even with large changes in sediment supply, suggests that channel width imposes an important local control on bed morphology and riffle-pool dynamics.

INTRODUCTION

Alternating vertical undulations in bed elevation, referred to as riffles and pools, are characteristic of both straight and meandering gravel-bed rivers with slopes less than 0.02 (Knighton, 1998). Areas of higher relative elevation with a symmetrical cross-section and coarser bed material are termed riffles. Conversely, pools have relatively low topography and characteristically have finer bed material (Richards, 1976). The diverse range of flows associated with riffle-pool sequences makes these features important for aquatic ecology and overall stream health (Allan and Castillo, 1995). Consequently, the creation or regeneration of riffles and pools is often a component of stream restoration projects (e.g. Pasternack and Brown, 2013).

The genesis and persistence of riffle-pool sequences is still not fully understood (Wohl, 2014). The velocity reversal hypothesis, first proposed by Keller (1971) and subsequently explored in numerous studies (e.g. Lisle, 1979; Keller and Florsheim, 1993; Clifford and Richards, 1992; Thompson et al., 1999; Thompson, 2011), suggests that at low discharge, flow velocities, and consequently sediment transport rates, are higher in riffles than in pools, but at high discharge this pattern reverses so that velocities and transport rates in pools exceed those in riffles. More recently, flow convergence routing (e.g., MacWilliams et al., 2006) has suggested that convergence of flow through constrictions is more important for riffle-pool maintenance than velocity reversal, an idea supported by Sawyer et al.'s (2010) observations and modeling of the Yuba River in California.

Downstream variations in valley and channel width have been shown to be important influences on the development and persistence of riffle-pool sequences. White et al. (2010) examined a rapidly incising, laterally-confined reach on the Yuba River and found that riffles were persistently located in areas of greatest valley width. One-dimensional numerical modeling by de Almeida and Rodríguez (2012) also suggests that riffles and pools can spontaneously emerge at wide and narrow locations in the channel, respectively, and that the relative grain size sorting between riffles and pools is dependent on unsteady flow. These studies have been valuable in demonstrating the importance of downstream width variations on the development and maintenance of riffle-pool morphology, but how riffle-pool sequences might respond to large changes in sediment supply remains poorly understood.

The Elwha River restoration project provides an opportunity to explore how dramatic changes in sediment supply interact with downstream variations in channel width to influence riffle-pool morphology. In this paper, we present field observations of river width and bathymetry collected during the first two years of the removal of Glines Canyon Dam. The objectives of this study are to characterize downstream patterns of bankfull width and to document changes in channel bed morphology in a relatively straight reach of the middle Elwha River before and after the release of a large amount of reservoir sediment. Our observations suggest that channel width can be an important control on the persistence of riffles and pools, even under conditions of large changes in sediment supply.

METHODS

Study Site: The Elwha River is located on the Olympic Peninsula in Washington State. It flows from its headwaters in Olympic National Park 45 miles to the Strait of Juan de Fuca in the Pacific Ocean. Historically, the Elwha river network has been very productive salmon system with typical annual spawning runs of 400,000 fish (Smillie, 2014). The Elwha was once a member of a select few Pacific Northwestern rivers that supported all five Pacific salmon species (Chinook, chum, coho, pink, sockeye) in addition to four species of anadromous trout (Steelhead, coastal cutthroat, bull, and Dolly Varden char). Beginning in 1910, Elwha Dam, the first of a series of two dams, was constructed at river mile 4.9 in the lower reaches of the river. The dam was poorly constructed and subsequently failed in 1912. However the dam was rebuilt and completed by 1913 (Crane, 2011). Twelve miles upstream, Glines Canyon dam was constructed at river mile 17 and completed by 1926. The dams provided the neighboring town of Port Angeles and its paper mill with inexpensive hydropower. The dams lacked fish passage, however, and it has been estimated that spawning returns were reduced to fewer than 3,000 fish annually (Smillie, 2014).

As decades passed it became clear that the dams were inefficient at generating power and it appeared that their costs to the ecosystem exceeded their economic benefits. In 1992, President George H. W. Bush signed the Elwha River Ecosystem and Fisheries Restoration Act into law. This transferred ownership of the dams to the federal government and allocated funds for dam mitigation. Following reservoir sedimentation modeling and laboratory experiments by Bromley et al. (2011), it was determined that the sedimentation issues could be managed by removing the dams in a controlled manner. It has been estimated that up to 34 million yd^3 of sediment had been trapped in the reservoirs with the majority (~28 million yd^3) behind Glines Canyon Dam in

Lake Mills (Draut and Ritchie, 2015). Beginning with Elwha Dam in Fall of 2011, both dams have gone through a stepped down removal process and periods of holding to allow reservoir sediments to stabilize and anadromous fish to move through the Elwha main stem and into tributaries. Elwha Dam was completely removed in March of 2012 and the final 30 ft. of Glines Canyon Dam was blasted away in August of 2014 completing the removal project. Turbidity issues due to increased reservoir sediment have occurred at a downstream water treatment plant, but overall the project has gone to plan and is viewed as a major success among large-scale dam removal projects.

The field site used for this study is a reach of the middle Elwha River located between the two former dams (Figure 1). This site has a relatively low sinuosity of 1.06, is close to the USGS stream gage at McDonald Bridge, and is far enough away from both dam sites that the local hydrologic regime is probably not significantly altered from backwater effects created by the former Elwha Dam. During the time period we are examining (from before dam removal until November 2013), approximately 7.8 million yd^3 of sediment was released from the former Lake Mills (East et al., 2015).

Bathymetric Boat Surveys: Throughout the Elwha restoration project, the U.S. Bureau of Reclamation (USBR) and National Park Service (NPS) have collected bathymetric data as part of their sediment management monitoring program, documenting the morphological evolution of the Elwha River (Bountry, 2014). Data sets are available from July 2011, before the dam removal, through their most recent survey in November 2013. Boat survey data has been refined to reduce the data set to points most representative of the channel thalweg (J. Bountry, personal communication, 2013). The reach we are using is located between river stations 50+000 and 53+000 (Figure 1). This stationing corresponds to the distance in feet upstream from the river mouth at the Strait of Juan de Fuca, with the "+" stationing analogous to a comma. In this analysis, we use bathymetric datasets collected by the USBR on July 20, 2011, May 9, 2013 and August 1, 2013.

Bankfull Width Mapping: To obtain an understanding of how channel width might interact with riffle-pool morphology in the Elwha system, a series of aerial images available on Google Earth were used to characterize downstream patterns of bankfull width in the study reach. Aerial photos from June 6, 2009, September 3, 2012 and July 5, 2013 were selected because of their temporal proximity to the bathymetric surveys of interest. For each aerial photo, bank lines corresponding to the bankfull discharge were estimated and digitized. Indicators such as sand bars, dense vegetation, and terraces were used to visually estimate bank locations. The channel centerline was also digitized by estimating the current thalweg under normal flow conditions. These geometric data were exported as KML files and converted to shape files in ArcGIS. The banks were used to develop a polygon containing both banks and the extents of the river reach. Cross-sections perpendicular to the centerline were created at 1-ft intervals and trimmed within the boundaries of this polygon.

Hydrologic Analysis: Flows in the study reach during the period of interest were characterized using streamflow data from USGS gage 12045500 at McDonald Bridge. Both daily average values and daily maximum 15 minute instantaneous peaks were gathered over the period of interest in this study (September 10, 2011 to June 28, 2014). These values were plotted against

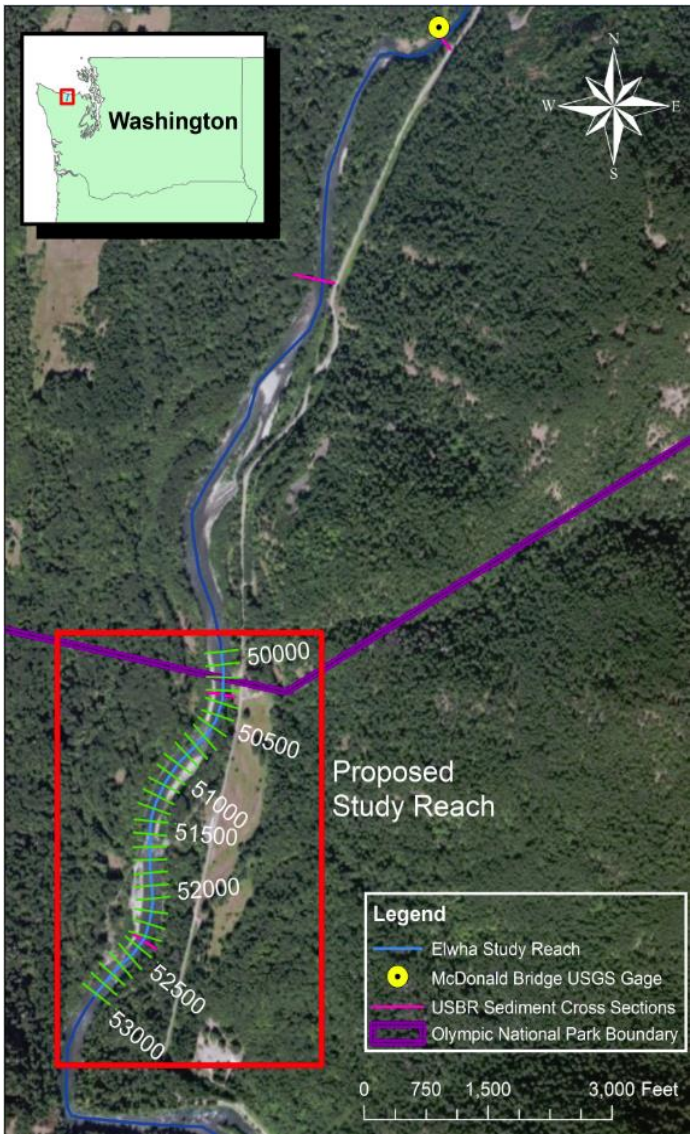

Figure 1 Elwha study reach between river stations 50+000 – 53+000 between former dam sites.

time to generate a hydrograph for the Elwha River below Glines Canyon Dam during dam removal. Annual peak flow values were collected as well, with hydrologic data available beginning in 1897. These data were then ranked from highest to lowest discharge. The recurrence interval for each flow in the annual maximum series were calculated using a Weibull plotting position technique

$$T = \frac{R}{n+1} \tag{1}$$

where R is the overall rank of that discharge in the annual maximum series, n is the number of peak flow values, and T is the return period of that particular flow in years.

RESULTS AND DISCUSSION

Sequential Pool Filling and Evacuation on the Elwha: Figures 2-4 show the evolution of the bed and water surface profiles in the study reach over the period of interest. The baseline dataset from July 20, 2011 (before dam removal) shows three clearly defined riffle-pool sequences within this reach as depicted with the brown line in Figure 2. At the time of the survey, the discharge was 2,340 cfs and the reach displayed a typical riffle-pool backwater profile. The average bed slope across the reach at this time was 0.0063.

By the May 9, 2013 survey, the pools had aggraded significantly, and the morphology approached a plane bed condition with a similar average slope of 0.0063 (Figure 3). At that time, Glines Canyon Dam had been partially removed and fine reservoir sediment was readily available to be transported. During the survey, the discharge was 3,390 cfs and the water surface profile was relatively flat and shallow, as would occur under quasi-normal flow conditions. This reduction of backwater effects induced by reduced riffle-pool relief suggests an increase in sediment transport capacity.

The August 1, 2013 profile has an average slope of 0.0064 and shows the reemergence of pools in their former locations (Figure 4). Up to 5 feet of incision took place between the May and August 2013 surveys. The water surface profile shown in Figure 4 indicates that the redeveloped riffles and pools produced locally-strong backwater effects under the summer low flow discharge of 851 cfs at the time of the survey. This morphodynamic adjustment suggests that there was a sharp reduction in upstream supply and the fine sediment that had filled the pools was evacuated.

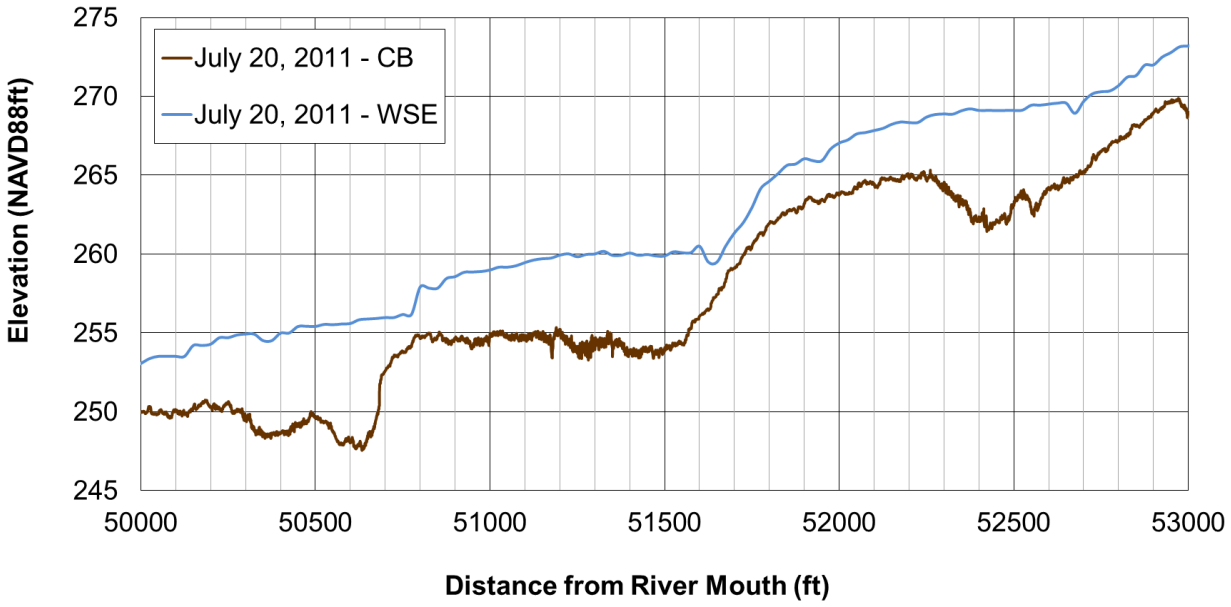

Figure 2 July 2011 channel bed and water surface profiles of the study reach before dam removal showing well developed riffle-pool morphology inducing a backwater profile (where CB is channel bed and WSE is water surface elevation).

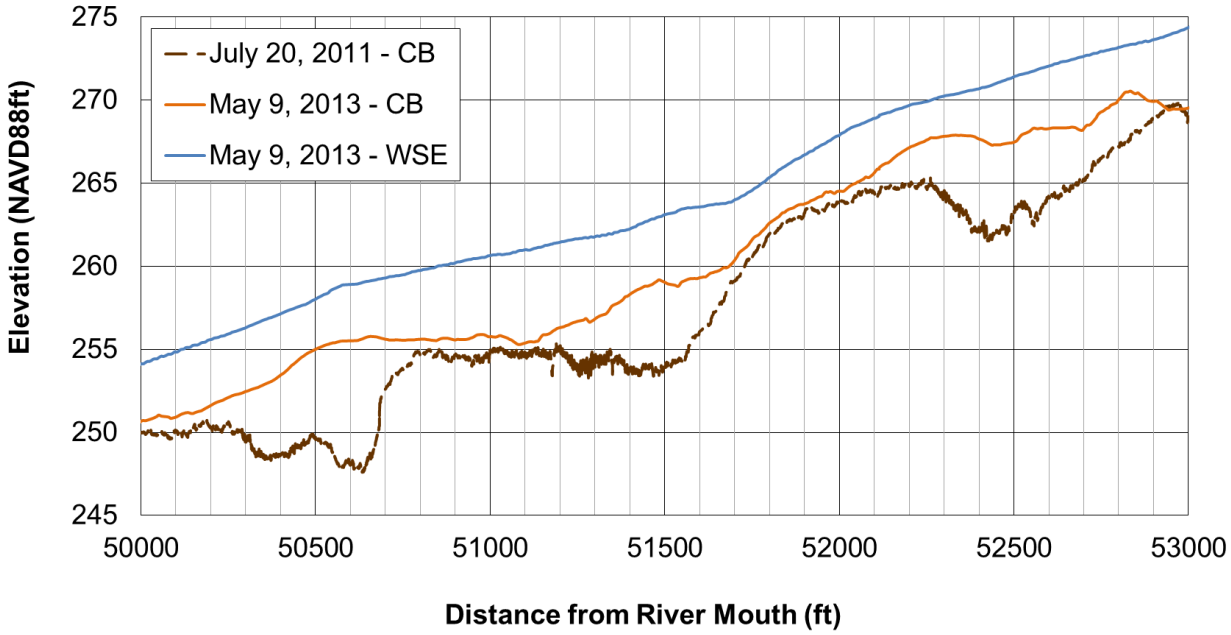

Figure 3 May 2013 channel bed and water surface profiles of the study reach during dam removal depicting temporary pool filling and a flattened water surface (where CB is channel bed and WSE is water surface elevation).

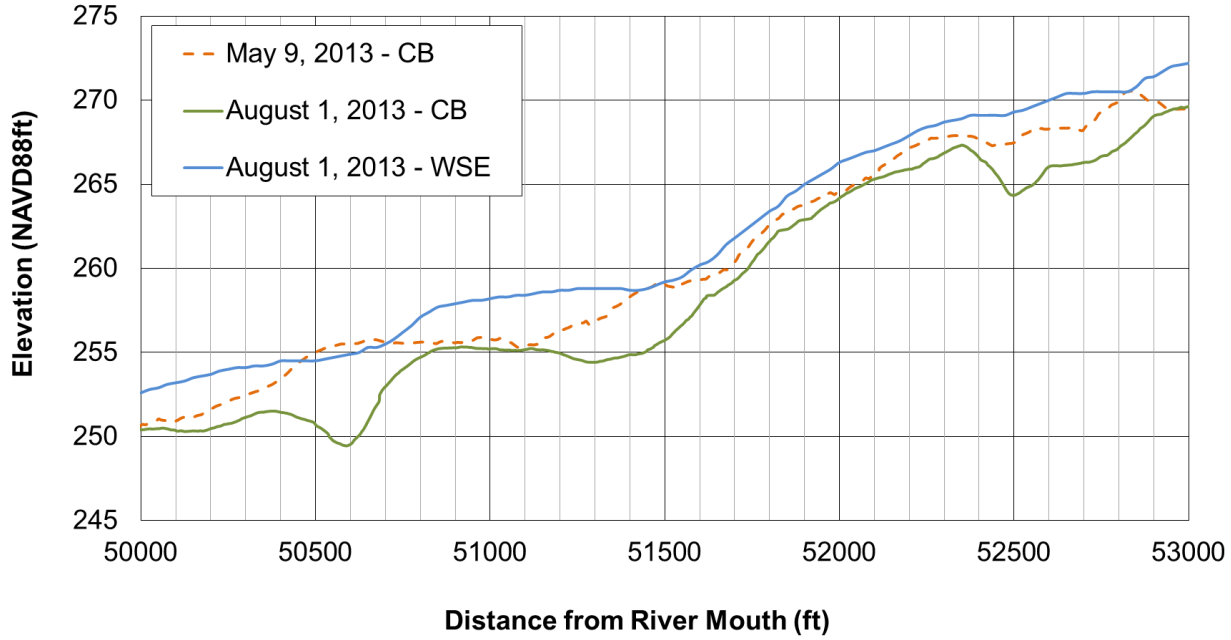

Figure 4 August 2013 channel bed and water surface profiles of the study reach during low flow conditions showing pool evacuation and the reemergence of riffle-pool morphology with reduced sediment supply (where CB is channel bed and WSE is water surface elevation).

Downstream patterns of bankfull width: The bankfull channel width of the study reach identified with Google Earth and spatially aligned with bed topography surveys is presented in Figure 5. The channel width ranged from about 100 to about 275 feet, with an average of approximately 180 ft. For each dataset, the channel showed a distinct downstream pattern of narrowing and widening with a wavelength of about 1000 ft, or 5-6 average bankfull widths. This pattern was consistent between 2009 and 2013, with relatively little change in bankfull width occurring during that time period.

The bathymetric survey data shows the three pools coinciding with the most constricted portions of the channel and riffles forming in the widest locations (Figure 5). Although the pools filled in temporarily, their reemergence at the same location suggests that channel width provides an important local control on pool persistence over a short time frame under conditions of dynamically changing sediment supply.

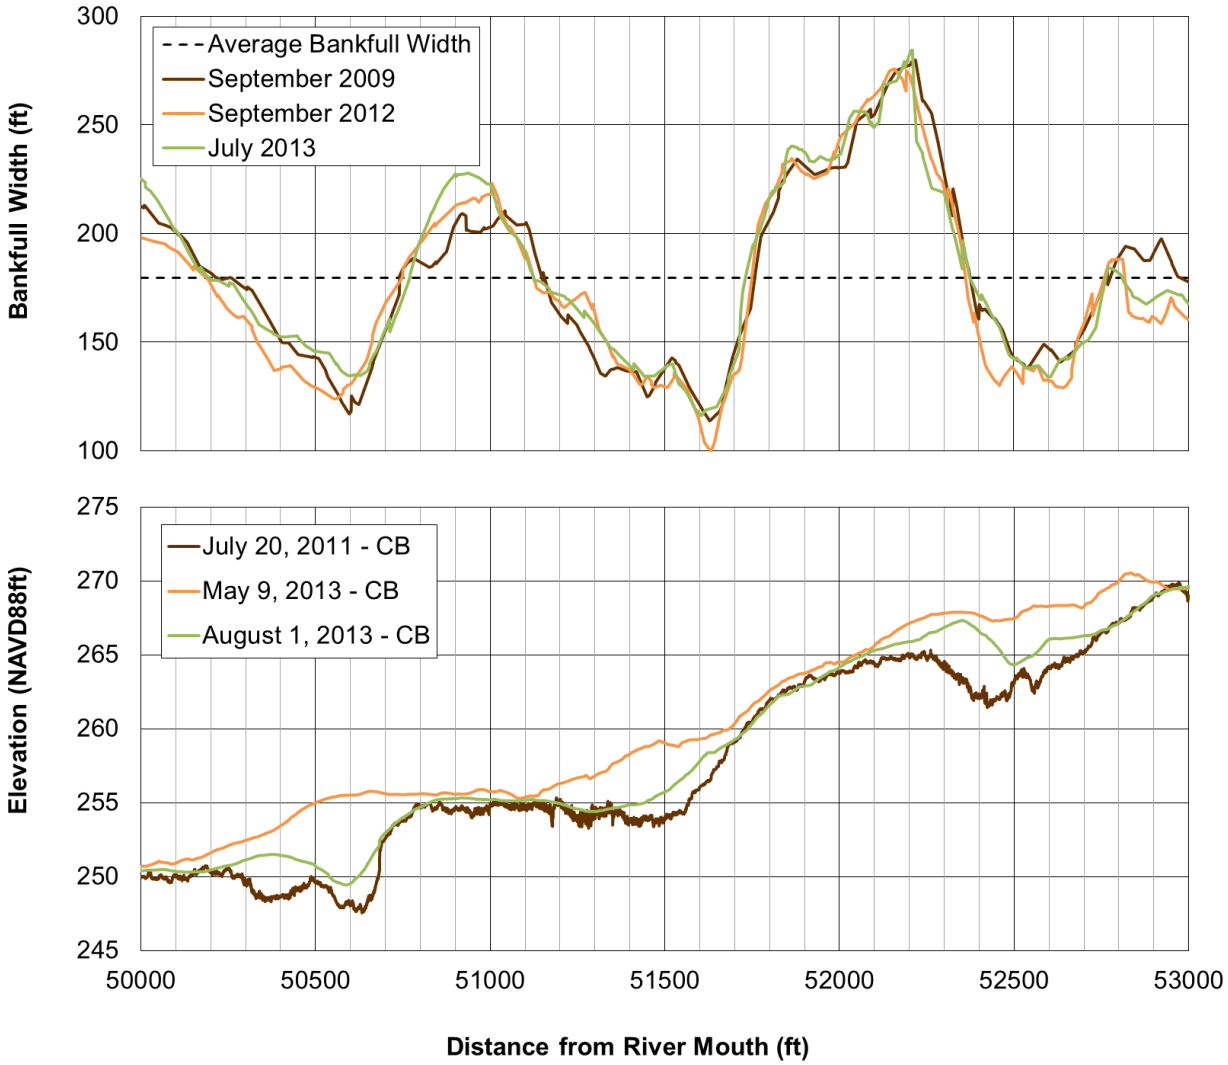

Figure 5 Coupling of bankfull channel width from Google Earth and bathymetry from in the Elwha Study Reach (where CB is channel bed).

Hydrologic Regime during Dam Removal: The flow record from the USGS gage at McDonald Bridge from September 10, 2011 to June 26, 2014 (Figure 6) shows a rain and snowmelt driven hydrologic regime typical of Pacific Northwestern watersheds at moderate elevations **(**Climate Impacts Group, 2014**)**. In a typical water year there is a peak due to winter storms, a recession and then another peak in late spring or early summer due to snowmelt runoff and "rain on snow events". In addition, the overall magnitude of peak flows showed the lack of a major channel-forming flow event exceeding bankfull conditions (Figure 6). A bankfull flow is typically defined as the discharge that fills the main channel and begins to spill onto the floodplain **(**Leopold, 1994**)**. It is considered very influential on geomorphic processes and often characterized as the discharge that has a recurrence interval of 1.5-2 years **(**Leopold, 1968; Williams, 1978; Andrews, 1980**)**. Table 1 shows the computed 1-, 1.5-, and 2-year recurrence interval flows for the Elwha River at the McDonald Bridge gage. During the time period of interest only three instantaneous peaks reached the 1.5-year value and none exceeded the 2-year flow. This period of relatively mild hydrology suggests that there were likely no overbank flows and major channel forming discharges probably did not occur. Therefore, the channel width may have acted as an important driver in the geomorphic processes that did occur, such as the observed pool filling and evacuation.

Peak Flow Recurrence Interval (yrs)	Peak Flow (cfs)
1	4,680
1.5	10,300
2	13,848

CONCLUSIONS

Channel width has been shown to exert a local control on the development of riffle-pool morphology in certain environments (de Almeida and Rodriguez, 2012) and lead to pool maintenance through flow convergence routing (MacWilliams et al., 2006). Riffle-pool systems such as the Elwha develop and maintain riffle-pool topography due to this variable width condition. From the perspective of fluid momentum and sediment continuity, these expansions and contractions create variations in shear stress that induce preferential scour in pools and deposition across riffles.

Field results from the Elwha show that bankfull channel width imposed a local control on the locations of riffles and pools from 2011-2013, even when the system is undergoing dramatic changes associated with the removal of a large dam. The transient pool-filling apparent in the repeat longitudinal profiles and the re-emergence of the pools at the same locations, combined with the lack of large, channel-forming hydrologic events, suggests that the downstream changes in channel width provided an important control on the location and persistence of riffles and pools.

Understanding how and why pool filling after dam removal occurs will be important to salmon recovery efforts in coastal river systems. Pools provide critical holding locations for migrating fish to rest in as they navigate upstream to spawning grounds. If we can understand why temporary pool filling takes place and limit its occurrence during critical migratory time periods, this could enhance salmon recovery efforts.

ACKNOWLEDGEMENTS

We are grateful to Tim Randle and Jennifer Bountry at the USBR for providing access to their bathymetry data and valuable discussions. This work was partially supported by the National Science Foundation grant EAR-1425067.

SCOUR AND SUBSEQUENT REPAIR AT LOCK & DAM 25

Timothy Lauth, P.E., Hydraulic Engineer, US Army Corps of Engineers – St. Louis District, St. Louis, MO, Timothy.J.Lauth@usace.army.mil; David Gordon, P.E., Chief, Hydraulic Design Section, US Army Corps of Engineers – St. Louis District, St. Louis, MO, David.Gordon@usace.army.mil; Matthew Rector, P.E., Hydraulic Engineer, US Army Corps of Engineers – St. Louis District, St. Louis, MO, Matthew.A.Rector@usmc.mil; William Moeller, P.E., Structural Engineer, US Army Corps of Engineers – St. Louis District, St. Louis, MO, William.J.Moeller@usace.army.mil;

INTRODUCTION

Lock and Dam 25 is a U.S. Army Corps of Engineers navigation structure located at Upper Mississippi River mile 241.4 on the Mississippi River near Winfield, MO. Events in early 2011 led to a sustained necessary deviation from the normal operations practices for the roller and tainter gates, forcing the majority of the flow of the Mississippi River through gates 12 through 17 (the gates closest to the Illinois bank) for almost five months. This sustained deviation led to significant scour in the river bed downstream of the dam and adjacent to the lock, requiring repairs underneath the intermediate wall and downstream slab, removal and replacement of a portion of the downstream slab, and placement of rock for downstream slope protection and global stability of the structure. The following will outline the change in conditions at the structure and the subsequent necessary repairs.

DEVIATION, RESULTS, AND REPAIRS

The Operations Deviation: On March 6, 2011, at approximately 3 PM, operations of Lock and Dam 25 (L&D25) underwent a change that would lead to a necessary deviation from normal dam operation practices for nearly five months. The initiating change is outside of the scope of this paper; this paper is intended to focus on the deviation and its effects. The deviation consisted of routing the majority of the flow that would normally flow through a combination of all of the gates primarily thru Gates 12 to 17 (a plan view is presented in figure 1). From March 6 to July 26, the flow rate varied from approximately 107,000 cfs to 317,000 cfs for an average of approximately 216,000 cfs. Normal operations resumed at the lock and dam on July 26, 2011. As necessary for repairs, gates were closed by compensating with corresponding openings of other gates.

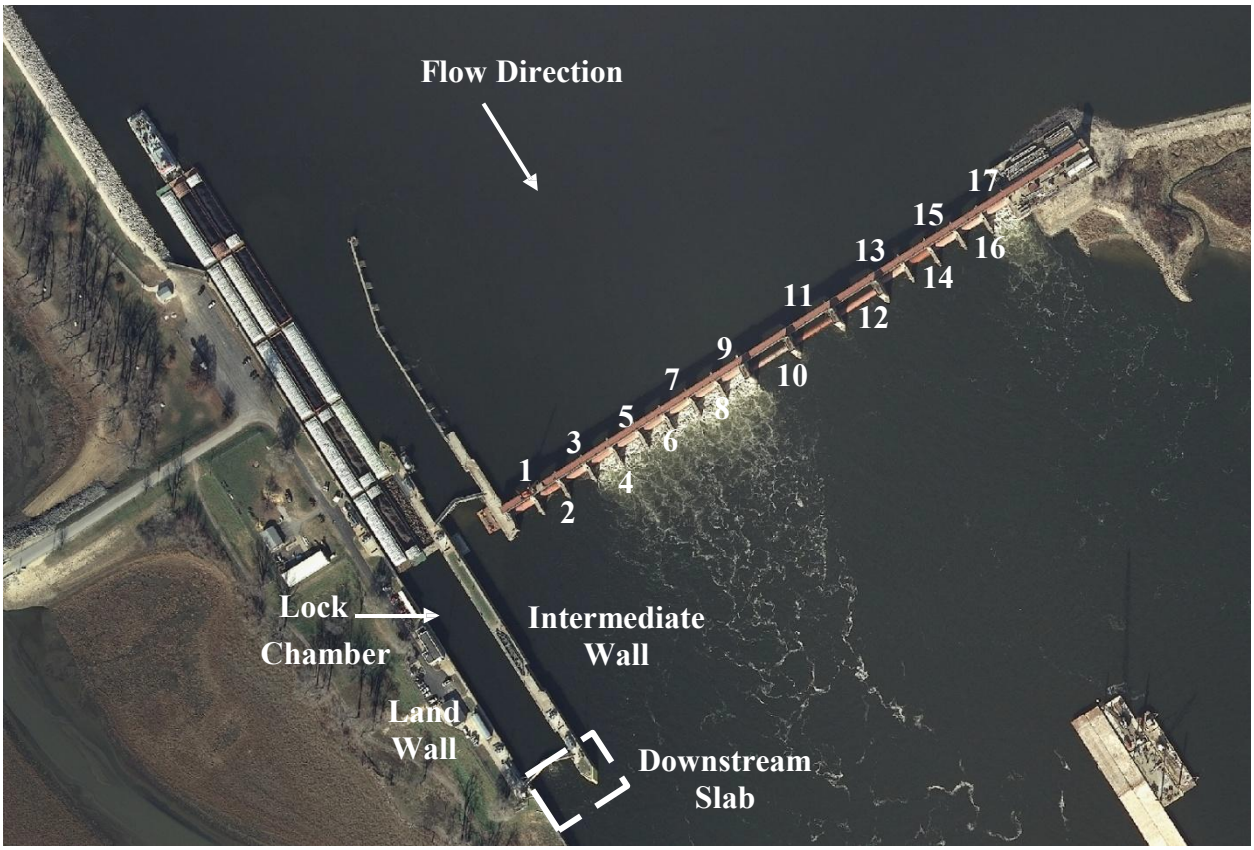

Figure 1 Plan view of L&D25 during late fall 2012, releasing approximately 48,000 cfs during normal operations.

Video taken March 17, 2011 (flow of approx. 127,000 cfs, figure 2) showed standing waves downstream of the open gates suggesting that supercritical flow was present outside of the stilling basin. This contrasts with normal flow conditions at the same approximate flow rate (figure 3), where energy dissipation is more three-dimensional and contained within the stilling basin. Additionally, anecdotal evidence from the surveying crew and other boats involved with the repair noted strong surface currents to the point that many areas downstream were deemed unsafe to survey until normal operations resumed. The hypothesis that energy dissipation was no longer contained in the stilling basin is further supported by looking at the head before and after the deviation (figure 4). The data shows that from approximately 120,000 cfs to 220,000 cfs, a head of up to 2.5 feet higher than normal was otherwise measured. For typical open river conditions (gates out of the water), flow is not forced under a gate, leading to a head of approximately 1 ft or less. When the flow is greater than 1foot, it is typically due to a regulated pool condition forcing the flow underneath the Tainter and roller gates, downward towards the stilling basin. In this case, a head representative of a regulated pool condition existed during what would normally be an open river condition. The higher head suggests flow was not passing through the structure as intended, with the possible result that energy dissipation that would normally occur in the stilling basin as designed was potentially happening downstream through the scour of downstream sediments.

Figure 3 Downstream view of L&D25 on May 23, 2012 showing similar flow conditions

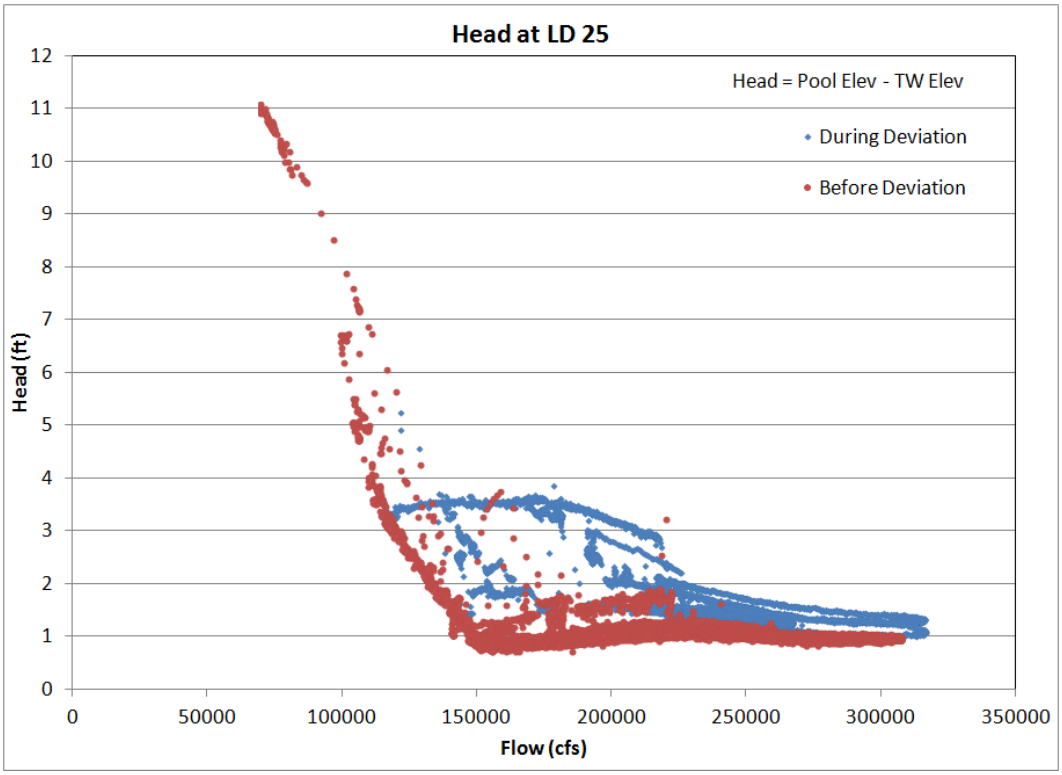

Figure 4 Head for different flows before and during deviation

The Results of the Deviation: The St. Louis District took a number of multibeam hydrographic surveys upstream and downstream of the dam for monitoring purposes. These surveys showed fluctuating deposition and erosion upstream and downstream of the dam as sediment waves moved through the system. The first comprehensive hydrographic survey following the deviation was taken on August 2,2011. The survey revealed significant downstream scour, well outside of the normal fluctuations. The four scour holes downstream of the lock and dam before the deviation had transformed into two deeper holes. The two primary interest areas for scour were downstream of Gates 12 to 16 and along the Intermediate Wall (I-Wall). The scour downstream of Gates 12 to 16 scoured over 55 ft of material in the worst scour locations, and over 30 ft at the deepest location (figure 5). Reports of shallow areas downstream of the lock and dam from the navigation industry prompted the collection of a pre-dredge hydrographic survey. The survey revealed excess material downstream of the lock and further downstream in the navigation channel that was not present the year before; assumedly, this was partially the material that had scoured out downstream of the dam and rock used as protection near the slab. The material further downstream in the navigation channel was removed with St. Louis District's Dredge Potter; the material immediately downstream of the lock could not be dredged due to the large rock mixed with the sand.

In the immediate vicinity of the I-Wall, loss of material along and downstream of the I-Wall (over 45 ft at the worst location) led to a partial failure of the downstream slab (figure 6). This slab serves to prevent undermining of the I-Wall due to the lock's discharge ports and tows entering and leaving the lock. Due to the slab failure, the lock was instructed to halt usage of the I-Wall's discharge ports, increasing the time required for lockages and leaving the lock with no redundancy for emptying the lock chamber.

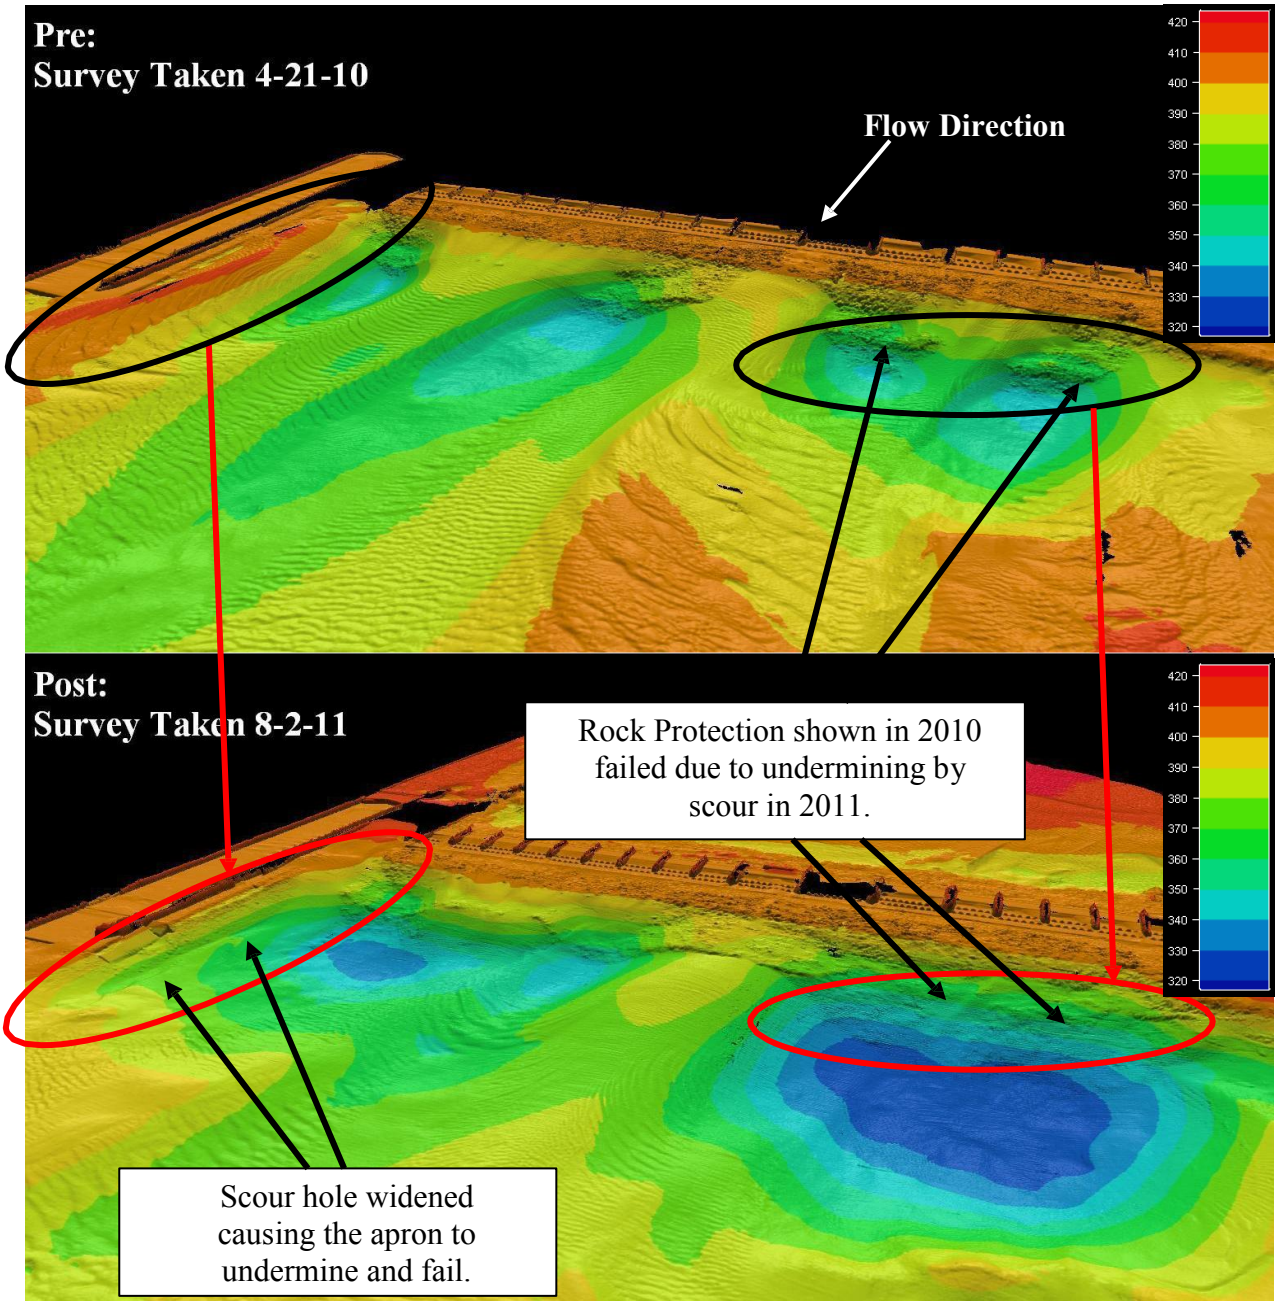

Figure 5 Before and after hydrographic surveys downstream of L&D25

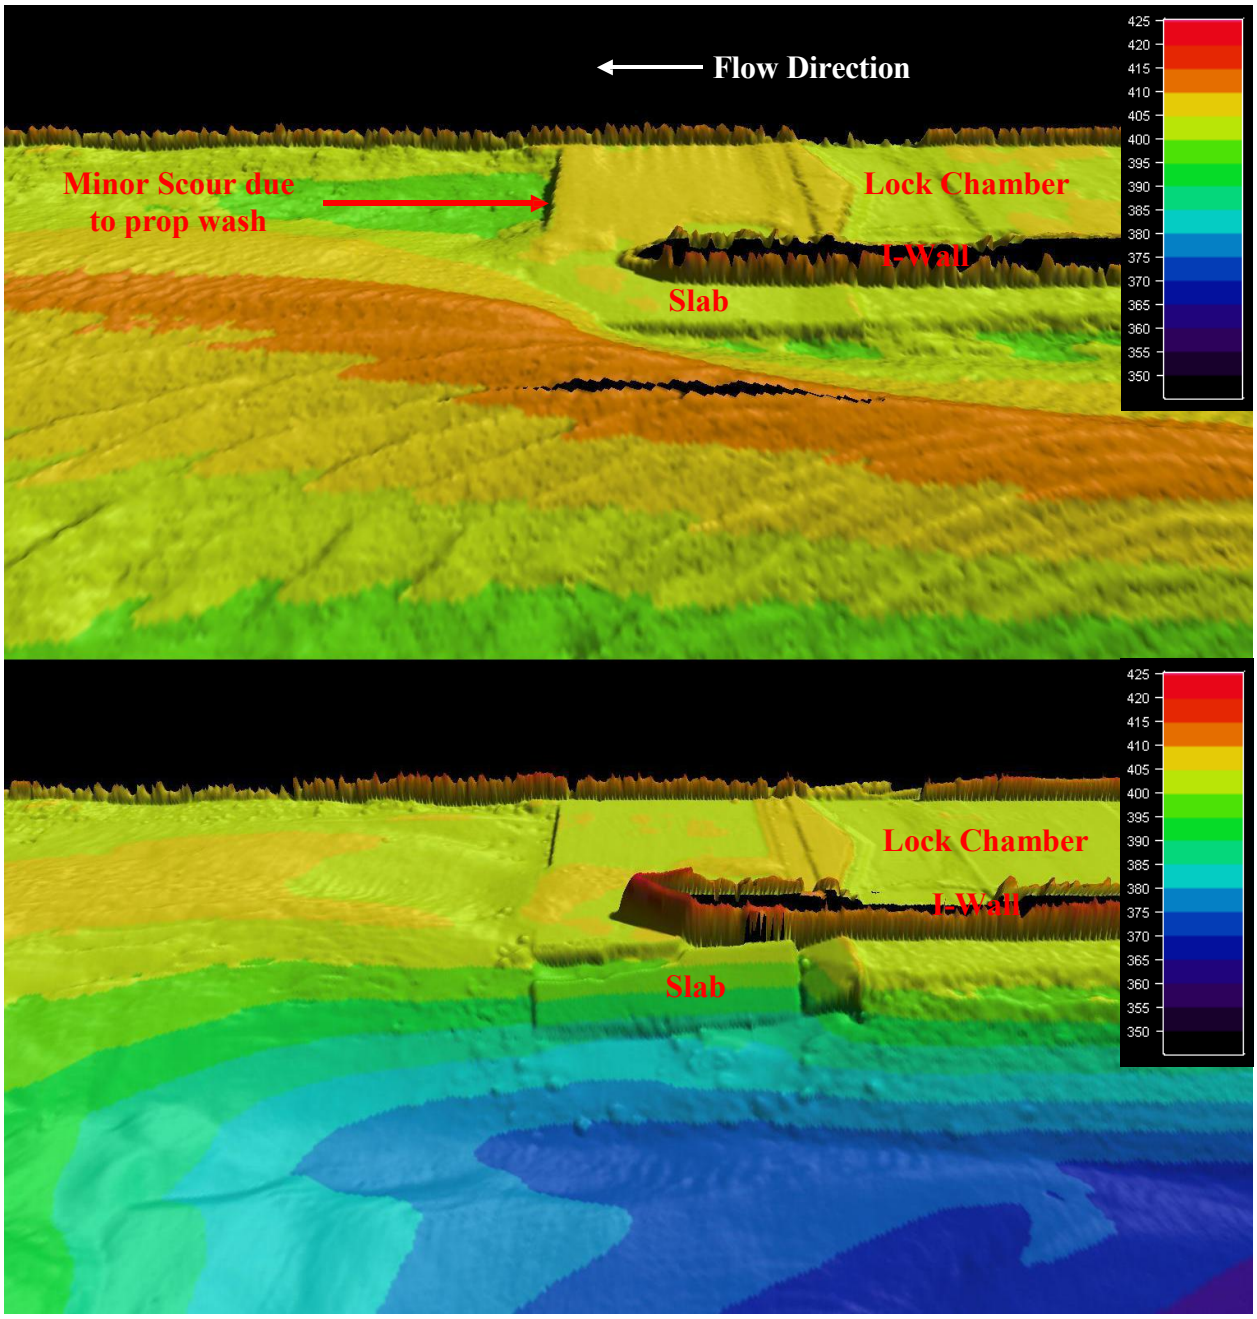

Figure 6 Before and after hydrographic surveys of downstream slab

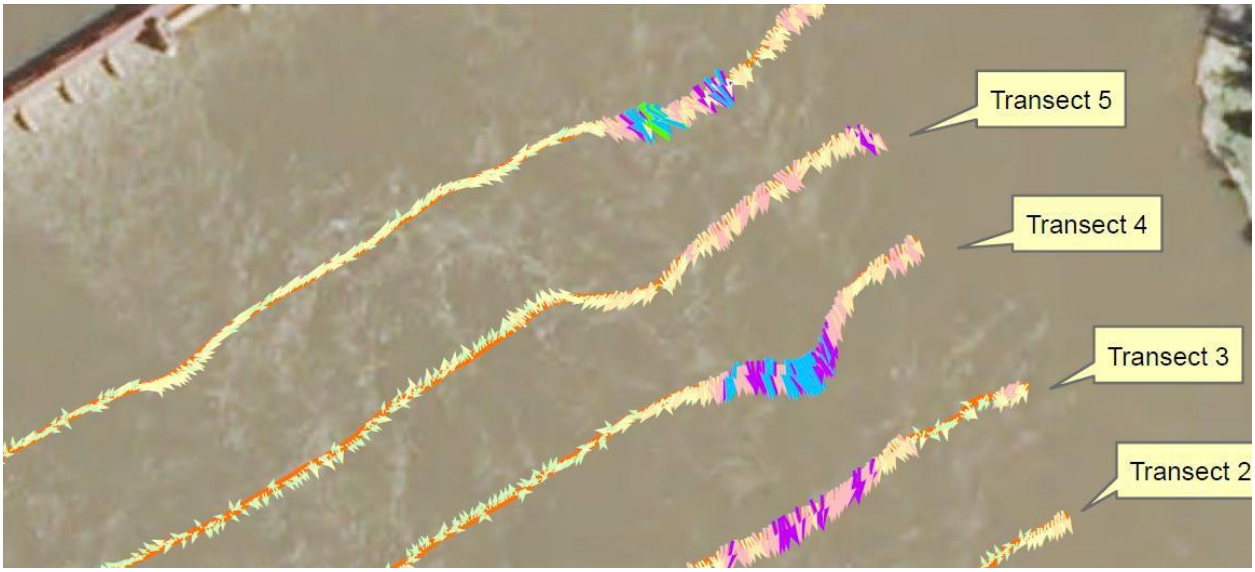

Figure 7 Velocity magnitudes and directions processed from ADCP data collected

It was suggested that scour adjacent to the I-Wall was partially caused by a significant eddy back towards the I-Wall that developed downstream of the dam due to the reliance on Gates 12 to 17 to pass flow. Anecdotally, the eddy was mentioned by pilots of survey and contractor repair boats. To test to see if an eddy back towards the I-Wall did in fact occur during releases through principally Gates 12-17, this condition was simulated. Unfortunately, the same flows passing through the dam during the deviation could not be simulated due to the time of year (measurements were taken around approximately 53,000 cfs, figure 7). The results of the ADCP collection showed some transects, particularly Transect 5, demonstrated flow vectors back towards the dam, supporting the eddy hypothesis.

Initial analysis after identifying the scour determined that there were two significant problems: 1) the potential of a global stability failure of the I-Wall due to loss of adjacent material, and 2) the potential for undermining of I-Wall and additional undermining of the slab surrounding the intermediate wall beyond what had already failed. Calculations were run to determine the stability of the lock and dam, particularly the I-Wall. The global stability of the I-Wall was found to be an issue, and plans were made to support the slope adjacent to the I-Wall with material in the repairs. Multiple boat-based multibeam surveys were used to monitor the location of the broken slab pieces, as the slab began to slide into the adjacent scour hole.

Multiple dive inspections were undertaken in the vicinity of the I-Wall, slab, downstream of the lock chamber, and land wall. The dive inspections revealed scour underneath the slab adjacent to the broken off section of the slab, downstream of the lock, and underneath the I-Wall. Verbal descriptions were used to characterize the scour occurring in each location. To better improve the knowledge of the undermining of the intact slab and position of the failed slab portion, an in-situ multibeam sonar device was used. A company was contacted and a demonstration was scheduled with a corresponding dive. The multibeam device was mounted on both a tripod and metal plate on the bottom of the river for different scans, and scans were taken from multiple placements around the area of interest (figure 8). From the scans, a better picture of the broken slab was

developed and the extent of intact slab undermining was better determined, allowing for better quantities estimates for the repair design.

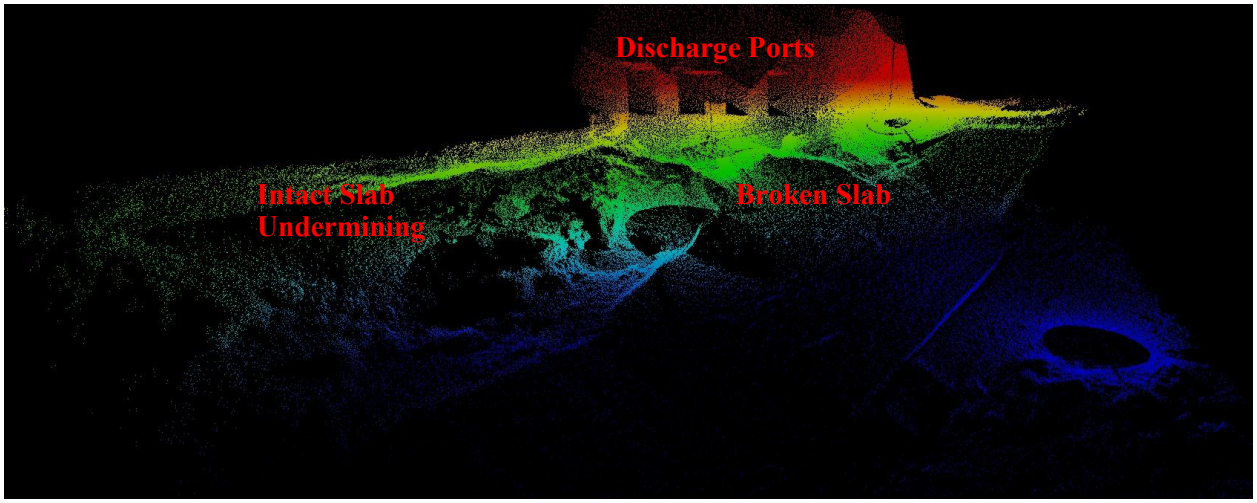

Figure 8 In-situ multibeam survey results

The Repairs: Phase I of the repair contract was awarded on February 8, 2012. Phase I consisted of filling in voids beneath the downstream edge of the slab. Holes were cored through the slab to fill the void. To contain the grout, a sheet pile wall was constructed along the edge of the slab from the landside wall to the eastern edge of the I-Wall. To prevent further downstream scour due to tows entering and exiting the lock chamber, the bed downstream of the slab and sheet pile wall was protected with 40 ft of 2,200 lb riprap.

An emergency repair was required to address undermining of the I-Wall itself. An initial dive inspection on September 24, 2011 identified an undermined area of approximately 6 ft long 1 ft below the base of the lock wall concrete extending at least 3 ft under the lock wall. At the time, the diver could feel that the timber piles that support the wall were exposed. Subsequent dive inspections identified the scour as both lengthening the width of the scour hole and its extents under the I-Wall. To repair this undermining, a 35 ft long, leave-in-place form was designed to cover the mouth of the scour hole. This form was designed with two holes, one at the bottom and top, so that grout could be pumped in the bottom hole until it filled the hole enough to run out the top, so that excess grout was not pumped under the I-Wall leading to a stability issue.

Phase II of the repair contract was awarded on May 25, 2012 for approximately $5.1 million dollars. The Phase II repair consisted of: 1) removing the failed slab, 2) construction of the remainder of the sheet pile wall along the slab edge including the dimensions desired to rebuild the slab, 2) grouting to re-establish the slab and fill voids underneath the intact slab section, 4) placement of rock to support the slope adjacent to the I-Wall, and 5) placement of stone downstream of Gates 11-16 to maintain the slope to the toe of the scour hole. The stone placed on the slope adjacent the I-Wall was constructed in two phases, the first to support the slope before the driving of the sheet pile and slab repair, and the second filling out the slope adjacent to the slab repair. During the design phase for the second phase of the repair, there had been discussion about the potential need for a thicker layer of additional rock downstream of Gates

11-16 to more completely rebuild the slope, including a supporting berm. This idea was rejected as it was thought normal operations would re-establish an approximation of the prior sediment deposition patterns downstream; this has since proven to be the case.

The project was completed in January 2013. Since the project was completed, as mentioned above briefly, the bed has begun to re-establish its pre-deviation form – a sediment deposition has developed adjacent to the I-Wall, two scour holes of less depth have formed downstream of Gates 1-9, and deposition has occurred in the scour hole downstream of gates 11-16 (figure 9). Monitoring of the I-Wall instrumentation has revealed no significant movement. Since project completion, the St. Louis District has returned to taking yearly hydrographic surveys upstream and downstream of the lock for monitoring purposes.

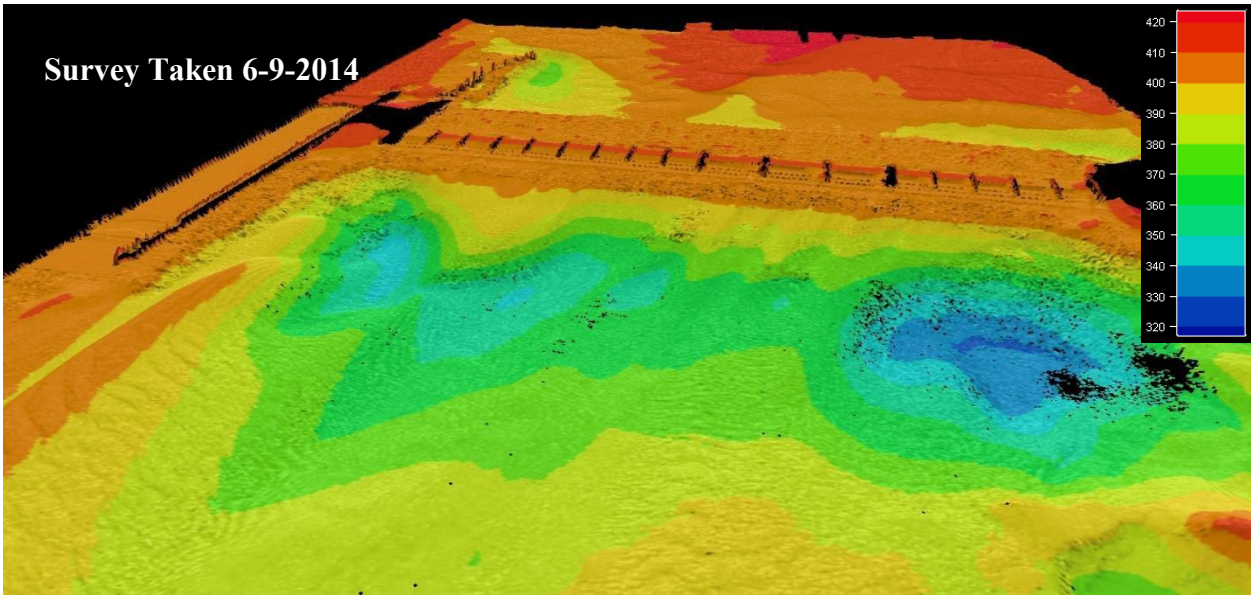

Figure 9 Most recent hydrographic survey

CONCLUSIONS

In March 2011, circumstances necessitated a deviation from normal operations at Lock and Dam 25 for nearly five months, with the large majority of flow being passed through Gates 12-17. Surveys and dive inspections after normal operations resumed revealed significant scour downstream of Gates 12-16 and adjacent to the Intermediate Wall. The scour adjacent to the I-Wall had led to the failure of a portion of the slab downstream of the lock, undermining of a portion of the I-Wall, and a global stability issue. Over the next roughly 1.5 years, repairs were done to return the lock to normal operations.

There were multiple lessons from the scour and subsequent repair from a hydraulics/sedimentation standpoint. The initial interest at the onset of the deviation from a hydraulics standpoint put a smaller emphasis on downstream scour, although this would later be the primary concern. Coupled with this, the potential that the hydraulics should change so drastically that energy dissipation may not have been largely confined to the stilling basin was

not the primary consideration during the deviation itself. Once the scour was identified after the deviation ended, the availability of multibeam surveys, both boat-based and for the first time in the St. Louis District in-situ, allowed for detailed monitoring of the site conditions, alternative development, and later, construction progress. The need for detailed monitoring extended to dive inspections, which revealed the critical I-Wall undermining. Lastly, the bed downstream of the dam has shown that, without any outside drivers, a riverbed will work to re-establish its equilibrium condition.

GEOMORPHIC ADJUSTMENTS ON THE UPPER MISSOURI RIVER IN RESPONSE TO DAM MANAGEMENT AND FLOODING

ABSTRACT

The Missouri River has had a long history of anthropogenic modification with considerable impacts on riparian ecology, form, and function. During the 19th and 20th century, the Missouri River basin experienced several massive dam-building efforts for irrigation, flood control and the generation of hydroelectric power. The river today has over 1/3 of its length inundated by reservoirs, and another 1/3 channelized with the flow managed for recreational use, fisheries, and habitat maintenance. In this study we examine how massive flooding in 2011 affected the geomorphic adjustments related to river management.

Our study is conducted along the 70-mile free flowing Upper Missouri River reach bounded upstream by the Garrison Dam (1953) and downstream by Lake Oahe Reservoir (1959) around the City of Bismarck ND. The Upper Missouri River has had its hydroperiod greatly reduced and stabilized by the presence of these dams. Typical discharges prior to the dam ranged from 10,000- 100,000 cubic feet per second (cfs) and fell to 30,000-45,000 cfs afterwards. In response, sedimentation rates and patterns along the river have had over 50 yrs to adjust to this new regime. The largest flood since dam regulation occurred in 2011 following an abnormally high snow pack season and a week-long rain event in the headwaters. Flood releases from the Garrison Dam began in May 2011 and peaked in June with a flow of approximately 150,000 cfs, more than triple that of normal peak loads for two weeks. The 2011 flood has highlighted the critical need for quantifying the complex interaction between the regional geomorphology and human activities.

The dam releases have had a discernible impact on the Missouri River throughout this section, such as reduction in sediment loads and channel bed degradation. A quantitative investigation of the historical impacts of the dams on channel planform, morphology, and sediment dynamics is necessary to provide a baseline to assess the impact of the 2011 flood. We have created a spatial-temporal conceptual model of the governing fluvial and deltaic processes for the reach. Ecological and geomorphic effects of dams and reservoirs have been well documented at specific sites, however relatively little attention has been paid to their interaction along a river corridor. We examine the morphological and sedimentation changes in the Upper Missouri River between the Garrison Dam and Oahe Dam. Through the use of historical aerial photography, stream gauge data, and cross sectional surveys we demonstrate that the impacts of the upstream dam do not completely attenuate to natural conditions before the backwater effects of the downstream

reservoir begin. Analysis of historic cross-sections and channel planform resulted in a series of geomorphic classifications along river.

The segment between the Garrison and Oahe dams was divided into five geomorphic reaches termed: *Dam Proximal, Dam-Attenuating, River-Dominated Interaction, Reservoir-Dominated Interaction, and Reservoir*. The Dam Proximal reach of the river is located immediately downstream of the dam and extends 50 km downstream and contained 22 cross-section sites. The cross-sectional data and aerial images suggest that the Dam Proximal reach of the river is eroding the bed, banks, and islands. All sites experienced an increase in cross-sectional area. The areal extent of islands in the Dam Proximal Reach in 1999 was 43% of what is was in 1950. The Dam-Attenuating reach extends from 50 to 100 km downstream of the dam and contained 14 cross-section sites. The islands in this reach are essentially metastable (adjusting spatially but with little net increase or decrease in areal extent). The reach itself has experienced net erosion with respect to the bed and banks, but to a lesser extent than the Dam Proximal reach. Twelve cross sections in the Dam-Attenuating reach show an increase in cross-sectional area. The reach gained 16% in island area from 1950 to 1999. All major islands present in 1950 were still present in 1999 with mostly similar geometries and distribution. The River-Dominated Interaction reach extends from 100 to 140 km downstream of the dam and contains 11 cross-sections. This reach is characterized by an increase in islands and sand bars and minimal change in channel cross-sectional area. Four of the sites have erosion and 5 of the sites are depositional (2 show no change). The areal extent of island area in this reach in 1999 was 150% greater in 1950. The Reservoir-Dominated Interaction reach is located 140– 190 km downstream from the Garrison Dam and contains 11 cross-sections. Reservoir effects vary both annually and seasonally due to changing reservoir levels creating a recognizable deltaic morphology. The Reservoir- Dominated Interaction reach is characterized by aggrading islands, sand bars, and the flooded meander bends (former meanders that have been flooded by the reservoir). Nine sites indicate deposition. The active extent of this reach can migrate drastically from year to year depending on the reservoir level. The Reservoir reach (Lake Oahe) is depositional but the channel morphology is stable. This reach extends from approximately 190 km to just upstream of the Oahe Dam; 512 km downstream from Garrison Dam. Cross-sections in this section extend into the first 100 km into this reach. All 12 cross sections in the Oahe reach shows deposition. It should be noted that because the lower floodplain is impounded (unlike other sections of the river), the deposition that occurs is spread out laterally rather than vertically. Thus, even though the cross-sectional area for the surveyed sample transect in this reach has changed, the overall change in channel capacity is only 2.5%. General channel morphology remains stable and all pre-dam islands in this reach are submerged under several meters of water.

Results show that the 512 km between the Garrison and Oahe Dam is not enough distance to isolate their influence on the river and therefore requires that they are not considered separately in impact investigations. The conditions which created the current morphology of the Upper Missouri river are likely found in many other rivers across the US. Most major rivers in the US have dams which are proximal longitudinally and are likely interacting in a similar way as the Garrison and Oahe Dams. In a GIS analysis of 66 major rivers within the contiguous United States, 73% of 404 dams surveyed are separated by less than 100 km. Dams were identified using USACE National Inventory. For each river, only the main river stem was considered and river distance was delineated in ArcGIS to the nearest km. We propose a conceptual model of how a sequence of interacting dams might impact river geomorphology (Figure 1) based on our

results. We call this morphologic sequence the Inter-Dam Sequence, and we present a simplified model based on the Upper Missouri River that could be easily adapted to other river reaches. Although the morphologic sequence is a useful conceptualization, there are clear limitations to these results. This model likely only applies to large dams on alluvial rivers. Dams on rivers that are controlled by bedrock or where morphologic adjustment is limited by vegetation or cohesive banks may respond differently than the model presented here. Similarly, the downstream effects of small dams will likely attenuate over much shorter distances. However, this framework is a helpful advancement in our understanding of longitudinal responses to multiple dams.

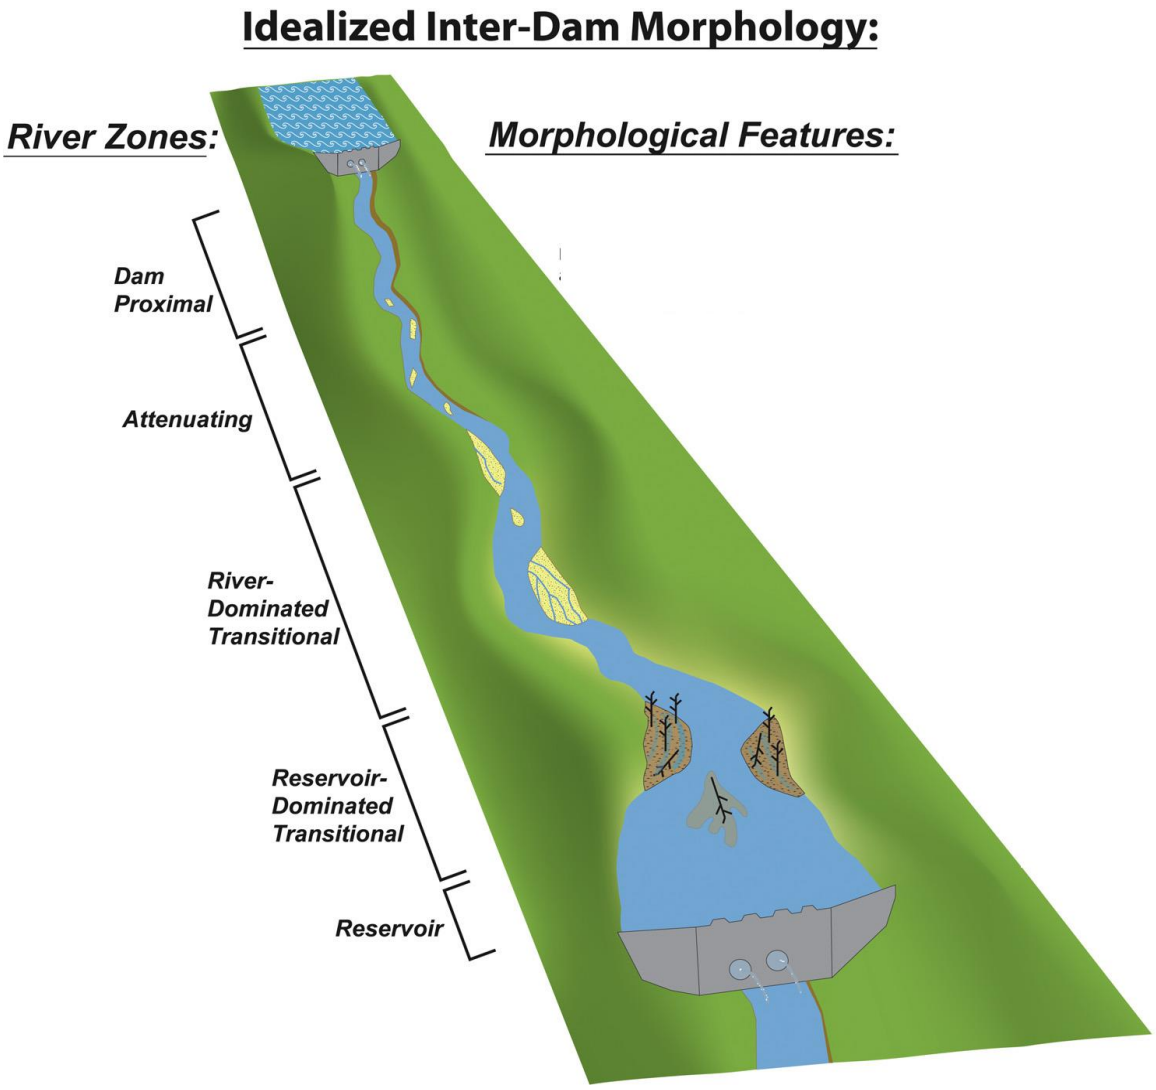

Figure 1 Idealized inter-dam morphology based on the geomorphic classification of the Missouri River.

Topic Area: [Remote sensing]; Dam Removal/Rehabilitation; sediment yield and transport modeling, Fluvial Geomorphology

Subthemes: Innovation in measurement, management, and prediction of sediment in water and watersheds; dam removal, dam rehabilitation, and stream restoration; adaptive management

Elwha and Glines Canyon dams impounded about 28 million yd^3 ± 4 million yd^3 of sediment in Lake Mills and Lake Aldwell. Removal of these dams represents the largest dam removal and managed sediment release in U.S. history, with roughly a 20 year supply of coarse sediment and a 5 year supply of fine sediment released from October 2012 to March 2013 alone. Monitoring changes during dam removal presents a significant challenge due to limited monitoring resources, the large area affected by dam removal (approximately 16.5 river miles with an average valley width of about 3000 ft) and the near-real-time need for data from both reservoir and river reaches for adaptive project management decisions.

A rapid-deployment, low-cost method was developed to collect aerial imagery and generate orthoimagery and digital elevation models (DEMs) of the Elwha River during removal of Elwha and Glines Canyon dams. Imagery is collected with a firmware-modified consumer-grade camera and processed using structure from motion algorithms to produce a spatially accurate DEM with sub-foot resolution and orthoimagery with ~5 inch ground sample distance. A network of RTK GNSS surveyed ground control points (GCPs) with aerial targets are used to reference the DEM and orthoimagery to a geographic coordinate system and enable surface comparison using GIS tools. Flights are conducted on a weekly to monthly basis depending on hydrology and project progress, at a cost of roughly $300/flight. Imagery can be processed to produce DEMs and orthophotos of a specific reach in as little as 24 hours if needed.

Orthoimage resolution allows identification and measurement of features such as individual logs and sediment texture differences. Data are used to determine maximum inundation/erosion width, map banklines and evolution of depositional and erosional features such as midchannel bars and logjams, and to evaluate significant features affecting river morphology such as logjams and channel braidedness. The temporal frequency of flights makes it possible to compute bank erosion rates, meander migration rates, and the evolution of potential hazards.

DEMs are produced at 0.5 meter resolution. Features such as terraces, small channels, and individual logs can be identified. DEMs are used to calculate erosion volumes by comparing DEMs between flights, as well as comparing DEMs to LiDAR data, profile and cross-section surveys, and the pre-project surface model. DEMs also provide a measure of erosion slope along the reservoirs, and are used to calibrate the reservoir erosion model guiding dam removal. Comparison with LiDAR and RTK GNSS survey data indicate that DEMs provide an accurate tool with quantifiable error estimates and can be used to measure slopes and make volume calculations.

Elwha PlaneCam data have proven instrumental in monitoring difficult-to-reach areas, providing near-real-time updates to sediment erosion volumes during the project, and providing a high resolution spatial and temporal record of changes throughout the area affected by the removal of Elwha and Glines Canyon dams. Data from this survey method will produce a record of the project that is detailed enough to be mined for future research, yet rapid enough to provide feedback to calibrate models and guide project managers during dam removal.

COLLECTION AND INTERPRETATION OF RESERVOIR DATA TO SUPPORT SUSTAINABLE USE

Gregory L. Morris, GLM Engineering COOP, San Juan, Puerto Rico
gmorris@glmengineers.com

Abstract. Sustainable reservoir management seeks to retard sedimentation and reduce its adverse impacts, ultimately achieving an equilibrium between sediment inflow and outflow while sustaining storage capacity to maximize project benefits.

Sedimentation data has traditionally been collected with the objective of simply documenting the timewise decline in reservoir capacity and computation of reservoir "useful life." However, if the decision is made to manage the reservoir in a sustainable manner the available data needs to be analyzed differently, and additional data will be required to better understand sedimentation processes and develop management alternatives. This paper outlines some of the shortcomings of existing datasets and identifies data interpretation strategies and additional data types that can support sustainable reservoir management.

INTRODUCTION

Data on reservoir sedimentation has traditionally been collected with the objective of documenting the decline in storage capacity over time and accounting for its impact on the various reservoir pools. Most sedimentation datasets consist of periodic bathymetric surveys, presenting survey results as a change in volume over time, updating the elevation-volume curve and perhaps plotting representative cross-sections. Many reservoirs have never been surveyed at all.

When the decision is made to manage a reservoir for sustainable use instead of simply documenting its demise, it becomes necessary to: (1) re-process existing data to extract additional information, and (2) obtain additional and different types of data needed to better understand the sedimentation process, how it is changing over time, and to assess strategies for sustainable management. Sustainable management strategies are described by Morris and Fan (1997) and have been categorized in Figure 1.

RESERVOIR BATHYMETRIC DATA

Limitations of Bathymetric Datasets

Bathymetric data are used to document the change in reservoir volume over time, which is essential information for extrapolating future reservoir volume, discerning changes in sediment yield with time, and calibrating sediment transport models used to evaluate management alternatives. It is necessary to understand the limitations and potential problems with these datasets to interpret them properly and to plan a data collection program that supports sustainable management.

Bathymetric data are, for the most part, assumed to be accurate. However, many US and international datasets reveal significant error. When there are very few survey data, errors may go unrecognized. Consider, for example, reservoir volume data shown in Table 1.

Data from 5 of the 13 reservoirs are highlighted in bold red because they show that either total reservoir volume or the conservation pool volume has increased since reservoir construction. This is obviously an impossible result and therefore the affected data are deemed in error. However, the data for all the reservoirs are affected by error, but the potential for error is not noticed in the other reservoirs because the error is not as large or occurs in the opposite direction, thereby indicating an erroneously high rate of volume loss instead of a volume increase. However, because data for the other reservoirs have passed the "test of impossible results" they are tacitly accepted as accurate.

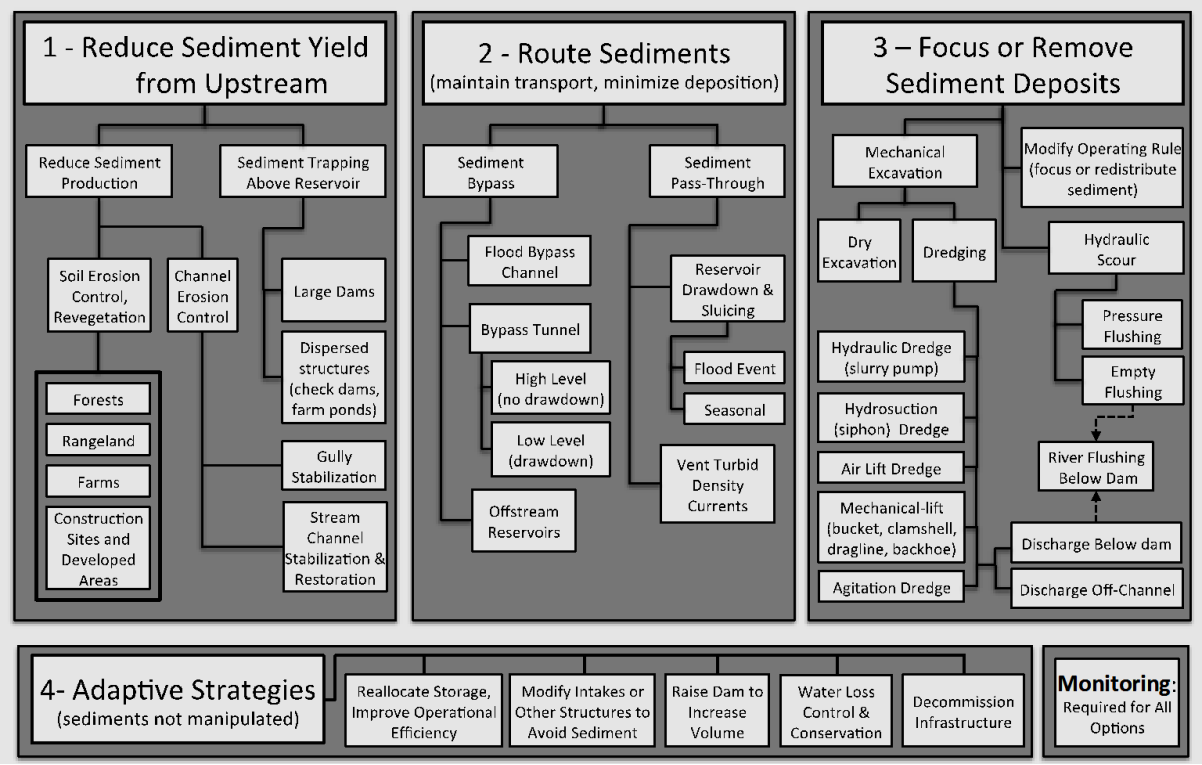

Figure 1 Strategies for sustainable reservoir management (after Morris, 2014).

Bathymetric errors can originate from a variety of sources. The original pre-impoundment reservoir volume is often not of high accuracy. It may have been determined by conventional ground survey, by photogrammetric methods, or computed from published topographic mapping. Post-impoundment volume surveys necessarily use different techniques. The ***range-line*** method has been used conventionally, but since the 1990s the ***contour method*** has come into widespread use. A contour survey collects a high-density of position and depth data points measured by GPS and sonar, from which the sediment surface is mapped and the volume computed by mapping or survey software. Survey methodologies are summarized by Ferrari and Collins (2009) and Ferrari (2006a).

All surveys incorporate errors, and these errors are not necessarily easy to detect since the bathymetric data collection process is typically open-ended without the check that occurs, for example, in a conventional topographic survey which may close back to the point of origin. As an example, consider the reservoir survey data presented in Figure 2. The data were collected on different days with the boat running track lines oriented perpendicular to each other on each day. The resulting checkerboard pattern, with both high and low survey lines, was the result of not

having the bathymetric equipment properly calibrated; different days produced track lines having different elevations for the same area. Because bathymetric track paths are typically parallel and do not repeat the same area, this type of error would not normally be detected.

Table 1 Reservoir Capacities for Corps of Engineer Reservoirs, Baltimore District.

Basin and Reservoir	Watershed (km^2)	Dam Closure Year	Last Survey Year	Storage Loss (%)	
				Below Top of Conservation Pool	Below Top of Flood Pool
North Branch Potomac River Basin

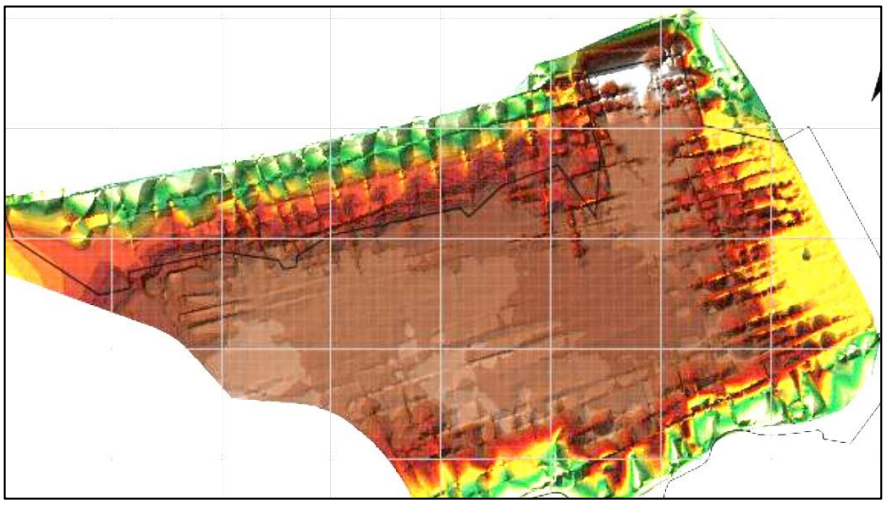

Figure 2: Bathymetric survey showing irregular gridded lines in the reservoir.

A potentially large source of error is associated with changes in methodology, such as changing from pre-impoundment to post-impoundment surveys, or from range-line to contour surveys. Given the differences in field measurement methods, together with the variety of computational techniques available for making volume computations, a change in methodology can generate a significant change in the measured volume, independent of sedimentation. Even contour survey

computational algorithms represent a potential source of error of some significance. For example, Ortt et al. (2000) analyzed digital datasets from Loch Raven and Prettyboy reservoirs in Maryland using two different software algorithms, resulting in volume differences of 1.4% and 2.2% respectively due to software differences alone.

Consider the data for John Redmond Reservoir in Figure 4, showing a recent increase in reservoir volume. The last survey was performed by the contour method, the prior surveys by range-line. The volume shift coinciding with the changed methodology makes the sedimentation trend unclear.

For sustainable management, the principal objective of repeated surveys is to calculate the rate of sedimentation, and not to simply achieve a more accurate measure of the current reservoir volume. For this reason, when changing survey methodologies it is always appropriate to compute the new volume measurement by both the old and the new methodologies. To support this dual-computation, the new survey track lines should be planned to insure that each of the original range lines is replicated to provide the necessary data needed for volume computation by the old method. By comparing the survey volume by the two methods, the difference in apparent volume due to the changed methodology may be separated from the physical volume change due to sedimentation.

Changing Sedimentation Rate

Data from U.S. reservoirs frequently show that the rate of volume loss is not constant, but tends to decline over time (see Figure 3 and Figure 4). The most important factors that probably contribute to this result are: (1) sediment compaction, and (2) declining sediment yield due to erosion control or upstream dams. Reduced trap efficiency due to volume loss is probably not an important consideration in reservoirs which still retain much of their original volume (Brune, 1953). Changes in measurement methodology would probably not introduce a uni-directional bias, and at many sites the measurement methodology is unchanged.

A timewise change in sedimentation rate will not be observable absent data from multiple surveys. Drawing a trend line from the pre-impoundment volume through a single bathymetric survey data point 20 or 30 years following impoundment may provide a poor estimate of the long-term sedimentation rate. For example, if only the pre-impoundment (1949) and the 1981 survey data were available for Harry Strunk Reservoir, the projection of capacity loss based on these two data points alone would be remarkably different from the situation revealed with more complete data, as illustrated by the difference in the trend lines drawn in Figure 3.

For many federal reservoirs the datasets needed to detect changing in rates of volume loss do not exist. For example, 70% of the Bureau of Reclamation's 400+ storage facilities have not been surveyed since initial impounding, and another 20% have only been surveyed once (Ferrari and Collins 2006).

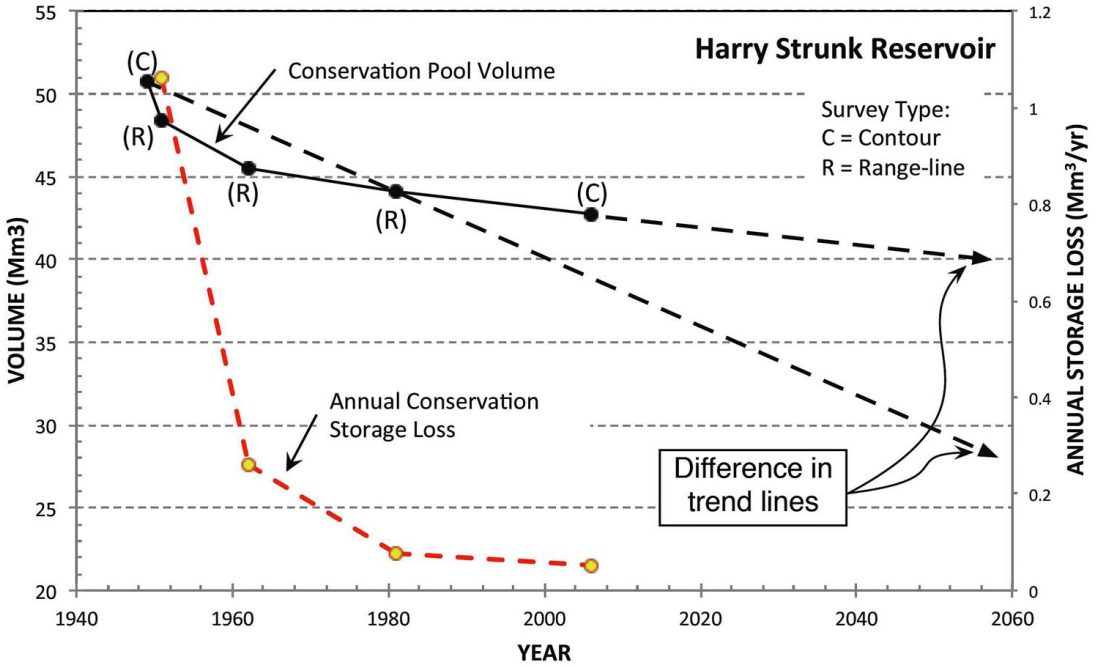

Figure 3 Timewise decline in reservoir volume and rate of storage loss at the Bureau of Reclamation's Harry Strunk Reservoir with trend lines superimposed (historical data from Ferrari 2006b).

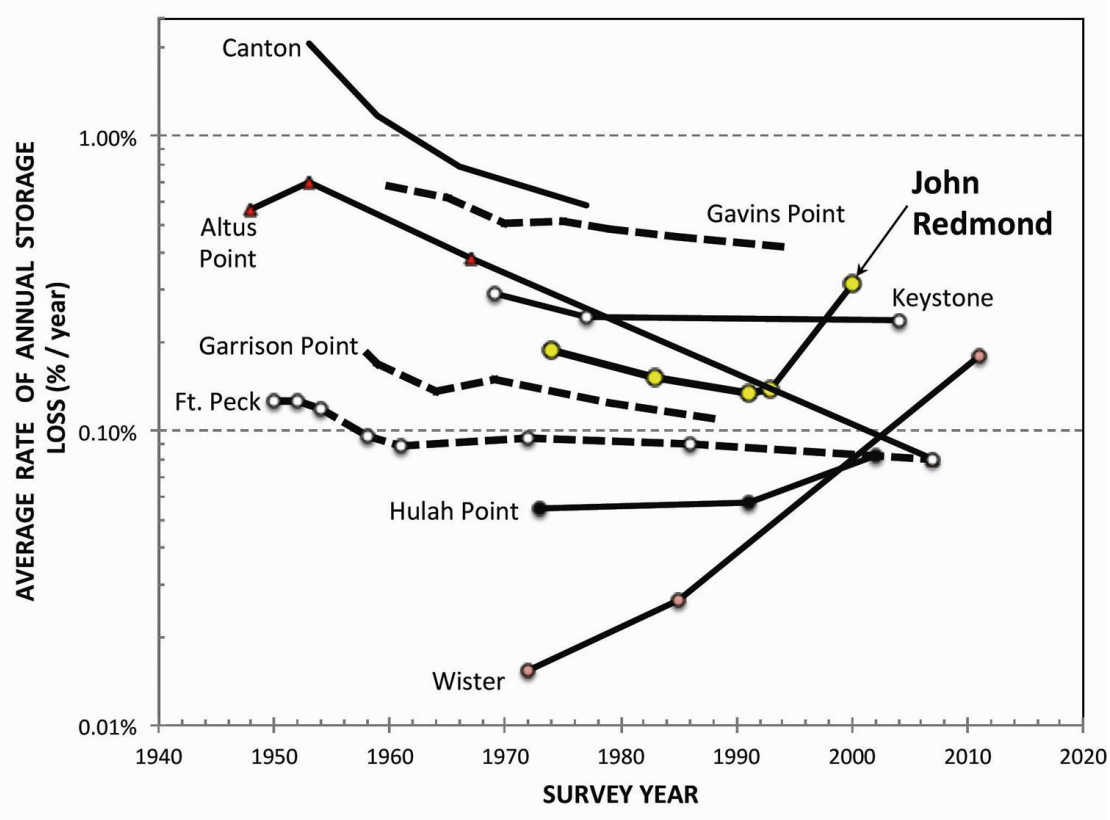

Figure 4 Change in rate of storage loss at several Corps of Engineers reservoirs in the Tulsa and Omaha districts.

Longitudinal Reservoir Profiles

Insight into the sedimentation process can be gained by plotting the timewise change in the reservoir's longitudinal bottom profiles. Profiles revealing horizontally-bedded sediment at the dam indicate that turbid density currents are transporting significant volumes of sediment to the dam which is not being released (Figure 5). Longitudinal profiles can also be used to monitor the pattern of delta advance (Figure 6) as influenced by the reservoir operational levels. It is quite difficult to deduce these patterns by examining changes in the elevation-volume curves over time (Figure 7). Although simple to construct and highly instructive of the sedimentation process, longitudinal profiles are not normally plotted in sedimentation studies. It can also be useful to prepare a graph showing a longitudinal plot of cumulative sediment volume. Existing datasets may be reprocessed to display this information.

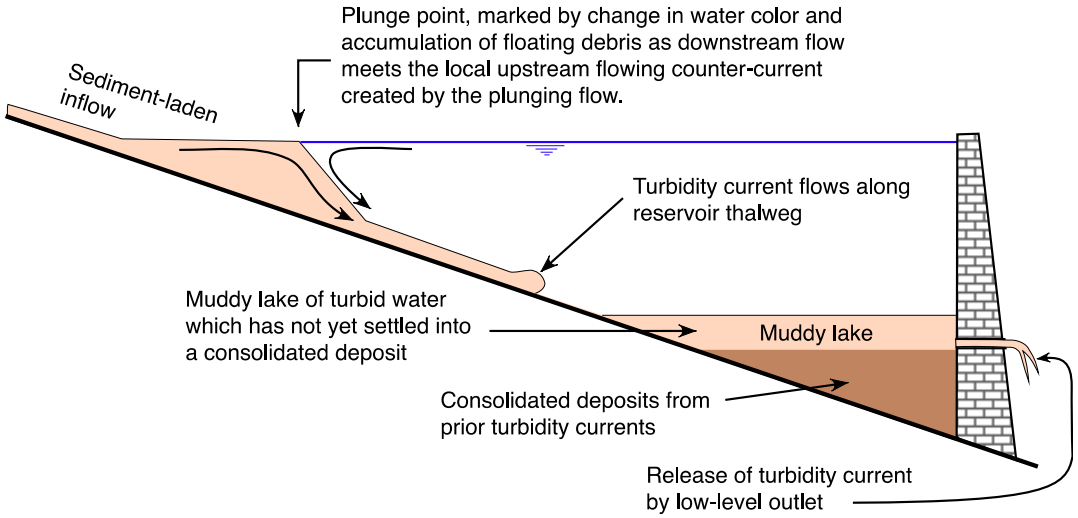

Figure 5 Longitudinal profiles can reveal the presence of turbidity current deposits at the dam.

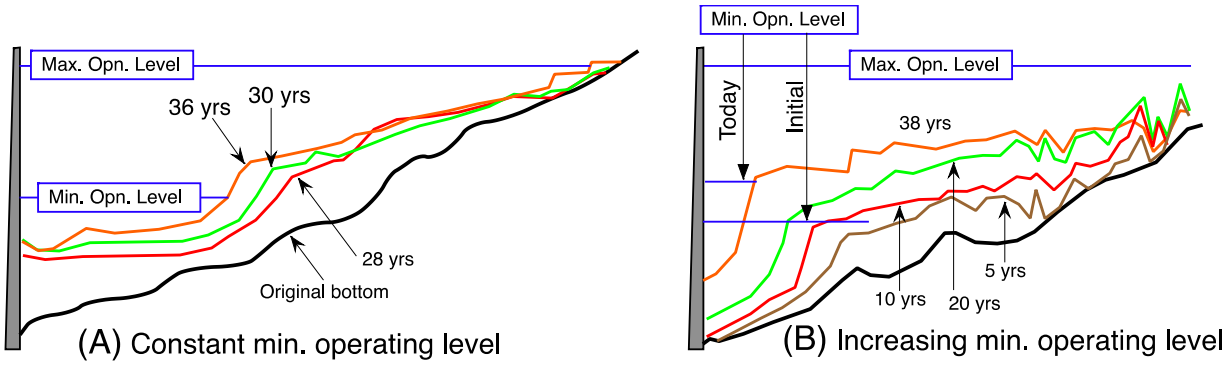

Figure 6 Longitudinal profiles showing different patterns of delta advance.

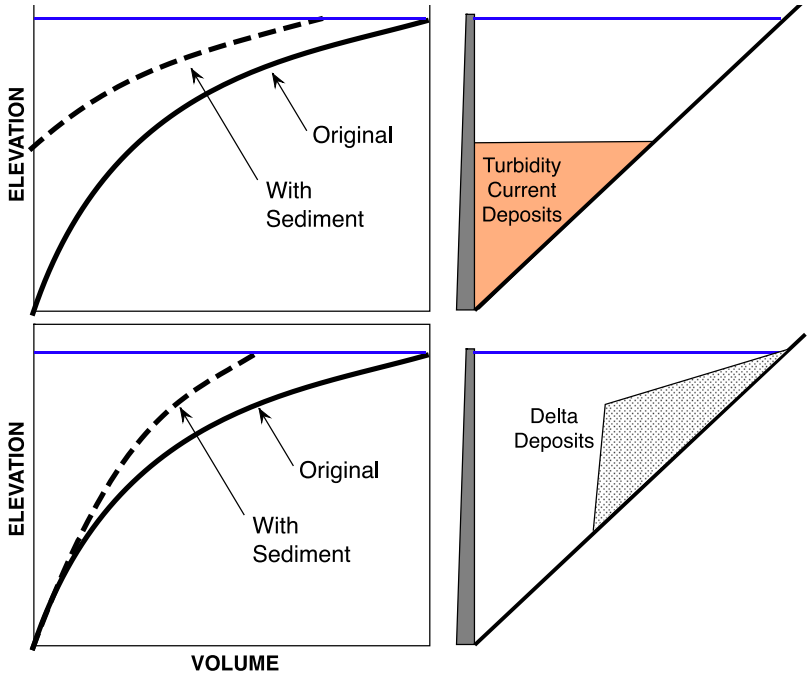

Figure 7 Change in shape of elevation-volume curve over time as influenced by the predominant pattern of sediment deposition in a reservoir.

SEDIMENT CORES

Sediment cores may be obtained from the bottom of a reservoir by conventional geotechnical boring equipment working from a floating platform. For example, at Tarbela Reservoir, Pakistan, ten cores penetrating up to 60 m of sediment thickness to reach the original reservoir bottom were obtained operating from a barge during 56 working days. This did not include time consumed by weather delay when the water was too rough to work (SMS Consultants, 2013). This is a costly and time-consuming sampling alternative. In contrast, for core lengths not exceeding about 3 to 4 m, low-cost vibracore equipment may be used for rapidly sampling multiple locations each day. Vibracore sampling and analysis protocols are described by Bennett et al. (2013). Portable vibracore equipment used to sample in water up to 60 m deep in a hydropower reservoir in Colombia is illustrated in Figure 8. The objective was to obtain bulk samples to determine how far sand was being transported in the direction of the power intake during reservoir drawdown, when the sandy delta is subject to scour and sediment remobilization.

Sediment cores are not routinely collected in reservoirs but can be important aids in understanding and managing the sedimentation processes. Because sediments deposit in an episodic nature, the sediments in a reservoir will be layered, and samples from the top of the deposits will not provide representative information. Sample cores are required to obtain a more representative characterization of the deposit characteristics for determining representative values for parameters such as grain size, bulk density, organic content, and sediment chemistry. Because sandy delta sediments will advance and prograde over previously deposited fines, the composition of the top part of the bed may be different from the bottom. Depending on the management strategy, the composition of the deeper sediment may or may not be a concern.

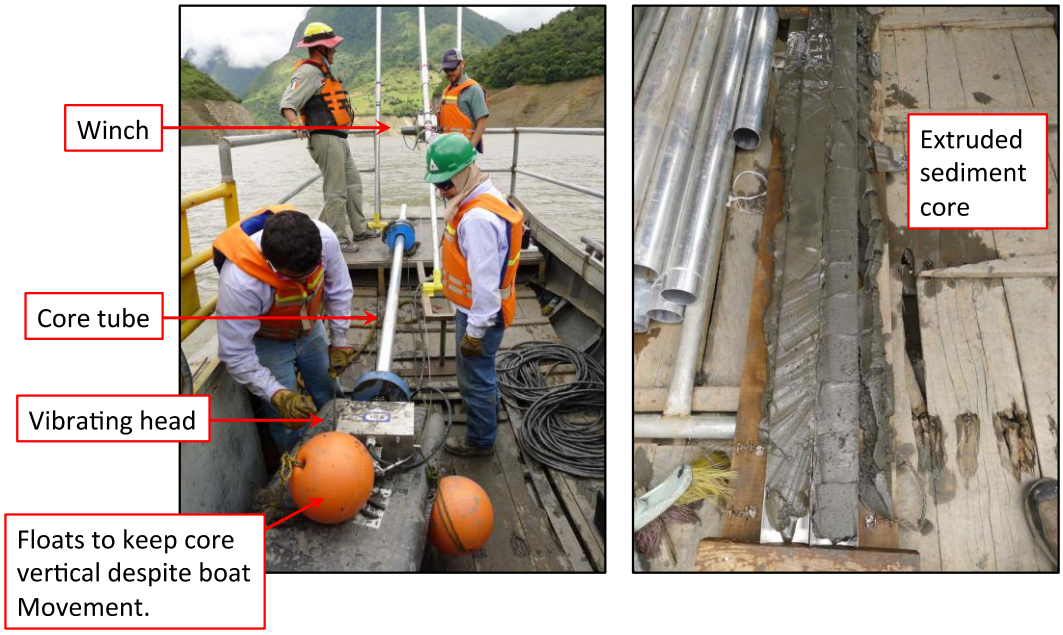

Figure 8 Battery operated vibracore used for sampling sand concentration near a hydropower intake.

Computing Sedimentation Rate

When the original volume of a reservoir is unavailable or uncertain, fully penetrating cores in combination with a dual-frequency bathymetric survey (sub-bottom profiler) can map both the top and bottom of sediment deposits. Cores are useful to confirm the bulk density of the deposits and to confirm the depth to original ground (sediment thickness) as identified by the sonar data. This approach will not work if reservoir sediments contain methane gas from organic decomposition, since the sonar signal is strongly reflected by the air-water interface created by bubbles in the sediment.

If there is a datable stratigraphic horizon within the sediment that can be identified in the cores, this can also provide additional information on relative rates of sedimentation on either side of the event horizon. Horizons may be created by a large wildfire, volcanic eruption, contaminant discharge, and the cesium-137 layers from atmospheric testing of thermonuclear weapons that started in 1952 and peaked in 1963 (Cox et al., 2002).

Determining Bulk Density

To determine sediment yield from sediment volume requires knowledge of the dry bulk density of the sediment deposits. Bulk density varies with sediment grain size, and generally decreases moving downstream in a reservoir. Higher bulk densities occur in coarse delta sediment and lower bulk densities in fine grained sediments near the dam. The bulk density of fine sediment is not static but increases over time (and with depth) due to the weight of overlying sediment. Because sediment is not uniformly deposited, in some areas of the reservoir (and particularly near the delta face), bulk density will also vary with depth due to sediment layers of different

grain sizes. Sediment cores can provide direct measurements of bulk density. Juracek (2006) provides information on sampling strategies for bulk density determinations.

Sediment Characteristics

Particle-size distribution data for different areas of the reservoir can provide useful information for calibrating sediment transport models. In hydropower plants, sand more than about 0.2 mm in diameter is generally considered to be highly abrasive, making it essential that is be excluded from the power intake. Sediment cores extending upstream from the intake can provide information on the grain size and percentage of sand, and can monitor its rate of advance toward the power intake. Knowledge of organic content, potential contaminants, and other parameters may be needed prior to excavating and discharging sediment, and samples required for this analysis are also normally obtained by cores.

DAILY SEDIMENT BALANCE

Sediment routing strategies (Figure 1) are based on the tendency for sediment discharge to be highly concentrated in time. Routing techniques reduce the rate of sediment accumulation by maintaining sediment-laden flood flows in motion, either passing them around the storage zone (sediment bypass) using offstream reservoirs or sediment bypass tunnels, or by passing sediment-laden flow though the storage zone with the minimum detention time or by releasing submerged turbid density currents. Given the episodic nature of sediment inflow events, daily discharge and concentration datasets are required to analyze these strategies, and depending on the site continuous (e.g., 15 minute) data may be required for refinement of the analysis and for subsequent operational purposes.

Aside from the difficulty and cost of acquiring reliable suspended sediment data, a significant disadvantage lies in the potentially high variability of sediment yield over time, particularly in mountainous watersheds. Large floods will frequently deliver sediment volumes that exceed several years of “normal” hydrology. Capturing data from these events, which may have a large impact on long-term sediment yield and the degree of success of a sediment routing strategy, requires a data collection platform that can withstand extreme floods and hurricanes, plus the good fortune to have the gage’s funding period coincide with an extreme event.

CONCLUSIONS

Today’s inventory of reservoirs cannot be managed in a sustainable manner without substantially expanded data collection and improved data analysis. The most critical issue at this point is to survey reservoirs at regular intervals to better determine the long term rates of storage loss, and document the timewise variability in these rates. These data can help identify reservoirs with the highest priority for management.

Many reservoirs in which capacity was previously determined by the range-line method will next be surveyed by the contour method. When changing methodologies it is essential to perform the new survey using both the old and the new methodologies, so that the volume change attributable to the change in methodology can be differentiated from the actual change in reservoir volume due to sedimentation.

While gage stations and daily data collection are essential for understanding sediment transport dynamics and developing workable management strategies, they do not substitute for good bathymetric datasets.

ABSTRACT

Sediment accumulation is a problem in many large reservoirs in the United States and around the world, including Tuttle Creek Lake in the Kansas River basin. A one-dimensional unsteady flow and sediment model was built for Tuttle Creek Lake using the Hydraulic Engineering Center – River Analysis System (HEC-RAS) Version 5.0 Beta. This paper provides an overview of Tuttle Creek Lake, describes the model setup, highlights how features new to HEC-RAS 5.0 operated in the modeling effort, and provides model results from a proof-of-concept model run. This model will be used to evaluate the technical feasibility and effectiveness of altering the reservoir operations to decrease sediment trapping efficiency.

INTRODUCTION

Sediment accumulation is a problem in many large reservoirs in the United States and around the world. Available storage is decreasing while demand for water is increasing. Downstream, channels degrade and reduced sediment supply threatens sediment-dependent aquatic species (Haslouer et al., 2005). Removal of accumulated sediment from large reservoirs tends to be prohibitively expensive. This underscores the need to optimally operate large reservoirs to decrease sediment deposition in the first place.

Tuttle Creek Lake is a large, Corps of Engineers reservoir in the Kansas River basin that provides flood control, water supply, recreation, and environmental benefits. Tuttle Creek Lake provides water supply to Manhattan, Kansas and provides releases to the Kansas River that benefit water users in Topeka, Lawrence, and Kansas City, Kansas. In addition, Tuttle Creek Lake releases water when necessary to provide navigation flows on the Missouri River.

As of 2009, the total storage up to the multipurpose pool level and flood control pool level were approximately 252,000 ac-ft and 2,118,000 ac-ft, respectively (USACE, 2012). The pre-construction estimate for the sedimentation rate in the multi-purpose pool was 4,151 ac-ft/yr

ac-ft/year. Based on repeated bathymetric surveys, the average sediment accumulation is estimated at 3,594 ac-ft/year (KWO, 2012). Since completion of the dam in 1962, 43% of the original multi-purpose storage volume has been lost to sediment accumulation. The current operational procedure for Tuttle Creek Lake traps 98% of all sediment, including fine silts and clays (Juracek, 2011). Dredging with upland disposal of the dredged material is prohibitively expensive, given the large quantity of incoming sediment load.

A one-dimensional unsteady flow and sediment model was built for this project using the Hydraulic Engineering Center – River Analysis System (HEC-RAS) Version 5.0 Beta (USACE, 2015, Gibson et al., 2006) to evaluate the technical feasibility and effectiveness of altering the reservoir operations to decrease sediment trapping efficiency. This model uses features that are new to HEC-RAS 5.0, including unsteady sediment modeling and customized RULES to calibrate ungaged inflows.

The model will assess trap efficiency response to alternate management strategies, assuring that they also meet current flood control reservoir functions. Operational changes within existing constraints may only decrease trapping efficiency slightly (Lee and Foster, 2013), but even a slight decrease in sediment trapping can save significant money compared to maintenance dredging. Small decreases in trapping efficiency over time can form a part of larger sediment management strategy.

MODEL SET-UP

Model cross-sections extend from the Big Blue River upstream of the reservoir, down through the reservoir to the confluence with the Kansas River, and on the Kansas River from Fort Riley to Wamego. Two additional major tributaries to Tuttle Creek Lake, the Little Blue River and the Black Vermillion River are included as point loads rather than modeled cross-sections. Figure 1 provides a general vicinity map of the project area including major components of the HEC-RAS model.

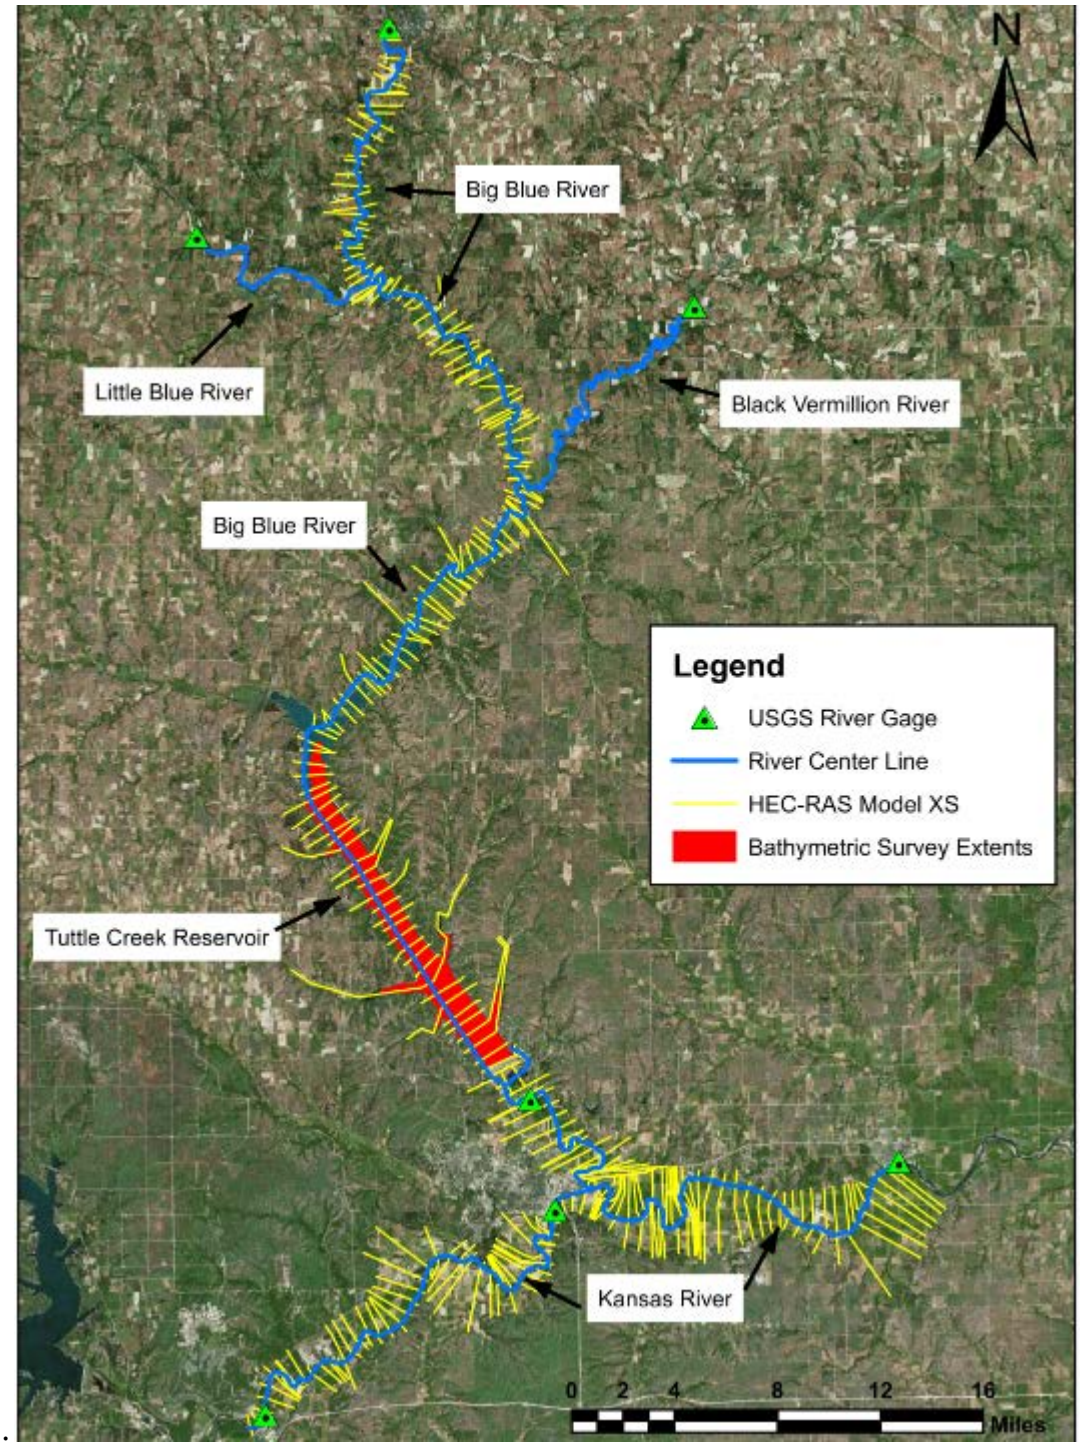

Figure 1. Model Schematic

DEVELOPMENT OF INITIAL BATHYMETRIC SURFACE

Model creation and calibration require a baseline survey to build model geometry and a final survey to compare to model output. Two recent bathymetric surveys were available, in 2000 and 2009 (Figure 2). The 2000 bathymetric survey had low point density (1.6 points per acre) and produced a surface with interpolation errors and insufficient channel detail. The 2009 survey had a much higher point density (25.8 points per acre) which provided excellent definition of the reservoir and channel bottom.

The following procedure compensated for insufficiencies in the 2000 data. First, a surface was interpolated from the 2009 survey points. The vertical change from 2000 to 2009 was computed at each 2000 bathymetric point using the 2009 surface. Then, these individual point changes were interpolated to create a surface of bed change from 2000 to 2009. Finally, this bed change surface was subtracted from the 2009 surface to create a more representative 2000 surface. Figure 3 illustrates model cross-section 18.17 cut from the original 2000 surface and from the 2000 surface created using the using the bed change method described above. As seen in Figure 3, the bed change method produced a more reasonable cross-section shape and a physically justifiable deposition pattern. Accordingly, the model cross-sections were derived using the 2000 bathymetric surface developed using the bed change method.

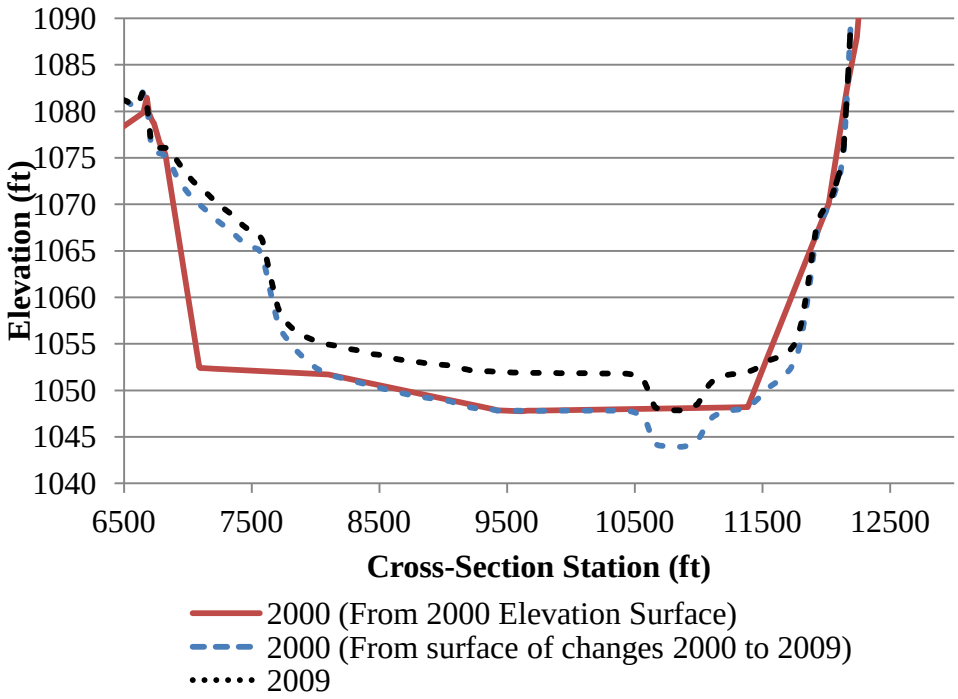

Figure 3. Cross-section Comparison of Surface Interpolation Methods, Model RS 18.17

FLOW AND SEDIMENT BOUNDARY CONDITIONS

Data from USGS gaging stations produced the relationships between flow and suspended sediment load at the three major tributaries to Tuttle Creek Lake seen in Figure 4. Daily suspended sediment loads were associated with daily inflows to the reservoir. Bed load data was not available and values were estimated as a percentage of suspended sediment loads.

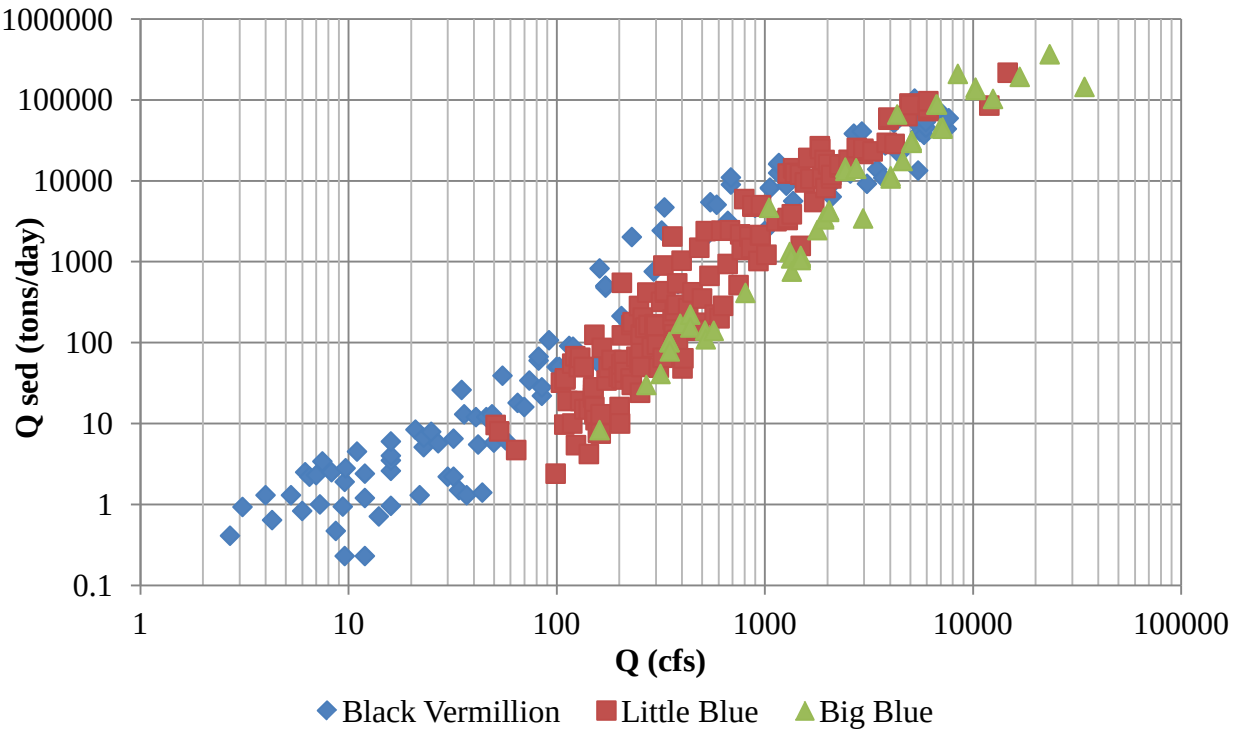

Figure 4. Suspended Sediment Loads on Three Major Rivers Flowing into Tuttle Creek Lake

Boundary load gradations were inferred from detailed gradation data collected by USGS from 2008 – 2010 (Juracek 2011). As seen in Figure 5, the sediment size composition on the Big Blue River and Little Blue River depend on the flow rate, while the Black Vermillion River load gradations are independent of flow. In Figure 5, solid lines represent gradations developed from measurements, while dashed lines represent extrapolation included for modeling purposes.

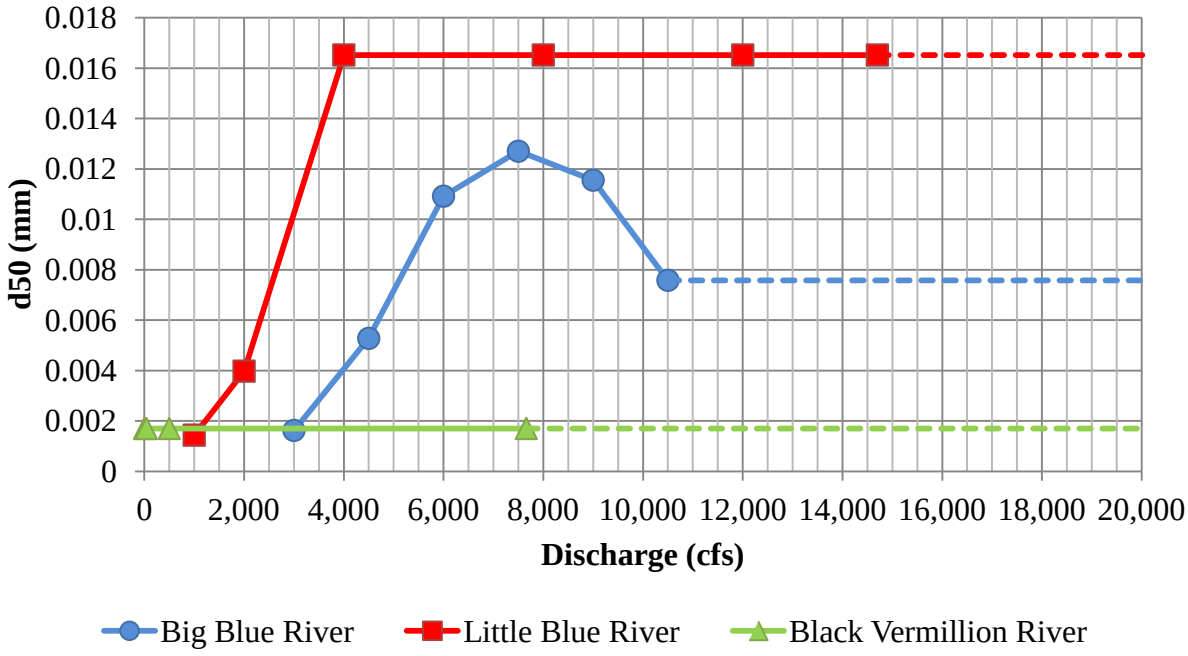

Figure 5. Suspended Sediment Median Grain Size (D50) on Major Tuttle Creek Tributaries.

NEW HEC-RAS FEATURES

UNSTEADY SEDIMENT

HEC-RAS 4.1 included a quasi-unsteady flow model for use in sediment modeling, simulating hydrodynamics with a series of steady flows. This simplification adequately describes many hydraulic systems because sediment-response time scales are so much longer than hydraulic-response time scales. However, reservoir scenarios are inherently unsteady, requiring explicit volume tracking and mass conservation to simulate system behavior. HEC-RAS 5.0 integrates sediment transport features with the unsteady flow module. This not conserves volume by coupling sediment transport with the Saint-Venant equations, but also makes a suite of reservoir modeling tools native to the unsteady flow modeling environment available in the context of sediment transport simulations.

RULES FOR CALIBRATION OF UNGAGED FLOW

HEC-RAS 4.1 included the RULES editor, a simple scripting language for building operational procedures for reservoir gates in unsteady flow. With the inclusion of sediment modeling in the unsteady flow environment, the RULES scripting language is available for reservoir sediment models (Gibson and Boyd, 2014). In this model, custom RULES allowed the solution to a

hydraulic calibration challenge. Inflow from the three gaged tributaries systematically summed to less than the recorded flow downstream of the reservoir, suggesting ungaged inflow contributions. However, reservoir storage effects prevented a straight-forward calculation of the daily ungaged inflows. Rather, custom code in the rules editor computed the daily series of ungaged inflows based on historic daily reservoir stages.

PROOF-OF-CONCEPT SEDIMENT MODEL

Sediment transport was added to the unsteady flow model for the calibration period (20 July 2000 to 14 September 2009). As a proof-of-concept, loads and gradations were significantly adjusted to approximate total volume and longitudinal distribution of reservoir deposits (Gibson and Pridal, 2015). Figures 6 and 7 plot model and measured values for the local and longitudinally-summed cumulative volume of bed change. These results will change as hydraulics and operations are refined. As seen in Figures 6 and 7, HEC-RAS 5.0 can model sediment transport during complicated unsteady reservoir operations and can approximate historic sedimentation.

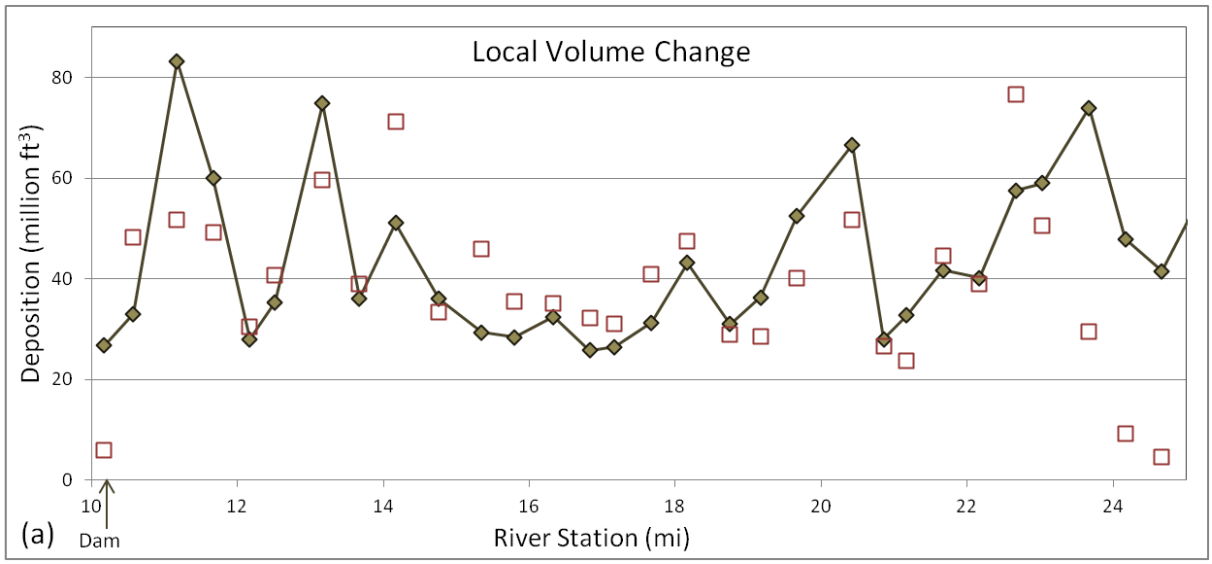

Figure 6. Model results compared to measured local deposition volume change from July 20, 2000 to Sept 14, 2009

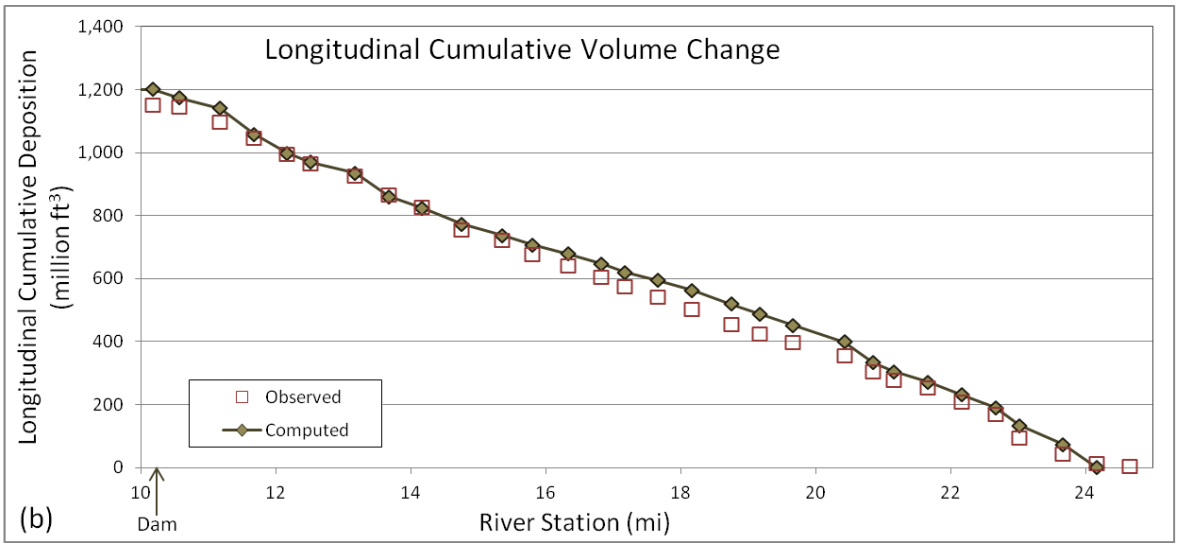

Figure 7. Model results compared to measured to longitudinal cumulative (summed from upstream to downstream) deposition volume change from July 20, 2000 to Sept 14, 2009

The addition of sediment to the stable unsteady flow model introduced numerous model instabilities, which required additional troubleshooting. The sediment model required a smaller time step, interpolated cross sections, and other stabilizing measures to run, which translated to longer run times. However, once the model achieved stability, the unsteady hydrodynamics and operational rules provided computational fidelity and alternative flexibility beyond what is possible in a quasi-unsteady approach.

CONCLUSION/NEXT STEPS

This paper described the initial development of a one-dimensional HEC-RAS 5.0 mobile-bed model for modeling and predicting sediment accumulation in Tuttle Creek Lake. This model utilizes new features in HEC-RAS 5.0 including Unsteady Sediment and new features in the RULES editor. Additional measures to ensure model stability were required beyond those necessary to produce a stable hydraulic model. As of this writing, calibration is in the early stages and all results are preliminary. This model demonstrates the utility of HEC-RAS 5.0 for sedimentation analysis of large reservoirs. Future work will quantify the reduction in sediment accumulation possible at Tuttle Creek Lake through changes to reservoir operational procedures.

DEVELOPING A SEDIMENT MANAGEMENT PLAN FOR PAONIA RESERVOIR

Kent Collins, Hydraulic Engineer, Bureau of Reclamation, Denver, Colorado, kcollins@usbr.gov,
Sean Kimbrel, Hydraulic Engineer, Bureau of Reclamation, Denver, Colorado, skimbrel@usbr.gov

INTRODUCTION/BACKGROUND

Paonia Dam and Reservoir are located on Muddy Creek, a tributary of the North Fork Gunnison River in western Colorado (Figure 1). Based on the most recent bathymetric survey of the entire reservoir, conducted in June 2013, the estimated average annual rate of sedimentation has been 101 acre-feet per year (Collins, 2014). Since dam closure in 1962, nearly 25% of the reservoir's original 20,950 acre-foot capacity has been lost to sediment deposition. At that rate the reservoir would be completely filled with sediment in another 150 years, gradually reducing the available pool over time. Long before sediment levels reach the full pool elevation however, reservoir intakes and outlet works are affected, adversely impacting project operations. In 2010, the outlet works became plugged with sediment and debris, emphasizing the urgency of formulating an effective sediment management plan for the impending deposition problem.

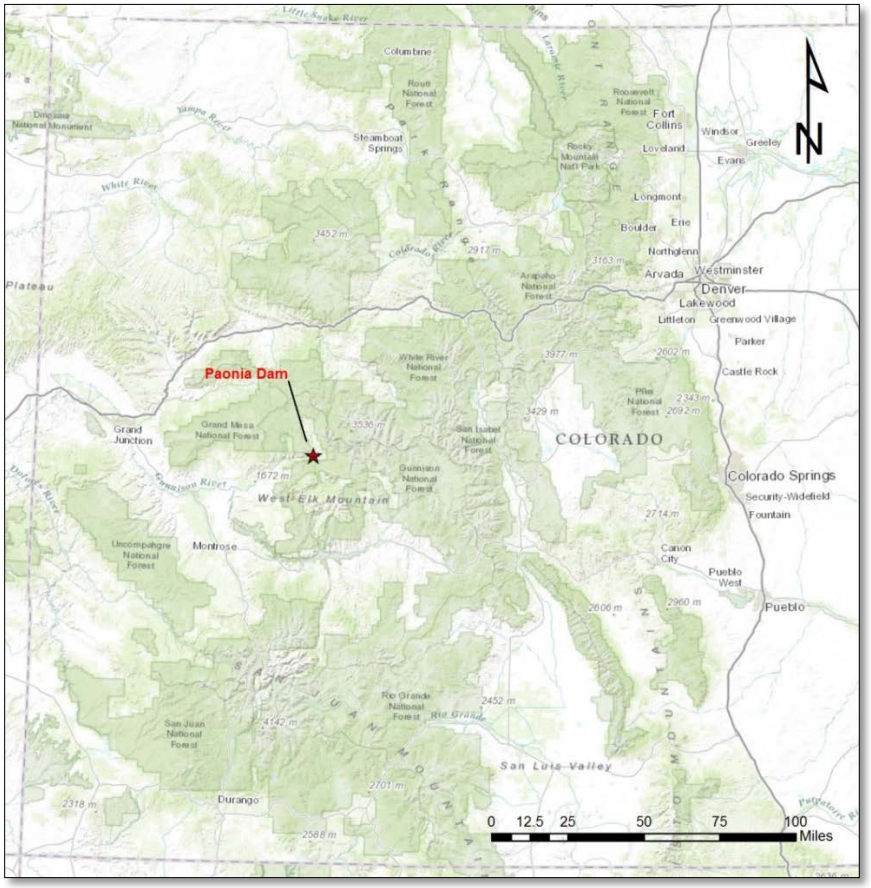

Figure 1 Paonia Dam and Reservoir on Colorado's western slope approximately 150 miles southwest of Denver

Although occasional sediment flushing was performed as early as 1997, starting in 2010-2011, annual operations were changed to include keeping the reservoir low and flushing sediment through the outlet works in early spring before filling the pool for irrigation (Denison, 2015). Until fall 2014 the flushing strategy through the long, narrow reservoir (pool is approximately 3 miles long and 0.2 miles wide) successfully maintained the outlet works, preventing them from becoming plugged. Reservoir drawdown in late-October revealed the reservoir dead pool had completely filled with sediment and the outlet works were plugged with cohesive sediment and submerged debris. Due to the recent discovery of accelerated sediment deposition rates, the original study objectives of developing a long-term plan to manage inflowing and deposited sediment more efficiently were altered to include short-term strategies for water delivery during the upcoming 2015 irrigation season.

Figure 2 Sediment deposition at Paonia Reservoir outlet works intake tower, October 2014

The Sedimentation and River Hydraulics Group of Reclamation's Technical Service Center in Denver, Colorado is leading an effort to study the past and current sediment issues at Paonia Dam and Reservoir, evaluate feasible sediment management alternatives, and formulate a plan for future operations and monitoring. The original study was built on historical and recently collected data, and the existing knowledge base to develop a comprehensive, sustainable sediment management plan. The initial study plan was executed in three phases:

- **Phase 1** consisted of an initial site visit to map and sample existing reservoir bottom sediments, a preliminary site evaluation upstream and downstream of the dam, establishment of time-lapse photo sites, and taking initial ground-based photos. Pebble counts were collected in Muddy Creek upstream of the reservoir and ground surveys were conducted for a limited distance upstream of the reservoir and downstream of the dam;
- **Phase 2** included a bathymetric survey of the entire underwater portion of Paonia Reservoir (June 2013) and 7 miles of the river downstream of the dam (May 2013), and collection of underwater core samples of reservoir bottom sediments. The bathymetric survey was used to generate a current area-capacity relationship for the reservoir and establish a baseline for comparing future data and other monitoring tasks; and
- **Phase 3** involved the evaluation of current and past operations and sediment management practices, investigation of feasible sediment management methods, focusing on those best suited for Paonia Dam and Reservoir, and providing recommendations for future sediment management operations and project monitoring. Survey and sediment data collected during previous phases were used to construct a one-dimensional mobile bed model to numerically simulate sediment transport for evaluating past, present, and potential future sediment management options.

The 2014 sediment deposition occurred during the execution of Phase 3 of the original study plan. Phase 3 analyses and tasks were modified to accommodate the new information. A reconnaissance visit/visual site inspection and GPS topographic survey were performed in November 2014. The new topography data was used for determining the additional volume of sediment and for numerical model calibration and validation. The immediate focus of the numerical model changed from simulating typical hydrographs for evaluation of long-term sediment management operations to mimicking likely spring runoff scenarios and dam operations for formulating potential short-term water delivery solutions. Once a short-term fix is identified and implemented, the numerical modeling efforts will be redirected towards the formulation and evaluation of possible long-term sediment management solutions.

2014 SEDIMENT DEPOSITION ISSUES

Beginning in 2011, Paonia Reservoir has been drawn down each year in late fall for outlet inspection, then again in early spring for sediment flushing prior to irrigation season. Reservoir drawdown in October 2014 revealed approximately 10 feet of sediment had deposited at the intake tower since June 2013, raising the lake bottom 6 feet above the sill of the outlet works (Figure 3). The June 2013 bathymetric survey measured the reservoir bottom elevation 4 feet below the outlet works sill. Figure 3 shows the steady loss of storage capacity along with the consistent increase in reservoir bed elevation at the outlet works (Western Engineers, Inc., 2006). While effective for flushing sediment through the dam outlet, yearly drawdown of the reservoir likely increased deposition rates in the dead pool.

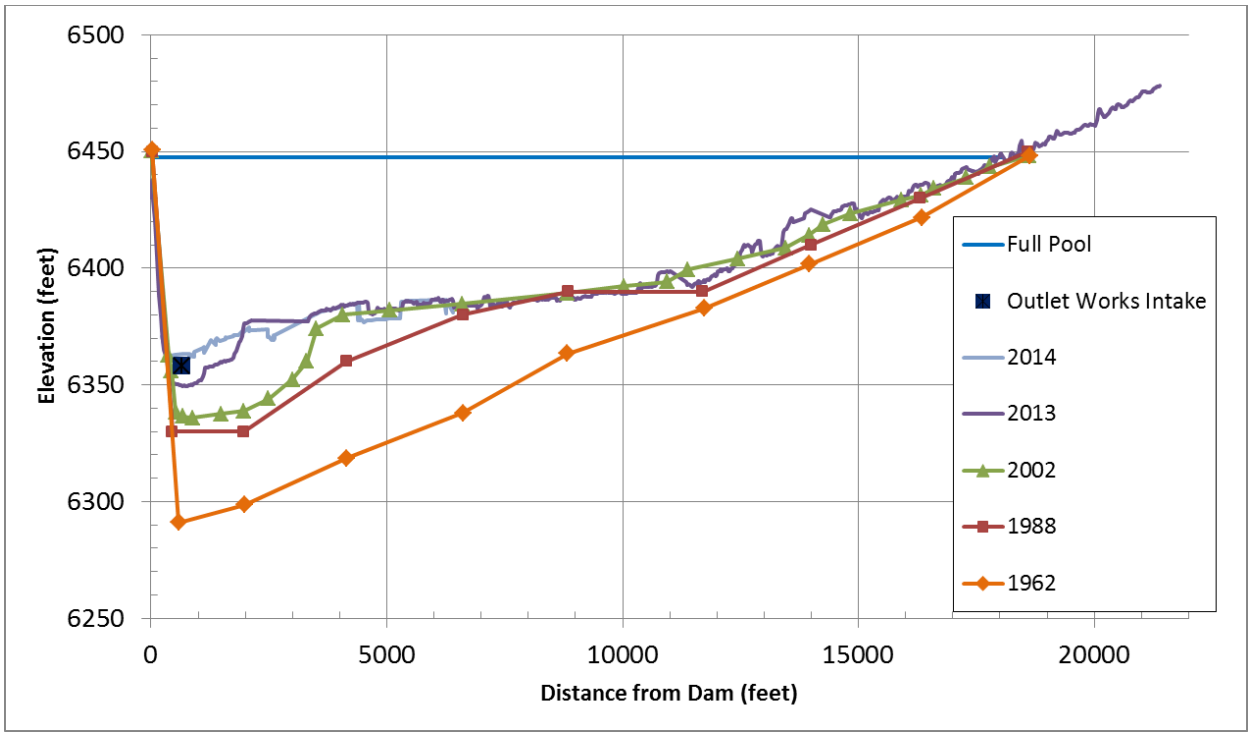

Figure 3 Paonia Reservoir survey profiles since dam closure in 1962

In 2014, increased sediment inflows resulting from high spring runoff caused the delta front to migrate more than 1,200 feet downstream towards the dam, over-filling the dead pool and partially burying the outlet works intake tower (Figure 4). Fire Mountain Canal Company and Northern Water Conservancy District crews immediately began 10-hour daily shifts removing the sediment and debris around the inlet tower using a long-reach excavator while clearing the trash racks by hand (Figures 5 and 6). Even at low flows, constant excavation and clearing were required to maintain an open outlet. Each morning when maintenance crews returned to the site, submerged debris and fine, cohesive sediments had blocked the intake tower trash racks as much as 6 feet above the sill elevation, backing water upstream.

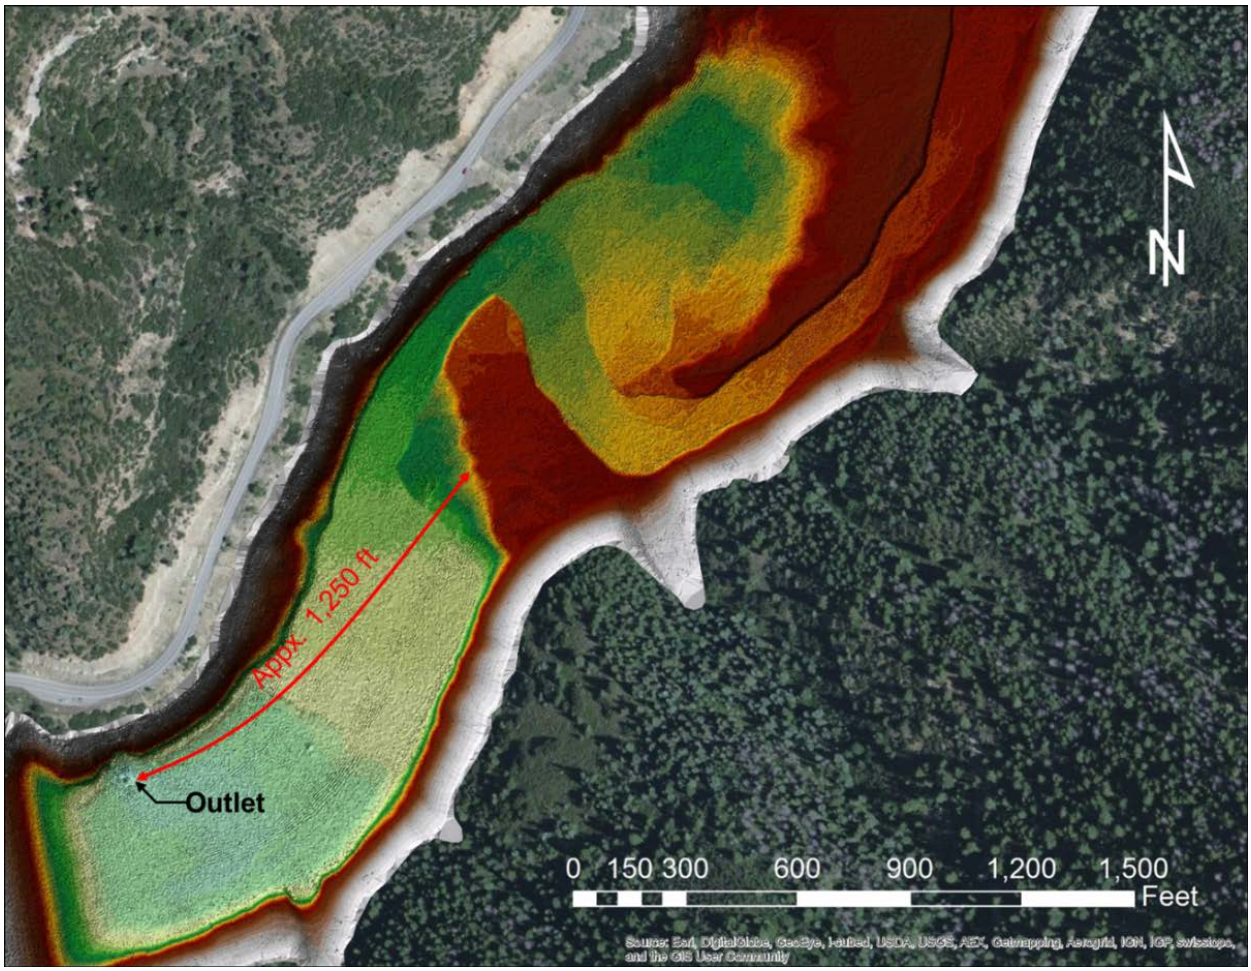

Figure 4. Plan view map of lower Paonia Reservoir showing the delta front in June 2013 and the migration distance required to partially bury the intake tower of the outlet works

Figure 5 Long-reach excavator removing sediment and debris from intake tower at Paonia Reservoir, November 2014

Figure 6 Manual clearing of intake tower trash racks to maintain open outlet works at Paonia Reservoir, November 2014

Manual clearing of debris and sediment around the outlet works occurred for over two weeks until sediment levels near the outlet works intake remained at or near sill level overnight and until ice began forming in the low flow channel near the tower. The outlet works high pressure gates were then closed and the water surface elevation of the reservoir returned to normal winter operation levels, several feet above the top of the intake tower, to avoid any issues with ice.

FUTURE SEDIMENT MANAGEMENT ENDEAVORS

For Spring 2015 dam operations, and for the future of Paonia Reservoir, several short- and long-term reservoir sediment management options are currently being investigated:

- Proposed Short-Term Management Analyses/Options:
    - Debris Management
    - Minimum Pool Level to Force Deposition at Upstream Delta
    - Temporary Siphon System to Maintain Irrigation Releases
- Proposed Long-Term Management Analyses/Options:
    - Outlet Works Modification/Replacement for Sediment Sluicing
    - Sediment Sluicing Efficiency with Numerical Sediment Transport Modeling
- Analyses of Downstream Impacts (e.g. Fisheries, Infrastructure)
- **GOAL**: **Sustainable Management of Reservoir Sediments**

Abstract: The Pueblo de Cochiti (Pueblo), in cooperation with the U.S. Army Corps of Engineers, Albuquerque District (USACE-SPA), conducted a program of studies, known as the Cochiti Baseline Study, to define existing and historical environmental conditions of the Cochiti Dam and Lake located on tribal lands of the Pueblo de Cochiti, New Mexico. These included numerical sediment transport modeling of the Rio Grande upstream and downstream of Cochiti Dam completed by WEST Consultants. The purpose of this study was to better understand the impacts of reservoir sedimentation on the sediment processes in the study reach over time, to provide a tool to better manage the project within the Tribe's resource objectives and to help evaluate potential sedimentation effects on Tribal resources that could result from possible future changes in dam operations.

Cochiti Dam, closed in 1973, was constructed primarily for flood control and sediment retention. The dam traps sediment, reducing the suspended sediment loads downstream between 87% and 98%, and has created a lacustrine delta in the reservoir headwaters. The reach below Cochiti Dam responded to dam closure in typical ways including: thalweg degradation, bed armoring, and channel narrowing. The study reach is a highly complex system from a sediment transport perspective due to the two primary sediment inflows: the Rio Grande contributing primarily coarse-grained, non-cohesive sediment to Cochiti Lake, and the Rio Chama contributing primarily fine-grained, cohesive sediment.

This study applied the mobile-bed module of the USACE Hydrologic Engineering Center's River Analysis System (HEC-RAS) software to model sediment erosion, entrainment, transport, and deposition processes of cohesive and non-cohesive sediments. Cohesive sediment erosion/deposition parameters were estimated based on measured responses of samples collected in the lacustrine deposits in Cochiti Lake. Sample responses were measured using the Engineering Research Development Center's SEDflume mobile laboratory (erosion rates) and the Particle Imaging Camera System (PICS) developed by Smith and Friedrichs (settling properties). The numerical model utilized a volumetric limiter on the continuity routing for sediment deposition in the reservoir. Working with HEC and USACE-SPA, WEST developed a well-calibrated HEC-RAS model considering the system's complex cohesive aggregation processes. This base conditions model replicated the deltaic profile evolution spatially and temporally. The calibrated model was robust to wide ranges of sediment input parameters. Finally, this calibrated model was used to predict prototype response to a limited range of

representative theoretical future reservoir operation scenarios and to qualitatively assess long-term reservoir sustainability associated with these scenarios.

This effort determined that, while sediment could be redistributed higher in the reservoir and upstream canyon using increased pool elevations, operational constraints imposed by the dam infrastructure (e.g., minimum pool elevation) will make it difficult to pass significant sediment downstream with drawdown scenarios. The model predicted virtually no change in the downstream virtual river reach in response to the reservoir scenario modeling. These models are being used to help assess sustainability in a responsible and proactive manner. The models support the evaluation of a wider range of future operation scenarios by the Pueblo and USACE-SPA, within a virtual environment, thereby avoiding harmful effects to the actual environment, and permitting evaluation of (fully-reversible) impacts from alternative mitigation strategies.

INTRODUCTION

The Pueblo de Cochiti (Pueblo), in cooperation with the U.S. Army Corps of Engineers, Albuquerque District (USACE-SPA), conducted the Cochiti Baseline Assessment, a series of studies to define the existing and historical environmental conditions of the area surrounding Cochiti Dam and Lake on and near the Pueblo de Cochiti Reservation, New Mexico. The purposes of these studies were two-fold: first, to define existing conditions of the system, and second, to investigate and characterize impacts that have occurred to resources on Pueblo de Cochiti lands from operation and maintenance of Cochiti Dam and Lake. This information is being used to evaluate the potential effects on Tribal resources resulting from possible future changes in operations at Cochiti Dam and Lake. One of the studies within the Cochiti Baseline Assessment was a sediment modeling study of the Rio Grande upstream and downstream of the dam and reservoir, which is documented in this paper. Cochiti Dam, which began operation in 1973, was constructed primarily for flood control and sediment retention; many secondary uses exist for this reservoir as well, such as recreation.

Worldwide, the rate at which reservoir storage volume was added outpaced population growth from 1950 through about 1980. The rate of dam construction began to decrease in the 1980s, as it has continued to do to this day (Annandale, 2013). Even with increasingly efficient use of water resources, for an increasing world population to continue to beneficially utilize a much slower-growing amount of storage, the need to sustainably manage reservoir storage is paramount. The impact of reservoir sedimentation further complicates this need, as do the uncertainties imposed by climate change.

Morris and Fan (1998) summarized reservoir sustainability into three key parameters: water quantity, quality, and diversity. Sustainable use maintains all three of these parameters at a level equal to or higher than current conditions (or historic conditions, considering the system in question). All three of these issues have been impacted in the Rio Grande due to the closure of Cochiti Dam. As Morris and Fan (1998) point out,

> *Reservoirs also require unique natural components (dam sites having appropriate topography, hydrology, geology) and engineered components (dam, delivery canals, etc.). Replacement of the engineered components has no purpose if the storage volume is lost to sediment accumulation… A number of factors indicate that reservoirs should be*

> *considered as irreplaceable resources, no less important than [groundwater] aquifers, and should be designed and operated in accordance with the objective of sustained long-term utilization.*

These principles can readily be applied to the case study of Cochiti Dam. Drought and water scarcity issues of the western United States are often highlighted in popular media (*e.g.*, Bryan, 2014). Population growth, increasing dependence on irrigated agriculture, climate variability, and others factors threaten water quantity, in this region and worldwide (Morris and Fan, 1998). Dam closure already impacted water quality in the Rio Grande and impacted critical habitat of some endangered species with less turbid, cooler water being released from the reservoir. Changes in bed substrate particle size distribution and channel geometries downstream of the dam have also impacted aquatic and riparian habitat (USACE, 2007). Finally, the dam impacted both ecological and cultural diversity (Sallenave et al., 2010). Therefore, stakeholders must reach a consensus on future sustainable use of this reservoir. This definition may not be a fixed target, but a moving one. For example, if a continued future drought were to threaten downstream water supplies, would the impacted stakeholders possibly repurpose Cochiti Reservoir for water supply use? Annandale (2013) points out that prudent water resource planning should consider the ways that climate change might affect water supply reliability and sustainability. While water supply was not an objective in the design and construction of Cochiti Dam, its primary flood control purpose shares the requirement of excess water storage capacity with that of water supply projects. How might the sediment that depletes this available storage capacity be more effectively managed to preserve or prolong the useful benefits of the project while lessening impacts to the surrounding environment? Questions like these lie at the heart of reservoir sustainability, and the problems facing each new generation for sustainable water resources can only be solved through continuing study and communication of issues that arise.

Due to these concepts of sustainable use and oftentimes conflicting definitions of sustainability for different stakeholders, governmental agencies and other private entities have studied sedimentation problems along the Rio Grande for several decades. Several of these studies proposed projects to reduce bed aggradation while maintaining water quality, quantity, and diversity for downstream use. Channel modifications, levees, and dams were constructed to reduce flooding in Albuquerque and other areas, control sediment concentrations in the river, and increase sediment transport capacity.

Cochiti Dam reduces peak flows in the Rio Grande River below the dam to less than 10,000 cfs compared to common peak flows greater than 10,000 at the Otowi gage (the nearest gage upstream of the dam) and some flows in excess of 20,000 cfs throughout the period of record. The dam reduces the suspended sediment loading in the flows downstream of the dam between 87% and 98% (USACE, 2007; Novak, 2006). MEI (2002) estimated that Cochiti Dam traps approximately 1,100 acre-feet of sediment annually, releasing clear water with very low sediment concentrations, subjecting the downstream reach of the Rio Grande to highly erodible flows. As a result, there has been significant thalweg degradation downstream of the dam as well as some slight channel narrowing. The median bed sediment sizes have increased from an average of 0.1 mm in 1962 to an average of 24 mm in 1998 (Novak, 2006), armoring the bed downstream of the dam. Dam effects diminish downstream because of tributary sediment delivery and in-channel sources of sediment.

The purpose of this study for the Pueblo was to analyze present and historic geomorphic processes of Cochiti Lake and the Rio Grande River in the reservoir influence area with emphasis on landforms, erosion, sediment transport, and deposition. This study analyzed historical and new landscape-scale topographic, geomorphic, and sediment data, and developed two sediment transport models. Modeling objectives included:

- Identify past and current geologic and geomorphic conditions of the Rio Grande River channel and floodplain in the Cochiti Lake influence area;
- Assess sediment erosion, transport, deposition, and routing into, through, and downstream of Cochiti Lake; and
- Evaluate the influence on sediment mobilization, transport, and deposition for select reservoir operations scenarios to better understand prototype behavior.

The sediment transport models provided to the Pueblo and USACE-SPA were a tool for assessing long-term reservoir sustainability, especially in the event that alternative dam operations are proposed. This study explicitly considered water quantity impacts of reservoir storage losses to reservoir sedimentation. The models assessed changes in location and magnitude of erosion and deposition upstream and downstream of the dam. The models also support future ecological and human health risk assessments (water quality), and diversity analyses. This paper will focus on reservoir sustainability considerations in light of water quantity issues.

A model was developed for each of the two study areas: from below the Otowi gage to Cochiti Dam, and from below Cochiti Dam to Angostura Diversion Dam (located just upstream of the confluence of the Jemez River with the Rio Grande). WEST analyzed topographic, geomorphic, and sediment data, built the sediment transport models, and ran the models for the various proposed operational scenarios.

STUDY SITE

The Rio Grande River drains approximately 11,695 square miles above Cochiti Dam including portions of northern New Mexico and southern Colorado. The Rio Grande River enters the Cochiti Reservoir just downstream of White Rock Canyon, which has a slope of 10 ft/mile. Cochiti Dam is the upper limit of the "Middle Rio Grande Valley." This reach of the Rio Grande stretches from Cochiti Dam to the Elephant Butte Reservoir approximately 190 miles downstream. In the portion of the study reach below Cochiti Dam, the Rio Grande has cut an alluvial valley in the semiarid desert 100 to 300 feet deep and 1 and 3 miles wide. The elevation of the study reach drops from approximately 5,480 feet (NGVD 1929) at the thalweg of the Rio Grande near Otowi Bridge to approximately 5,100 feet (NGVD 1929) near the crest of the Angostura Diversion Dam, approximately 20 miles downstream of Cochiti Dam.

Important tributaries that feed the Rio Grande near the study reach include (from upstream to downstream) the Rio Chama, Santa Cruz River, and Santa Fe River above Cochiti Dam; and the Galisteo Creek and Jemez River below Cochiti Dam. Several smaller streams also feed the Rio Grande within the study reach. Although the water supply from these tributaries do not typically deliver most of the total volume of water transported in the study reach, these tributaries can provide major sources of water and sediment during certain hydrologic conditions.

GEOMORPHIC ASSESSMENT OF THE STUDY REACH

Two primary factors affect the geomorphology and sediment conditions of the upper study reach (i.e., above Cochiti Dam): the geologic control of White Rock Canyon and the water level in Cochiti Lake. Horizontal restrictions imposed by the canyon limit the Rio Grande planform in this reach. It cannot migrate laterally more than a few hundred feet at any location (i.e., approximately 2-3 times the typical top width of the river flow). The meander paths are constantly shifting and adjusting locally in the lateral direction (i.e., bend growth or bend decay) and longitudinally (i.e., down-valley migration) in response to hydrologic and sediment loading, but the general river path is confined to a meander band defined by the canyon walls.

The upstream sediment loads contain substantial fine materials. The main stem of the Rio Grande usually delivers mostly coarse-grained sediment (i.e., >62.5 μm), while the Rio Chama load can be dominated by fine-grained sediment (i.e., ≤62.5 μm). The load diversity generates alluvial "stratigraphy," alternating "layers" of coarse and fine sediment deposited along the banks of the Rio Grande and in the reservoir delta depending on the primary sediment source during the event represented. The material along the river subsequently erodes through bank failure and mass wasting processes delivering highly graded (poorly sorted) non-cohesive suspended sediment and bedload including fine sands to boulders.

The geomorphology and planform of the study reach shift to a much more depositional system above Cochiti Dam, immediately below the confluence of the Frijoles Canyon Creek and the Rio Grande River, because of the effects of the reservoir backwater. In 1992, the thalweg elevation near Frijoles Canyon Creek was 5,359.8 feet NGVD29. During the period from 1975-1996, the reservoir exceeded 5,350 feet NGVD29 several times (primarily between 1985 and 1988). Therefore, backwater frequently affects the area downstream of Frijoles Canyon and influences the geomorphic transition in this reach. This backwater effect created a significant headwater delta in the reservoir (see Figure 1).

Many studies and reports have characterized the geomorphology of the Middle Rio Grande downstream of Cochiti Dam and upstream of Angostura Diversion Dam (Novak, 2006; Sixta, 2004; Porter and Massong, 2004; MEI, 2002; Richard, 2001; Leon, 1998). These reports generally identify two primary geomorphic changes occurring in this reach as a response to the closure of Cochiti Dam: (1) streambed degradation throughout this reach and the bed armoring; and (2) a change in planform of the river from a braided, flat-bottom river in the early 1900's to a single-thread, meandering, deeper river. Additionally, most of these reports conclude that this reach is approaching a state of dynamic equilibrium. The rate of vertical (i.e., bed elevation) or horizontal (i.e., lateral migration, stream narrowing, and avulsion) change has reduced significantly since the period immediately following dam closure and are not expected to increase significantly in the near future. Anthropomorphic modifications have also reduced the rate of vertical and lateral erosion. The channel has been armored to mitigate stream bed degradation, and 115,000 Kellner jetty jacks were installed in the overbanks of the Middle Rio Grande between 1954 and 1962 (Grassel, 2002) to address lateral migration.

NUMERICAL SEDIMENT TRANSPORT MODELING

Calibrated fixed-bed hydraulic models built in HEC-RAS were used to develop HEC-RAS sediment transport models (USACE, 2011). Fixed-bed hydraulic model development followed standard procedures including: spatially georeferenced cross sections derived from digital elevation data, downstream reach lengths, bank stations, Manning's roughness coefficients, and ineffective flow areas. Each of these items was determined with the requisite engineering judgment and standard of practice. While the development of an accurate fixed-bed hydraulic model is an essential pre-requisite developing a mobile-bed sediment transport model (HEC, 1993; Thomas and Chang, 2008), this paper will focus on sediment transport modeling, methods and results.

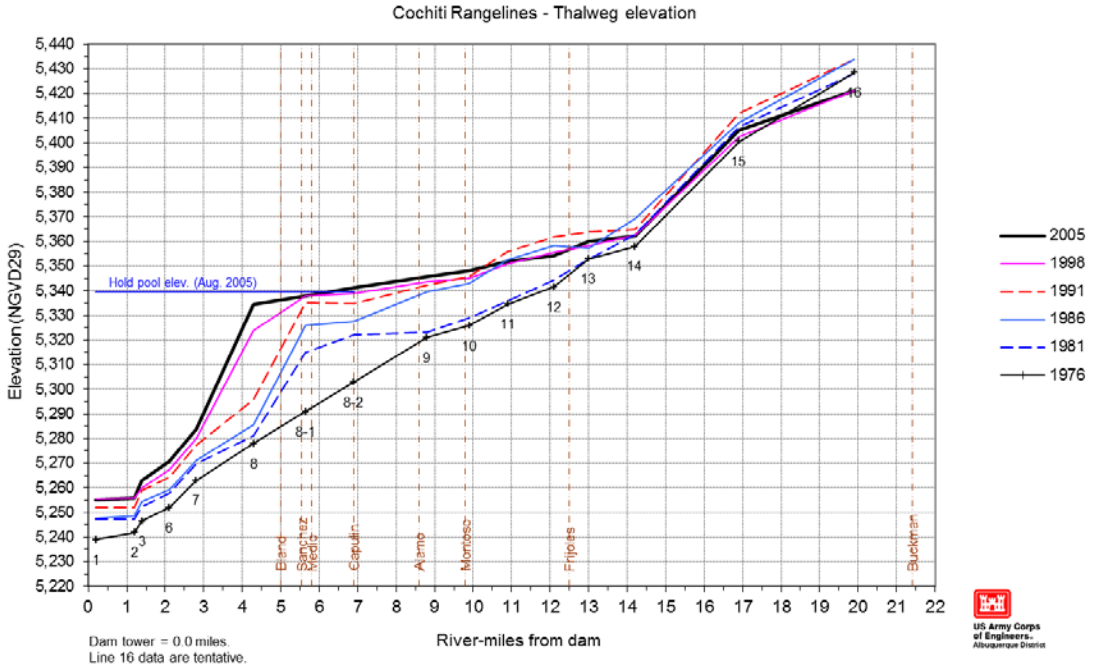

Figure 1. Growth of Cochiti Reservoir headwater delta based on Range Line surveys provided by USACE-SPA for survey years 1976, 1981, 1986, 1991, 1998, and 2005.

The base condition sediment transport models required input data (e.g., inflowing sediment loads, bed sediment gradations, suspended sediment gradations, and cohesive sediment parameters); calibration and verification. The different hydraulic and sediment conditions of the study reach upstream and downstream of Cochiti Dam, and the limitations of the quasi-unsteady hydrodynamic model in HEC-RAS when this study was conducted, the two reaches were modeled and discussed separately.

The base condition sediment transport models upstream and downstream of the dam included hydrology from shortly after dam closure in 1975 to present. The average bed elevation, (ABE) for each cross section at the end of each calibration period was compared to the average bed elevation of the measured cross section at the end of the same calibration period. Adjustments were made to the base conditions model such that the computed ABEs would reasonably

approximate the measured ones. Upstream of the dam, these adjustments included primarily changes to calibrated gradations and volumes of inflowing sediment load. Downstream of the dam, these adjustments included primarily changes to calibrated bed sediment gradations. Once the base conditions models were calibrated and verified, they were executed to predict future conditions for operational evaluation scenarios, as described in the next section.

The sediment transport module in HEC-RAS (USACE, 2011; Gibson et al., 2006) is a one-dimensional, movable boundary, open channel flow model designed to simulate stream bed profile changes over fairly long time periods. One dimensional sediment modeling can be very effective in reservoir scenarios, but there are some limitations inherent to the 1D framework. For example, it cannot simulate meander development or compute a lateral distribution of sediment load across a cross section. Finally, sediment transport results are strongly dependent on which transport function is selected and whether it was developed for the range of hydraulic conditions and sediment grain sizes representative of the study reach. It is paramount that an experienced modeler assesses the model results in light of these limitations.

Sediment Transport Model Upstream of Cochiti Dam: The quasi-unsteady flow model used for sediment transport in HEC-RAS 4.1 (the version available at the time of this study) approximates a hydrograph with a series of steady flows. Mean daily flow at the Otowi USGS Gage (USGS Gage ID 08313000) and mean daily water surface elevation at Cochiti Dam were provided by the USACE-SPA for the calibration period from 1975-2009 for the model upstream of Cochiti Dam. A maximum computational time step of one half of an hour was used for the computations. The hydrology used in the model consisted of a condensed record of mean daily flow values for the Rio Grande River at Otowi Bridge for flows greater than 1,000 cfs.

The Rio Grande River is the major sediment source, delivering most of the inflowing sediment to the study reach upstream of Cochiti Dam. Sediment loads from tributaries upstream of Cochiti Dam and downstream of the Otowi Gage are minor. The upstream load (inflowing sediment load and gradation from the Rio Grande) was developed from a combination bedload from the Española Sediment Transport Study (MEI, 2009) and the suspended sediment load data collected by the USGS. The D50 was approximately 0.07 millimeters indicating that inflowing load included both coarse-grained, non-cohesive sediment and fine-grained, cohesive sediment.

Sediment loads from tributaries upstream of Cochiti Dam were estimated based on the report completed by Resources Technology, Inc. (1994) for the USACE-SPA. This report developed regression equations for sediment loading based on drainage area. An additional correction based on a later study (Tetra Tech, 2005) was also applied to this methodology.

WEST used several bed sediment gradations collected by the USGS at gages in the study reach, including the Rio Grande at Otowi Bridge and the Rio Grande near White Rock, to define model bed gradations. The D50 of these samples were generally between 0.5 and 1.0 millimeter. Also, the USACE Engineering Research and Development Center (ERDC) collected core samples in the reservoir for this study. The D50 were all in the fine-grained, cohesive soils range (i.e., particle diameters less than 62.5 micrometers). ERDC also performed SEDFLUME analyses to parameterize the shear threshold, erosion rate, mass wasting threshold, and mass wasting rate for the Krone (1962) and Parthenaides (1962) algorithms used for cohesive sediment deposition and

erosion, respectively, in HEC-RAS. The τ_c of these samples varied from 0.79 Pa (1.65×10^{-2} lb/ft^2) to 0.12 Pa (2.51×10^{-3} lb/ft^2) and the erodibilities from 5.88×10^{-2} kg/m^2/sec (43.4 lb/ft^2/hr) to 3.78×10^{-3} kg/m^2/sec (2.8 lb/ft^2/hr), generally increasing with depth, but also influenced by the stratigraphy, alternating fine and coarse lenses from localized events in the main source tributaries.

A sediment transport function was selected based on a comparison of hydraulic and sediment parameters in the study reach with the range of data used to develop the transport functions. Copeland's (1989) modification of Laursen's (1958) relationship was used for this reach due to the significant contribution of fine sediments to the inflowing load. The model also limited sediment velocity to the water velocity to compute fine sediment deposition based on realistic residence times, which the Exner equation underpredicts without physical limiters.

WEST calibrated the model to twenty-three years (1975-1998) of bed change. After completing the calibration, a verification run was performed from 1998 to 2005 to demonstrate that the selected algorithms and parameters were robust. The results of the final verification run after model calibration are included in Figure 2. Additionally, the model replicated downstream bed fining (approaching the dam) (Figure 3). Corresponding sensitivity analyses were performed on this data to determine the sensitivity of the results to the variation in modeling parameters including sediment transport function, Manning's roughness, cohesive parameters, and others.

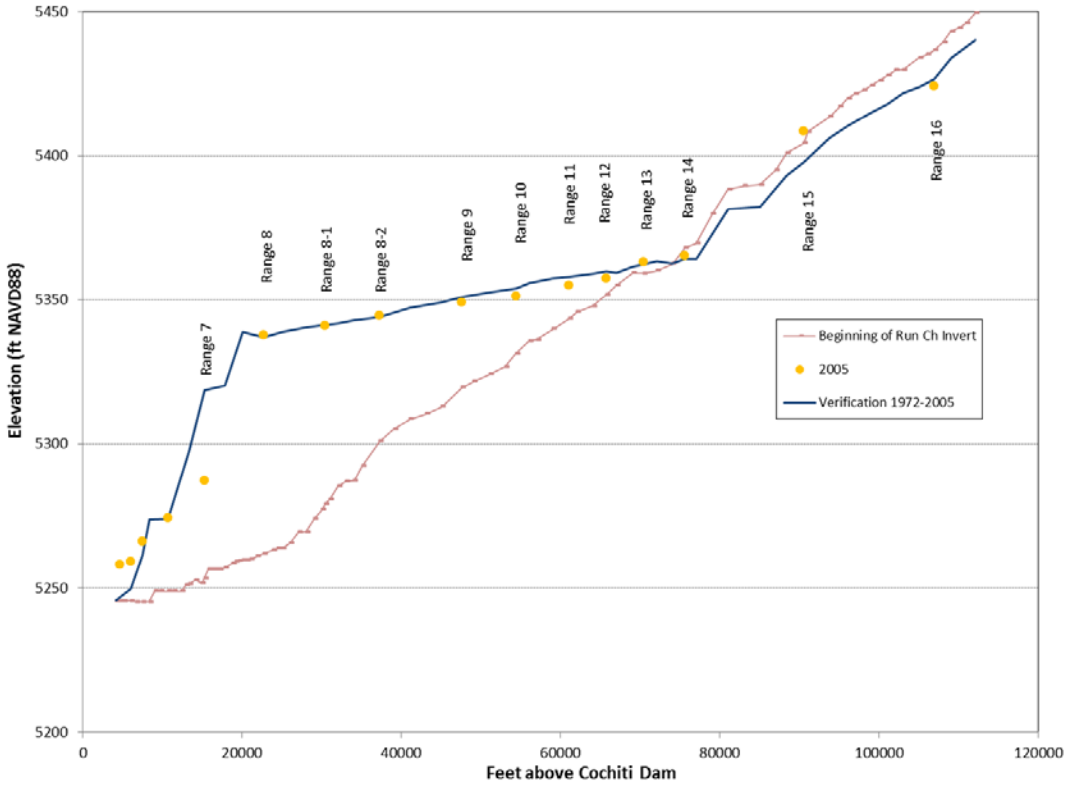

Figure 2. Bed profile results from the calibrated HEC-RAS model for the verification period (1975 – 2005) compared to measured data (points) in 2005.

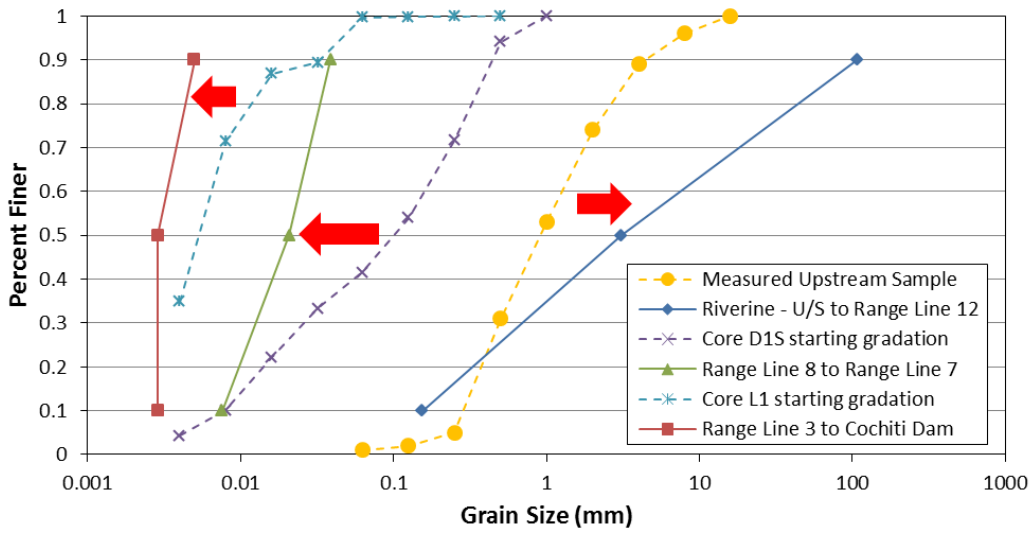

Figure 3. Reach-averaged bed gradation results from the calibrated HEC-RAS model for the verification period (1975-2005) shown in solid lines compared to the initial conditions data used in the sediment transport model shown in dashed lines; arrows indicate the direction of coarsening or fining of the bed.

Sediment Transport Model Downstream of Cochiti Dam: Mean daily flow at the USGS Gage below Cochiti Dam (USGS Gage ID 08317400) and a normal depth downstream boundary condition at Angostura Diversion Dam were used for the calibration and verification period from 1975-2009 for the model downstream of Cochiti Dam. A maximum time step of 0.5 hours was used as the computational time step with a condensed record of mean daily flow values for the Rio Grande River below Cochiti Dam for flows greater than 1,000 cfs.

Unlike the study reach above Cochiti Dam, the Rio Grande does not supply a significant source of sediment to the study reach below Cochiti Dam due to the trapping efficiency of the dam itself. Therefore, the primary sediment sources to the reach downstream of the dam are the local tributaries: Peralta Canyon, Borrego Canyon, Galisteo Creek, Arroyo de la Vega de los Tanos, Arroyo Tonque, and others. Sediment loads from tributaries downstream of Cochiti Dam were estimated based on the report completed by Resources Technology, Inc. (1994) for the USACE-SPA. This report developed regression equations for sediment loading based on drainage area. An additional correction based on a later study (Tetra Tech, 2005) was also applied to this methodology. Gradations for the tributary inflowing sediment loads were derived from sampling routines and estimates from these two studies.

Bed gradations downstream of Cochiti Dam were based on samples collected by the USGS at gaging stations in the study reach, including Rio Grande below Cochiti Dam and the Rio Grande at San Felipe. The D50 of these samples before dam closure were between 0.5 and 1.0 millimeter. Time series sampling at these locations showed bed coarsening over time, increasing the D50 at these locations by more than an order of magnitude. The final calibrated HEC-RAS sediment transport model reflected this bed coarsening over time.

A sediment transport function was selected based on a comparison of hydraulic and sediment parameters in the study reach with the range of data used to develop the individual sediment

transport functions available in HEC-RAS. Yang's equation (1973, 1984) was used for this reach due to the inclusion of both sands and gravels in the transported sediment load.

The model was run for a period of twenty-three years (1975-1998) as a calibration period. After completing the calibration, a verification run was performed from 1998 to 2009 to verify the modeling output, and results matched closely with observed values. Sensitivity analyses were performed for this model as well.

OPERATIONAL EVALUATION SCENARIO MODELING

This study also evaluated the influence of reservoir operation scenarios on sediment mobilization, transport, and deposition to evaluate scenarios outside of normal operations, providing a tool to assess conceptual alternate dam operations. The models can assess the relative location and magnitude of erosion and deposition upstream and downstream of the dam for operational alternatives evaluation, and support future ecological and human health risk assessments. It should be noted that this study only developed modeling tools for future operational alternative evaluations; no approved operational alternatives were developed herein.

USACE-SPA and WEST engineers computed reservoir boundary conditions (elevations and outflows) to model the three possible operational evaluation scenarios in the HEC-RAS quasi-unsteady flow model. These three operational alternatives were then implemented in the numerical sediment transport models, beginning with the final conditions of the calibrated base conditions model and run into the run into the future for 50 additional years.

Under current operations, the only permanent storage in Cochiti Reservoir is the 1,200-acre surface area pool that is used for recreation. During non-flood flows, the lake must be kept at a constant elevation to maintain this surface area requirement. There is no sediment management strategy based on the congressional authorization of this dam (USACE, 1996).

The first scenario increased reservoir elevations, raising the operational elevation approximately 50 feet (5,340 to 5,390 feet NGVD29). This scenario stored water for other possible uses (e.g., water supply for irrigation, additional recreational uses, etc.) recruiting sediment deposition further upstream in the reservoir headwater.

The second scenario drew the reservoir pool down for extended periods to erode the large headwater reservoir delta. The alternative was constrained by a minimum drawdown elevation of 5,322 feet NGVD29 to avoid unfavorable conditions at the reservoir outlet intake. However, the model was "stressed" to the operational constraints, dropping the reservoir level to 5,323 feet NGVD29 for the whole drawdown to evaluate the maximum possible response to this operational technique.

The third scenario lowered the reservoir seasonally (in the winter) to 5,323 feet NGVD29, then refilled the reservoir to the current operating elevation of 5,340 feet NGVD29 in the summer. The model drew down the reservoir gradually at the end of the Middle Rio Grande Valley irrigation season, to an elevation of 5,323 feet NGVD29, and the reservoir level stayed at this lowered pool for one month. The reservoir was then refilled in the spring back to an elevation of

5,340 feet NGVD29. This operation was designed to flush sediment from the reservoir and maximize the benefit of bypassing inflowing sediment load through the reservoir, while maintaining the standard pool for summer recreation. The cycle was repeated annually for the entire 50-year simulation period.

Results of the three scenarios compared to continuing normal operations in the reservoir for 50 years into the figure are included in Figure 4. The model did not compute significant sediment transported through the reservoir because of the physical characteristics of the reservoir itself and infrastructure limitations prohibiting further drawdown at this time. It did, however, indicate significant influence on the upstream deposition distribution was possible.

DISCUSSION

This paper attempts to answer questions regarding reservoir sustainability in terms of water storage capacity. In terms of usable reservoir life, defined by Morris and Fan (1998) as "*the period during which the reservoir may be operated for either its original or a modified purpose*," Cochiti Dam appears to be able to meet its originally intended purpose and a broad range of modified purposes for at least the next 50 years despite reservoir sedimentation.

The design philosophy when Cochiti Dam was conceived was based on an implied consideration of reservoir storage as an exhaustible resource. Annandale (2013) presents a convincing argument for the consideration of reservoir storage as a potentially sustainable resource. Because of the economics of dam construction, most prime sites for reservoir storage creation have largely been exhausted, with only less desirable and more-costly locations remaining. Thus, adding more reservoir capacity becomes more costly, and the need to preserve existing storage becomes more important in the hierarchy of approaches. Couple this with the uncertainties of watershed sedimentation from climate change, and the capacity issue becomes more complex. Understanding the sedimentation behavior of the project becomes an important planning and management tool in this respect.

The final calibrated sediment transport models also provide tools for the Pueblo and the USACE-SPA to further assess water quality and diversity issues in the study reach towards holistic reservoir sustainability analyses. Unsteady sediment transport in HEC-RAS 5.0, released after this work was complete, simplified the process of defining future operational alternatives for reservoir sediment management (Gibson and Boyd, 2014, Shelley et al., 2015), which will make additional alternative evaluation easier.

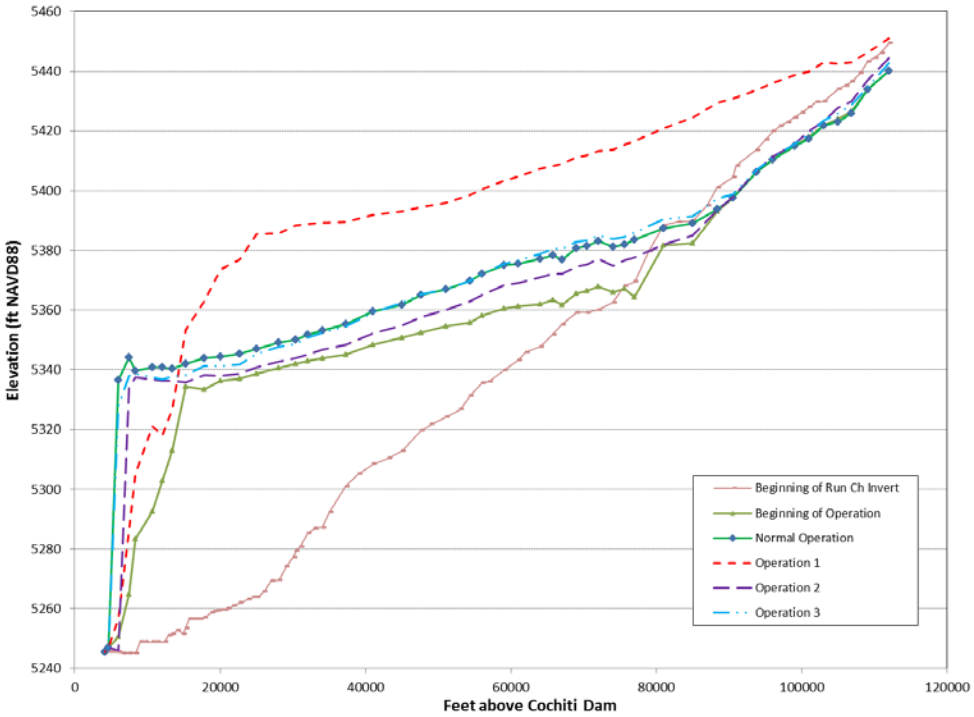

Figure 4. Bed profile results from various operational evaluation scenario HEC-RAS sediment transport models for the 50 year simulation window (2010-2059).

Limitations of this study include density current effects that probably affect Cochiti Reservoir (i.e. a "muddy lake effect" appears in range line profile plots) and remobilization of compacted alternating "layers" of cohesive and non-cohesive sediments in a lacustrine headwater delta, which will be explicitly modeled with future versions of HEC-RAS. The implications of climate change, and the associated response of watershed soils and vegetation, were also excluded from the current study, but are planned for future studies. As our knowledge improves regarding changes that might affect sediment supply to reservoirs, the ability to model and test reservoir responses will become more important. Sustainable solutions to reservoir sedimentation issues require a strong toolbox of continuously updating knowledge and information. In the case of Cochiti Reservoir, as in many other reservoirs, we must tackle the problem one step at a time.

Abstract: The Mississippi River and Tributaries (MR&T) Project is a comprehensive water resources project for flood damage reduction and navigation improvement on the Mississippi River. MR&T elements include levees, floodways, diversion structures, tributary basin improvements, and channel improvements such as meander cutoffs, bank stabilization, dikes and dredging. Understanding how these elements, combined with natural factors, such as floods and droughts, impact the historical, current, and future river morphology is a complex challenge for those tasked with managing the Mississippi River for floods, navigation, environmental restoration, and coastal wetland loss.

Mississippi River potamology (the science of rivers) studies advance understanding of how natural and man-made factors combine to impact river morphology regarding present and future flood damage reduction, navigation, environmental restoration, and coastal wetland projects. The US Army Corps of Engineers (USACE) has conducted numerous potamology studies dating from the 1800s to modern times. Major studies were often the result of floods and follow-on beneficial projects. The epic 1927 flood fostered the first official USACE *Potamology Investigations* that resulted in more than 70 reports. The 1973 flood drove additional USACE potamology studies (T-1 and P-1 reports). However, funding, staffing, and interest in potamology studies waned, becoming almost nonexistent in recent times. Lessons learned and projects implemented from USACE's 1940s–1980s potamology studies helped pass the record-setting 2011 flows. The 2011 Mississippi River flood renewed interest in potamology, resulting in the creation of the USACE Mississippi Valley Division's (MVD) new Mississippi River Geomorphology and Potamology (MRG&P) Program. The first report of the MRG&P was a review of the Lower Mississippi River Potamology Program, including a comprehensive bibliography of potamology reports (Biedenharn et al., 2014). This paper provides a short review of USACE Mississippi River potamology studies.

INTRODUCTION

The Mississippi River and Tributaries (MR&T) Project is a complex, comprehensive water resources project, that provides flood control within the alluvial valley and navigation improvement of the Lower Mississippi River (LMR). The LMR extends from Cairo, IL, to the Gulf of Mexico, a distance of almost 1000 miles. The primary elements of the MR&T Project include levees, floodways and diversion structures, tributary basin improvements and channel improvement features such as meander cutoffs, bank stabilization, dikes, and dredging. The historical, present-day, and future morphology of the LMR reflects an integration of all these

features combined with natural factors such as floods and droughts, hurricanes, tectonic activity, geologic outcrops, climatic variability, and sea level rise. Understanding how these various factors affect the short- and long- term morphology of the LMR is a complex challenge for the river engineers and scientists responsible for managing this system for flood control, navigation, habitat restoration and reducing the loss of coastal marshes and wetlands in Louisiana. Much of the knowledge about the morphologic character of the LMR was gained through the U.S. Army Corps of Engineers (USACE) Potamology Program, which began in the early 1930s in recognition of the need to develop a better understanding of the underlying principles responsible for the behavior of the river.

HISTORICAL POTAMOLOGY PROGRAM

The word "potamology" has its root in the Greek word "potamas" and is defined as the scientific study of rivers or the science of rivers. Over the years, the focus of the program evolved as new demands and challenges arose. However, by the early to mid- 1980s, the program basically ceased to exist. In this section, the history of the Potamology Program is described.

Pre-Potamology Studies. The Mississippi River is the third largest river system in the world; it is the largest navigable river system in the world; and it is an incredible economic engine and economic advantage for the United States. Industry and agriculture depend on its transportation infrastructure; it is a source of water and recreation for millions of citizens; it is a vital ecosystem and environmental treasure. And at times, it can show the brute force of nature through devastating floods. The Mississippi River was used throughout history by Native Americans for transportation. The first river structures were levees constructed by European settlers above New Orleans in the early 1700s.

The U.S. Army Corps of Topographic Engineers became involved early on in river operations - there are discharge records of the river dating back to 1817. Other information documents were produced through the 1800s, including the seminal "Physics and Hydraulics of the Mississippi River" report by Capt. A.A. Humphreys and Lt. H.L. Abbot, which is considered as the "*beginning"* of hydraulic engineering on the river (Humphreys and Abott, 1861). At the time, it was also widely considered as the "*final*" report on river engineering. Since then, the Mississippi River has shown that any potamology or river engineering studies should only be considered "*interim*" as the river is constantly changing, forcing USACE efforts to advance understanding and knowledge of river processes. A comprehensive discussion of the management and engineering philosophy during this early period is presented in Elliott (1932).

The beginning of official USACE potamology studies is directly tied to the decision by Mississippi River Commission (MRC) president Brig. Gen. Harley B. Ferguson in the early 1930s to implement a cutoff program on the Mississippi River. These initial efforts focused on the study of the alluvial processes and their application to the management of the river system. The first MRC studies were conducted at the U.S. Army Engineer Waterways Experiment Station (WES) during the period of 1932-1935. These studies focused on determining the most favorable alignment to stabilize the Mississippi River in connection with the initiation of the cutoff program.

Subsequent studies examined bed materials in the system, materials in transport, and meandering of alluvial channels. This work included model studies and field sampling and surveys. The efforts were conducted in the late 1930s to the mid-1940s.

MRC Potamology Investigations. The first official MRC "Potamology Investigations" were initiated in the fall of 1946. These were the most extensive and comprehensive such studies conducted at the time. The program examined meandering tendencies to develop modeling for future river projects, the causes of revetment failures to prevent future occurrences, means of channel stabilization other than revetment, and development and testing of comprehensive plans to improve specific troublesome river reaches.

The majority of the early investigations were conducted by WES (which was under MRC control until 1949) with field assistance by the USACE Memphis, Vicksburg, and New Orleans Districts. The work included extensive field observations at several points on the Mississippi River, large-scale laboratory projects, soils studies, and instrumentation development and evaluation.

The MRC Potamology Board was established in 1957 that consisted of representatives from the MRC; the Memphis, Vicksburg and New Orleans Districts; and WES. It was active until 1961 and helped foster completion of additional potamology investigations. The Board was re-established in 1963 and expanded to include the entire Lower Mississippi Valley Division; a representative from the St. Louis District was added to the Board. In 1963, the MRC also established a Potamology Research Branch in the Engineering Division to coordinate studies recommended by the Potamology Board. The Board and the Branch were instrumental in completing several investigations. Over the next two decades, the Board and Branch were active, but over time and reorganizations, they had ceased to be active functioning elements by the mid- to late- 1970s. The USACE Committee on Channel Stabilization, established by the Chief of Engineers in 1962, was also instrumental in completing several studies impacting Mississippi River channel problems in the 1960s to early 1970s.

Potamology Early Years. Over the course of the mid-to-late-1900s, potamology studies and programs evolved to meet new demands and challenges. In the 1930s and 1940s the focus was on man-made cutoffs and their impact on the channel system. The spotlight moved to revetment failures and improved revetment construction and materials from the late 1940s to the early 1960s. From the 1960s to 1972, the focus shifted yet again as the MRC worked to develop the best ways to manage troublesome reaches of the river. Research and investigative studies were spawned by these activities, providing much needed information that advanced the understanding of the complex processes that nature and man-made structures combined to shape the river and how the river adjusted over time.

Crisis situations focus attention on problems. On the Mississippi River, the 1927 flood was such an event. The 1927 flood not only was the catalyst for the MR&T, it also drove efforts such as cutoffs and channel stabilization. Funding was made available to advance potamology knowledge as a result. The potamology studies of the 1930s through the late 1960s were accomplished due to this investment and the efforts of dedicated staff.

As with any crisis situation, knowledge and training prior to the event help provide the best response. Such was the case in 1927 when decades of preliminary work and research led to the

MR&T – the policy, direction, and framework in this landmark legislation were not developed overnight. The same can be said for potamology studies over the years. These studies provided USACE knowledge and also a generation of expert staff with the engineering expertise needed to help manage the river.

As is human nature, once we experienced a "comfortable" period in river conditions (fewer major floods and somewhat stable average flows), many leaders believed that our understanding of river behavior was sufficient for the current state. As such, interest, and more importantly, funding in potamology related studies waned.

1973 Flood & T-1/P-1. The 1973 Mississippi River flood was a "wake up" call for river science and engineering. The spring flood produced river stages that were higher (up to approximately 5 feet higher in some locations) than expected. These higher stages made it apparent that the stage-discharge relationships were several feet higher than the previous stage-discharge relationships used to establish levee grades and other flood control features. Therefore, the potential existed for a significant reduction in the flood capacity over a major portion of the LMR. To help address this critical issue, the President of the MRC - Division Engineer, LMVD implemented two new potamology study programs.

The "LMVD Potamology Study (T-1)" was initiated on August 7, 1974. This study was basically a data assembly effort that provided a current "snapshot" of conditions and information that focused on the nine major factors that impact river behavior. Each factor was covered by a separate T-1 Work Package:

Work Package 1 – Review of the Cutoff Program

Work Package 2 – Inventory of Revetment and Dike Systems

Work Package 3 – Geological Inventory

Work Package 4 – Hydrology Factors

Work Package 5 – Hydraulic Factors

Work Package 6 – Inventory of Physical Characteristics

Work Package 7 - Inventory of Levees

Work Package 8 - Inventory of Dredging Activities

Work Package 9 - Inventory of Sediment Data

Work packages 1 and 5 were conducted by the USACE Vicksburg District; 2, 3, 4, 6, and 7 were done by the University of Missouri at Rolla for the USACE St. Louis District; 8 was compiled by the USACE Memphis District; and 9 was completed by WES for the USACE New Orleans District. This effort assembled a large mass of data to feed follow-on studies to determine primary cause and effect relationships related to the Mississippi River.

Building off the T-1 work packages, the LMVD Potamology Program (P-1) was developed. The P-1 Program focused on defining the cause-and-effect relationships that resulted in short- and

long-term changes in the stage-discharge relationships in the LMR and developing improved design concepts and construction criteria for channel stabilization. The program continued the advancement of the level of knowledge and understanding of the Mississippi River behavior, allowing USACE to develop the most efficient and cost effective flood risk reduction and navigation channel possible.

This program also expanded the USACE view of potamology with investigations of four major parameters: hydrology (highly variable stages), sedimentation (sediments on or near the channel bed scoured from one location and deposited downstream), channel geometry (variable alignment impacting flow and sediment transport), and man-made modifications (levees, cutoffs, revetments, and dikes).

In the mid-1990s, the USACE Mississippi Division (MVD) formed the River Engineering Study Team (REST) in an effort to revitalize potamology studies. The REST consisted of river engineers and scientists from the division and district offices. The first meetings of the REST occurred on board the *MV Mississippi* during the May 1995 Channel Improvement trip. The purpose of the REST was to recommend, set priorities, plan, direct, and publish results from river engineering investigations on the LMR, with an aim towards developing an understanding of the short- and long term cause and effect relationships between the observed channel morphology and the channel improvement features. The REST proposed four broad study areas: (1) analysis of hydraulic slope and vertical adjustments; (2) channel geometry studies; (3) sediment studies; and (4) short- and long term numerical modeling of channel morphology. Each of these study areas would consist of a number of individual sub-areas. Unfortunately, only a few REST studies were initiated, and within a few years, the REST team disbanded.

Although the REST no longer existed, the USACE districts did continue to conduct river engineering studies, generally aimed at specific troublesome reaches of the river. In 1995, the St Louis District Hydraulics Branch established the Applied River Engineering Center (AREC) with the aim to conduct applied river engineering studies on the Mississippi River in an office/laboratory environment. A key component of the AREC is the Hydraulic Sediment Response (HSR) model, which is a small-scale, physical sediment transport model used to replicate the mechanics of an actual river on an area the size of a normal table top. Since its conception, numerous river engineering studies have been conducted on the Mississippi.

Historical Potamology Data and Unpublished Reports. As discussed above, the publication of technical reports was a major accomplishment of the Potamology Program. However, perhaps equally important is the vast amount of historical data and unpublished studies that were conducted as part of the program. Typical types of data that were collected included detailed hydrographic surveys, sediment sampling (both suspended and bed material), velocity and current direction measurements, boring data, divided flow data, bed form data, geologic information, water surface slopes, and geomorphic assessments. Unfortunately, some of this information has already been lost, and most of the data and studies exist only in hard copy form in somewhat obscure locations in various offices and archive areas at the USACE district and division offices. This is a massive set of data that represents an extremely valuable resource, which not only provides an historical perspective of the river, but more importantly, could be used to inform present-day efforts to understand the river system. One goal of the MRG&P is to gather and organize this historical data so that it will be of use for future studies.

FUTURE CONSIDERATIONS

The record setting 2011 Mississippi River flood again stirred interest in potamology related studies. This time interest was not driven by problems or failures; it was how successful the system safely passed the record flows of this epic event. Just as the 1973 flood was a wakeup call, the 2011 flood should be an equally important benchmark for us to understand the reasons for the difference in river response to the two floods. The lessons learned from the potamology studies of the late 1940s to the 1980s, and implemented in the river since the 1973 flood, worked fantastically when put to the ultimate test. But USACE realized it had basically lost a generation of continued potamology advancement along with the experienced staff with that important knowledge.

While Mississippi River flood damage reduction and navigation issues continue to be a major emphasis of USACE activities, especially on the lower river, there are new demands, interests, and economic focus areas championed by the public, river users, and stakeholders in the vitality of this national asset. Environmental restoration, conservation, recreation, coastal land loss and erosion, water quality and supply (surface and aquifer) and other basin-wide and localized issues are requiring attention in today's society.

Environmental factors, such as habitat development, fisheries enhancement, recreation, threatened and endangered species, invasive species, water quality, etc. are all now major considerations in USACE site specific projects and system-wide management strategies. Many new, and probably future, Mississippi River studies are being funded and driven based on environmental challenges.

In the last several decades, there has been an increased environmental activity concerning habitat development related to USACE dikes in the river. Notches have been installed on the bankside of dikes to increase habitat development that have provided additional recreational opportunities as well. During the MRC Low Water Inspection stop in Vicksburg, Miss., on August 21, 2013, the President of the MRC conducted a ceremonial signing of MVD/ERDC report "Conservation Plan for the Interior Least Tern, Pallid Sturgeon, and Fat Pocketbook Mussel in the Lower Mississippi River," with representatives of the U.S. Fish and Wildlife Service (USF&WS) and ERDC (Killgore et al., 2014). Besides featuring amazing interagency cooperation between USACE and USF&WS, the report featured a major potamology/geomorphology element.

The USACE has also lost a generation of experienced staff with potamology skills and expertise. This is due to various impacts including hiring reductions, funding constraints, and changes in mission focus. This staff expertise cannot be imported overnight, but must be fostered and grown by hiring and supporting capable engineers and scientists, providing training and mentoring, supporting intra- and interagency cooperation, and other innovative practices. There should always be a cadre of skilled professionals to pass corporate knowledge and ideas to those following, and also to those leading as well. A revitalized Potamology Program will keep USACE staff immersed, and interested, in understanding the morphologic processes that drive the important Mississippi River system.

This effort will have both short-term (less than 20 years) and long-term (20 to 200 years) implications and emphasis. Some river projects could use potamology knowledge

implementation today. On the other hand, the river is still responding to the cutoffs initiated 75+ years ago. Decisions made and implemented in the near future could have positive (or adverse) impacts for centuries. The re-establishment of a "Potamology" type program for the Mississippi River is needed to ensure incorporation of the best science and management practices from an engineering and environmental perspective for the complex and diverse demands of the 21st century and beyond.

GRAVEL DEPOSITS ON LOWER MISSISSIPPI RIVER SANDBARS

Richie McComas, **Hydraulic Engineer, USACE Vicksburg District, Vicksburg, MS, Richie.McComas@usace.army.mil; C. Fred Pinkard Jr., Hydraulic Engineer, USACE, Vicksburg District, Vicksburg, MS, Freddie.Pinkard@usace.army.mil;**

Abstract: The Mississippi River is known for its large sandbars that appear on the inside of bends during times of low stage. These sandbars on the lower Mississippi River are predominantly a medium to fine grained sand. The flood of 2011 and the drought of 2012 showed near record stages on both ends of the staff gage. Gravel deposits were observed on sandbars throughout the lower Mississippi during the low water inspections in the summer of 2012. These gravel deposits are not normally seen on the lower Mississippi River.

In the summer of 2012 gravel was identified on several sandbars during waterborne and aerial inspections. The distributions of gravel deposits were not consistent along the length or width of the river. Deposits also seemed randomly placed on each sandbar. A sampling plan was under development when the stage of the Mississippi River started to rise rapidly. Samples were taken from five sandbars with observed gravel near Vicksburg, MS before the deposits were covered with water; three above and two below the Yazoo River confluence. Several stations were sampled at each sandbar. Wolman pebble counts were done at sandbars with large gravel and grab samples were taken at multiple depths for lab analysis.

Gravel deposits on the lower Mississippi River are of interest for environmental and engineering reasons. If the gravel beds are an armoring layer and always part of the sandbar, then they could possibly be fish spawning spots. Gravel armoring a sandbar is an important process to know when calculating sediment transport rates and for calibration of sediment models. This paper will look at the location, distribution, and size of the gravel beds along the U.S. Army Corps of Engineers, Vicksburg District's section of the Mississippi River. A hypothesis of the transport mode (flood of 2011 or bar armoring) and the source of the gravel will be discussed.

SEDIMENT AND CARBON SEQUESTRATION IN THE LOWER ATCHAFALAYA BASIN, LOUISIANA

EXTENDED ABSTRACT

Cliff R. Hupp, Research Botanist, U.S. Geological Survey, Reston, Virginia, crhupp@usgs.gov; Daniel E. Kroes, Research Ecologist, U.S. Geological Survey, Baton Rouge, Louisiana, dkroes@usgs.gov; Edward R. Schenk, Research Ecologist, U.S. Geological Survey, Reston, Virginia, eschenk@usgs.gov; and Gregory B. Noe, Research Ecologist, U.S. Geological Survey, Reston, Virginia, gnoe@usgs.gov

Background: Sediment and organic material sequestration are important ecosystem functions of forested bottomlands along river systems. This is particularly true along Coastal Plain streams in the southeastern United States as they approach tide dominated estuaries (Hupp, 2000; Ensign et al., 2014). Floodplains along these low gradient systems are among the last places for significant trapping and storage of sediment and associated material, including carbon rich organic material, before they reach highly valued, ecologically and economically critical estuarine systems (Hupp, 2000).

The Atchafalaya River Basin (a distributary of the Mississippi River, Fig. 1) contains the largest relatively intact, functioning riparian area in the lower Mississippi Valley. Approximately 25% of the Mississippi River (drainage area about 3,200,000 km^2) and all of the Red River (drainage area about 233,000 km^2) flows through the Basin on an annual basis. The entire suspended- and bed-sediment load of the Red River and as much as 35% of the suspended and 60% of the bed sediment load of the Mississippi River (Mossa and Roberts, 1990) are now diverted through the Atchafalaya Basin. As a result, the Basin experiences exceptionally high sedimentation rates at sites with high connectivity to the main river (Hupp et al., 2008).

Recent studies have shown that temperate coastal lowlands may be an important sink for carbon (Ludwig, 2001; Raymond and Bauer, 2001; Noe and Hupp, 2005; 2009; Bridgham et al., 2006; Aufdenkampe et al., 2011) and associated nutrients (Hupp et al., 2008; Noe and Hupp, 2009), which may be stored in these systems as organic rich sediment. Initial results (Hupp et al., 2008) suggest that the central Atchafalaya Basin may conservatively trap 6.7 Tg of sediment annually (approximately 15% of total load entering the Basin), of which over 820,000 Mg are organic material. The temperate lowland trapping function or global service has largely been untested and ignored by many models of global carbon flux (Battin et al., 2008; 2009). Studies of lowland fluvial systems such as the Atchafalaya Basin may be critical towards our understanding of global carbon cycling, which in turn has direct implications for nutrient processing and global climate change. Following initial sediment trapping studies by Hupp et al. (2008), we began a spatially expanded (Fig. 1), ongoing study with the objectives to quantify sediment trapping in range of environments including areas of high deposition rates, which may subsequently allow for quantitative estimates of annual carbon sequestration in the Atchafalaya Basin.

Approach: Sediment deposition rates, in both studies, are determined using artificial markers, feldspar clay pads at stations along transects positioned near waterways/bayous. These pads were/are measured annually for deposit thickness above the clay. We monitored 20 transects located in the central part of the Basin in the 2008 study (Fig. 1). We established an additional 16 transects in the lower (downstream) part of the Basin in 2010 (Fig. 1). Like the earlier study,

transects are located in a range of depositional environments from sites where new land is accreting in previously open river water (exceptionally high deposition rates) to areas identified as potentially low depositional, hypoxic backswamps with poor connectivity to sediment laden river water. Deposition rates were converted to sediment mass trapping rates using bulk density information from sediment samples collected along the transects. Additionally, the samples were analyzed for loss on ignition (LOI) to determine organic content. In the ongoing study, samples are analyzed for carbon, nitrogen, and phosphorus content, including the determination of the amount of carbon isotopes and ratios ^{12}C: ^{13}C and ^{13}C: N to infer general carbon sources.

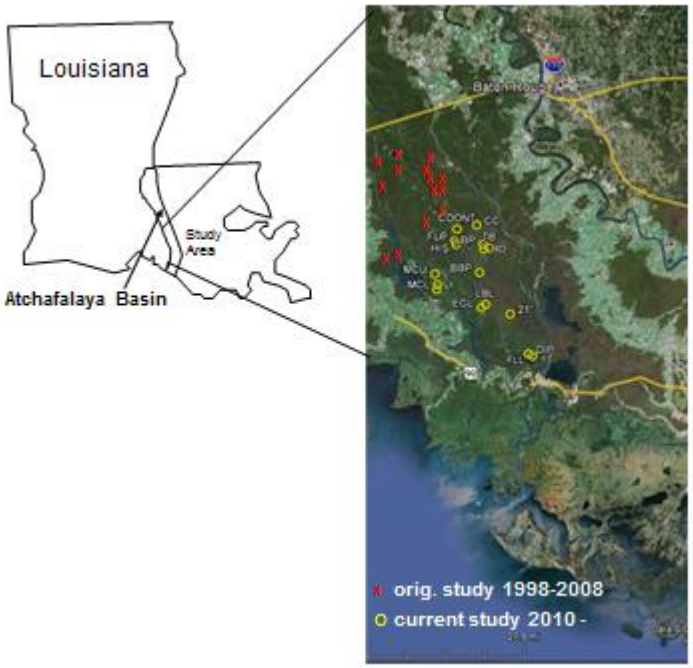

Figure 1 Location of study area in Louisiana. Transect locations in the central (red x's) and southern Atchafalaya Basin (yellow circles) for original and current studies, respectively, are shown.

Sediment and Carbon Trapping: The Atchafalaya Basin traps substantial amounts of suspended sediment annually; many areas have some of the highest documented sedimentation rates in forested wetlands of the United States (Hupp, 2000; Aust et al., 2012). Mean sedimentation rates ranged from about 2 to 40 mm y^{-1} in the central part of the Basin (Fig. 2A). Highest sedimentation rates occur in low elevations that receive sediment-laden water (high connectivity) from two or more sources, which may create slow velocities through hydraulic damming (D, E, and F transects, Fig 2A, Hupp et al., 2008). Mean sedimentation rates ranged from about 7 to greater than 150 mm y^{-1} in the actively aggrading lower part of the Basin (Fig. 2B). The highest sedimentation rates in this area are associated with island building in the main waterways and areas that receive water heavily laden with sediment from nearby channel cuts/canals and other hydrologic diversions (LI, HIS, and FLP, Fig. 2B). Low sedimentation rates throughout the Basin may occur on high levees or on low backswamps, both where there is little connection to river water because of high elevation or stagnant, sediment-depleted flow, respectively.

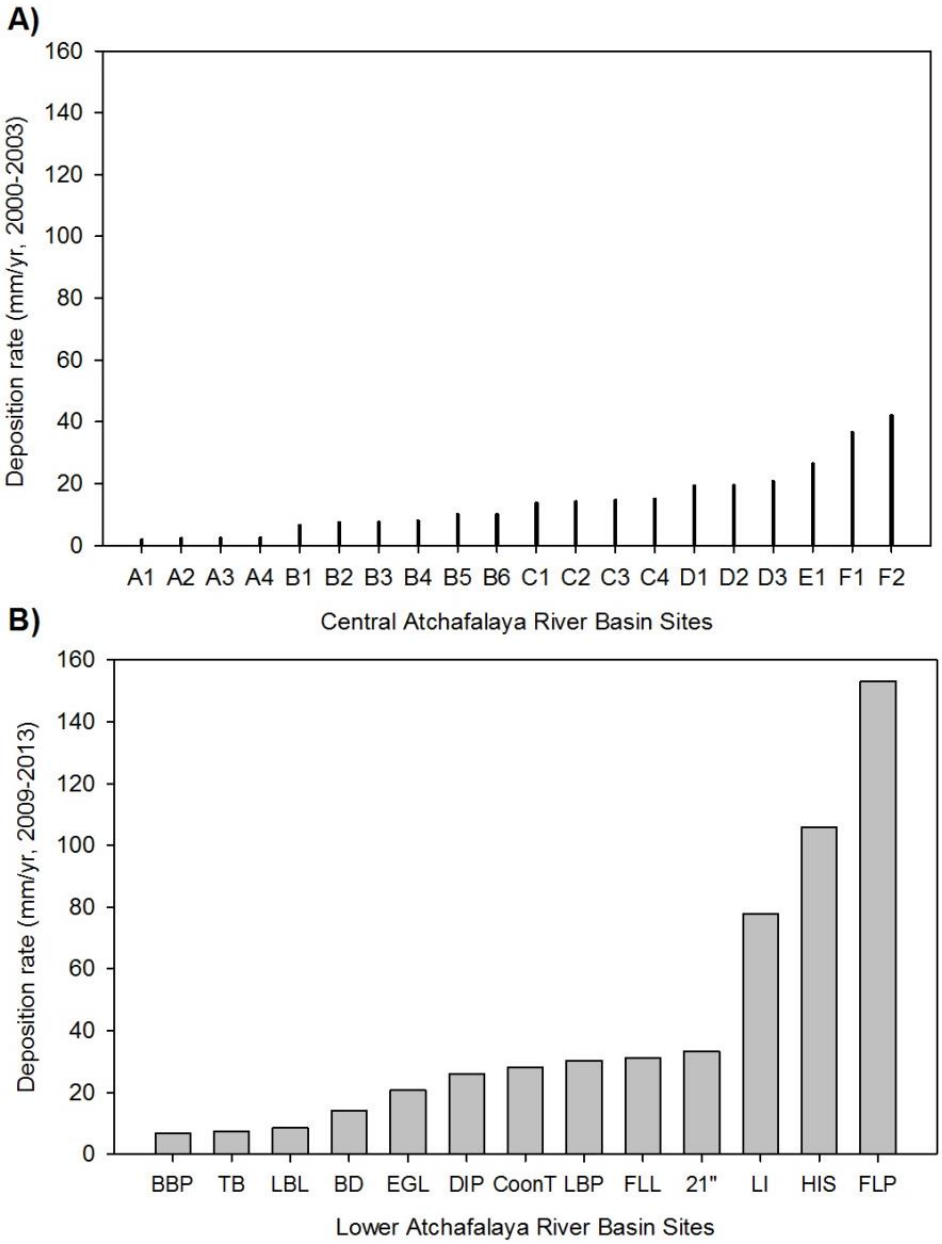

Figure 2 Sediment deposition rates in A, the central Atchafalaya Basin and B, the lower Atchafalaya Basin. Each bar represents the mean rate for named sites (indicated in Fig. 1).

Organic content in recent deposits is influenced by detrital inputs from on-site (in situ) sources (autochthonous) and from off-site material delivered by stream flow (allochthonous) that may be trapped as deposited sediment. Mean percentage organic material (LOI) was just over 10% and 16% in the central and lower parts of the Basin, respectively. This suggests that the Basin is an important area for organic material trapping (>800k Mg organic sediment of which 40% may be carbon) annually in the central Basin alone, Hupp, et al. 2008). The lower part of the Basin, with a higher mean organic content and order-of-magnitude higher maximum deposition rates than the central part of the Basin, undoubtedly traps substantially more organic material (mass estimates

have not yet been calculated). Studies using stable isotope measurements ($\delta^{13}C$, $\delta^{15}N$) have shown that the source of organic material maybe identified (Hackney and Haines, 1980; Craft et al., 1988) based on variance in vegetation utilization of C_3 versus C_4 photosynthetic pathways (forest vegetation-C_3, marsh/grass vegetation-C_4) and algal uptake of dissolved inorganic C. Carbon isotope values ($\delta^{13}C$) in the lower part of the Basin suggest that a range of carbon sources exist (Fig. 3). A large portion of Basin deposited carbon is probably allochthonous as 60% of samples have $\delta^{13}C$ values that are closer to that of river suspended sediment compared to forest leaf litterfall values. Thus, our results strongly suggest that the Atchafalaya Basin sequesters substantial amounts of allochthonous carbon (from the watershed) in addition to that produced in the Basin and that lowland alluvial areas (e.g. Lower Mississippi Valley) may be important sinks that should be considered in estimates and models of global carbon cycling.

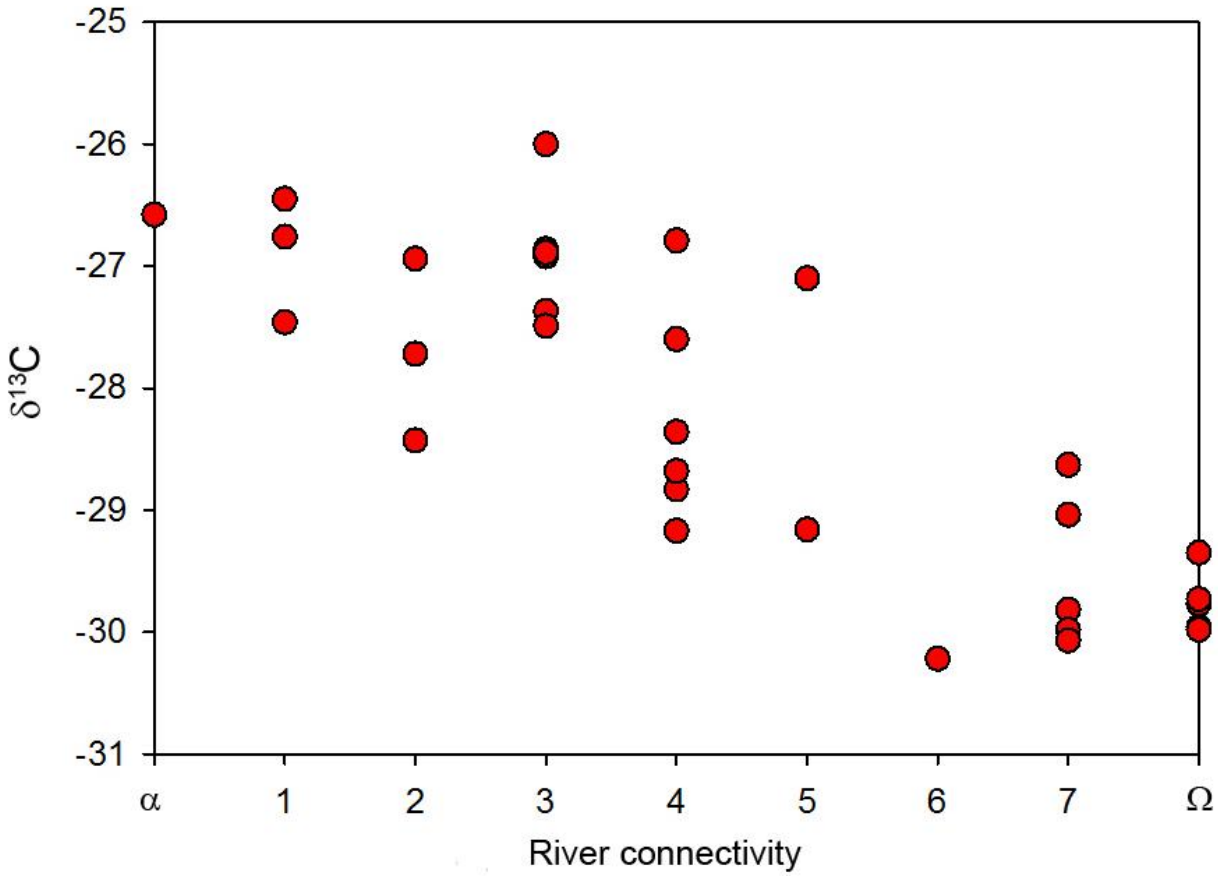

Figure 3 $\delta^{13}C$ values of deposited sediment along a gradient of river-water connectivity to floodplain in the southern Atchafalaya Basin. Sites were categorized into seven classes of connectivity, from high (1) to low (7) with connectivity decreasing from left to right along the x-axis. $\delta^{13}C$ of allocthonous, riverine suspended sediment (α) and autochthonous forest leaf litterfall (Ω) are included as potential end-members of organic sediment sources

MISSISSIPPI RIVER MODEL

Edmund M. Howe, P.E., Senior Hydraulic Engineer, United States Army Corps of Engineers, Memphis, TN, edmund.howe@usace.army.mil, 901-544-0876

INTRODUCTION

Project Background: The Great Mississippi River Flood of 2011 was the catalyst behind the creation of detailed, unsteady flow, hydraulic models of the Mississippi River and Tributaries (MR&T). The MR&T system was tested to new levels during the 2011 event, and the hydraulic models provide a means of evaluating the system performance. The Memphis, Vicksburg, and New Orleans Districts of the Corps of Engineers worked in parallel to create separate models of their systems. The 2011 Post-Flood Assessment and the National System Performance Evaluation were two studies that utilized the first iteration of these hydraulic models. A limited timeline to complete those two projects did not allow for a detailed calibration to a wide range of flows, and the scope of the studies only concerned relative differences to the 2011 event. For the Mississippi River Flow Line and Geomorphology Study, a more detailed calibration of the models was necessary. Each district collected more data and updated its individual models in order to resolve major issues unique to their locations and calibrate to a range of flows before attempting to combine them into one model. This report provides a brief description of the background of the development of the Memphis District model, examples of novel methodologies and assumptions involved in calibrating this large, one-dimensional HEC-RAS model, and some of the methodologies and results from the coupled one-dimensional and two-dimensional HEC-RAS model.

Model Background: The Memphis District portion of the HEC-RAS model originated from the Ohio River Community Model (ORCM). A Mini-Model version of the ORCM was used during the 2011 Flood by the National Weather Service (NWS) with the aid of the Hydrologic Engineering Center (HEC) in an attempt to forecast river stages and the activation of the Bird's Point-New Madrid Floodway (BPNM). The Mini-Model had upstream extents of Chester, Illinois on the Mississippi River and Smithland, Kentucky on the Ohio River. The downstream boundary was Caruthersville, Missouri which is located approximately 110 river miles downstream of the confluence of the Mississippi and Ohio Rivers. The "Mini-Model" was updated significantly by the Memphis District and extended downstream to Vicksburg, Mississippi to include the major tributaries that either contribute significant flow or experience a considerable backwater effect during high flood events. Inflows due to precipitation within the Memphis District model limits were estimated using NWS hydrologic models and further routed by the Memphis District hydraulic model.

Two-dimensional RAS models of the BPNM and the confluence of the Arkansas, White, and Mississippi Rivers were constructed for this effort due to the complexity of those sites. These models were calibrated and refined using the most advanced features available in RAS. RAS2D was being developed during the initial calibration and not all the current software features were available as the work progressed.

DATA

Flow and Stage Data: An unsteady HEC-RAS model is based on a series of assumptions to represent open channel flow in one-dimension, upstream to downstream. It is a robust and flexible model, but like all models it is limited to the accuracy of the input data in addition to its one-dimensionality. The best, most accurate data reasonably obtainable was used for the model development.

For the external and internal boundaries of the Memphis District, flow and stage data needed to be obtained from the United States Geological Survey (USGS), the St. Louis District, the Lakes and Rivers Division, the Little Rock District, the Memphis District, the Vicksburg District, and the NWS. The NWS computes data in Coordinated Universal Time (UTC) while many of the district offices report in their respective time zones, typically Central Standard Time (CST). This data was compiled, converted, and stored in databases using HEC-DSS in both UTC and CST. By switching the databases, the model has the capability of reading data in either UTC or CST.

The vertical datum used for the model is the North American Vertical Datum of 1988 (NAVD88). Many of the gage zeros have been tied to the NAVD88 datum by surveying– that conversion was applied directly to obtain elevation in NAVD88. Other gages have not been surveyed and Corpscon6 software was used to convert the gage zero in the National Geodetic Vertical Datum of 1929 (NGVD29) to NAVD88.

Many points within the model with a significant contribution of flow are monitored by gages by either the USACE or the USGS. Most are real-time stage gages, and flow measurements are taken periodically to develop the stage-flow relationship, but some are merely staff gages read daily. Because the 2011 flood produced some of the highest stages in recent decades, the number of flow measurements at these high stages for available for comparison was limited, which contributed to uncertainty in the model. All stage and flow data was checked to permit accurate calibration.

GIS Data: GIS data was necessary for the creation of the hydraulic model. The HEC Geo-RAS tools for ArcGIS were used to translate the vector and raster data into an HEC-RAS geometry. The projection and datum for the terrain model were USGS Albers Equal Area and NAVD88 (ft), respectively. The terrain model associated with the Memphis District geometry was created from sets of bathymetric data and Laser Imaging, Detection and Ranging (LIDAR) or Digital Elevation Model (DEM) datasets obtained during different years. The use of data obtained in various years was unavoidable due to the model boundaries extending into other districts. However, all the data for the terrain model were obtained no earlier than 2001

Post-2001 Flood surveys and After-Action Reports (AAR) were used to help determine final breach sizes or areas of overtopping and to gain a general knowledge of the flood history. Levees and floodwalls in the National Levee Database (NLD) essential to calibration were included in the model.

METHODOLOGY AND ASSUMPTIONS

General Assumptions: HEC-RAS is a one-dimensional modeling software that has the capability to model split flows, to calculate water surface profiles for gradually varied flows, and to model a single stream reach or a full network of interconnecting channels. It has the ability to model subcritical, supercritical, and mixed-flow profiles. The basic computation routine solves the one-dimension energy equation, taking into consideration energy losses due to channel and overbank friction in the longitudinal direction, and expansion and contraction losses at bridges, culverts, and natural constrictions. HEC-RAS neglects variables such as density and temperature. Because RAS is a one-dimensional model, all input must be assignable to a longitudinal coordinate. The modeling of large, elaborate river systems in one-dimension involves mathematical assumptions, requiring creative use of RAS features to approximate the three-dimensional hydraulics that exist in the field.

As the initial calibration was underway, a two-dimensional modeling capability in HEC-RAS was under development (HEC-RAS 5.0 Beta). Therefore, complex sites such as BPNM and the confluence of the Arkansas, White, and Mississippi Rivers were developed in HEC-RAS 5.0 Beta to obtain a more realistic model. HEC-RAS 5.0 Beta contains a 2-D finite-volume model that solves either the full 2-D Saint Venant equations or the 2-D Diffusion Wave equations. The software has the ability to perform combined 1-D Rivers and Storage areas with 2-D Flow Areas. The combined 1-D/2-D computations are performed together on a time step by time step basis, making the connections from 1-D areas to 2-D Flow Areas more accurate than modeling them separately. The grids for the 2-D areas created are discretized, and an elevation-volume relationship is computed for each cell based on the underlying terrain and bathymetry. The effort to refine and calibrate these 2-D areas was limited, partly because the software was only in a Beta version during the time of the initial calibration. However, the major limitation in the software for this initial calibration was that only one Manning N-value could be assigned to the cells at one site. Once the model was set up and stable, there were few variables available to change to calibrate the 2-D areas. The general expectation was that the application of a RAS 2-D model at a complex site would be more accurate than a 1-D model, regardless of the limitations of the 2-D feature available then. The areas modeled in 2-D were delineated in such a way to represent overbank flow – which is in better agreement with the single Manning's N-value limitation of the software.

In addition to the theoretical assumptions of the software code, assumptions are inherent in the input data before the model is ever created. Regarding the use of surveys from multiple years, the general assumption was that the overall volume for the system has not changed significantly in the past 10 years. Local differences in geometry from the use of older data were not quantified but were rectified by weighting the calibration of the model to the more recent events. The typical error of the published flow data for calibration is considered to range from plus or minus 2 to 8 percent, or more. . The USGS publishes the results of flow measurements taken and estimated accuracy. That accuracy is based on a number of variables such as weather conditions, turbidity, and temperature. Overall, the published flow data was considered the most accurate available.

Methodology for Calibration (1-D): Gaining an understanding how the flow data and geometric data functions in the model for a variety of flood events is a daunting task. Correcting

flow data or modifying the geometric data was considered part of the calibration process. Determining the locations and elevations of lateral structures and corresponding weir coefficients, the storage area volumes and layouts, ineffective flow areas, levee points, and Manning's N-values were the other key tasks in calibrating the Memphis District model.

After the quality check on the published flow data, the calibration to a range of flows began initially by changing Manning's N-values, working upstream to downstream. The 2002, 2008, and 2011 events were the target events used to calibrate the model. Although the 2011 event was the most recent and highest event, 2008 was used for calibration of some of the areas of great complexity. For example, in 2011 there were four major breaches between Cairo and Caruthersville (three of the breaches were intentional, for operation of the BPNM floodway). The unintentional breach was not a breach of a project levee. Since none of those four breaches occurred during the 2008 event ,the 2008 event was used to help isolate variables unique to the cross section geometry. In general, comprehensive data from 2002 to 2011 was used to determine elevation trends for the different levels of flow, with emphasis on the more recent events. Modifying the Manning's N-values was an iterative process conducted by analyzing the trends of flow versus the difference between computed elevations and observed elevations (residuals).

Because of the complex nature of the Mississippi River, adoption of a single Manning's N-value representing the channel for all levels of flow was not prudent. A 0.03 value for the channel was the initial trial Manning's N-value. The initial value was changed on cross sections considered local to a particular gage to obtain a close approximation to in-channel flows. These modified values were then varied with flow by a series of multipliers. For example, if the model residuals were showing that computed elevations were too low for flow ranges of 200,000 to 300,000 cfs, a multiplier greater than 1.0 was used on the Manning's N-values for a series of cross sections delineated for a particular gage during that flow range. This process is tedious, and an automated roughness feature within HEC-RAS was used to help determine reasonable multipliers to correct a high or low trend at the various flow rates.

The Automated Roughness Calibration feature within HEC-RAS was used as a guide for the lower flows. It was used as a time saving feature and not used exclusively in all locations. The automated roughness feature determines the trends of the residuals with flow rates and iteratively determines the multiplier needed to minimize the difference between the computed and observed elevations. The output of this feature was a series of multipliers for the different reaches for the range of flows. This data was adjusted by the modeler to provide smoother transitions. After the in-channel flows at the gages were reasonably calibrated, calibration to higher, out-of-bank flows began. The automated roughness feature did not work as well for higher flows as the geometric features, breaches, and hydrodynamics become more complex, but Manning's N-values were still varied at higher flow rates by the modeler. At higher flow rates, more effort was necessary to represent the conveyance in the cross sections. This became apparent as the computed elevations began to slip in time and peak too late. To represent the conveyance in a given cross section, the cross section had to be delineated horizontally by Manning's n values and schematic changes to the model were necessary.

The larger geometric or schematic changes to the model as a part of the calibration process generally were related to storage areas and lateral structures within the MR&T levee system that

represented breaches that occurred or areas where large overbanks existed in the original cross sections. Storage areas within the MR&T levee system were only used if an obvious high elevation restriction existed. Most of these areas are partially bound by spur levees jutting out almost perpendicular to the path of overbank flow. In the majority of circumstances, water backs up into these areas and does not actively convey downstream; therefore, storage areas were deemed appropriate. The profiles of the lateral structures that control the flow of water into the storage areas were often cut from elevations with little difference in elevation on either side of the structure. The weir coefficients were set to low values (0.1 to 0.7 typically). These lower values not only best represent the flow into or out of these areas, but also tend to be more numerically stable. Ideally, a stage-stage boundary condition between the cross sections and the storage areas would best represent the flow into or out of the storage areas for a range of events, but this capability was not available in HEC-RAS at that time. Other areas of large overbank distance that could not be delineated by obvious elevation restrictions were represented using other tools and methods available in the HEC-RAS interface.

When a long, flat overbank distance (this can be many miles for the Mississippi River) is present in a cross section, issues can arise when attempting to calibrate the model temporally and spatially. When water begins to flood the overbanks, the one-dimensional assumptions in HEC-RAS are not realistic. Specifically, when the computed water levels exceed elevations of the overbanks, RAS assumes that all the water in the overbanks is at an equal elevation to that of the river. In actuality, the water surface elevations near the levees are not the same as that for the channel. A drop in the calculated water surface can be seen as water levels begin to exceed elevation in the flat overbanks of the cross sections, due to the generally flat overbanks. For overbanks with side channels or more depth in the overbanks, too much increase in elevation is seen as these areas begin to compute as conveyance in the model. In some cases, water in the overbanks is essentially stored until water levels in the river drop – at which point that volume begins to return to the channel. These areas were handled with ineffective area points. There are other cases where the water in the overbanks does convey, but slowly. If these areas are treated as strictly ineffective areas, the model will compute too much storage. This subtracts too much volume on the rising side of the hydrograph and returns the overestimated volume on the falling side of the hydrograph. These areas instead were delineated horizontally with associated Manning's N- values. Large Manning's N-values such as 0.2 or 0.3 were used at the fringes of the cross sections to reduce the conveyance of this volume downstream. N-values this high are not listed in any hydraulic textbook strictly for describing roughness, but the complex hydrodynamics actually taking place cannot be modeled otherwise in a one-dimensional model. The energy losses occurring transversely and vertically have to be accounted for, in addition to the standard longitudinal losses, to obtain the correct timing of calculated elevations at the main stem gages. Using these high Manning's N-values, as well as varying the Manning's N-value with flow rates, most of the events could be calibrated satisfactorily. For cases of unusually high flow or events that had a long duration at levels which caused water to oscillate in and out of channel, additional levee points and ineffective areas were necessary for the model to compute accurate elevations without significantly delaying the timing of the peaks. Due to the one-dimensionality of HEC-RAS, the superelevation of the water surface cannot be modeled; however, the conveyances within the cross sections were reasonably modified to compute a close approximation to the observed elevations near the time they occurred. Much effort was spent attempting to calibrate to the events temporally and spatially, but in a one-dimensional model of this magnitude trade-offs have to be made. Aerial photography and the terrain model helped

tremendously in determining how to handle the overbank conveyances. Figures 1 and 2 show prime examples of overbank flow during the 2011 flood and a few of the different methods used by the Memphis District for modeling.

Figure 1 is aerial photography obtained during the 2011 flood. At the top right corner of the photograph a breach occurred in a spur levee. A storage area was used to model the volume shortcutting the Mississippi River. On the right descending bank, a large area is inundated and labeled Storage. This area is partially bound by a levee on the upstream side that did not fail during the flood. Water tends to back up into this area rather than convey in a downstream direction. The bottom right corner of the photograph shows overbank flow modeled with cross sections. The overbank area was considered to be low conveyance instead of storage, as it was not confined by high ground. The sections extended across the overbank approximately 3 to 4 miles. The profile for section A-A in Figure 1 is shown in Figure 2.

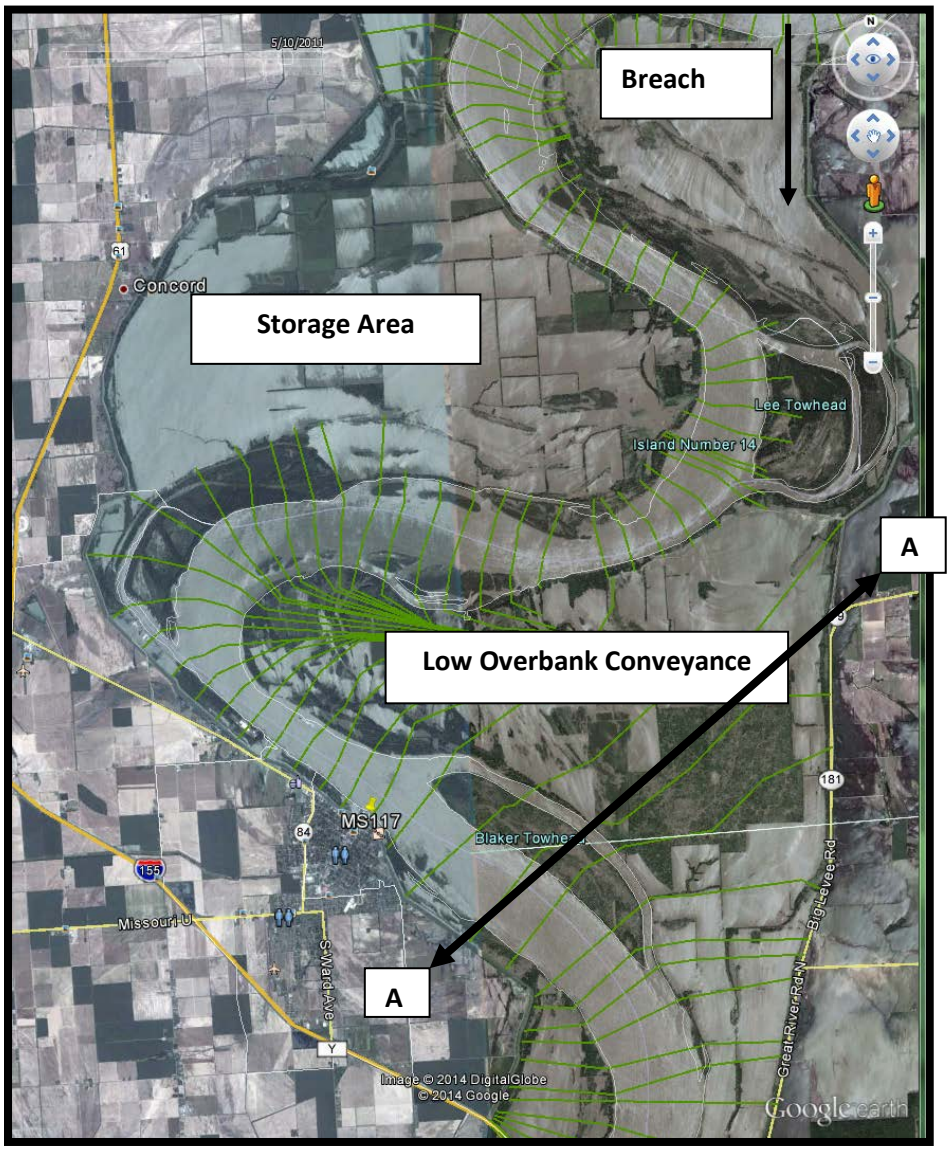

Figure 1 Photograph of Overbank Flow, May 2011

Figure 2 shows the profile for section A-A. The bars across the top indicate the Manning's N-value, as well as its conveyance delineation along the stationing of the profile. The two channels had clearly identifiable banks and were assigned N-values of 0.032. The overbank between the two channels was assigned an N-value of 0.11. The left side of the profile corresponds to the large overbank that has water which conveys downstream slowly. The Manning's N-value there was raised to a 0.17 in order to allow little conveyance downstream. From the plan view in Figure 1, it is clear that the flow in the overbank for this area was not stored, rather it moves slowly through the overbanks downstream. Also in Figure 2, a levee point is present at approximately 22,000 feet from the left overbank. However, this point does not represent a real levee; instead, the point limits flow from being computed in the first 22,000 feet of the cross section until that point is overtopped. Use of such levee points helps to transition the model transversely to fully out of bank flow.

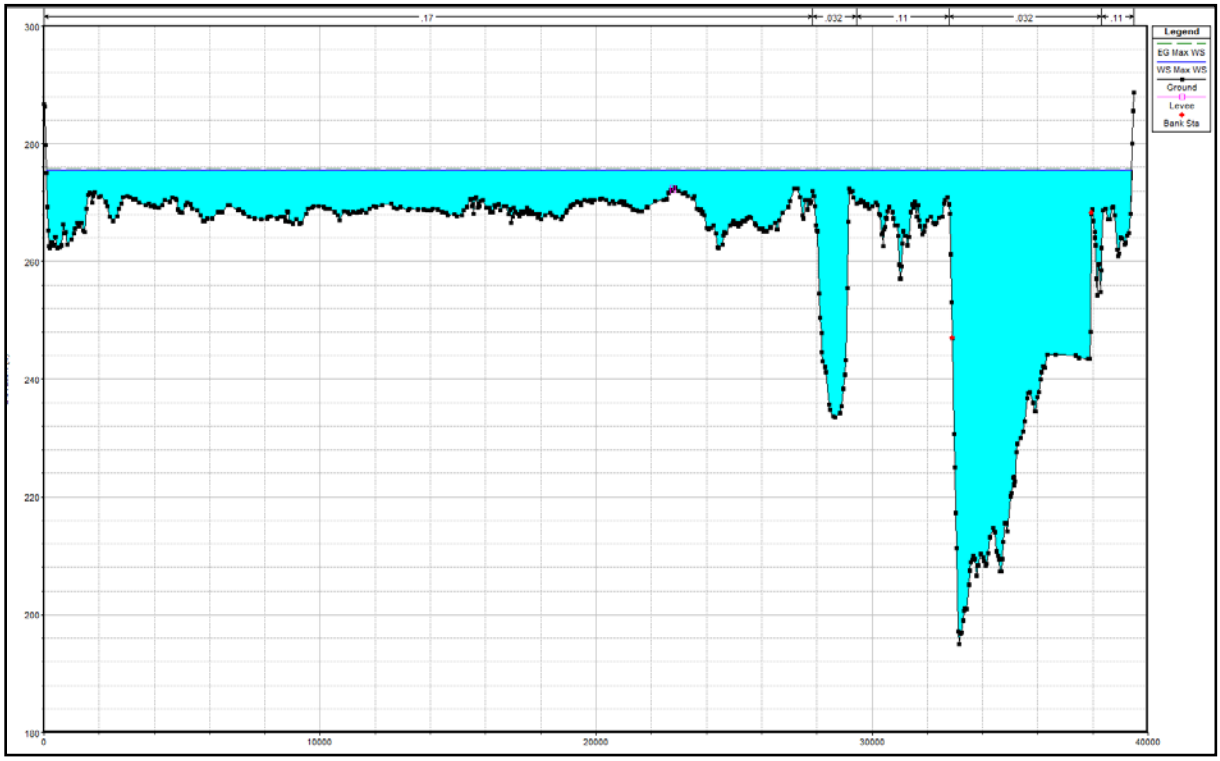

Figure 2 Section A-A – Example of Low Conveyance Overbank Flow

RESULTS AND CONCLUSIONS

Calibration Results: The calibration of the Memphis District hydraulic model focused on the 2002, 2008, and 2011 events primarily, but continuous data from 2002 through 2011 was run through the model as well. In general, gages that recorded hourly stage data were used for a detailed calibration analysis, but intermediate gages with daily data, high water marks, or staff gages with intermittent data were also used for refinement of the model. Table 1 shows results for each of the 3 primary events, and Table 2 shows results from the 10 year simulation from 2002 to 2008. In Table 1, results are listed for locations along the Mississippi River from Chester, Illinois downstream to Arkansas City, Arkansas. For each event and location, the accuracy of the model is described by listing the percent of calculated stages within 0.5 and 1.0 feet of the observed data and the average error. Also, the difference in peak elevations between calculated and observed stages is listed. For all three events the general tendency is for the model to more accurate at the upstream end than at the downstream end. Average errors and differences at peaks are less than 2.0 feet and typically less than 1.0 feet.

RECENT AND HISTORICAL SEDIMENT LOADS IN THE LOWER MISSISSIPPI RIVER

Colin Thorne, University of Nottingham, Nottingham, UK, Colin.Thorne@nottingham.ac.uk; Kevin Knuuti, USACE Cold Regions Research and Engineering Laboratory, Hanover, NH, Kevin.Knuuti@usace.army.mil; Oliver Harmar, Environment Agency, Leeds, UK, Oliver.Harmer@environment-agency.gov.uk; Chester Watson, Biedenharn Group, Fort Collins, CO, Chester@ChesterWatson.com; Nick Clifford, Kings College, University of London, London, UK, Nicholas.Clifford@kcl.ac.uk; David Biedenharn, Biedenharn Group, Vicksburg, MS, Biedenharngroup@yahoo.com

Abstract: This paper reports the results of a study initiated by the USACE Engineer Research and Development Center (ERDC) and funded by the USACE New Orleans District that assembled available data on sediment loads in the Lower Mississippi River (LMR) and assessed its reliability and temporal variability. The database that resulted includes modern data collected by USACE New Orleans and Vicksburg Districts and historical measurements extending as far back as the mid-19th Century. In using the database, it is important to recognize variability and uncertainty in the records and a preliminary assessment was performed using the record for Tarbert Landing. The average annual measured load at Tarbert Landing between 1963 and 2005 was ~150 million tons, varying between 70 and 230 million tons. The median annual coarse suspended-sediment load over the same period was highly variable, varying from 5 to 80 million tons. The trend apparent in 19th and late-20th Century average loads suggests that, as widely perceived, there has been a long-term decline in the average annual suspended sediment load. This simple statement must, however, be treated with an appropriate degree of caution because: (i) robust statistical treatment of the data is hampered by gaps in the available records; (ii) data are sourced from multiple locations; (iii) there are high but unquantified uncertainties associated with early measurements of sediment load; and (iv) calculated measured loads underestimate the coarser fractions of the suspended load, and do not include sediment transported as bed load at all. Regression analyses for data from Tarbert Landing during the period 1959 to 2005 indicate that on-going, declining trends in suspended-sediment concentrations may have been partially offset by an increasing trend in water discharge, resulting in there being no significant trend in the annual sediment load. The database is available free and may be obtained on request from any of the authors, making the data easily accessible both in the USA and globally.

OVERVIEW

This paper reports the results of a project performed by Nottingham University, Halcrow (now part of CH2MHill) and the Biedenharn Group, in collaboration with the Army Corps of Engineers' Engineer Research and Development Center (ERDC), Vicksburg, Mississippi. The project assembled available data on sediment loads in the Lower Mississippi River, assessed its reliability, demonstrated its variability and performed a preliminary examination of historical trends.

The Lower Mississippi River extends from Cairo, Illinois to the Gulf of Mexico and currently transports approximately 150 million tons of sediment annually. Historically, the quantity and caliber of sediment derived from catchment erosion have been affected by changes in land-use and river management; increasing in the 19th and early-20th Centuries, before decreasing due to soil conservation and improved land management. The supply of sediment from tributaries is also believed to have decreased markedly as a result of river engineering and management. Specifically, the construction of large dams as part of the Mississippi River and Tributaries (MR&T) Project has trapped sediment that would otherwise have been supplied to the Mississippi, particularly by the Missouri River. Marked changes have also occurred in the extent of eroding banklines along the Mississippi and these must have reduced the input of sediment derived from that source. For example, during the last 3 decades, a sustained construction program of bank revetments and dikes has produced a stable planform alignment that has almost eliminated the input of sediment due to bank erosion. Finally, extensive dike fields installed in the Lower Mississippi River for navigation have trapped substantial quantities of sediment that might otherwise have been transferred downstream.

The Mississippi River Basin has been subjected to numerous alterations in the past century that have affected sediment loads in the river. The resulting decline in sediment loads in the lower river has been documented by several investigators. However, there is no consensus on the degree of reduction as a proportion of the previous 'natural' or undisturbed load, the time profile of that reduction or how current trends may change in the future. For example, based on the record for Tarbert Landing, Keown *et al.* (1981) suggest that the total annual suspended-

sediment load declined from 427 million tons prior to 1963 to 251 million tons by 1981. Robbins (1977) compared measured suspended-sediment records for the periods 1921 to 1931 and 1967 to 1974 and found that total suspended-sediment loads had decreased by roughly 40% since 1931 at both Arkansas City and Vicksburg. Extending the historical analysis further by using data from the Humphreys and Abbot (1861) report, Kesel (1988, 1989) suggested that total suspended-sediment loads in the Lower Mississippi River declined by approximately 80% in the period 1851 to 1982. These large reductions may not be unreasonable given the magnitude of the dams, length of revetments, and effectiveness of soil conservation programs in the basin.

Questions concerning past, present, and future temporal trends in the sediment load of the Lower Mississippi River are pertinent because the redistribution of available Lower Mississippi River sediment is vital to on-going efforts to reduce land loss and restore coastal marshes and wetlands in the Mississippi Delta. Cumulative land loss in Louisiana over a 50-yr period represents on the order of 80% of the coastal land loss in the United States. The Louisiana Coastal Area (LCA) was released by the United States Army Corps of Engineers (USACE) in 2004 and included consideration of approximately twenty-three diversions of water and sediment from the Mississippi River, with a total diversion capacity in the range of 150,000 to 200,000 cfs. This does not include the Third Delta diversion, with a proposed capacity of 120,000 to 240,000 cfs. The proposed LCA diversions pose significant management and engineering challenges and will require detailed modeling to support their design. The availability of reliable data on flows and associated sediment loads to support modeling would seem to be a prerequisite for meeting these challenges successfully.

Research to make available reliable sediment-transport data focused on compiling a database of measured suspended-sediment loads. Building this involved: (i) accessing recent measurements collected by the USACE New Orleans and Vicksburg Districts; and (ii) assembling available historical measurements extending as far back as the earliest available records, from the mid-19th Century.

Variability and historical trends in the sediment load are of great importance to plans to redistribute Lower Mississippi River sediments to restore coastal marshes and wetlands. Preliminary analysis focused on sediment load measurements at Tarbert Landing, which was selected because it is located in the upper part of the Mississippi Delta and, therefore, can be considered to be representative of the load available to the coastal region; and because it has the longest record of routine monitoring.

The average annual load at Tarbert Landing between 1963 and 2005 was approximately 150 million tons, varying between a minimum of 70 million tons and a maximum of 230 million tons. The median annual coarse load over the same period is highly variable, varying from 5 to 80 million tons.

Examination of historical measurements from the 19th and 20th Centuries suggests that there has been a long-term decline in the average annual load. This simple conclusion must, however, be treated with caution because:

(i) robust statistical treatment of the data is hampered by large gaps in the record;
(ii) data are sourced from multiple locations;
(iii) there are high but unquantified uncertainties associated with early measurements of sediment load; and
(iv) calculated measured loads will underestimate the coarser fractions of suspended load, and do not include sediment moving as bed load at all.

Linear regression analyses for data from Tarbert Landing during the period 1959 to 2005 indicate that on-going, declining trends in suspended-sediment concentrations may have been partially offset by an increasing trend in water discharge, resulting in there being no significant trend in the annual sediment load.

The analyses reported below are preliminary. It is proposed that further analyses be performed by researchers with Federal, state, and local agencies, as well as interested parties in the academic and private sectors. This study has facilitated further analyses by compiling a comprehensive database of available measured sediment-load data for the Lower Mississippi River and making it freely available and easily accessible. Copies of the database may be obtained from any of the authors of this paper.

Definition of sediment-transport terms: To avoid confusion in the interpretation and analysis of the database, the definitions of different types of sediment load referred to in this report are defined below.

Total Sediment Load: total mass of granular sediment transported by the river. This can be broken down by source, transport mechanism or measurement status.

Measured Load: portion of the total load measured by conventional suspended-load samplers. It includes a large proportion of the suspended load but excludes that portion of the suspended load moving very near the bed (that is, below the sample nozzle) and the entire bed load.

Unmeasured Load: portion of the total load that passes beneath the nozzle of a conventional suspended-load sampler, by near-bed suspension and as bed load.

Bed Load: component of total load made up of particles moving in frequent, successive contact with the bed. Transport occurs at or near the bed, with the submerged weight of particles supported by the bed. Bed load movement takes place by processes of rolling, sliding or saltation.

Suspended Load: component of the total load made up of sediment particles moving in continuous suspension within the water column. Transport occurs above the bed, with the submerged weight of particles supported by anisotropic turbulence within the body of the flowing water.

Bed-material Load: portion of the total load composed of grain sizes found in appreciable quantities in the stream bed. The bed-material load is the bed load plus the portion of the suspended load composed of particles of a size that are found in significant quantity in the bed (often taken to be coarser than D_{10} of the bed material).

Wash Load: portion of the total load composed of grain sizes finer than those found in appreciable quantities in the stream bed (often taken to be finer than D_{10} of the bed material).

Coarse Load: portion of the total load composed of grains coarser than 0.063 mm. The coarse load of the Mississippi River consists almost entirely of sand finer than 2 mm.

Fine Load: portion of the total load composed of grains finer than 0.063 mm. The fine load of the Mississippi River consists of silt and clay.

DATA ANALYSIS

Data sources: The project built on a previous database of suspended-sediment and bed-material measurements compiled by Thorne *et al*. (2001), which assembled sediment measurements made in the Lower Mississippi, Atchafalaya, Red, and Old Rivers since the 1970s. This project extended the existing database by compiling all available historic measurements made within the USACE Vicksburg District and New Orleans District (*i.e.* downstream from Arkansas City). Data were compiled from a variety of sources including: USACE Vicksburg District, USACE New Orleans District, US Geological Survey and a wide range of historical records by multiple organizations, extending back to the 1850s.

Data were obtained in a variety of formats and with differing amounts and types of post-collection processing of the original field measurements. The project report (which is available from the US Army Engineer Research and Development Center or the authors) provides a summary of post-1930 data sets including the location of sampling, the organization undertaking data collection, the time period covered, and a brief description of information contained within each data set. Data include measurements of some, or all, of the following variables: suspended-sediment concentration and particle size, discharge, suspended-sediment discharge, and flow velocity. Available metadata information describing the types of sampling, sampling strategy, and laboratory procedures are provided in the project report. The sediment sampling stations from which sediment data were collected and included within the database are listed in Table 1.

Seasonal variability: Seasonal variability in measured sediment concentrations and loads was investigated using the record for Tarbert Landing between 1963 and 2005. When analyzing variations in sediment concentration and

load, it is important to consider variations in discharge; seasonal flow exceedance curves for Tarbert Landing are shown in Figure 1. As a very general rule, during periods of peak flow in the spring, discharge is approximately double that during periods of peak flow in the fall. Discharge is, however, highly variable in any season, with 5% exceedance flows being typically three times higher than 95% exceedance flows.

Variations in coarse and fine sediment concentrations between 1963 and 2005 are shown using box and whisker plots in 2(a) and 2(b), respectively. In these plots, the 25th and 75th percentiles define the box, the minimum and maximum values define the whiskers, and the monthly median is indicated by the central bar. Concentrations of coarse suspended-sediment vary from 350 to less than 50 ppm, being both higher and more highly variable during winter and spring (Figure 2(a)).

Fine suspended-sediment concentrations range between 150 and 250 ppm and though they are less variable seasonally, intra-month variability can be extreme: for example concentrations measured in April varied from around 60 to close to 1,000 ppm. 3(a) and 3(b) illustrate variation in measured coarse and fine suspended-sediment loads at Tarbert Landing, respectively. Monthly loads have been calculated by summing daily loads estimated using the concentration interpolation method.

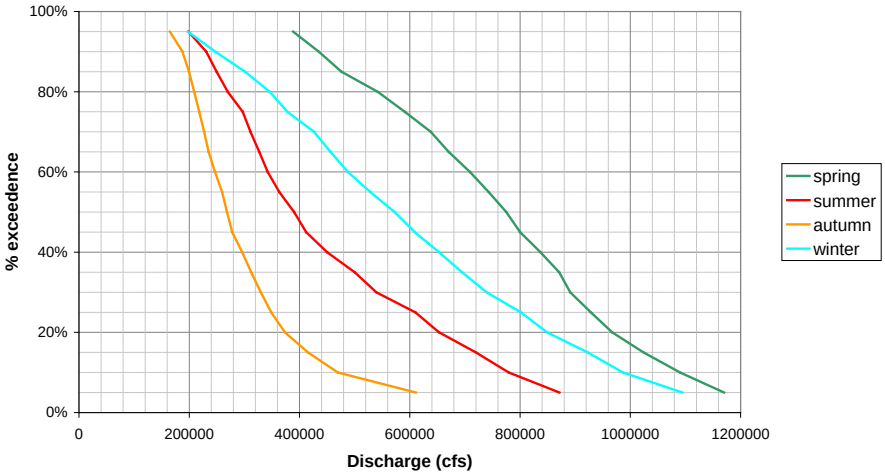

Figure 1 Seasonal flow-duration curves at Tarbert Landing (1963 to 2005).

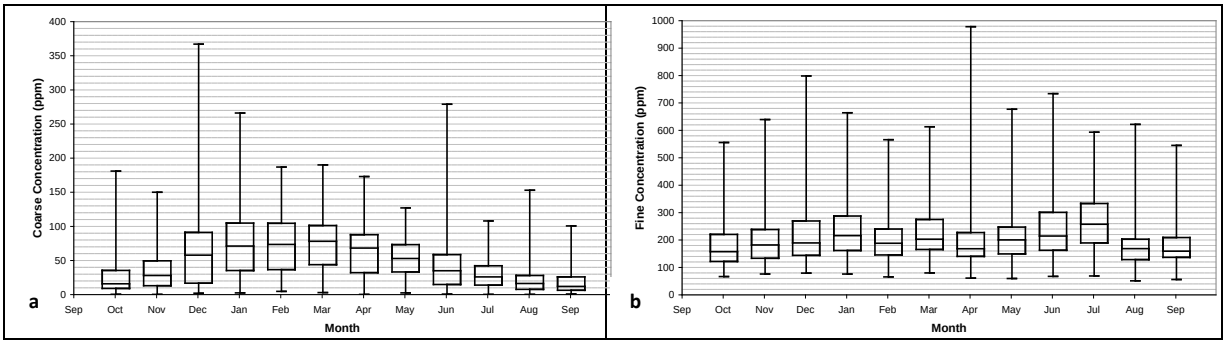

Figure 2 (a) Coarse suspended-sediment concentrations at Tarbert Landing (1963 to 2005).
(b) Fine suspended-sediment concentrations at Tarbert Landing (1963 to 2005).

High seasonal variability in monthly coarse suspended-sediment loads is evident in 3(a). For example, the median coarse load during Spring is approximately fifteen times that in the Fall. The same pattern is present for monthly total loads (Figure 3(b)), although the range of variation is smaller. Intra-month variability is also greater during the spring, particularly for the coarse load.

To further investigate the seasonal variations in the grade of sediment in transport, the cross-section-averaged D_{50} (median) and D_{90} (90th percentile) grain sizes were calculated and these are plotted in
Figure and 4(b). It should be noted that size gradations are not available for the clay fraction (sediment finer than 0.0039 mm).

The median (D_{50}) grain size at Tarbert Landing is overwhelmingly silt-sized though it does coarsen slightly during the winter and spring. The D_{90} is generally coarse silt during summer and fall, but coarsens to very fine sand during winter and spring, when discharges are higher. This indicates that suspended-sediment in the Lower Mississippi River is composed predominately of sediment smaller than fine sand, which differentiates it from the bed material, which is typically coarser than fine sand. As the bulk of the measured suspended load comprises sediment that is finer than that found in appreciable quantities in the bed, the load of the river can be said to be dominated by wash load.

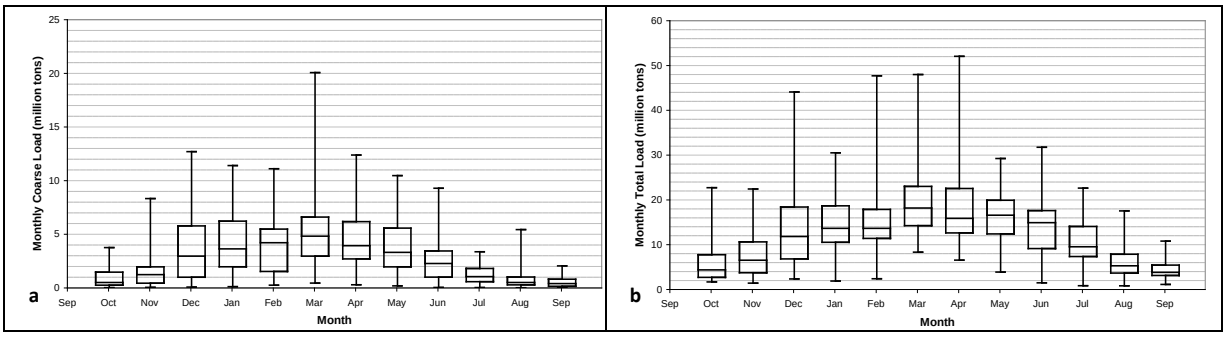

Figure 3 (a) Variation in monthly coarse suspended-sediment loads at Tarbert Landing (1963 to 2005). (b) Variation in monthly total suspended-sediment loads at Tarbert Landing (1963 to 2005).

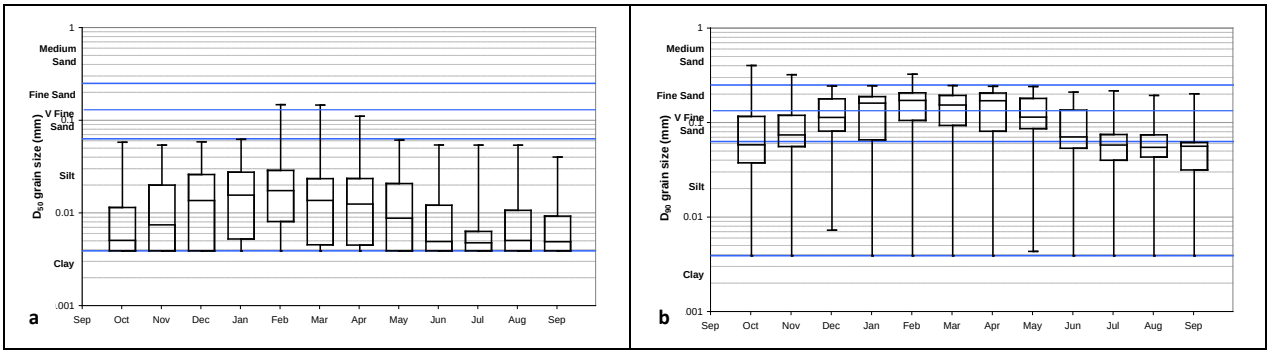

Figure 4 (a) Monthly variation in D_{50} at Tarbert Landing (1963 to 2005). (b) Monthly variation in D_{90} at Tarbert Landing (1963 to 2005).

Trend Analysis:

Historical trends: Historical trends in sediment load were investigated by plotting calculated annual loads for Tarbert Landing alongside historical loads based on older records that either reported annual loads, or included measurements from which annual loads could be calculated (Table 2). The results are plotted in Figures 5 and 6, which support the existence of a marked decline in sediment loads. However, in estimating how much loads and concentrations have decreased, caution must be exercised for four reasons. First, pre-1963 data were obtained from four different locations (Carollton, Baton Rouge, Red River Landing, and South Pass) and loads estimated from records at different gauging stations can vary considerably. Second, there are large gaps in the data during the first half of the 20th Century. Third, comparisons of loads between the 19th and late-20th centuries are limited by the high uncertainty concerning the early estimates of annual load. While the early data provide valuable insights, they are not sufficient to support statistical comparison to later data. Fourth, annual loads are based on measured suspended-sediment loads that almost certainly under-represent the coarser fraction of the suspended-sediment load, and do not account for bed load at all.

Recent trends: To assess whether loads in the Lower Mississippi River are continuing to decrease, a preliminary analysis of the Tarbert Landing data was conducted and Figures 7, 8 and 9 illustrate recent trends in annual sediment concentrations, suspended loads, and water discharges between 1959 and 2005. While scatter is present in data representing fine and total concentrations in Figure 7, P-values for the regression lines fitted to these data indicate downward trends that are statistically significant. Conversely, there is no significant trend in concentrations of coarse sediment. With respect to the annual sediment loads plotted in Figure 8, a slight, but statistically insignificant increasing trend is apparent in the coarse sediment loads. Fine and total loads appear to have slight downward trends, but these are also not statistically significant. Thus, while there may have been a slight decline in fine and total sediment concentrations between 1959 and 2005, the change in annual load is statistically insignificant. Lack of significant trends in sediment loads is unexpected given the decreasing trends identified in fine and total sediment concentrations. This apparent paradox may be explained at least in part by a slight, though statistically insignificant,

increasing trend in annual water discharges in Figure 9. The decline in sediment concentrations may have been partially offset by increasing water discharges, resulting in there being no significant change in the annual sediment loads.

It is important to note that this analysis is preliminary and it is recommended that full assessment be undertaken to investigate the complex behavior represented in the historical and recent records (*e.g.*, temporal periodicity, periods of no change, periods of slow change, periods of short-term, rapid change) employing the appropriate statistical techniques in time-series and trend analyses.

Table 2 Sediment records used in assessing historical trends.

Dates	Sampling Station	Source Organization	Available Data Types	Key Uncertainties
1964-2005	Tarbert Landing, RM 306	USACE New Orleans District	Coarse, fine, and total suspended-sediment concentrations at 2- to 4-week intervals	Frequent changes in sampling strategy, especially in period 1990 to 1994.
1959-1963	Red River Landing, RM 302	USACE New Orleans District, obtained from Old River Hydroelectric Study archives	Coarse, fine, and total suspended-sediment concentrations at 2- to 4-week intervals	This record is labeled as Tarbert Landing although measurements in the period 1959 to 1963 were taken 4 mi downstream at Red River Landing. Discharge measurements from the Tarbert Landing record have been used in sediment-load calculations.
1956-1958	Baton Rouge, RM 230	USACE New Orleans District, obtained from Old River Hydroelectric Study archives	Daily records for coarse, fine, and total concentrations	Unknown how daily record has been calculated. Discharge from Tarbert Landing record has been used in sediment-load calculations.
1949-1969	Baton Rouge, Red River Landing, and Tarbert Landing	USACE New Orleans District, reported in Old River Hydroelectric Study	Annual loads	Only available as calculated annual loads. Therefore, was not possible to estimate uncertainty from sampling strategy and annual load calculation.
1931	Red River Landing, RM 302	USACE, obtained from Paper U (1931)	Discharge and average concentration for surface, mid and near bottom samples, taken every 2 to 7 days over a 6-mo period	Annual load calculated by using a rating-curve approach to extend the 6 mo of data. Indicative error bars have been used in Figures 8 and 9 to show the high uncertainties associated with this approach.
1879-1893	South Pass, below Head of Passes	Quinn Survey, reported by Kesel (1995)	Annual loads	Large indicative error arrows have been used in Figures 8 and 9 to indicate high uncertainty in using this data to represent sediment loads in the main Lower Mississippi River.
1851-1853	Carollton, RM 103	Forshey – obtained from USACE Paper H (Vogel, 1930)	Approximately weekly measurements of discharge and average total concentration over a 2-yr period	In Figures 8 and 9, arrows have been used to indicate possible additional uncertainty due to location transfer.

ACKNOWLDEGEMENTS

The database described in this paper was compiled by the authors through a project funded by the U.S. Army Corps of Engineers New Orleans District, under contract number 1106-EN-01, which was awarded to the University of Nottingham, UK and facilitated by the U.S. Army's International Research Office in London, England. In compiling the database created in this project, considerable assistance was provided by the USACE ERDC, USACE Vicksburg District, USACE New Orleans District, USACE Mississippi Valley Division, and the United States Geological Survey (USGS). The authors thank these organizations for their collaboration and cooperation.

SAINT-VENANT MODELING FOR LARGE RIVER BASINS – CHALLENGES AND DATA NEEDS

Ben R. Hodges, Assoc. Professor, Department of Civil, Architectural, and Environmental Engineering, University of Texas at Austin, hodges@utexas.edu; Frank Liu, Research Scientist, IBM Research Austin, frankliu@us.ibm.com; Alfredo Hijar, Graduate Student, University of Texas at Austin, ahijar@utexas.edu

INTRODUCTION

River networks in continental-scale river basins – e.g. the $O(10^6)$ river miles in the Mississippi basin – to date have used only with reduced-physics models. These models cannot represent the momentum dynamics and water depth evolution available with the full Saint- Venant (SV) equations derived by cross-section integration of the Navier-Stokes equations. Momentum and water depth are valuable for mechanistic sediment modeling, and hence their neglect in reduced-physics models is a severe limitation. Reduced-physics models are generally justified with the argument that SV models are too computationally expensive for large networks (Hodges, 2013). However, recent advances in computational methods have made SV equations a practical option (Hodges and Liu, 2014; Liu and Hodges, 2014), but challenges remain in developing large-scale applications. In this presentation we discuss the problems, challenges, and some possible solutions for creating data sets combining surveyed and estimated channel geometry over large river basins. The key open question is with regard to data requirements: *what is the level of cross-sectional detail that is actually needed for SV solutions, vice the data detail that is typically obtained in surveys?* Ideas from hydraulic geometry combined with historical stage-discharge data can be used to develop estimated cross-sectional data, which are useful where surveyed data are unavailable. Although it is likely that for the foreseeable future we will not have comprehensive survey data for entire river basins, we can use available data to estimate geometry for dynamic equation solutions rather than a priori reducing the physical processes represented.

SPRNT MODEL

The Simulation Program for River Networks (SPRNT) was developed by Liu and Hodges (2014) to demonstrate that the SV equations can be solved efficiently for large river networks without linearization. This initial work showed that $O(10^5)$ computational elements in a river network could be solved for an unsteady SV solution $330\times$ faster than real time using an ordinary desktop workstation without any parallel processing. As is the case for any SV solution method, SPRNT input data includes: (i) the river network topology, (ii) the channel slope (S_0) of each element in the network, (iii) representative channel cross-sections for each element, and (iv) the channel roughness. SPRNT uses the conventional Manning's n and a SV formulation with flow rate (Q), and cross-sectional area (A) as solution variables:

$$\frac{\partial Q}{\partial t}+\frac{\partial}{\partial x}\left(\frac{Q^2}{A}\right)+gA\frac{\partial h}{\partial x}=gA\left(S_0-S_f\right) \tag{1}$$

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} + q_\ell = 0 \tag{2}$$

where S_f is the friction slope and q_ℓ is the lateral flux from the landscape. The local water depth (h) is an auxiliary function that depends on the cross-section geometry i.e. $h = h(A)$. Using the Chezy-Manning equation for S_f allows one to write $AS_f = n^2Q^2F$, where $F = P^{4/3}A^{-7/3}$ is an equivalent friction geometry with P as the wetted perimeter of the cross-section. Note that $F^{-1} = AR_h^{4/3}$, where R_h is the traditional hydraulic radius that appears in the Chezy-Manning equation:

$$Q = \frac{1}{n} AR_h^{2/3} S_f^{1/2} \tag{3}$$

Thus F is simply a convenient approach to wrapping the cross-sectional dimensional relationships of Chezy-Manning into a single term. In SPRNT the full nonlinear discrete equations are solved with an iterative Newton-Raphson method using acceleration methods that have previously been applied in microprocessor design.

DATA NEEDS FOR SAINT-VENANT MODELING

The critical data needed for SPRNT are not detailed x:y surveys of every cross-section, but instead for auxiliary functions for $h = h(A)$ and $F = F(A)$ that are abstractions of the cross section. Obviously, given discrete x:y survey data it is straightforward to compute discrete h:A and F:A for each element. However, in the absence of comprehensive surveys: how can we approximate the auxiliary functions from other data? As a further issue, the discrete h:A and F:A functions for a survey will generally have significant discontinuities such that naive application of raw data provides jacobians for the Newton-Raphson solution in SPRNT that are insufficiently smooth. That is, the Saint-Venant partial differential equations can only approximate a smooth system, which a priori requires $h(A)$ and $F(A)$ be smooth functions, which in turn requires $A(h)$ and $\partial A / dh$ must be smooth. Turning this idea on its head, if we have some approximation of $A(h)$ that is smooth, we can easily obtain a smooth wetted perimeter $P(h)$ that is consistent with $A(h)$, and hence compute $F(A)$ and $h(A)$ functions for a SV solution. Thus, the critical question for SV modeling is not the precise, detailed survey shape of the cross-section, but what is a smooth approximation of $A(h)$ that can be estimated from available data? We are investigating several avenues for this approximation, which will be discussed in the presentation.

SYNTHETIC BATHYMETRY METHOD DEVELOPMENT, VALIDATION AND APPLICATION TO FIVE PACIFIC NORTHWEST RIVERS

Zachary P. Corum, PE, Hydraulic Engineer, USACE Seattle District, Seattle, WA, zachary.p.corum@usace.army.mil; Travis D. Ball, Hydraulic Engineer, PE, CFM, USACE Seattle District, Seattle, WA travis.d.ball@usace.army.mil; Matthew J. Hubbard, Engineer 1, Brown and Caldwell, Tacoma, WA, mhubbard@brwncald.com

Abstract: This paper presents a simple, robust, and relatively efficient workflow to create and "burn in" high resolution synthetic river bathymetry data into existing LiDAR datasets. The Synthetic Bathymetry (SB) method uses widely available GIS and hydraulic modeling techniques to create physically-based synthetic bed elevation data without introducing significant error in computed water surface elevations and average channel velocities, under conditions where discharge at time of DEM data acquisition is known. The SB method was applied and validated on a small, steep, braided cobble bed river, large and small cobble bed wandering rivers with wide floodplains, and a small, entrenched, low gradient river with tidal influence all in Washington State – as well as a very large, flat gradient reservoir reach in Montana. As a test of the validity of the approach the results of models based on SB data were compared against models based on traditional survey methods, and against models based on LiDAR alone. For low (base) flows, bankfull (2-year) and 100-year flood flows the differences in computed water surface elevations, inundation area, and velocity were small (MAE in water surface elevation of less than 1 foot for all 5 study reaches under low flow, and less than 1 foot for all but the reservoir reach under 2 year and 100-year flood flows). At lesser flood flows to bankfull flows, the MAE in stage is modestly higher, as compared with the baseline models. For the reservoir reach, the model results were generally poor during 100-year flood flows as compared with the other rivers, however the error reduction in water surface elevation (from use of an unadjusted DEM alone) was nearly 30 feet. The good to excellent agreement of the SB models to the baseline in four of the five study reaches is attributed to the ability of the SB method to create the flow area needed to convey flood flows at comparable stages and velocities as survey based models. The SB method holds promise for speeding up and reducing the cost of 1-D and 2-D hydraulic modeling efforts where multiple decimal place accuracy is not required. The SB method can significantly reduce error in cases where only a DEM is available, and reduce the need for tedious, subjective terrain data manipulation commonly associated with interpolation between widely spaced cross sections. The SB method could improve the quality of models in cases where site conditions (unstable channel, remoteness, turbidity, safety) prevent bathymetric data collection but otherwise allow for above-water aerial survey techniques (photogrammetry, satellite, LiDAR, Structure from Motion). Other potential uses include estimation of bed elevations to track sediment movement under rapidly changing conditions, such as below a dam removal.

INTRODUCTION

This paper presents a relatively simple technique for creating physically based riverine bathymetric data from digital elevation models (DEMs) and discharge data using GIS and the US Army Corps of Engineers software HEC-RAS (USACE 2014). For the purposes of this paper DEM pertains to topographic datasets derived from photogrammetry or Light Detection And Ranging (LiDAR) techniques. The method described in this paper results in a “burned in” or “eroded” (synthetic) river bottom within a digital terrain model that otherwise lacks bathymetric data. In shallow rivers the method has shown promise at preserving riffle crest elevations, side channels, and large in-channel roughness elements. The technique can be used for any case where flow is nominally unidirectional, confined within banks, and is either known or can be estimated at time of topographic survey. Virtually any 1-D or 2-D modeling package that allows for computation of inundation maps can use this method.

The method, termed herein as the synthetic bathymetry (SB) method, has several potential applications in the fields of hydrology, hydraulics and fluvial geomorphology and is best suited for determining reasonably accurate water surface elevations in situations where data is scarce and/or where projects do not require stringent accuracy. The method also allows for filling in gaps between surveyed cross sections without interpolation, which helps preserve the near bank, and mid channel topography (large roughness elements) that may be important for 2-dimensional model studies. It also allows for a physically based estimate of riverbed elevations below the water surface which can be valuable for estimating long term geomorphic change over large areas.

This paper investigates the relative accuracy of one dimensional hydraulic models constructed from surveyed cross sections, from DEM data alone, and from DEM data blended with SB data. Published flood insurance study data or recently calibrated survey-grade hydraulic models are used as benchmarks to test the validity of the results using SB data.

BACKGROUND

LiDAR data sets are becoming widespread and have quickly become some of the most valuable data for hydrologic, hydraulic and geomorphic studies. The LiDAR data is usually extracted and processed for inclusion in a numerical model of hydrologic processes. Due to technical limitations many LiDAR datasets lack elevation information below the water surface (bathymetry), requiring collection of channel data with other methods. Alternately, models are used without this data due to cost constraints, reducing the quality of the results. As survey and post processing technologies improve, terrestrial floodplain topography can be acquired for large study areas in the time it takes to fly along the river in a helicopter or airplane. Despite their high resolution, most available LiDAR data sets used to create DEMs do not include bathymetric LiDAR data (now possible with certain sensors and shallow, clear water conditions – see River Bathymetry Tool Kit (McKean et al, 2009)). Other recent innovative methods to remotely survey the channel bottom, which also require clear water conditions, include correlation of aerial imagery based DEMs to physical measurements of depth (Javernick et al, 2014). Currently, several technologies are available to acquire high resolution topographic and bathymetric data to support floodplain studies (Bangen et al, 2014). Many of these technologies are complex and costly to use. Considerable effort and skill are necessary to check, verify, and blend available data to create a seamless riverine terrain model. Also, due to the high equipment costs associated with some technologies and large data sets created by modern equipment, considerable effort and expense are necessary to acquire, maintain, and post-process these data. But as two dimensional modeling moves to the forefront of hydraulic engineering practice, the demands for bathymetric data will continue to increase.

Thus, the current state of the practice is one where engineers and scientists have a plethora of terrestrial data sets to choose from, from which any number of cross sections can be created. Below-water bathymetric data, however, remain sparse and difficult to acquire in many settings. Use of interpolated or "best guess" bathymetry in hydraulic models introduces unknown errors that add uncertainty and risk to project findings and decisions resulting from the modeling. Fortunately, many of the issues resulting from missing bathymetry can be partly overcome by applying first principles and combining off-the-shelf GIS and hydraulic modeling software. This paper presents and validates one such method, termed the Synthetic Bathymetry (SB) method that allows for automatic manipulation of terrain data to "burn in" SB data under the LiDAR water surface to address circumstances where underwater survey data is lacking but improved model accuracy is desired.

SYNTHETIC BATHYMETRY METHODOLOGY

Commonly used open channel flow numerical models allow for computation of fluid depth based on first principles of open channel flow (conservation of energy, continuity of flow, conservation of momentum). If a numerical backwater model is used, such as HEC-RAS (USACE 2014), to perform a standard step backwater calculation, the energy losses due to cumulative expansion, contraction, and roughness losses can be accounted for in estimating the local variation in hydraulic conditions, such as velocity, depth, and stage. As with most open channel flow models, the quality of the hydraulic output depends on the quality of the input, namely survey data and how well the modeler captures the characteristics of the terrain.

For purposes of floodplain modeling and mapping, the goal is typically to first compute the losses in energy (expressed as fluid head) using standard step backwater computations, then to map the resulting water surface elevations across the terrain data used to construct the model. All major changes in cross section, planform, slope, and roughness need to be represented in the model to yield good estimates of local and cumulative energy losses. If a river model is constructed accounting for local changes in slope, width and roughness, then the depths and velocities can still be computed even if the bed elevations are not known with high accuracy. In this situation the accuracy of the results will be biased by the initial error in the bed elevations. Recognizing that LiDAR provides an extensive and detailed record of the water elevation at time of survey (calibration data), we can write the following equation for the LiDAR surveyed water surface elevation (WSE_{Survey}) resulting from a hydraulic simulation of the flow elevation at time of the LiDAR flight:

$$\mathbf{WSE}_{\mathbf{Survey}} = \mathbf{WSE}_{\mathbf{initial}} - \mathbf{E}_{\mathbf{initial}} \quad (1)$$

Where E represents error, the difference between the computed elevation ($WSE_{initial}$).and the "true" elevation and If the water level in the LiDAR is treated as terra firma in the model cross sections (as a false river bottom), all flow will then occur above the "correct" elevation. Thus the depth of flow above the initial "false bed" is the error in equation 1.

$$\mathbf{E}_{\mathbf{initial}} = \mathbf{WSE}_{\mathbf{initial}} - \mathbf{Z}_{\mathbf{false\ bed}} = \mathbf{Y}_{\mathbf{initial}} \quad (2)$$

Where:

$\mathbf{Z}_{\mathbf{false\ bed}}$ = **Bare earth LiDAR elev** = $\mathbf{WSE}_{\mathbf{Survey}}$

$\mathbf{Y}_{\mathbf{initial}}$ = **initially computed flow depth (above raw DEM)**

Expressed spatially, across a raster grid, at all locations within a raster cell,

$$\mathbf{E}_{\mathbf{initial\ (ij)}} = \mathbf{Y}_{\mathbf{initial\ (ij)}} \quad (3)$$

Where i and j denotes the spatial location of a given raster cell of a given dimension. It is then proposed that,

$$\mathbf{Z}_{\mathbf{SB\ (ij)}} = \mathbf{Z}_{\mathbf{false\ bed\ (ij)}} - \mathbf{Y}_{\mathbf{initial\ (ij)}} \quad (4)$$

Where $Z_{SB\ (ij)}$ represents a synthetic river bottom elevation at a given raster cell. By subtracting the initially computed flow depth ($Y_{initial\ (ij)}$) from the false bed ($Z_{false\ bed\ (ij)}$) at every raster cell, the synthetic river bottom is "burned" or "eroded" into the DEM, creating the SB data set ($Z_{SB\ (ij)}$). Note that the error is specific to each location in the modeled space, and that modern versions of both open channel flow and GIS software are needed to perform the above calculations. In this paper, Arc GIS version 10.1 and HEC-RAS version 5.0 were used. This version of HEC-RAS allows for simulation of 1- or 2-dimensional flows and rapid computation of inundation depth rasters (Geotiff format) at all points in the model domain. SB data creation requires low flow inundation depth rasters to be created at the same resolution as the underlying terrain raster (Figure 1).

Figure 1 below illustrates a short a portion of two Dungeness River low flow hydraulic models created to test the effects of the different bathymetric data sources on model accuracy (see low flow calibration and high flow calibration sections of this paper for more discussion). Figure 1 shows how the raw, LiDAR Only (LO) DEM compares with a SB based DEM, and how the approach uses GIS raster math to calculate the elevation of the SB raster data at the grid cell scale. Note the greater area of inundation present in the LO low flow model results – which is due to the effects of the artificially high false bed in the DEM. Also note the planar contours of the channel bed present in the LO DEM as compared with the SB DEM.

Once the "burned" or "eroded" DEM is created the quality of the resulting data needs to be checked by running the low flow hydraulic model extracted from the SB data. The low flow model should include reasonable flow resistance parameters and the best estimate for discharge available throughout the model domain. Using the water surface profile plot options and comparing the initial DEM-based plan to the SB-based plan in HEC-RAS allows for verification that the results are reasonable (Figure 2). Our experience is that minimal tuning of n-values is necessary to provide good fit between the computed and surveyed low flow water surface elevations. Figure 2 is representative of the quality of fit that results when low flow data is known with confidence and high quality LiDAR is used.

In application of the SB workflow (described during talk) we found that there are common difficulties when calibrating to low flow surveyed water elevations extracted from the DEM. These typically occur at the downstream end of the model (if the starting water surface is assumed to equal the surveyed water surface). Our initial experiences suggest that starting the model at normal depth will overcome most downstream boundary problems. Increasing n values locally can be used to force the river to deeper depths where pools are known to be present. If calibration difficulties are encountered throughout the model, this is most likely an indication of poor discharge estimates in the model. Even if available survey data is outdated, it should be used as a check of the SB DEM. If the SB data is suspect, it should be replaced with traditional survey data.

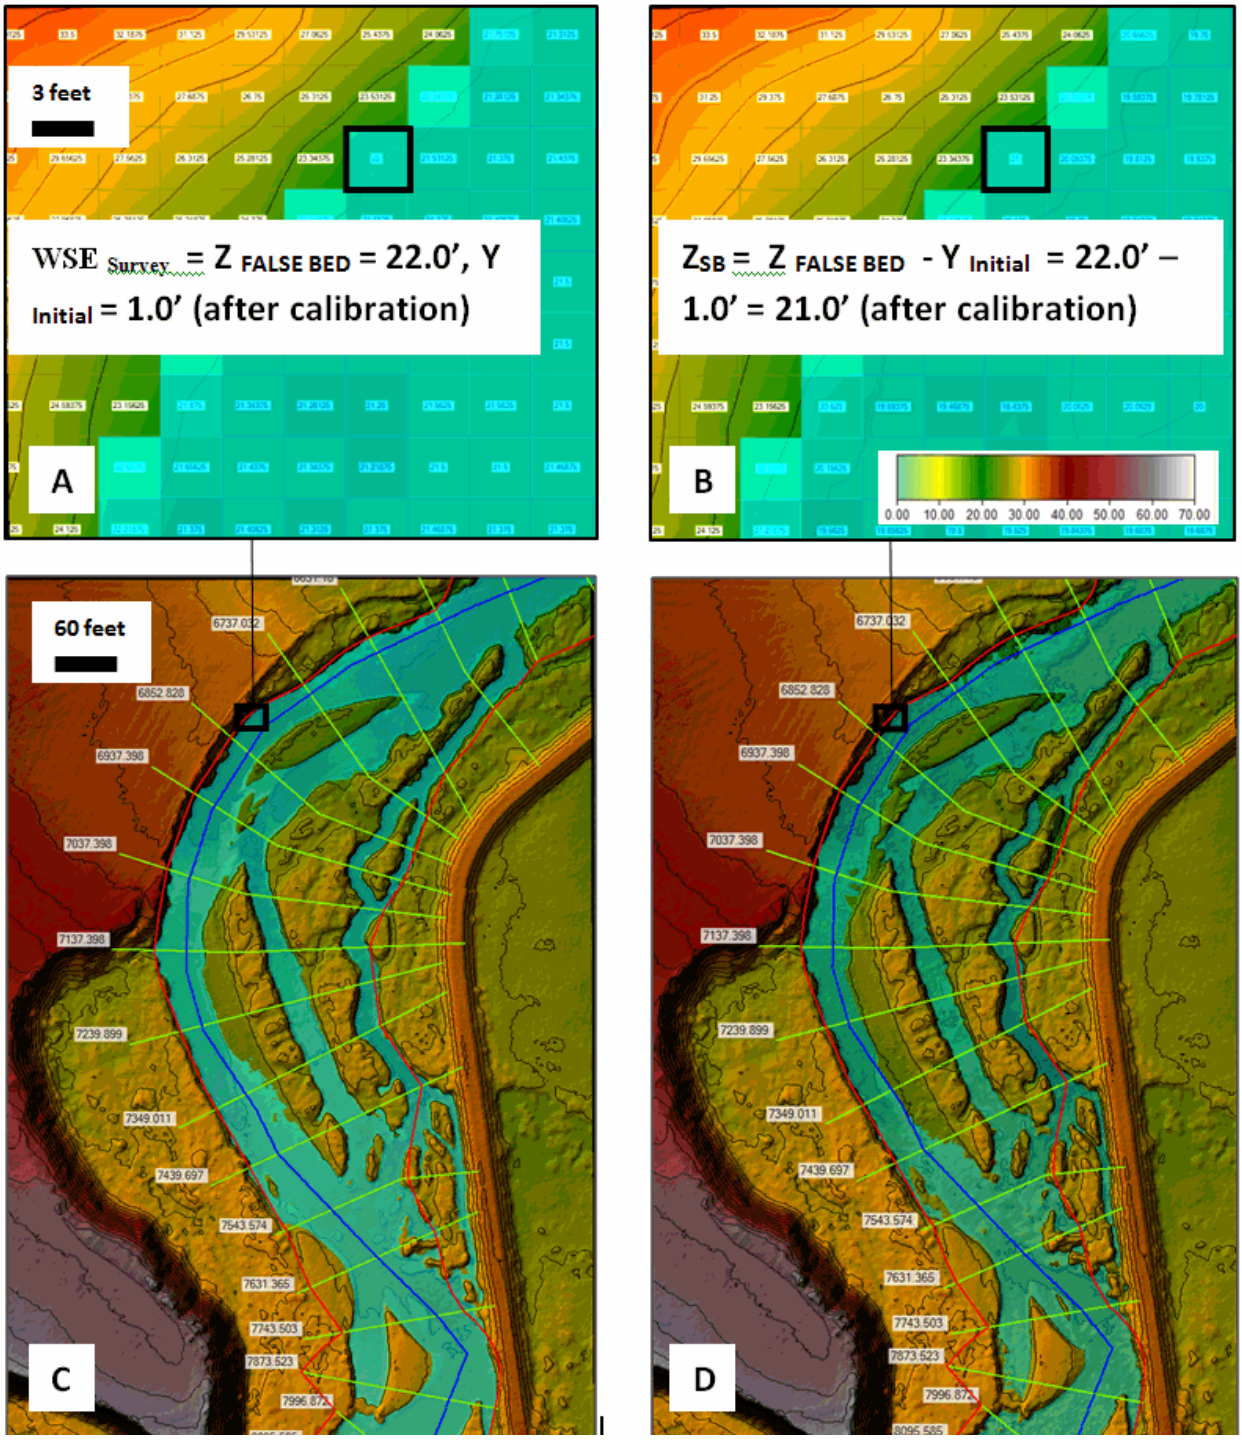

Figure 1: Dungeness River, WA (RM 1.3 to RM 1.6). (A) Close up showing initial LiDAR terrain grid cell center elevations ($Z_{FALSE\ BED}$). Each grid cell is 3 feet x 3 feet. Blue shaded numbers are cells that are wetted. Discharge at time of survey is 340 cfs. (B) Close up showing SB terrain computed grid cell center elevations (Z_{SB}), and how Z_{SB} is computed. (C) LiDAR terrain data overlaid with low flow hydraulic model cross sections, river centerline, banks, and resulting initial estimate of inundation area for flow at time of the LiDAR flight. Contour interval is 2 feet. Flow direction is south to north. (D) Synthetic bathymetry terrain data overlaid with low flow hydraulic model and computed inundation area. Note that all major geomorphic landforms with exception of deep pools are captured.

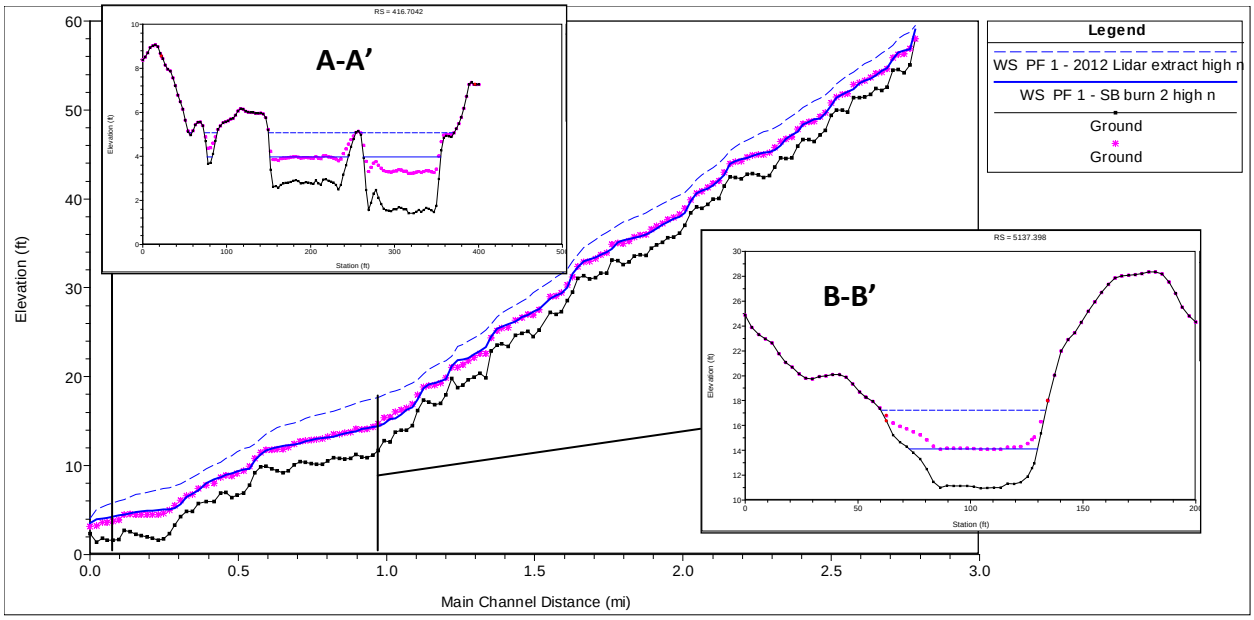

Figure 2 –Dungeness River, WA. Low flow hydraulic model verification against LiDAR surveyed water surface. In the water surface profile and cross sections the dashed blue line is initial estimate of water surface profile using LiDAR false bed elevation. Blue solid line is water surface computed after burning the initial depths into the LiDAR to create synthetic bathymetry (SB) data. Pink * is initial LiDAR surveyed water surface elevation (assumed to equal lowest point on cross section extracted from bare earth LiDAR) used to validate SB low flow model. Cross section A-A' shows how the method is able to burn side channels and main channels simultaneously while preserving large scale geomorphic features. The error in the depth is partly attributable to uncertainties about how much flow was in the main channel vs. the side channel. If the side channel was assumed dry, the main channel would have been stamped to a deeper elevation, which may have resulted in a better match. These errors are unavoidable without aerial photos to aid decisions on where to set limits of the channel in the model. Cross section B-B' is representative of how the method works in an ideal setting. The water surface matches the LiDAR survey, with minimal alteration of the cross section shape.

Note that the SB DEM is created after one or more calibration attempts to match low flow water elevations. This ensures that the low flow model and DEM have adequate conveyance to match low flow water surface elevations. In real rivers, as well as in numerical models, it is widely known that riffles are a primary control on flood elevations and that at high flows water surface elevations tend to follow a smoother longitudinal profile that drowns out bed elevation undulations more prominent at low flows. A fundamental assumption embedded in this approach is that as long as the SB DEM is the result of a well calibrated numerical model that captures riffle elevations (as shown in Figure 2 above), error in thalweg elevations between riffles will not significantly impact estimates of flood elevations. A primary goal of the high flow validation section of this paper is to test the validity of this assumption.

STUDY REACH DATA

Hydraulic models developed by others were acquired to establish baseline conditions for investigating the effects on the results of hydraulic models derived from ground survey based methods, from LiDAR alone, and from LiDAR blended with SB data. All baseline models used for validation purposes were developed by others. The Green River models were acquired from King County, prepared as part of a Preliminary Revised Flood Insurance Study (2007). The Skykomish River model was obtained from Snohomish County and was developed as part of a Revised Flood Insurance Study (2010). The Dungeness River model was developed by USACE Seattle District as part of a Feasibility Study (2014). The Clark Fork model was developed by USACE Northwest Division as part of the Columbia River Treaty Flood Risk Assessment (2012). All baseline models were used as-is, reflect real-world conditions and are based on modern modeling and mapping standards.

The Dungeness, Skykomish, and Green River in western Washington State, and the Clark Fork River, a tributary to the Columbia in Idaho and Montana were used for this study (Figure 3). For ease of comparison the Green River model was subdivided into the Middle and Lower Green Rivers based on a geologic reach break near river mile (RM) 32. All study reaches in Washington State are glacially modified alluvial floodplains, draining heavily forested mountains that have hydrology typical of the Puget Sound lowlands (high intensity fall and winter rains, spring snowmelt runoff). A flood control dam on the Green River caps flood flows at the pre-dam 2-year recurrence interval discharge, while the Skykomish and Dungeness are free flowing. In contrast, the Clark Fork River study reach is wholly contained by a bedrock gorge and is heavily influenced by hydroelectric dams located at both ends of the study reach, which causes the river to behave like a reservoir under all but the highest discharges.

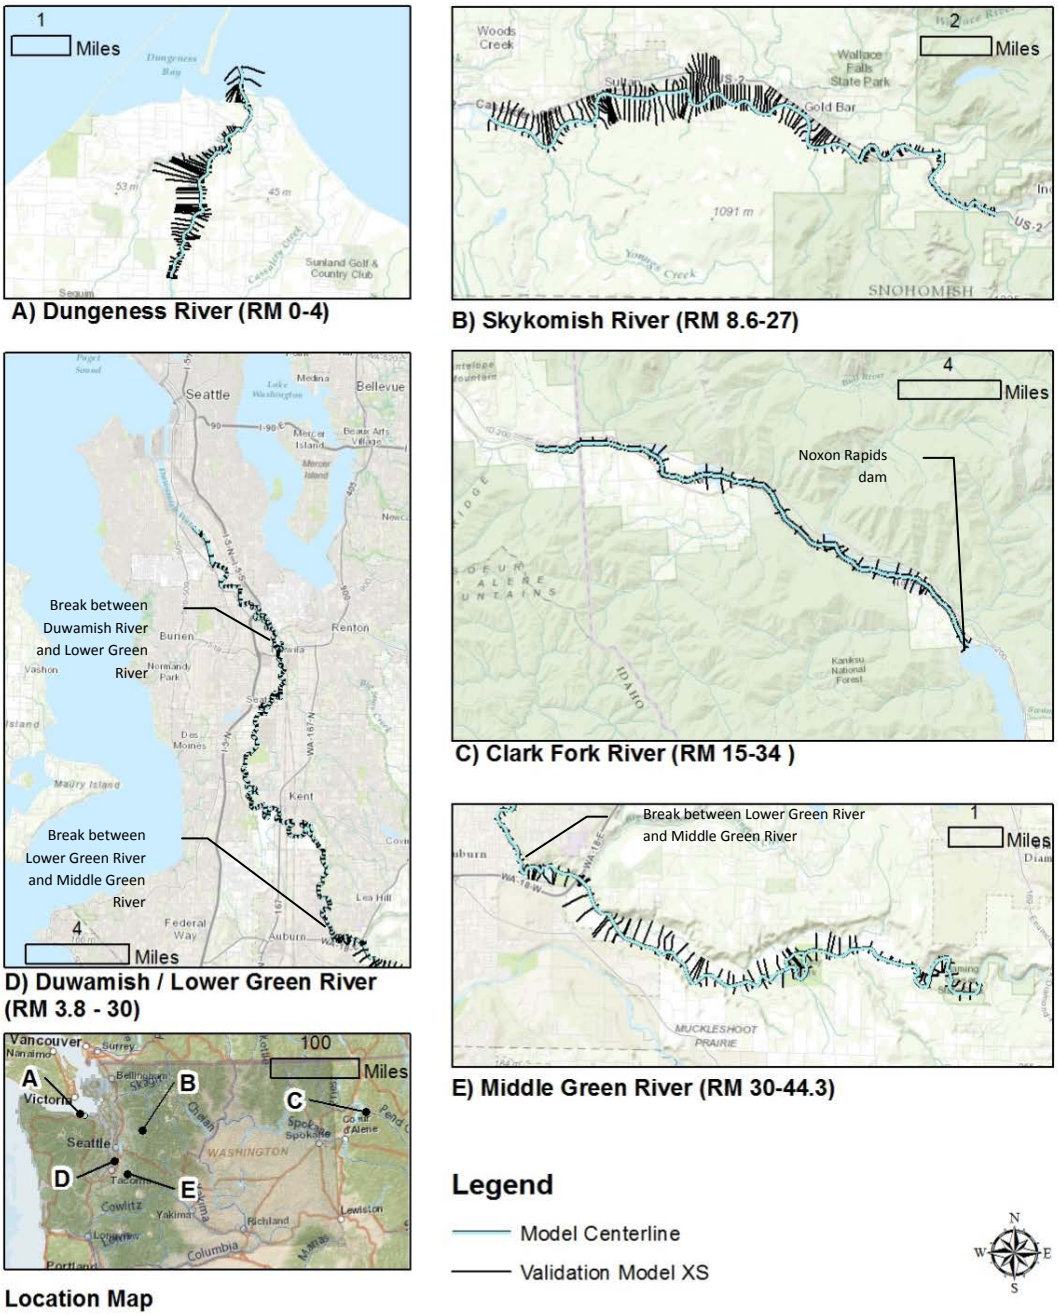

Figure 3: Location and vicinity maps of SB low flow and validation model reaches

The Dungeness River is the shortest and steepest of the study reaches, with the lowest 100-year discharge, while the Lower Green River is the longest and narrowest of the study reaches (Table 1). The flattest and most confined reach is the Clark Fork River – however the flat gradient is the result of a downstream dam. The natural valley gradient is much steeper given the canyon setting. The Dungeness, Skykomish, and Middle Green River are gravel/cobble bedded with boulders in places. The Skykomish River is the largest of the alluvial rivers studied, with large amplitude migrating meanders and wide floodplain All alluvial rivers studied are artificially confined by road embankments, revetments and levees near developed areas, the lower half of the Dungeness River and Lower Green River being the most confined. Hydrologic data available is of relatively high quality, with more than 80% of the study reaches gauged for all but the lower half of the Skykomish River. Flows at time of survey were about 10% of the 2 year discharge for the Dungeness and Green River, about 4% for the Skykomish, and about 22% for the Clark Fork, indicating that the discharge at time of survey was well below bankfull conditions.

Table 1: Study Reach Low Flow and Baseline Model Data

				Reach Average (Std Dev)		Discharge Estimates (cfs)		
Study Reach	**Length (miles)**	**Minimum % gaged in reach**	**Drainage Area (square miles)**	**EGL Slope & (EGL Stdev) (ft/ft) (1)**	**BFW/ BFD & (BFW/BFD Stdev) (ft/ft) (2)**	**@ time of survey**	**50% AEP (2-yr)**	**1% AEP (100-yr)**
A. Dungeness River, WA	2.8	95%	198	0.0044 (0.0024)	67 (95)	340	3,000	9,100

SB LOW FLOW MODEL CALIBRATION

The key issues affecting the quality of the results of the SB method are determining the extent of low flow model cross sections, estimating the amount of flow present within the model at time of survey, and deciding how much to refine the model to achieve good match to the surveyed water surface elevations.

Table 2 below summarizes the error in the SB and LiDAR Only (LO) computed water surface elevations – in low flow conditions – for the five study reaches with respect to surveyed water surface elevations at each transect location in the model, after one or two calibration attempts. Calibration consisted of adjusting Manning's n values in the channel for the low flow model to better match the LiDAR surveyed water surface. In cases where significant amounts of flow was diverted at different elevations into side channels we either isolated all the flow into the dominant channel by limiting the cross section width, or constructed a connected side channel reach. The results were compared with the surveyed water elevations, which are extracted from the low point on each model cross section. Alternatively one could have used a 2-D model to estimate water elevations in the main and side channels at low flow.

The results for all five study reaches provide excellent-to-good matches of the surveyed water elevations during low flow conditions (average difference in computed low flow elevation is less than 0.1 to 0.5 feet from surveyed

elevation). In contrast the average error using only the LiDAR data ranges from 1.8 to 5.6 feet (and more than 25 feet in the Clark Fork reservoir reach). Note that in all cases additional refinements of the SB data to better match surveyed elevations were possible, however we viewed the low flow results as favorable enough to proceed to high flow validation.

Table 2: Low flow SB derived hydraulic model results after calibration vs. LO hydraulic model results as compared with low-flow surveyed water surface elevations

Reach length (mi)	2.8		20.1		18.9		26.1		14.3	

The excellent results on the 26-mile long Lower Green River reach were surprising given the tidal influence, however the survey at low tide and trapezoidal channel shape helped ensure that much of the channel conveyance area was captured in the initial terrain data. The higher-than-average errors in the Skykomish model are attributed to large uncertainties in flow at time of survey, effects of split flows around gravel bars, and errors and artifacts in the older vintage LiDAR data (trees, etc.). The excellent results for the Dungeness are partly attributed to the modern techniques used to acquire and post process the LiDAR data and the presence of a stream gage within the reach. The Clark Fork River reach – which is a backwatered canyon upstream of a dam – actually fairs better in the low flow than high flow model run (discussed in next section) because the known water surface at the downstream pool drives the water surface profile throughout the reach.

The good to excellent results over a wide range of channel sizes, slopes, and geomorphic types suggests that the SB method is capable of creating low flow hydraulic models that closely match surveyed water elevations, while preserving major geomorphic features of the channel (Figure 1D, Figure 2). Additionally, use of LiDAR data without adjustment may result in errors (under low flows) that exceed tolerances for most types of engineering studies. The effects of using unadjusted bare earth LiDAR data or SB terrain data without further parameter adjustment for flood conditions are presented in the next section.

SB HIGH FLOW MODEL VALIDATION

To validate the SB (and LO) DEMs, baseline hydraulic models developed by others to estimate floodplain depths and elevations were modified by re-cutting all cross sections from the original LO DEM and from the SB DEM. The steady flow step backwater models were then run with the new cross section data but without any further parameter or boundary condition adjustments to determine how the errors in the underlying terrain data affected the model results for the “bankfull” 2-year (50% annual exceedance probability) and “base” 100-year (1% annual exceedance probability) flood events.

Table 3 below summarizes the error in computed water surface elevation, flow area, average channel velocity, and average channel shear stress for the five study reaches from SB-based model and LO-based model with respect to results computed from the baseline models. The error statistics shown in Table 4 represent reach averages of the cross sectional difference between the results for the SB model or LO model and the baseline model. The percent change in error in Table 3 represents the reduction in error resulting from use of the SB model vs. the LiDAR only model.

Table 3: Study Reach Average Absolute Error Residuals in Computed WSE, flow area, velocity, and shear stress for SB and LiDAR Models with respect to Baseline Model

Note 1 – Study average % change is the difference in the LO reach average error statistic and SB reach average error statistic divided by the reach average LO error statistic, then averaged for all reaches (excluding Clark Fork).
Note 2 – Study average % change includes Clark Fork.

From Table 3 we can see that the study reach median error in SB model computed water surface elevation (WSE) ranged from -0.4 feet (Lower Green River) to 0.7 feet (Clark Fork) for the 2-year event, and ranged from -0.3 feet to 4.9 feet for the 100-year event (same reaches). The Dungeness and Middle Green models have the best overall match of the baseline WSEs, with 0.2 feet or less error on average for both the 2 year and 100-year events. Figure 5 provides a representative comparison of computed water surface profiles for all study reaches. The improvement in results from use of the SB method is most pronounced for the Lower Green, Clark Fork and Dungeness, which are all highly channelized or confined. The unconfined Middle Green and Skykomish have overbank floodplains that convey much of the flood flow, causing the results to be less sensitive to use of SB data.

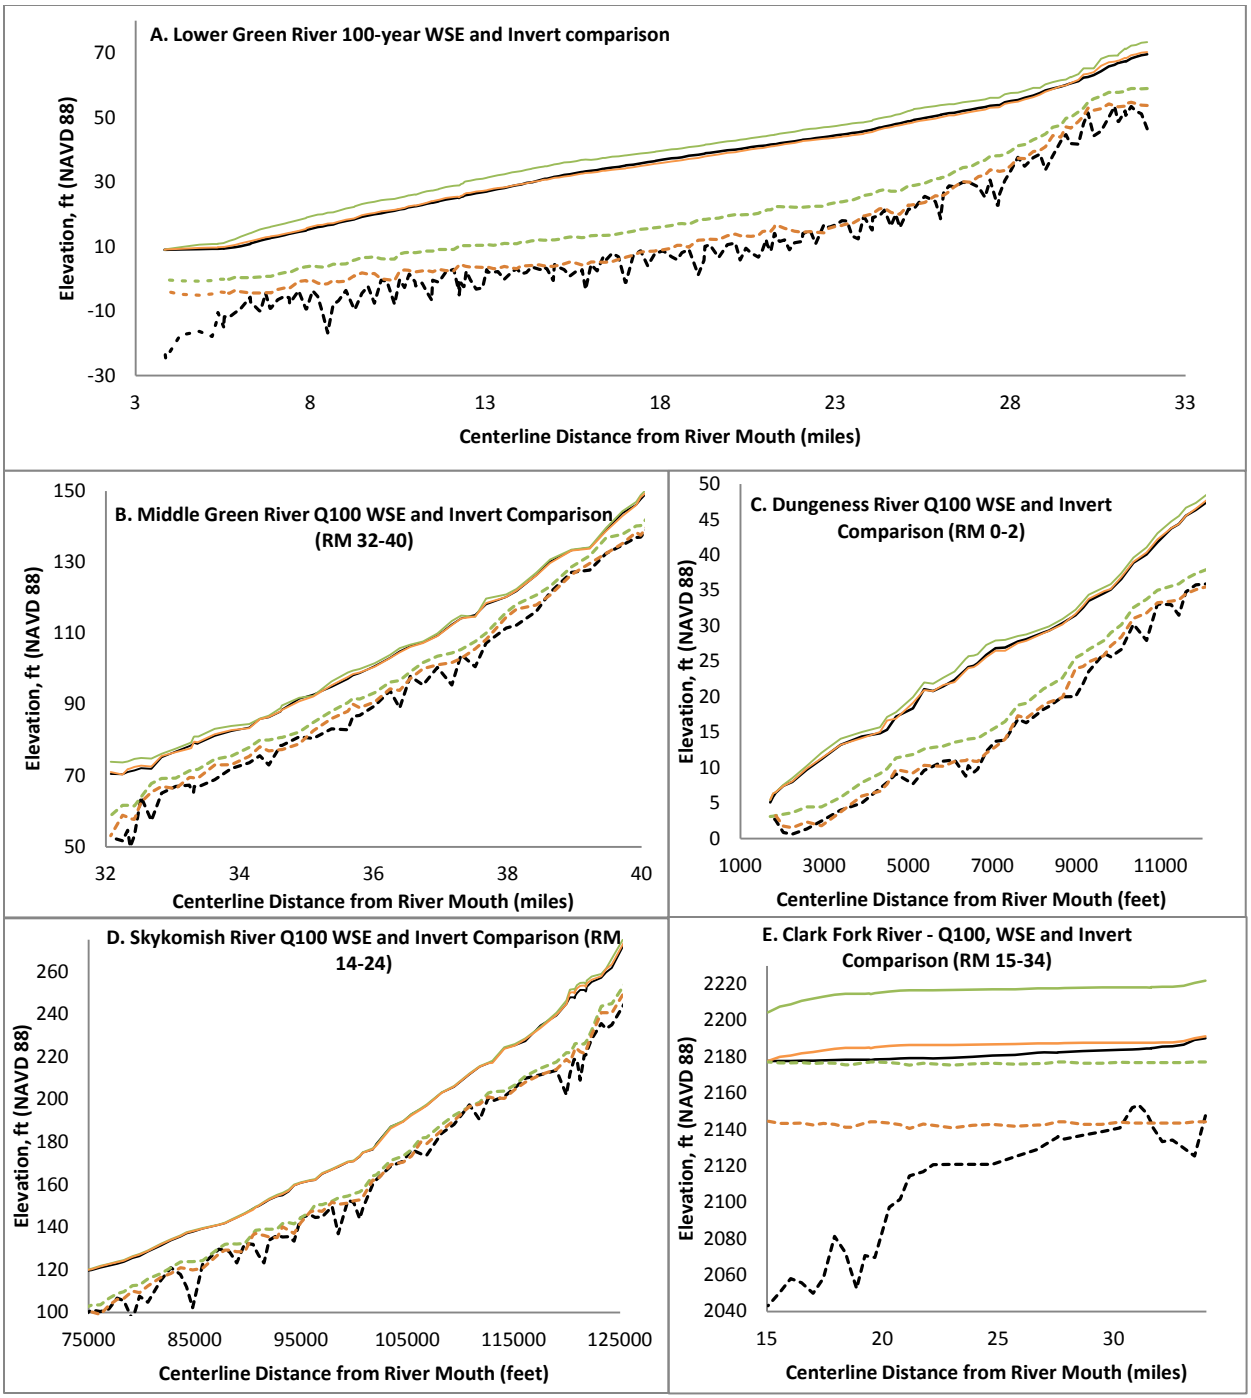

Figure 5. Computed 100-year flood water surface profiles and invert elevations for A) Lower Green (RM 3-32), B) Middle Green (RM 32-40), C) Dungeness (RM 0-2), D) Skykomish (RM 14-24), E) Clark Fork (RM 15-34). Green lines reflect initial bed elevation and computed WSE from original LO data, orange lines reflect SB bed elevation and computed WSE from SB data, black lines reflect surveyed bed elevation and computed WSE from baseline RAS model. Solid lines are computed WSEs, dashed lines are invert elevations.

The limitations and benefits of the SB method are seen from inspection of the Clark Fork results. Clearly the method cannot reproduce the river invert elevations submerged under the dam backwater, however the model still reduces average error in stage by more than 25 feet if one had used the LiDAR alone. For all but the Clark Fork the SB channel invert tracks the elevation of existing riffles quite closely, and results in hydraulic models that closely match

those of the baseline model in terms of WSE, flow area, velocity, and shear stress. Compared with models based on use of LiDAR alone, results are significantly improved for all study reaches.

The slight upward bias in flood stage resulting from the SB approach (under normal conditions) and more pronounced upward bias from use of LiDAR data without adjustment is when comparing total inundation area. Inundation area error is 0-5% in all reaches using the SB method, compared to 2-50% using the LO model. The error for the 2-year event is higher than that of the 100-year event for all but the channelized (trapezoidal) Lower Green. At higher stages the other reaches use more floodplain conveyance – which is not affected by the bathymetric data collection method.

SUMMARY

The SB method allows for creation of reasonable synthetic channel bathymetry data from LiDAR data, flow information, and widely available GIS and hydraulic software. The quality of the results can be easily demonstrated by comparing computed water elevations and velocities to the DEM water surface elevation at time of survey and to baseline model results or to high water marks. For this study the SB method results (comparison of computed flood stage to baseline) were excellent for a short steep sediment laden river with recent LiDAR and a gage within the reach, and poor for a reach upstream of a dam where true channel depths were many times that estimated using the SB approach. For a low gradient tidal river and medium gradient gravel bed river the results were very good. On a medium gradient wandering gravel bedded river with older LiDAR and higher uncertainty over low flow discharge the data were generally good to poor in isolated areas near bridges.

For all five study reaches the SB method significantly reduces the errors resulting from use of cross sectional data derived from LiDAR alone but does not eliminate the errors. This trend of reduced error is observed for all the flows analyzed and all the hydraulic parameters analyzed, other than depth. The median and average error when compared to baseline hydraulic models was typically less than 1 foot at bankfull stages, and under ideal conditions was less than 0.5 ft at 100-year flood stages. A river reach that is significantly affected by downstream backwater caused by a dam was used to check the quality of the method under non-ideal conditions. While the stage errors at low flow were less than 1 foot, the SB method was not able to create enough conveyance to pass 100-year flood flows with less than 4.7 feet of error (reach average). While this result at first glance is poor compared with the other reaches studied, the relative reduction in error compared with using a DEM without bathymetry is about six-fold. The location within a bedrock canyon suggests the error may not be significant with respect to adjacent development.

DISCUSSION

Under low and 2-year flood conditions we observed good to excellent matches of baseline and SB water surface elevations for all five study reaches, with the MAE of less than 1 foot for all but the Clark Fork reservoir reach. (Note that the results presented in this paper are not being compared to observed conditions at high flows which means that while the SB model results may provide a good match to the baseline model, the quality of the SB model with respect to real world conditions has only been evaluated for low flows and not under flood conditions). For nearly all flows and reaches, the results of the validation effort were surprisingly good (for the parameters that are typically meaningful for analysis and design, with the exception of maximum depth) considering that the SB based models lacked below-water survey data. This suggests that in similar conditions we would expect to have similar results, provided the quality of datasets and approach used to derive the SB data are similar.

To understand why the SB data results in a model that agrees well with the baseline, consider the significant error in maximum depth associated with models that still provided good to excellent estimates of flood stages (Figure 5) and inundation area. Concurrently, the good results of flow area, velocity, and stage shown in Table 3 (resulting from a 1-D step backwater model) suggest only reasonable estimates of cross sectional area, slope, and roughness are required. Because we are simulating physics of flow in one dimension, using open channel flow equations, all flow is assumed to be down valley, contained within banks, steady and uniform. During low flows, when LiDAR is typically acquired, these conditions are satisfied more often than not. We are simply using physical equations in the SB method (hydraulic model) to tell us how much space (area or volume) flow “takes up” at a given location. Then we are using GIS to create that space below the surface of a DEM for the river so it can pass the surveyed flow at the surveyed elevation. These results appear to confirm our primary assumption that as long as riffles are captured in the SB DEM that errors in flood stage will be small.

The quality of the results in this study are likely related to the setting and quality of the underlying data used to create the SB data. Reaches where the river was confined (Dungeness, Lower Green) with a trapezoidal cross section had the best agreement with the baseline models. The effort to create and apply SB data is significantly less than that needed to perform channel surveys. In less than one day we were able to use the technique to create a 40 mile long model that matched the baseline model computed 100-year flood elevations by less than 0.5 ft on average. While reach average hydraulic conditions computed from 1-D SB based models tracked closely with the baseline models, errors were higher at bankfull stages than at flood flows when the floodplain is active. Other difficulties were encountered where significant backwater was present, at hydraulic constrictions, and abrupt changes in grade or bed elevation. While no effort was made to calibrate the SB models to historical high water marks, we are confident that the close agreement with the baseline model results (with the exception of the Clark Fork) would allow for good calibration with reasonable parameters.

While the SB method will typically result in a DEM that includes a wider and shallower river than exists, it avoids the creation of artifacts common with using educated guesses or automated techniques to "burn" channels into DEMs from sparse survey data. For example all features above the water surface are preserved rather than "averaged out" as occurs when topography is created from widely spaced cross sections. This preserves side channels and bars that may be important for capturing flow paths or effects of macro roughness elements, however it will not capture deep pools or submerged features that may be important for habitat studies. This implies that a potential benefit of the SB approach is to improve the accuracy of a DEM (and model) between surveyed sections.

THE NEED FOR DUE DILLEGENCE AND REFINEMENT

This paper presents the promising results of a validation study of a method to create synthetic bathymetry for five rivers in the Pacific Northwest of varying size and geomorphic character. Until such time that the method has been validated for a wider range of channel types and rivers by other practitioners, we must recommend against applying it in cases where higher resolution survey grade data is warranted (i.e. life safety is of concern). In cases where flow data at time of DEM survey is lacking or uncertain, the SB approach will not provide reliable results, and could result in under-estimation of flood risk. Field data (discharge-elevation rating curves) may be needed to ensure the results are reasonable or to improve results. The potential cost savings of this method, while attractive, implore practitioners to collect detailed calibration and verification datasets to demonstrate the quality of the underlying SB data and model results. Models developed with this approach should be flagged as such, and a calibration and verification write-up should be included with model documentation. Before applying the SB method to a reach lacking a baseline model it is strongly recommended that one first independently validate the approach on a reach with a survey grade calibrated model to ensure that the approach is providing reasonable results. Further validation studies of the SB method with 1-D and 2-D unsteady state models are also recommended.

AKNOWLEDGMENTS

The authors appreciate the support of Seattle District staff and management and Clallam County, King County, and Snohomish County that provided baseline hydraulic models and data used to conduct the study. The authors wish to thank an anonymous reviewer that significantly improved the quality of the final manuscript.

Abstract: Hydrological characteristics in the arid/semiarid southwest create unique challenges to watershed modelers. Streamflow in these regions is largely dependent on seasonal, short term, and high intensity rainfall events. The objectives of this study are: 1) to analyze the unique hydrology of a watershed located in the southwestern USA; and 2) to evaluate the Soil and Water Assessment Tool (SWAT) applicability on this watershed. USGS historical precipitation and stream discharge patterns were analyzed to determine the hydrological characteristics of the upper San Pedro watershed. It was found that runoff was decreased in downstream gauging locations because of transmission loss due to low groundwater level. Based on this analysis, the SWAT model was calibrated to reflect the unique hydrological characteristics of the watershed. After calibration, the Nash-Sutcliff efficiency (NSE) coefficient and coefficient of determination (R^2) values were above 0.5 (except the NSE coefficient for annual calibration at Redington gauge), and percent bias (PBIAS) were in the range of ±25% (except annual calibration at Charleston gauge), suggesting satisfactory model performance. The SWAT model, set up with the optimal parameters, generally reflected the hydrological characteristics of this arid/semiarid watershed.

Keywords: Arid/semiarid watershed; hydrology; San Pedro River Watershed; SWAT model; transmission loss

INTRODUCTION

Given the growing demand for water due to urban growth and the likelihood of decreasing precipitation due to climate change, water sustainability has become a dominant issue in the arid/semiarid regions such as the Southwestern USA. To address a nation's or a region's water-related sustainability problems, one of the key elements is to characterize and quantify water resources for different future scenarios including different Landuse and Landcover (LULC) and climate in order to develop better management practices. In the arid/semiarid areas, it has been a great challenge to quantify the water resources due to limited access and monitoring systems on the land and limited capability of hydrological and water quality models to handle the unique hydrology associated with these regions (Baillie et al. 2007, Yu et al. 2011). To accurately model a watershed, the basic hydrology of the region must first be understood.

Streamflow formation after rainfall storm events and interactions with groundwater and vegetation must be properly represented in the model. In arid/semiarid regions, peak discharge and the overall flow regime are mostly produced by extremely variable, high intensity, and short duration rainfall (Syed et al. 2003, Goodrich et al. 1997, Hernandez et al. 2000, Ouessar et al. 2009, Pilgrim et al. 2009, Ghaffari et al. 2010). The processes of streamflow generation and interactions with groundwater and vegetation may be different from humid regions (Pilgrim et al. 2009). For example, transmission loss to the aquifer was found to be a major component of the hydrological processes in the arid/semiarid region.

Models, such as the Soil and Water Assessment Tool (SWAT), are commonly used for future projection and alternative scenario assessment. Using spatially variable data of elevation, soil, and LULC, the model is capable of simulating major hydrological processes including evapotranspiration (ET), surface runoff, percolation, lateral flow, groundwater flow (return flow), transmission losses, and ponds (Arnold et al. 1998) and keeping track of water balance components and crop yields of different land units at various temporal scales. Input data and model outputs are processed through a GIS interface. The model utilizes an interface that is very user friendly and allows users to develop modifications using model documentation and source code (Ouessar et al. 2009, Neitsch et al. 2005). Although SWAT was designed to evaluate the impact of LULC change on watershed hydrology and water quality and has been widely applied for watershed scenario analysis, its application in the arid/semiarid regions has been few but increasing in recent years (Ghaffari et al. 2010, Ouessar et al. 2009, Veith et al. 2010, Gassman PW 2007). Therefore, the objectives of this study are: 1) to analyze the unique hydrology of a watershed located in the southwest of the US, and 2) evaluate SWAT applicability on this arid/semiarid watershed.

METHODS AND PROCEDURES

Study Area and Its Background Information: The upper San Pedro Watershed originates in Sonora, Mexico near Cananea and flows north into southeastern Arizona, USA (Figure 1). In this study, the investigation area is composed of the upper San Pedro Basin and a part of the lower San Pedro Basin to the Redington USGS gauge (Figure 1). For convenience, the entire study area is referred as upper San Pedro in the text.

The upper San Pedro Watershed has a drainage area of about 7,400 km^2, and lies between latitude 30°54′ and 32°30′ N and longitude -110°48′ to -109°45′ W. Elevations in the watershed range from 900 to 2900 m, and annual rainfall ranges from 300 to 750 mm (Biggs 2009). As shown in Table 1, the LULC classes in the watershed mainly include woodland (oak and mesquite together make up 14%), desertscrub (32%), grassland (35%), agriculture crops (2%), urban (2%) (Saleh et al. 2009). Most soils in the San Pedro watershed are gravelly, medium and moderately coarse-textured (USDA). They are nearly level to very steep soils on dissected alluvial fan surfaces. Major soil series include Sierravista (Loamy-skeletal, mixed, superactive, thermic Petronodic Calciargids), Diaspar (Coarse-loamy, mixed, superactive, thermic Ustic Haplargids), Libby (Fine, mixed, superactive, thermic Petronodic Ustic Paleargids), and Forest (Fine, mixed, superactive, thermic Ustic Calciargids). These soils are characterized as well-drained soils with moderately high to high permeability. Major municipal areas along the San Pedro River from south to north are Cananea (Mexico), Hereford, Sierra Vista, Ft. Huachuca, Charleston, Tombstone, St. David, Benson, and Redington (Figure 1).

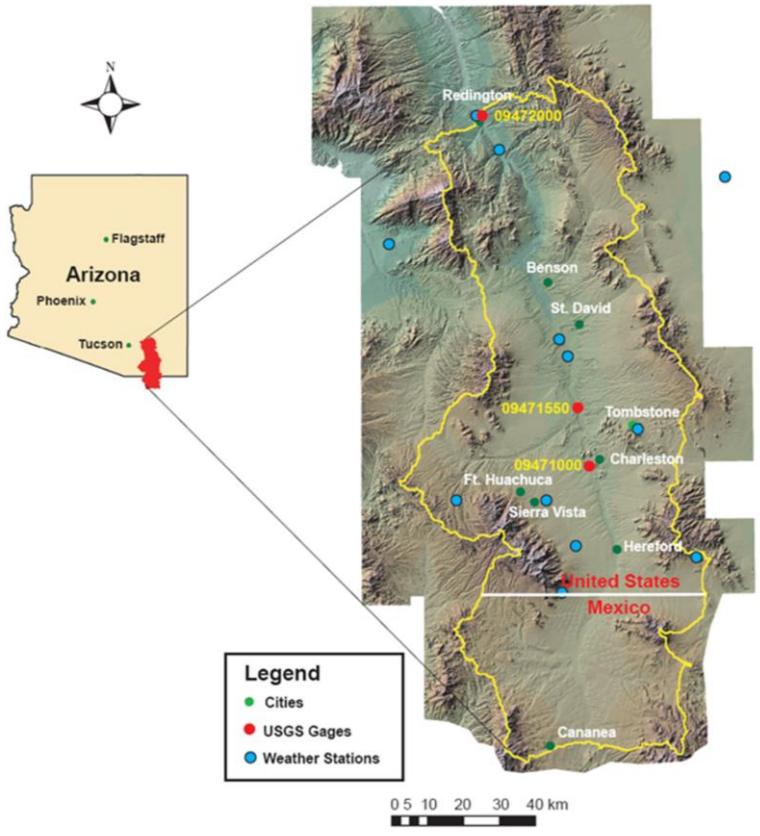

Figure 1 Locations of rural and municipal areas, USGS monitoring gauges, and weather stations in the upper San Pedro watershed (modified from (Kepner et al. 2000)).

The San Pedro River is the last remaining river in southern Arizona that has long perennial reaches (Kennedy and Gungle 2010). The San Pedro River headwaters flow north from Sonora, Mexico into Arizona where the river merges with the Gila River which flow into the Colorado River and finally empties into the Gulf of California. The Upper San Pedro River Basin is noted as a highly diverse ecosystem and important migratory bird habitat and is often studied for its vulnerability to landscape changes due to over development and lowering of the groundwater table (Steinitz 2003, Stromberg et al. 1996, Stromberg et al. 2005, Orr and Colby 2004, Arias 2000, Webb and Leake 2006, Steiner et al. 2000). Trend analysis of the San Pedro River at Charleston, Arizona shows a more than 50 percent decrease in annual streamflow during the 20th century (Thomas and Pool 2006). Efforts to conserve the Upper San Pedro basin are confounded by water rights, international mining

operations, conservation of protected riparian zones, and economic considerations (Steiner et al. 2000, Steinitz 2003). Historical trends show decreases in riparian vegetation and baseflow and storm runoff volumes since the 1900s caused by human induced changes to the landscape and climate changes (Webb and Leake 2006).

Streamflow Data Collection and Analysis: Streamflow data from the USGS stream gauge stations 09471000 San Pedro River at Charleston (31°37′33″ N and 110°10′26″ W), 09471550 San Pedro River near Tombstone (31°45′03″ and 110°12′02″), and 09472000 San Pedro River at Redington (32°22′50″ N and 110°26′45″ W) were downloaded from the USGS website (http://waterdata.usgs.gov) for flow analysis, model calibration and validation.

Locations of those USGS gauges stations are displayed in Figure 1. The Redington gauge station (09472000) is located downstream (north) of the other stations and drains the entire watershed area, which is about 7493 square kilometers. The other two gauge stations Charleston (09471000) and Tombstone (09471550) drains approximately 3159 and 4454 square kilometers, respectively.

To effectively calibrate the model, streamflow trends at three stations were analyzed first to understand the hydrological characteristics of the watershed. Since concurrent streamflow data for all three stations were only available from 1967 to 1985, a streamflow hydrograph (Figure 2) was plotted for the year 1985 to analyze and compare daily discharge characteristics at the three gauge locations. Annual runoff (Figure 3), the sum of monthly runoff downloaded from the three USGS gauge stations, for each location was plotted from1967 to 1985 to analyze annual runoff differences at three sites. The Redington gauge station (09472000) has the largest drainage area (7493 square kilometres), followed by the Tombstone (09471550). The Charleston gauge station (09471000) has the least drainage area (3159 square kilometres).

SWAT Model Description: The Soil and Water Assessment Tool (SWAT) model is a continuous, long-term, physically based semi-distributed model developed to assess impacts of climate and land management on hydrological processes, sediment loading, and pollution transport in watersheds (Arnold et al. 1998). In the SWAT model, a watershed is divided into subwatersheds or subbasins, which are further partitioned into a series of hydrological response units (HRUs). HRUs are uniform units that share unique combinations of soil and land use. Hydrological components, sediment yield, and nutrient cycles are simulated for each HRU and then aggregated for the subbasins.

The hydrological cycle simulated in SWAT is based on the water balance equation:

$$SW_t = SW_0 + \sum_{i-1}^{t} (R_{day} - Q_{surf} - E_a - w_{seep} - Q_{gw})$$

where, SW_t and SW_0 are the final and initial soil water content on day i (mm H_2O), t the time steps on day i, R_{day} the rainfall that reaches the soil surface on day i (mm), Q_{surf} the surface runoff on day i (mm), E_a the evapotranspiration on day i (mm), w_{seep} the interflow on day i (mm), and Q_{gw} is the baseflow on day i (mm) (Neitsch et al. 2005).

The simulated hydrological components include evapotranspiration (ET), surface runoff, percolation, lateral flow, groundwater flow (return flow), transmission losses, ponds, and water yield (Arnold et al. 1998). Evaporation and transpiration are simulated separately in SWAT: evaporation is computed using exponential functions of soil depth and water content and transpiration is estimated using a linear function of potential evapotranspiration (PET) and leaf area index. Three methods can be used to estimate PET: Hargreaves (Hargreaves et al. 1985), Priestley-Taylor (Priestley and Taylor 1972), and Penman-Monteith (Monteith 1965). The Pennman-Monteith method was used to calculate PET in this study. Surface runoff is simulated using a modification of the Soil Conservation Service (now the Natural Resources Conservation Service) Curve Number (SCS-CN) method (USDA, 2004) with daily rainfall. Curve number values used for runoff estimation are based on soil type, LULC, and land management conditions (Rallison and Miller 1981) and are adjusted according to soil moisture conditions (Arnold et al. 1993). Percolation is estimated using the combination of a storage routing technique and a crack-flow model (Arnold et al. 1998). The lateral flow is estimated simultaneously with percolation using a kinematic storage model (Solan et al. 1983). The groundwater flow (baseflow) into a channel is calculated based on the hydraulic conductivity of the shallow aquifer, distance from subbasin to main channel, and water table height (Hooghoudt 1940). Transmission loss, amount of water removed from tributary channels by transmission, is calculated using procedures described in the SCS Hydrology Handbook (USDA, 2007). The canopy interception is estimated based on the canopy storage which is a function of vegetation type.

Water yield, total amount of water leaving the HRU and entering main channel, is equal to surface runoff plus lateral flow and baseflow, and minus transmission loss and pond abstractions (Neitsch et al. 2005).

Model Input Preparation: The basic SWAT model inputs include a digital elevation model (DEM), soil data, LULC data, and meteorological data. The DEM was derived from the National Elevation Dataset (NED) of USGS with 1 arc-second resolution (Gesch et al. 2002), and the soil data was from the State Soil Geographic (STATSGO) database. The LULC data of 1992 and 1997 used for this study was from the NALC project (Landsat Multi-Spectral Scanner) and Landsat Thematic Mapper (Kepner et al. 2002, USEPA 1993). For climate information, daily maximum and minimum temperature, precipitation, solar radiation, relative humidity and wind speed are needed to account for temporal variations in weather. This data can be historically measured, generated using the SWAT built in WXGEN weather generator model (Sharpley and William 1990), or supplied to SWAT using a combination of the two methods. For this study, daily precipitation and minimum-maximum temperature from Jan. 1960 to Apr. 2008 were acquired from the National Climatic Data Center (NCDC). Twelve meteorological stations were found within or nearby the upper San Pedro watershed (Fig. 1). Missing records of daily observations of precipitation and minimum-maximum temperature were interpolated from weather data within a radius of 25 miles using the method developed by Di Luzio et al. (2008). The rest of the weather information (solar radiation, relative humidity and wind speed) used in SWAT simulation were generated by the WXGEN weather generator model (Sharpley and William 1990).

The area for stream definition was set as 3500 Ha, upon which the upper San Pedro River basin was divided into 116 subbasins. The divided subbasins matched 12-digit Hydrologic Unit Codes in the upper San Pedro watershed. The subbasins were further divided into HRUs based on the land use, soil, and slope types (0.1%, 1%, and 5%). The number of HRUs differs when using different LULC maps. As an example, the numbers of HRUs for 1992 and 1997 LULC are 2146 and 2225, respectively. There are 10 classes of LULC and 23 soil types in the upper San Pedro watershed. Watershed parameterization includes the calculation of subbasin geometry parameters from DEM and the assigning values to HRUs through inner database. The database of the SWAT model includes parameter values for crops, urban, and soils, such as CN2 values (SCS runoff curve number for moisture condition II), SOL_AWC (Available water capacity of the soil layer), LAI (leaf area index), and other soil physical and hydraulic properties. Values were assigned to each HRU based on its LULC class and soil type during the parameterization process. The simulation was initialized by setting default values of each parameter, a five year warm up period was applied to erase the impact of initial condition for the model calibration and validation.

SWAT Model Sensitivity Analysis, Calibration and Validation: A sensitivity analysis was first performed on parameters affecting streamflow using Latin hypercube (10 intervals) and one at a time (OAT) analysis with a ±5% parameter change (van Griensven et al., 2006). The analysis was done using the model set up with 1992 NALC LULC data and average streamflow response at the watershed outlet (subbasin 1) for five years from 1990 to 1994.

After sensitivity analysis, the model was calibrated by manually editing sensitive parameters for hydrological components (surface runoff, baseflow, lateral flow, ET, and channel transmission loss). Sensitive parameters on hydrological components were also reviewed from past sensitive studies of the model (Veith et al. 2010) and hydrological studies of the arid/semiarid areas (Hernandez et al. 2000, Goodrich et al. 1997). In this study, the lateral flow was assumed to be zero, because no obviously impervious layers in soil profiles, such as black shales, which were pre-required for the lateral flow to be generated, were observed in the watershed. The lateral flow was reduced to a very low level (close to zero) by changing the adjust factor for lateral flow (Adjf_latq) from the default value of 1 into 0.02 during SWAT simulations. Baseflow should be a very small portion recharging back to the stream because very large portions of the upper San Pedro River are ephemeral. At the Redington gauge (down- stream), the river only contains water during and immediately after a storm event and is dry the rest of the year. At the Tombstone and Charleston gauges (upper-stream), although the river flows intermittently, the water supply may not be from baseflow for the relatively higher elevation (corresponding to deeper groundwater table level values) than down-stream. Thus the baseflow was eliminated from simulations by reducing threshold water level in shallow aquifer for re-evaporation (REVAPMN) and enhancing the re-evaporation coefficient and threshold water level in shallow aquifer for baseflow (GWQMN).

Due to the availability of LULC (1992 and 1997) and the USGS data, simulations for model calibration were performed using the model set up of 1992 NALC LULC data which was also used for the sensitivity analysis. Annual (water year) and monthly streamflow from Oct. 1986 to Sept. 1995 at two USGS gauges (Redington and Charleston, Fig. 1) were used for model calibration. After model calibration, simulations for model validation were set up using 1997 Landsat Thematic Mapper LULC data; and annual (water year) and monthly streamflow

at Tombstone (10/1996 – 09/2005) and Charleston (10/1995 – 09/2005) were used for model validation. Validation was not performed at the Redington gauge station because monitoring data were not available after 1995. Three commonly used criteria were used to evaluate the model's performance on calibration and validation: Nash-Sutcliff efficiency (NSE) coefficient, coefficient of determination (R^2), and percent bias (PBIAS).

RESULTS AND DISCUSSION

Unique Hydrological Characteristics of the San Pedro River Watershed: Precipitation within the San Pedro Basin is generally characterized by a bimodal trend with a majority (about 70%) of the rainfall falling during the summer monsoon season (approximately mid-June to mid-October) and a minority (about 20%) during the winter wet season (early December to April) with the remaining throughout the rest of the year (Baillie et al. 2007). The Upper San Pedro watershed is characterized as semiarid conditions, and the sources of flow are attributed to intermittent precipitation governed by monsoon type rainfall events. As shown in Figure 2, the bimodal precipitation trend is reflected by the daily discharge data for 1985 plotted for each gaging station (Charleston, Tombstone, and Redington). In most channel locations (Figure 2) in the San Pedro River, low or intermittent baseflow with ephemeral peak discharge occuring during sporadic storm events was observed.

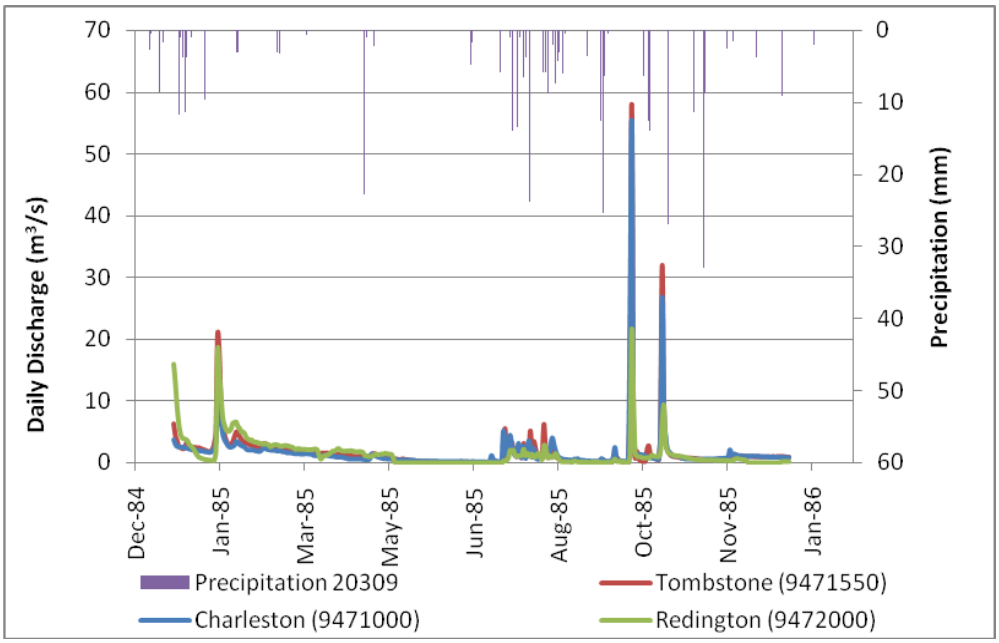

Figure 2 Daily Discharge (m^3/s) for from Jan. 1985 to Dec. 1985

Streamflow in gaining portions of the river is generally perennial; however, several sections of the upper San Pedro River can be classified as both gaining and losing reaches where streamflow is intermittent and associated with a mixture of monsoon water sources and aquifer sources stored in the alluvial groundwater. According to a USGS report released in 2010 (USGS, 2010), both gaining and losing reaches exist upstream from the gaging station near Tombstone. At the Tombstone gaging station, upstream groundwater flow to the vicinity of the stream is less than the volume of water removed by ET during the growing season; therefore, during the summer there is generally no base flow. The reach between the Charleston gauge and the Tombstone gauge is primarily losing (Kennedy and Gungle 2010). Following the summer monsoon, the water stored in near stream sediments must remain saturated for perennial flow to exist; however as shown in Figure 2 (1985 hydrograph), the summer flow is often insufficient to maintain flow in the fall, and thus, the upstream influent flow must re-saturate these sediments resulting in increased transmission loss and decreased to nonexistent streamflow conditions. The Redington station is the furthest downstream from the San Pedro River headwaters yet overall has the smallest response to rainfall events compared to the upstream stations. Transmission losses in the stream channel are likely responsible for this trend and must be considered accordingly when using a distributed model to simulate hydrologic conditions in this watershed. This trend is also noted in Figure 3 which depicts the annual runoff at each station from 1967 to 1985 (streamflow data is only available during 1967 to 1985 for all three gauge stations). Though the Redington station is hydrologically a larger stream order than the upstream gauge station locations, flow at Redington is characterized by containing the least amount of storm runoff and little baseflow

conditions. Larger order streams typically have greater baseflow and steadier flow conditions; however, this phenomena is not observed in this semiarid stream systems due to transmission losses and other factors, such as increased ET. Goodrich et al. (1997) found that the role of channel processes in semiarid watersheds becomes more critical in describing the peak runoff response as the size of drainage area increases. Transmission loss due to channel infiltration, evapotranspiration processes, and limited spatial uniformity of rainfall become dominant factors which limit the linearity of basin response to storm events in semiarid regions. Therefore, the accuracy of using a unit hydrograph, which assumes linearity in the response, in determining watershed runoff response in semiarid watersheds is not reliable due to the nonlinearity of the system.

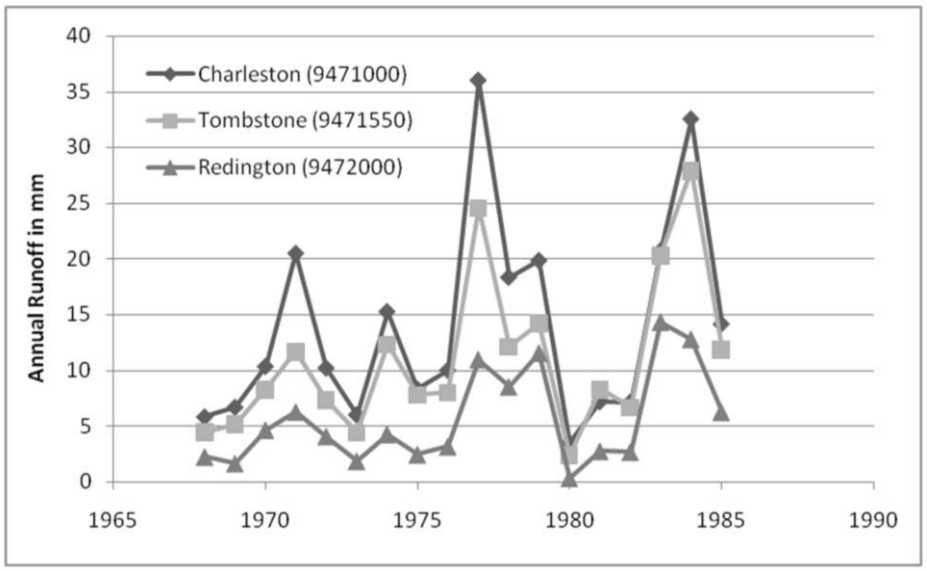

Figure 3 Annual Runoff at three gauges stations from 1967 to 1985

A recent USGS study statistically accounted for streamflow variations due to fluctuations in precipitation and found that predominant factors for the decrease in annual streamflow beyond fluctuations in precipitation and air temperature include changes in watershed characteristics, human activities, or changes in seasonal distribution of bank storage (Thomas and Pool 2006). Possible changes in watershed characteristics that may have influenced streamflow trends are changes in riparian vegetation, changes in landcover (mesquite invasion), and changes in stream-channel geomorphology. Human activities that may have influenced streamflow trends are ground-water pumping, construction of runoff-detention structures, urbanization, and cattle grazing. Seasonal pumping from wells near the river for irrigation in the spring and summer were a significant factor affecting streamflow; however, year-round pumping from wells in the regional aquifer away from the river did not significantly impact streamflow in the river (Thomas and Pool 2006).

Sensitivity Analysis and Calibration/Validation Results: The most sensitive input parameters are shown in Table 1. Those parameters are consistent with other SWAT parameter uncertainty and sensitivity analysis done for arid/semiarid conditions. The SWAT model is highly sensitive to surface runoff parameters (CN2, ESCO, SOL_AWC) and basin parameters (CH-K2) when the watershed is characterized by the intense and inconsistent precipitation events (Veith et al. 2010). High ratios of evaporation to precipitation may overwhelm the SWAT subsurface parameters (Veith et al. 2010); as does increased transmission loss due to stream bed geology and channel condition (gaining or losing) (Cataldo et al. 2010, Baillie et al. 2007). Since there is no persistent snowpack in the mountains of the San Pedro River Watershed, snowmelt and snowfall parameters were not shown to be sensitive for this watershed.

Surface runoff is the major water supply for the stream. Whereas, we noticed that streamflows were often under-estimated for light rainfall events and over-estimated for large rainfall events. Woodward et al. (2002) found that runoff estimates could be enhanced for relatively light rainfalls and be reduced for relative large rainfalls by changing the initial abstraction ratio to be 0.05 from its originally defined value of 0.2. Thus, to calibrate surface runoff, we set the initial abstraction ratio to be 0.05 and edited the CN2 (SCS runoff curve number) to a relatively low value to match the change of initial abstraction ratio. Channel transmission loss is a large portion (4% - 100%) of the water balance in the Walnut Gulch Experimental Watershed, a sub-watershed of the upper San Pedro River basin (Cataldo et al. 2010). USGS records show that monthly streamflow (in volume) at

downstream locations (Redington gauge) is not always larger than in upperstream (Tombstone and Charleston gauges), indicating that transmission loss exists for the major channel (stream order 4 and 5). However, it's hard to quantify the ratio of channel transmission loss to total water recharge. To calibrate the transmission loss, we set the TRNSRCH (Fraction of transmission loss partitioned into deep aquifer) to be 1 and manually edited the effective hydraulic conductivity of channel (CH_K2). The optimal values for SWAT calibration were listed in Table 1.

Table 1 Top ranking sensitive parameters (in the order of ranking) and their description, default and calibrated values that were used in the model calibration/validation (*, the multiple sign, indicates that default parameter values are multiplied by the number shown).

Parameter	Default	Description	Calibrated Value
Adjf_latq	1	Adjust factor for lateral flow	0.02
λ	0.2	Initial Abstraction Ratio	0.05
CN2	30-92	SCS runoff curve number for moisture condition II	*0.58
ESCO	0.95	Soil evaporation compensation factor	0.05
Revapmn	1	Threshold water level in shallow aquifer for revap	0
SOL_AWC	0.01-0.19	Available water capacity of the soil layer	*1.4
Sol_K		Saturated hydraulic conductivity of first layer	
CH_K2	0	Effective hydraulic conductivity of channel	0.6
GW_Revap	0.02	Revaporation coefficient	0.2
GWQMN	0	Threshold water level in shallow aquifer for baseflow	100
TRNSRCH	0	Fraction of transmission loss partitioned into deep aquifer	1

The comparison between simulated and observed annual (in water year) and monthly streamflow for the periods of calibration (Oct. 1986 – Sept. 1995) and validation (Oct. 1996 – Sept. 2005) are shown in Figures 4 and 5, respectively. Overall, a good match can be seen between simulated and observed values. The NS and R^2 values for the annual (in water year) and monthly calibration and validation are listed in Table 2. All NS and R^2 values are above 0.5 (except NS coefficient for annual calibration at the Redington gauge), and PBIAS are in the range of ± 25% (except annual calibration at the Charleston gauge), suggesting satisfactory model performance (Moriasi et al. 2007). Although the overall performance of the model is satisfactory as shown in Figures 4 and 5, and Table 2, a large difference was observed for the water year of 1992 at the Redington gauge and in 1993 at both the Redington and Charleston gauges. Intuitively, the simulated values seem more reasonable because they match the rainfall patterns as shown in Figure 4. Possible reasons for the discrepancies are the limitation of the curve number method. First, high uncertainties could be generated by using daily total rainfall depth as SWAT input. As an example, a large amount of streamflow (4.21 mm) at the Redington gauge on Aug. 1992 simulated in the SWAT model was mainly attributed to a daily rainfall of 127.8 mm on Aug. 24, 1992 in the downstream of the watershed close to the Redington gauge. Whereas, the rainfall depth at that day could be the combination of several relatively small rainfall events, which may not be able to generate significant runoff (recorded streamflow in Aug. 1992 is 0.58 mm). Second, the curve number method fails to consider the effects of duration and intensity of precipitation. For instance, runoff could be generated by some high-intensity, short-duration, limited areal extent summer thunderstorms (Simanton et al. 1996) near the observation gauges. Whereas, those limited areal extent summer thunderstorms may not be simulated by the SWAT model for a large extent.

Another reason for simulated streamflow peaks not fully matching with observations is due to the high heterogeneity of rainfall across the watershed. Rainfall events in the upper San Pedro watershed were mainly composed of high-intensity, short-duration, limited areal extent summer thunderstorms (Thomas and Pool 2006, Kennedy and Gungle 2010). The high heterogeneity of rainfall may not be fully represented by weather stations used in SWAT simulations in this study. Syed et al. (2003) used interpolated values from raingauges and found that the storm event's areal coverage, location within the watershed, and intensity are factors that impact runoff generation, which vary greatly as catchment size increases. SWAT has been shown to adequately simulate streamflow using sparse raingauge data over large arid basin areas, especially when combined with precipitation data estimated from radar predictions (Yu et al. 2011).

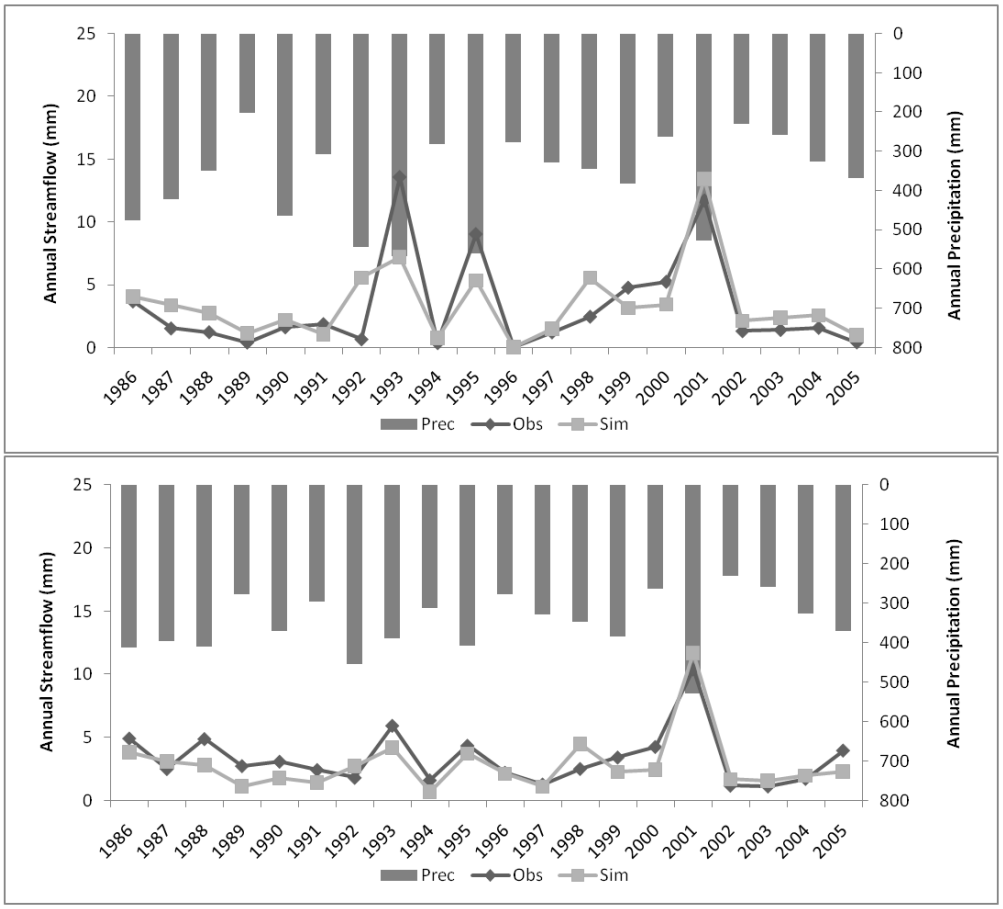

Figure 4 Annual (in water year) precipitation and simulated and observed streamflow in the upper San Pedro Watershed. Upper: Redington (1986 – 1995) and Tombstone (1997 – 2005) gauges; Lower: Charleston gauge (1986 – 2005).

A calibrated and validated SWAT model can be used to assess current conditions in the watershed, and then be used to evaluate alternative management scenarios. SWAT provided good correlation of simulated streamflow conditions, which have been applied to scenario analysis of management practices aimed to evaluate the effects of landuse changes on hydrological response (Ouessar et al. 2009, Ghaffari et al. 2010, Hernandez et al. 2000). Arid/semiarid watersheds are often coupled with issues of data availability. SWAT simulations using remote sensing input data have adequately simulated overland flow, channel flow, and transmission losses in watersheds where streamflow and climatic data are lacking (Al-Dousari et al. 2010, Hernandez-Guzman et al. 2008). The SWAT model has been found useful in arid/semiarid watershed analysis of the effect of landuse changes on hydrological properties and changes of water balance components due to crop management (Ghaffari et al. 2010, Hernandez et al. 2000).

Table 2 Criteria for examining the accuracy of calibration and validation (the validation period at Tombstone gauge is from Oct. 1996 to Sept. 2005).

Index	Calibration (10/1985 - 09/1995)				Validation (10/1995 - 09/2005)			
	Redington		Charleston		Tombstone		Charleston	
	Yearly	Monthly	Yearly	Monthly	Yearly	Monthly	Yearly	Monthly
NS Coefficient	0.45	0.56	0.82	0.52	0.94	0.57	0.93	0.55
R^2	0.66	0.57	0.66	0.55	0.84	0.70	0.82	0.70
PBIAS	1.94	-1.29	25.46	24.63	-16.27	-9.23	1.38	3.00

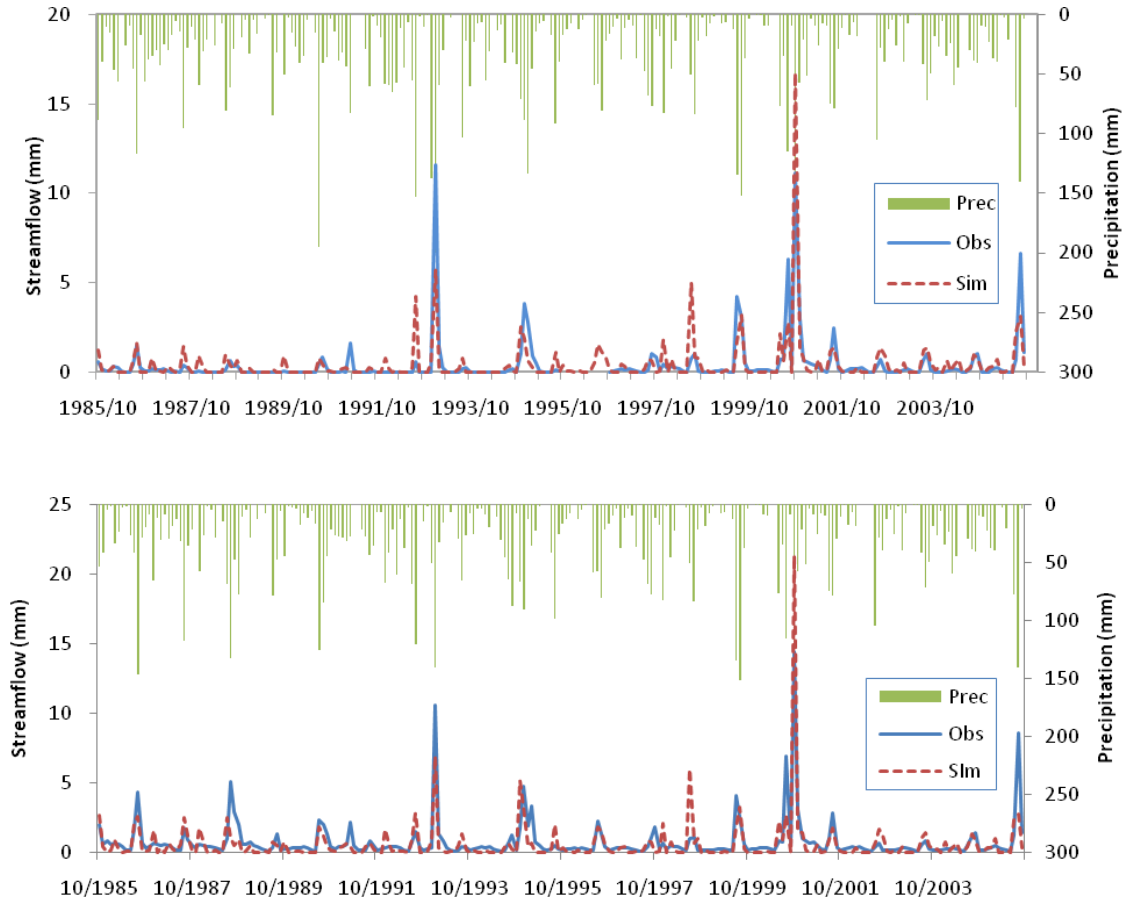

Figure 5 Monthly precipitation and simulated and observed streamflow in the upper San Pedro watershed. Upper: Redington (10/1985-09/1995) and Tombstone (10/1996-09/2005) gauges; Lower: Charleston gauge (10/1985-09/2005).

CONCLUSIONS

Identifying the impacts of LULC changes on hydrologic processes is the basis for watershed management and ecological restoration efforts. Semiarid regions of the southwest United States have unique hydrologic characteristics that create challenges for watershed modelers. Streamflow in these regions is largely dependent on short term, high intensity rainfall events during the summer monsoon season. In this study, the hydrology of the upper San Pedro watershed was assessed based on review of USGS trend analysis reports, historical precipitation and stream discharge patterns. Based on the hydrological characteristics of the region, SWAT sensitivity analysis for this watershed and findings from other studies performed under similar watershed conditions, sensitive SWAT model parameters were determined and calibrated to achieve suitable simulations of the watershed hydrologic processes. The SWAT model input parameters were modified to simulate the limited baseflow conditions, increased ET and transmission loss, and decreased runoff in downstream gauge stations observed in the watershed. All NS and R2 values were above 0.5 (except NS coefficient for annual calibration at the Redington gauge), and PBIAS were in the range of ± 25% (except annual calibration at the Charleston gauge), suggesting satisfactory model performance. Thus, the SWAT model, set up with the optimal parameters obtained through model calibration, generally reflects the hydrological characteristics of this arid/semiarid watershed. A calibrated and validated SWAT model can assess current conditions in the watershed, and then be used to evaluate alternative management scenarios.

INTRODUCTION

KINEROS2 (K2) originated in the 1960s as a distributed event-based rainfall-runoff erosion model abstracting the watershed as a cascade of overland flow elements contributing to channel model elements. Development and improvement of K2 has continued for a variety of projects and purposes resulting in an informal suite of K2-based modeling tools. Like any detailed, distributed watershed modeling tool, the K2 suite of tools can require considerable time to delineate watersheds, discretize them into modeling elements and then parameterize these elements. These requirements motivated the development of the Automated Geospatial Watershed Assessment (AGWA) tool. This ESRI ArcGIS-based tool uses nationally available, GIS data layers to parameterize, execute, and visualize results from the SWAT and KINEROS2 models. By employing these two models, AGWA can conduct watershed modeling and assessments at multiple time and space scales. The objectives of this paper are to: 1) Provide background in the development of K2 and AGWA; 2) Provide an overview of new features; 3) Briefly describe recent novel applications; and 4) Discuss plans for future model improvements.

KINEROS2 / (K2) – History: The USDA-Agricultural Research Service (ARS) initiated development of KINEROS2 (KINematic runoff and EROSion), or K2 in the late 1960s as a distributed event-based rainfall-runoff model. Conceptualization of the watershed in this form enables solution of the flow-routing partial differential equations in one dimension. Rovey (1974) coupled interactive infiltration to this model and released it as KINGEN. After substantial validation using experimental data, KINGEN was modified to include erosion and sediment transport as well as a number of additional enhancements, resulting in KINEROS, which was released in 1990 (Woolhiser et al., 1990; Smith et al., 1995).

KINEROS has been applied over a wide range of scales, from plot (<10 m^2) to large watersheds on the order of a thousand square kilometers. However, it has only been thoroughly validated for watersheds on the order of a hundred square kilometers where sufficient observations exist in

experimental watersheds (Goodrich et al., 2004). It was originally developed as an event-based model. Simulation times can vary from tens of minutes for small plots to more than a day for larger watersheds depending on the respective runoff response time. Computational time scales are dictated by adherence to the Courant condition (Roberts, 2003). Computational time intervals are automatically adjusted in the current model implementation, and the user can select the time interval at which simulation output is reported. Subsequent research with and application of KINEROS has led to additional model enhancements and a more robust model structure, which have been incorporated into the latest version of the model: KINEROS2 (K2).

Specialized versions of the event-based KINEROS2 model range from a flash-flood forecasting tool and the continuous KINEROS-OPUS biogeochemistry tool. The K2 flash flood forecasting tool is being tested with the National Weather Service (NWS) to provide timing and magnitude of peak flows from rapidly responding flash flood storms, that is useful information currently not available using NOAA/NWS flash flood forecasting methodologies at NWS offices. It assimilates the NWS Digital Hybrid Reflectivity (DHR) radar product in near-real time and can simultaneously run ensembles using multiple radar-reflectivity relationships (Unkrich et al., 2010). In addition to simulation of runoff and sediment transport, KINEROS-OPUS (K2-O2) can simulate management, plant growth, nutrient cycling (nitrogen, phosphorus and carbon), water quality and chemical runoff (Massart et al., 2010). K2 has also been coupled with a continuous energy-balance snow model and lateral saturated subsurface transport (K2-SM-hsB; Broxton et al., 2014). In addition, K2 has been used as the engine for runoff generation and routing for the overland transport of manure-borne pathogens and indicator organisms (K2-STWIR). STWIR was released as a separate software package (Guber et al. 2010) followed by sensitivity and uncertainty analysis (Guber et al., 2014). A relatively thorough overview of the theoretical background of K2, including several applications, is presented by Semmens et al. (2008). More recently, Goodrich et al. (2012) provided further details on K2 and included a discussion of model limitations, expectations, and strategies and approaches for K2 calibration and validation. K2 is open-source software that is distributed freely, along with associated model documentation and example input files (www.tucson.ars.ag.gov/kineros).

AGWA History and Overview: The Automated Geospatial Watershed Assessment (AGWA) tool was initially released in 2002 (Miller et al., 2002) to support the parameterization and execution of K2/KINEROS2 and the Soil Water Assessment Tool (SWAT; Arnold and Fohrer, 2005). AGWA parallels other efforts (ArcSWAT, BASINS, MWSWAT, HEC-GeoHMS, ArcAPEX) that use Geographic Information Systems (GIS) to support the application of hydrologic models, but distinguishes itself by offering models that allow it to be used on a continuum of spatial and temporal scales, ranging from hillslopes (~hectares) to large watersheds (>1000 km^2) and from individual storm events (minute time steps) to continuous simulation (daily time steps over multiple years). Like K2, AGWA is open-source software available from the AGWA website (Miller et al., 2007; www.tucson.ars.ag.gov/agwa). This site also contains documentation, supporting references, tutorials, and a user forum. Support for K2 and AGWA is typically accomplished via the user forum, e-mail, and phone communication. We also welcome visitors to the USDA-ARS Southwest Watershed Research Center to work with model developers on application projects and/or model improvements.

The development of AGWA has been a joint effort with the USDA-ARS SWRC, US EPA LEB, University of Arizona, and University of Wyoming. It has been under continual development to incorporate new features and functionality and has seen multiple major and minor releases, including but not limited to: AGWA 1.3 for ArcView 3.x in 2002 (initial AGWA release); AGWA 2.0 for ArcGIS 9.x in 2007 (initial ArcGIS/ArcMap 9.x release); AGWA 2.4 for ArcGIS 10.x in 2011 (initial ArcGIS/ArcMap 10.x release); and AGWA 3.x for ArcGIS 10.x in 2013 (current major release for ArcGIS/ArcMap 10.x).

The guiding principles for the development of AGWA include: 1) that it provides simple, direct, transparent, and repeatable parameterization routines through an automated, intuitive interface; 2) that it is applicable to ungauged watersheds at multiple scales; 3) that it evaluates the impacts of management and be useful for scenario development; and 4) that it uses free and commonly available GIS data layers. From the very first release in 2002 to the most current release in 2015, AGWA has followed these guidelines to ensure it can be used by the widest possible audience, which, to name a few, includes multiple EPA regions (Burns et al., 2013a; Barlow et al., 2014; and Korgaonkar et al., 2014), land use impact studies on water resources in Africa (Baker and Miller, 2013), predictive modeling of oil and gas development impacts (Miller et al., 2012), and numerous Federal Agencies working collaboratively on Dept. of Interior National Interagency BAER (Burned Area Emergency Response) teams modeling hydrological impacts of wildfire (EPA, 2014; Goodrich et al., 2012) and for the Natural Resources Conservation Service (NRCS) Conservation Effects Assessment Project (CEAP).

AGWA has been integrated into the EPA Council for Regulatory Environmental Modeling (CREM) Models Knowledge Base[1] as well as the Registry of EPA Applications, Models and Databases (READ)[2]. All versions of AGWA have been included in the Downloadable GIS Tools section of the EPA EnviroAtlas[3]. In addition a Certificate of Networthiness (CoN) has been obtained for AGWA that enables its use on U.S. Army cyber infrastructure. Additional information and details on AGWA are presented in the following section as there has not been a recent detailed publication on AGWA unlike K2 (Goodrich et al., 2012).

AGWA Data Requirements and Process: **AGWA supports watershed modeling efforts by including functionality that steps through all stages of a watershed assessment, including: watershed delineation; watershed discretization into discrete model elements; watershed parameterization; precipitation definition; model simulation creation; model execution; and model results visualization. Various data are required to support this functionality, including: a raster-based DEM (digital elevation model); a polygon soil map (NRCS SSURGO, NRCS STATSGO, or FAO soil maps are supported); and a classified, raster-based land cover (NLCD, NALC, and SWGAP datasets are supported via provided look-up tables, however other datasets may also be used if accompanied with a respective look-up table). AGWA does not require observed precipitation or runoff to drive the models when used for relative assessment/differencing between scenarios, and can use user-defined**

depths and durations, user-defined hyetographs, or design storms to drive K2, and included weather station-based generated, daily precipitation (U.S. only) to drive SWAT. However, high-quality rainfall-runoff observations are required for calibration and confidence in quantitative model predictions (Goodrich et al., 2012). The AGWA process is described in more detail below and in Figure 1.

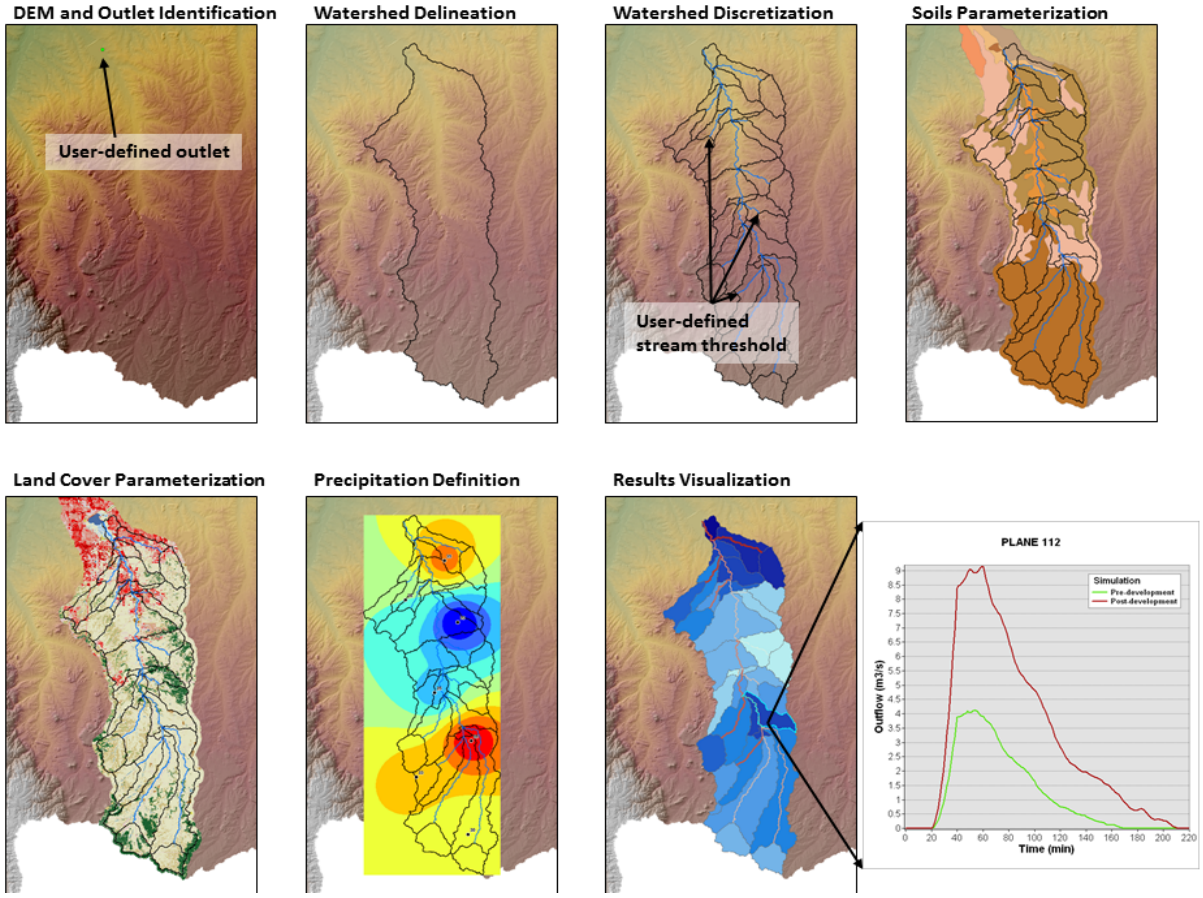

Figure 1 The required steps in AGWA to perform a watershed assessment. A DEM is used to delineate the watershed, subdivide it into model elements, and parameterize the elements in conjunction with the soils and land cover layers. Precipitation drives the model and model results are imported and visualized in the GIS. For any model element selected hydrographs and sedigraphs can be displayed (lower right).

Watershed Delineation: Watersheds delineation is performed by, at a minimum, selecting a workspace location, delineation name, DEM, and watershed outlet. If the DEM has not been filled to ensure proper drainage, AGWA will fill it. Likewise, if a flow direction raster and a flow accumulation raster have not been selected, AGWA will create them in the delineation process. Selecting a watershed outlet entails selecting a pre-existing outlet point or by defining an outlet and snapping it to the highest flow accumulation value within a user-defined search radius. Alternatively, the user can delineate a group of watersheds using multiple pre-existing outlet points or by selecting an area of interest (such as a political, management, or administrative

boundary) and defining a maximum extent for the group of watersheds. Watershed delineations are stored as feature classes within a geodatabase created during this step.

Watershed Discretization: Watershed discretization is performed by defining a stream network for the watershed delineation and subdividing the watershed based on the stream network. Various methods exist for creating the stream network, including: a minimum accumulated area required for stream definition (contributing source area, or CSA, approach); a minimum accumulated flow length required for stream definition (flow length approach); or a pre-existing stream network approach where stream initiation is defined by the upstream most points of a user-selected, existing stream network snapped to the underlying stream network of the DEM (the upstream most points are snapped to the highest flow accumulation or highest flow length within a user-defined snapping distance). Model selection is also defined during the watershed discretization step because the models have non-compatible watershed representations. Watershed discretizations are stored as feature datasets containing single polygon, polyline, and nodes feature classes within the geodatabase created in the watershed delineation.

Watershed Parameterization: Watershed parameterization is performed by intersecting the model elements from the watershed discretization with the DEM, a DEM-derived slope raster, a soils polygon, and a land cover raster. The model elements are then characterized using the topographic, soil, and land cover properties from the layers they intersect and these parameters are stored in related tables (with a parameterization name to identify it) within the geodatabase created in the watershed delineation.

Precipitation Definition: Precipitation definition is performed differently for each model because of the difference between event-based precipitation versus continuous daily precipitation. For K2, precipitation is created using user-defined hyetographs, user-defined depths and durations, pre-defined design storms, or raster-based precipitation surfaces representing return period-duration depths. For non-user-defined hyetographs, K2 precipitation events can be represented with a uniform intensity or with an intensity derived from the SCS Type II distribution. For SWAT, precipitation is created by selecting one or more rain gages and providing a continuous, daily rainfall record for each gage. If more than one rain gage is selected, AGWA will create Thiessen polygons to intersect with the watershed discretization to area-weight the depth assigned to each subwatershed. For all models, precipitation is stored as flat text files in a (precip) directory that is nested in the workspace location defined in the watershed delineation step under subdirectories named for the watershed delineation and watershed discretization.

Model Simulation Creation: Model simulations may be created following the precipitation definition step for K2, or after the watershed parameterization step for SWAT if the model will be driven by weather station generated daily rainfall values. Creating K2 simulations requires defining a simulation name, and selecting a watershed discretization, a parameterization of that discretization, and a precipitation file created for that discretization. Optionally, parameter multipliers may also be defined for K2. For SWAT, similar steps are required, but additional selections must also be made. The user may elect to forgo selecting a precipitation file (and also a daily temperature file) and instead generate daily precipitation (and temperature) using a user-selected weather station. The user must also define the start and end date of the simulation as

SWAT is a continuous model. Optionally, the user may define subbasin adjustment factors, groundwater parameters, crop types, and a results output timestep (the model runs on a daily timestep regardless of the results output timestep). For both models, simulations are stored as flat files in a directory named for the simulation name that are nested in the workspace location defined in the watershed delineation step under subdirectories named for the watershed delineation and watershed discretization.

Model Execution: Model execution is performed by selecting a watershed discretization and a simulation already created for that discretization. Model execution is separated from model simulation creation to provide the user the ability to edit model input files following simulation creation but prior to model execution. This capability allows the user to rerun existing simulations limitlessly if changes are made to the simulation outside of AGWA.

Model Results Visualization: Model results visualization is performed by selecting a watershed discretization, importing/re-importing completed simulations, and selecting model outputs to map onto the watershed discretization. A variety of outputs can be displayed for any upland or channel model element including major water balance components and fluxes. K2 can also display hydrographs for simulations. Both models can calculate differences between two simulations as either an absolute difference or a percent difference.

NEW FEATURES

AGWA: AGWA 3.x, the current major release cycle (i.e. the left-most number of the version number) of AGWA was released in 2013 (Burns et al., 2013b). It incorporates new functionality, new models, user interface changes, usability improvements, and bug fixes. With the move to ArcGIS 10.x, deploying AGWA offered the opportunity to switch from a custom installation program that registered the AGWA components so that they could be recognized by ArcMap to using ESRI ArcGIS add-in functionality. The add-in deployment process is both faster and more user-friendly. The move to AGWA 3.x also saw the opportunity to support more raster and vector input types in AGWA, also resulting in a more user-oriented experience.

The upgrade from AGWA 2.x to AGWA 3.x entailed refactoring of the look-up tables used to store parameterizations so that they are more relational. This rivals the upgrade from AGWA 1.x to AGWA 2.x, when delineations and discretizations moved from a GRID and shapefiles into feature classes within a geodatabase. The significance of this upgrade in AGWA 3.x is the flexibility it allows to create and store countless parameterizations without needing to create simulations for each parameterization to store the parameterization information. With the ability to create and store multiple parameterizations in place, AGWA 3.x built on this new functionality to allow users to perform batch parameterizations. This can be of great assistance if the user has multiple, lengthy scenarios/parameterizations to run that would otherwise require user interaction at in-opportune times. Batch simulation functionality was also added to further enhance the ability to work with multiple scenarios/parameterizations.

The release of AGWA 3.x also included the Rangeland Hydrology and Erosion Model (RHEM; Hernandez et al., 2015) in a desktop application. The inclusion of RHEM required changes to both the stream definition methodology in the discretization step and also the slope definition

processing in the parameterization step. To try and better define complex hillslopes shapes, a stream definition methodology based on flow length instead of flow accumulation was added to the discretization process. Additionally, support for using an existing stream network like National Hydrologic Dataset (NHD) to define the stream network and starting points of first order channels was also added to take the guesswork out of picking an appropriate flow length or flow accumulation threshold. RHEM also supports complex slope profiles, so the slope definition process was enhanced to include a complex slope weighting process versus the existing uniform slope weighting for overland flow planes contributing laterally to channels. The complex slope weighting process uses a methodology derived from Flanagan et al. (2011) where the representative slope profile is derived by weighting slope values along flowpaths at certain distances away from the channel by their flow length and flow accumulation. This weighting process assumes longer flow paths and flow paths with greater flow accumulation contribute proportionally more to the slope profile (and associated processes) than shorter flow paths with less flow accumulation.

KINEROS2 / K2: The erosion and sediment transport models from the RHEM (Wei et al., 2007; Hernandez et al., 2015) were incorporated into K2 and linked to the overland flow model. The overland flow model in K2, which represented a uniform slope, was extended to duplicate the original RHEM's ability to represent complex hillslope profiles (as well as uniform slopes). The RHEM hydrology model used the Green-Ampt infiltration equation, and while there is a parameter in the K2 infiltration equation that controls the transition of water content across the wetting front, it can approach but not duplicate piston-flow behavior. Consequently, the K2 infiltration model was extended to include an explicit Green-Ampt option.

The K2 urban element is a composite element consisting of up to six overland flow areas representing various combinations of pervious and impervious surfaces contributing to a paved crowned street. It represents an abstraction of one half of an urban/suburban street, and was validated and used successfully by Kennedy et al. (2013) in a highly instrumented suburban catchment. It has been modified to incorporate features representing LID/GI practices, including water harvesting, retention/infiltration basins, and pervious pavement (see Korgaonkar et al., 2015).

The K2 model was developed with a tree structure, where upstream elements can only contribute to a single downstream element, which is typical of natural watersheds. To address partial diversion of flow such as for irrigation, into constructed wetlands, etc. a diversion element has been introduced. This element can divert water and sediment from a single upstream element to as many as 10 downstream elements. Diversion rates are determined from a user-supplied tabular relationship between the inflow rate from the upstream element and the rates diverted into each downstream element.

The version of K2 that was designed to run as a forecast tool in National Weather Service Forecast Offices (K2-NWS) using real time weather radar data (Unkrich et al., 2010) can now utilize data from the National Weather Service Radar Product Central Collection Dissemination Service FTP server. The data typically appears on the server within 1-2 minutes of acquisition by the radar and allows K2-NWS to run in real time outside of a NWS Weather Forecast Office. The radar file decoder used by K2-NWS has also been upgraded to ingest the new dual

polarization Digital Precipitation Rate (DPR) product. The new product uses a finer resolution, 1-degree by 250 meter polar grid, but the decoder can also down-sample the data to the legacy 1-degree by 1 km grid.

NOVEL APPLICATIONS

KINEROS2 / K2: K2-NWS was successfully applied to the 128 km^2 semi-arid Fish Creek basin located in the Anza Borrego State Park near Borrego Springs, California (Schaffner et al., 2014a). As there is no stream gage at the forecast point, the model calibration was based on categorical flood magnitudes (minor flood, moderate flood, major flood, etc.) rather than estimated discharge values. The calibration included seven rainfall events representing a full range of conditions from below flood stage up to the record flood event. Two sets of parameters were identified; one set optimized for below the major flood level and the other for larger flood levels. Calibration was successful in reproducing both the category and estimated time of peak flood. In forecast mode, the model provided an average lead time of 98 minutes to the initial flood stage, and 63, 50 and 48 minutes for minor, moderate and major flood stages respectively.

The calibration from Fish Creek was subsequently tested at nearby Borrego Palm Canyon, 70 km northwest of Fish Creek (Schaffner et al., 2014b). The goal was to evaluate whether the Fish Creek parameters could be used as a regional calibration, which would reduce the resources needed to set up the model at similar locations. The 56 km^2 Borrego Palm Canyon watershed was instrumented with a USGS stream gage from 1950 until September 10, 2004 when the gage was destroyed by a large flow. In 2002 the watershed was burned by a wildfire, with about a third suffering moderate burn severity and the rest low severity or unburned. Four test events were selected, one from 2003 with rainfall mostly over the lightly burned area, and the rest from 2013. Peak flows from simulations of the four events using the Fish Creek parameters fell within or close to the observed flood categories, suggesting that regional calibrations could be a viable option when resources are limited or when calibration data is unavailable.

AGWA: In studies by Burns et al. (2013a) and Barlow et al. (2014) a methodology was developed to characterize the hydrologic impacts of future urban growth through time. Future growth is represented by housing density maps generated in decadal intervals from 2010 to 2100, produced by the US-EPA Integrated Climate and Land-Use Scenarios (ICLUS; Bierwagen et al., 2010) project. ICLUS developed future housing density maps by adapting the Intergovernmental Panel on Climate Change (IPCC) social, economic, and demographic storylines to the conterminous United States. To characterize the hydrologic impacts of future growth, the housing density maps were reclassified to National Land Cover Database 2006 land cover classes and used to parameterize the SWAT model using AGWA. Burns et al., (2013) conducted this effort in the international San Pedro Basin in southeast Arizona and did not find a substantial impact on average surface runoff or on sediment yield at the watershed outlet for all scenarios. However, over smaller subwatersheds where development was concentrated the hydrologic changes are more significant. Barlow et al. (2014) found similar results in the South Platte Basin that contains the greater Denver, Colorado metro region.

AGWA was used by the Department of Interior National Burn Area Emergency Response (BAER) team for rapid post-fire watershed assessments on the Elk Wildfire Complex that burned

over 130,000 acres east of Boise, Idaho in August of 2013. Initially, the BAER team identified ~16,000 treatable acres within the burned watersheds that consisted of high burn severity and steep slopes. AGWA was used to simulate the watershed response for pre-fire and post-fire conditions to identify areas of high-risk for runoff and erosion. The interdisciplinary BAER team used spatially explicit AGWA results in an interactive process to locate polygons across the burned area that posed the greatest threat to downstream values-at-risk. The group combined the treatable area, field observations, professional judgment, and AGWA output to target seed and mulch treatments that most effectively reduced the threat. Using this process, the BAER Team reduced the treatable acres from the original 16,000 acres to between 2,000 and 4,000 acres depending on the selected alternative. The final awarded contract for post-fire mulch treatments cost roughly $600/acre, therefore, BAER/AGWA targeted treatment applications resulted in a total savings of ~$7.2 to $8.4 million by only treating the reduced acreage (EPA, 2014).

Since wildfire severity impacts post-fire hydrological response, fuel treatments can be a useful tool for land managers to moderate this response. Sidman et al. (2015) conducted a spatial modeling approach that couples three models used sequentially to allow managers to model the effects of fuel treatments on post-fire hydrological impacts. Case studies involving a planned prescribed fire at Zion National Park and a planned mechanical thinning at Bryce Canyon National Park were used to demonstrate the approach. Fuel treatments were modeled using FuelCalc and FlamMap within the Wildland Fire Assessment Tool (WFAT). The First Order Fire Effects Model (FOFEM) was then used to evaluate the effectiveness of the fuel treatments by modeling wildfires on both treated and untreated landscapes. Post-wildfire hydrological response was then modeled using KINEROS2 within AGWA. This approach provides a viable option for landscape scientists, watershed hydrologists, and land managers hoping to predict the impact of fuel treatments on post-wildfire runoff and erosion and compare various fuel treatment scenarios to optimize resources and maximize mitigation results.

FUTURE PLANS AND MODEL DEVELOPMENT

The AGWA GI (Green Infrastructure) tool (Korgaonkar et al., 2015) will undergo further testing and be released with a future version of AGWA. Eventually the K2-O2 continuous biogeochemical model will be coupled with the AGWA GI tool to provide capabilities to simulate plant growth, evapotranspiration, and nutrient transformations to address water quality. For post-fire watershed assessments an effort is underway by Sheppard et al. (2015) to locate high quality pre- and post-fire rainfall, and runoff data to improve procedures for adjusting post-fire infiltration, roughness, and cover parameters as a function of burn severity, pre-fire cover type, and time from fire to track recovery. A need has also been identified for post-fire flood inundation modeling on a reach scale near values of interest (e.g. structures, camp grounds, etc.). A tool is under development to take peak post-fire discharge generated from AGWA from either a design storm or observed historical storm and compute inundation in cases where significant backwater effects are absent. LIDAR or ground acquired channel cross-section data collected by BAER field crews assist in making this a viable tool. An automated channel cross-section extraction tools is also under development where LIDAR topographic data is available.

At present AGWA uses nationally available land cover maps that are static and only provide information on the type of cover but not its condition (an average condition is assumed in

AGWA). The ready availability of time varying remotely sensed vegetation products from satellites like MODIS provides an opportunity to ingest time varying measures of cover into AGWA. An AGWA tool to automatically ingest remotely sensed cover measures is under development. Initial results indicate that relatively large changes in cover condition (e.g. fires) are required to have a substantial impact on watershed response.

Small impoundments such as stock ponds are ubiquitous in much of the west and serve as a common management practice to provide water for cattle and wildlife. In addition they can be highly effective in trapping sediment and contaminants tightly bound to sediment. An AGWA pond tool is under development to allow the user to select a variety of pond types and geometries to rapidly place them within the channel network parameter file so scenarios for the type and number of ponds to reduce peak runoff rates or achieve load reductions can be made. Finally an internet version of AGWA is under development. Key issues for this project include where and how large geospatial and remotely sensed data sets will be stored and served.

Abstract: Increasing urban development in the arid and semi-arid regions of the southwestern United States has led to greater demand for water in a region with limited water resources and has fundamentally altered the hydrologic response of developed watersheds. Green Infrastructure (GI) practices are being widely adopted to mitigate the impacts of development on water quantity and quality. However, Geographic Information System (GIS) based watershed tools for rapid GI planning and assessment that operate from the lot-to-subdivision-to-watershed level are lacking. The Automated Geospatial Watershed Assessment (AGWA) tool was modified to allow the design and placement of a small set of GI practices in order to simulate urban hydrology with and without GI features. This software development effort was undertaken to take advantage of the advanced, physically-based infiltration algorithms and geometric flexibility of the Kinematic Runoff and Erosion (KINEROS2) watershed model. The resulting software provides an up-to-date GIS GI assessment framework that automatically derives model parameters from widely available spatial data. The software is also capable of manipulating GI features and simulating at the lot-scale within a graphical interface to conveniently view and compare simulation results with and without GI features. The AGWA GI software was tested at the lot level with and without GI features to validate the water balance and to verify steady state runoff rates. Testing was also conducted at the subdivision level, without GI features, as high-resolution rainfall-runoff observations were available from a subdivision in Sierra Vista, Arizona. Testing at both these scales confirmed programming integrity and the capability to realistically simulate urban hydrology, indicating that the software can realistically represent and simulate storm runoff responses for the selected GI features. The AGWA GI tool offers a foundation for the incorporation of a broader array of GI features.

INTRODUCTION

Urbanization has numerous effects on a watershed as it replaces vegetation and pervious open areas with impervious surfaces such as roofs, driveways, parking lots, and roads. The introduction of impervious surfaces has significant impacts on watershed hydrology, especially in regard to drastic reductions in infiltration of rainfall, resulting in increased runoff volumes, peak discharges, and higher energy releases. Increased runoff results in lower groundwater recharge and base flows in humid regions (Leopold, 1968)

Traditional storm water management techniques involve transporting the water away from urban areas as quickly as possible; reducing lag times, and increasing runoff volume and peak flows (Hood et al., 2007; Leopold, 1968). The Department of Environmental Resources of Prince George's County, Maryland, pioneered Green Infrastructure (GI, also referred to as Low Impact Development or LID) to mitigate the urbanization impact of increasing impervious surfaces (County and June, 1999). As opposed to traditional storm water management practices, GI aims to preserve the pre-development hydrology using a variety of cost effective on-site design techniques that store, infiltrate, evaporate, and detain runoff. Prince George's County introduced a new concept of Integrated Management Practices (IMP), that include many GI practices such as bioretention cells or basins, dry wells, filter strips, vegetated buffers, level spreaders, grassed swales, rain barrels, cisterns, and infiltration trenches. GI practices help reduce the need for more traditional storm water management techniques such as curb-and-gutter systems or large detention basins.

GI practices have been implemented and evaluated all around the world. Much effort has been put into the modeling of these practices to aid in decision making with respect to design, cost, efficiency, and effectiveness (Ahiablame et al., 2012a; Elliott and Trowsdale, 2007). Models that simulate GI practices include the Storm Water Management Model (SWMM) (Rossman and Supply, 2010), Long-Term Hydrologic Impact Assessment – Low Impact Development (L-THIA-LID) model (Ahiablame et al., 2012b), System for Urban Storm Water Treatment and Analysis Integration (SUSTAIN) (Lee et al., 2012), Hydrologic Simulation Program – Fortran (HSPF) (Bicknell et al., 2001), and BMP Decision Support System (BMPDSS) (Cheng et al., 2009).

This paper demonstrates the use of the Automated Geospatial Watershed Assessment (AGWA) tool to design and model GI practices in urban environments. The AGWA GI software serves as a decision support tool, applicable at the lot-, subdivision-, and small watershed-scales. It utilizes several of the features of the KINEROS2 rainfall-runoff and erosion model that are well suited to arid and semi-arid watersheds (Goodrich et al. 2012).

GREEN INFRASTRUCTURE PRACTICES

A small subset of GI practices, commonly used in arid and semi-arid regions, was selected for incorporation into the modeling tool. These include bioretention systems, permeable pavements and rainwater harvesting systems.

Bioretention systems are depressions filled with highly permeable soil, and planted with vegetation. These systems allow storm water to pond and infiltrate, thereby supporting vegetation growth while achieving storm water retention, pollutant removal, and groundwater recharge. Smaller-scale bioretention systems are also referred to as rain gardens and their design and effectiveness are more dependent on lot sizes and placement within the watershed.

Permeable pavements are paved surfaces that reduce runoff by allowing infiltration. These are usually designed as a matrix of concrete paver blocks with voids filled with sand, gravel, or soil. These voids encourage infiltration of storm water into the underlying soil layer.

Rainwater harvesting includes the use of rain barrels and cisterns to retain rooftop runoff for future use. Rain barrels tend to have a storage capacity of less than 0.38 cubic meters (100 gallons) and are usually placed above the ground. Cisterns have a capacity of more than 0.38 cubic meters and can be self-contained, above-ground, or below-ground systems.

AGWA AND KINEROS2

The AGWA tool provides a GIS user interface for two hydrologic models - the Kinematic Runoff and Erosion model (KINEROS2) and the Soil and Water Assessment Tool (SWAT) (Daniel et al., 2011, Miller et al., 2007). AGWA is a customized toolbar in ESRI ArcMap that uses existing spatial datasets in the form of digital elevation models, land cover maps, soil maps, and weather data as inputs (figure 1). These inputs are processed to prepare input parameters for hydrologic models. The simulation results are quantified and imported back into AGWA for spatial display and analysis. The interoperability of KINEROS2 and AGWA is described in Goodrich et al. (2012).

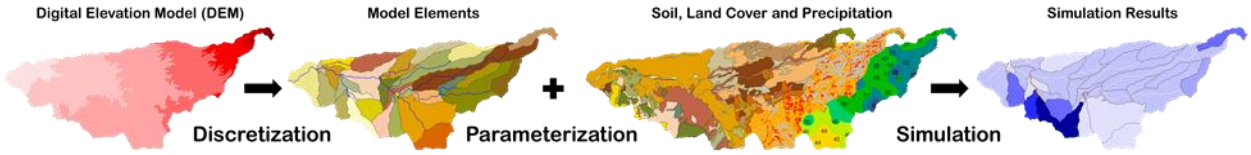

Figure 1 AGWA Workflow

KINEROS2 is a distributed, physically based model that simulates runoff and erosion for small watersheds. It utilizes kinematic equations to simulate overland flow, over rectangular planar or curvilinear hillslopes, and channelized flows, through open trapezoidal channels (figure 2) (Woolhiser, et al., 1990; Goodrich et al., 2012). KINEROS2 has dynamic infiltration in which the infiltration is coupled with the routing, and flow depth is computed with a finite difference solution of the kinematic wave equations and the Smith-Parlange infiltration equation at each finite difference node. This makes the model particularly well suited to simulate runoff-runon conditions over surfaces with distinctly different infiltration or cover characteristics. In addition to the standard overland flow (planar or curvilinear) and channel modeling elements, KINEROS2 also has an Urban modeling element (figure 2) that consists of up to six overland flow areas that contribute to one-half of a paved, crowned street with the following configurations: (1) directly connected pervious area, (2) directly connected impervious area, (3) indirectly connected pervious area, (4) indirectly connected impervious area, (5) connecting pervious area, and (6) connecting impervious area. The Urban modeling element represents an abstraction of a typical subdivision. Kennedy et al. (2013) evaluated the urban element and concluded that KINEROS2 could successfully model urban residential watersheds with this abstract representation of different surface types and runoff-runon combinations.

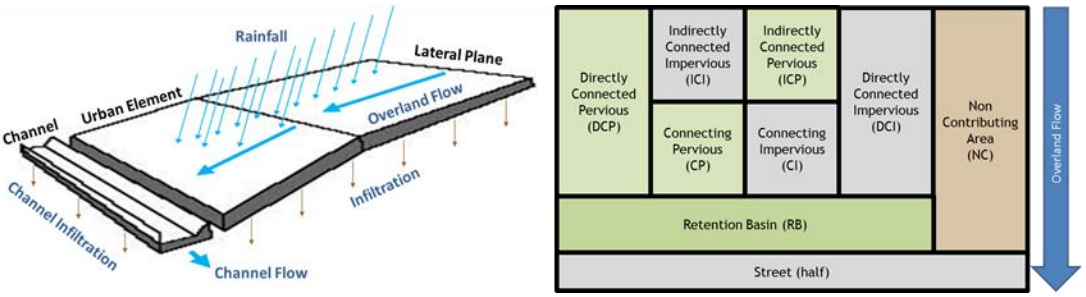

Figure 2 KINEROS2 element and Urban element components.

Very few software packages exist that can provide a decision-support system with spatial, robust, and accurate modeling capabilities. Popular models lack the physical routing of water through the watershed, provisions for erosion modeling, or the use of a spatial tool. The robustness of KINEROS2 and the GIS interface provided by AGWA creates the option to use these in unison to provide a powerful modeling platform for GI practices in urban development scenarios.

WORKFLOW

Based on the existing AGWA functionality, a modified workflow was designed to utilize KINEROS2 to simulate urban environments and GI practices. The modified workflow was developed in the .NET Framework using Microsoft Visual Studio 2010. C# and VB.NET were the programming languages used. ESRI provides an ArcObjects software development kit for the .NET Framework to build Windows applications with GIS functionalities. With the help of ArcObjects, Windows-based forms were developed which could use existing GIS functionalities in ESRI ArcMap. The description for each step in the workflow is given below.

Setup Urban Geodatabase: The Setup Urban Geodatabase form allows the user to provide a location and a name for a geodatabase, which becomes the workspace for feature classes and tables that are created in subsequent processes. The user also provides the subdivision parcels and a corresponding road layer in the form of polygon feature classes.

Flow Routing: Flow routing is an important step in simulating an urban subdivision as post construction flow paths are typically different from pre-development topography. KINEROS2 requires the path that water will follow from the lot to the basin outlet. The Urban element in KINEROS2 assumes all of the rainfall flows from the lot towards the street. The street is assumed to be crowned to allow the routing of water along the streets. With the help of the Flow Routing form, the user draws flow paths on the parcel feature class using built-in drawing tools in ESRI ArcMap. Once saved, the flow paths are checked by the software to ensure that all parcels are associated with a flow path, and that they fall within the boundaries of the parcels. Using these flow paths, a conceptual flow map (figure 3) draining towards the outlet is created.

Parameterization: The Parameterization step defines KINEROS2 input parameters based on geometry, land cover, and soils properties for each parcel. The user provides inputs to the Element Parameterization form and the Land Cover and Soils form. The first form defines element parameters, including the parcel width field, house area, driveway area, slope, street width, cross slope, and grade, all of which can also be defined using fields from the feature

classes or with user-defined values. The second form defines land cover and soils parameters, including: canopy cover fractions; impervious, pervious, and street roughness; and impervious and pervious interception values. A Soil Survey Geographic (SSURGO) soil map is required along with the corresponding database to prepare soil parameters. For each soil mapping unit in SSURGO soil map, AGWA applies these parameters uniformly to all the parcels in the subdivision that intersect that soil mapping unit, and spatially, averages the parameters when parcels intersect multiple soil mapping units. Additionally, AGWA stores all of these parameters in tables, which allows the user to modify these values using data from field surveys or other sources.

Figure 3 Flow routes drawn by the user on the La Terraza subdivision in Sierra Vista, AZ.

Green Infrastructure Design and Placement: The Green Infrastructure Design and Placement tool allows users to design and place retention basins, permeable pavements, or rainwater harvesting systems on one or more parcels in a subdivision. Each design can be saved in the Geodatabase with a unique name. A combination of these designs can be saved as a "Placement Plan".

Retention Basins: A retention basin design requires the width, length, and depth of the retention basin in order to calculate the area and volume associated with it. In addition to the above dimensions, KINEROS2 requires the soil saturated hydraulic conductivity of the retention basin. Water from the lot is assumed to flow into the retention basin before flowing on to the street half.

Permeable Pavements: Design parameters for permeable pavements can be provided in the form of length and width, or selecting the "Same as driveway area" option. Using this option,

AGWA calculates the permeable pavement area based upon the driveway area defined in the Element Parameterization step. A soil saturated hydraulic conductivity value is also required. The permeable pavement driveways allow infiltration of water based on the hydraulic conductivity provided by the user.

Rainwater Harvesting: For the design of a rainwater harvesting system, the volume of the rain barrel (or cistern) can be provided, or can be calculated using the height and diameter of the rain barrel. Rainwater falling on the roof of the house is captured by this rainwater harvesting system.

Precipitation: KINEROS2 accepts rainfall data in the form of time-intensity pairs or time-depth (where depth represents accumulated depth) pairs. AGWA allows the user to provide rainfall data in the form of precipitation frequency grids, design storm tables, user-defined depths, or user-defined hyetographs. Rainfall is assumed to be applied uniformly over the entire subdivision area. If observed rainfall is available from more than one rain gauge, KINEROS2 employs a piece-wise planar space-time interpolation scheme that can also accommodate radar-rainfall estimates. This functionality remains unchanged from the original AGWA implementation. More information can be found in the AGWA Documentation on the AGWA website (www.tucson.ars.ag.gov/agwa/ or http://www.epa.gov/esd/land-sci/agwa/).

Write Input Files: In the Write Input Files step, AGWA aggregates all the inputs that were provided in the preceding steps and prepares input files required by the KINEROS2 model. The user selects the flow routing table, parameterization, placement plan table, and precipitation file, and provides a unique name for the simulation.

Execute KINEROS2 Model: In the Execute KINEROS2 Model step, the user selects a simulation and runs the KINEROS2 model. A command prompt displays the progress of the simulation and whether it was successful or if it encountered any errors. The output file (.out), which summarizes the hydrology for each urban element, is created in the simulations directory by the model. AGWA imports these values in the next step.

View Results: The View Results form allows the user to visualize the results of the KINEROS2 simulation. AGWA allows the user to visualize the output for each parcel in the form of infiltration, runoff, and accumulated runoff volumes, as well as absolute and percent differences between two simulations. Infiltration and runoff volumes (figure 4) results are visualized for each individual parcel. Accumulated runoff (figure 5), which is comprised of the runoff from each parcel along with the runoff from the upland parcel, can be visualized along the street.

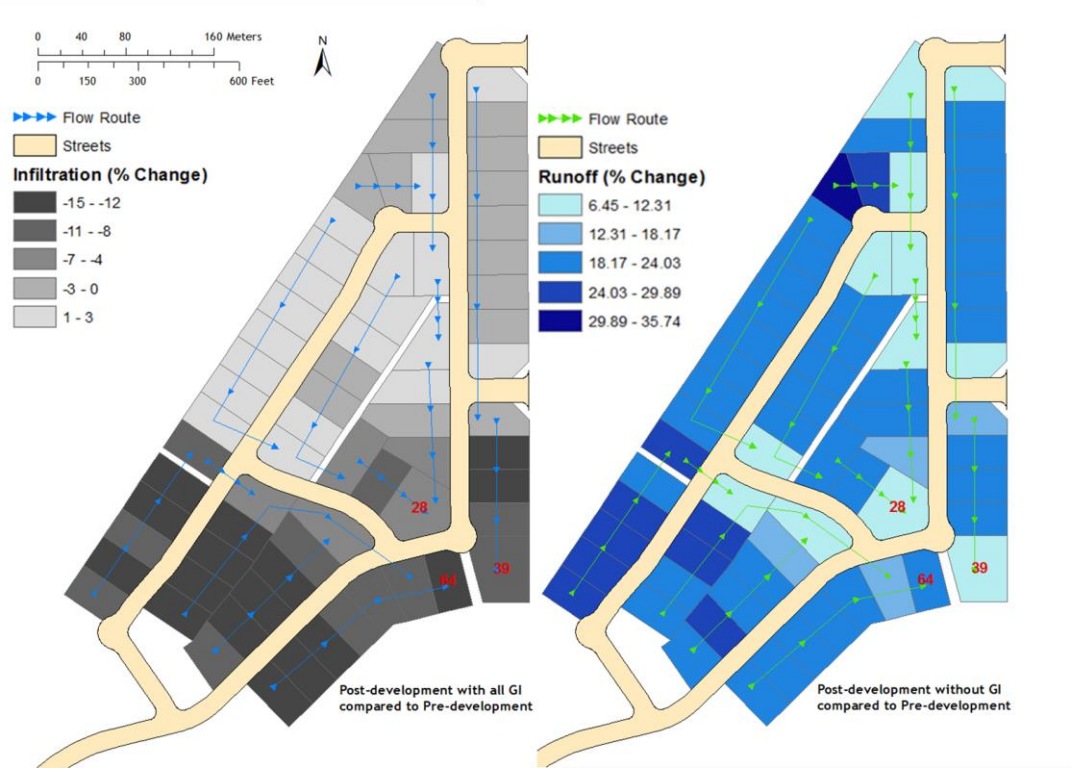

Figure 4 Visualization of the AGWA GI infiltration and runoff results for parcels.

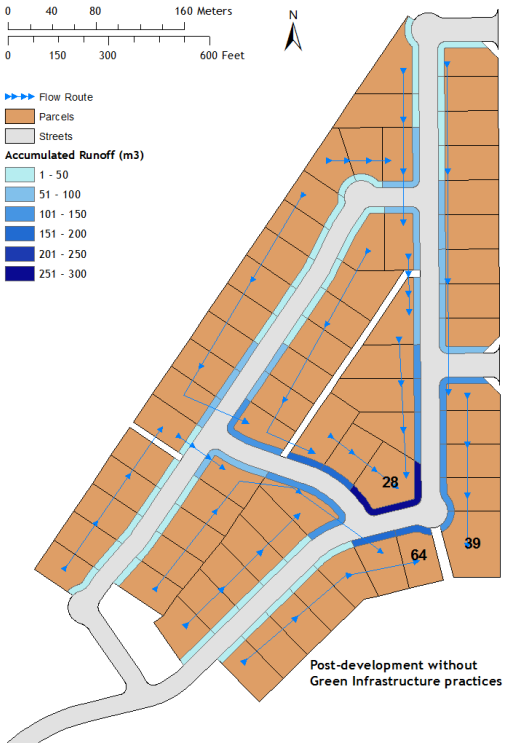

Figure 5 Visualization of the AGWA GI flow accumulation results on the roads.

TESTING

Lot Level: Verification of the Urban element at the lot-scale was approached by confirming the following: 1) Event volumes of hydrologic components are balanced properly; and, 2) Steady-state runoff rates based on a constant rainfall intensity with a configuration of areas with known infiltration rates. To test both, an element was created representing a typical lot in the La Terraza subdivision and was used in six scenarios (Table 1): pre-development; post-development without GI; retention basins; permeable pavements; rainwater harvesting; and all GI practices.

Table 1 Description of the lot-scale verification scenarios.

Pre-development	Empty lot with a street and soils attributes obtained from the NRCS SSURGO soils spatial database
Post-development (without GI)	Lot with a house area of 2500 square feet and a ~12 feet by 19.5 feet impermeable driveway (21.76 square meters)
Retention Basin	Post-development parameters with the addition of a retention basin with a hydraulic conductivity of 8.3 in/hr (~210 mm/hr) and sized with a surface area of approximately 72 square feet and a depth of ~10 inches, yielding a retention capacity of ~60 cubic feet (~444 gallons)
Permeable Pavement	Post-development parameters with a permeable driveway with a hydraulic conductivity of 8.3 in/hr (~210 mm/hr)
Rainwater Harvesting	Post-development parameters with a rainwater harvesting feature with a capacity of ~500 gallons (1.9 cubic meters)
All GI practices	Post-development parameters along with all of the above GI practices

Verifying the water balance is a basic accounting exercise that ensures model inputs equal model outputs plus any change in storage. In this exercise, a 12.5 mm/hr rainfall event was applied for a duration of two-hours onto a lot size of 0.1933 hectares, yielding a total rainfall volume of 96.66m^3; this rainfall volume is the model input. Model outputs include interception, infiltration, storage, and outflow in cubic meters. For all scenarios, the error for the water balance was less than 1 percent.

Effective hydraulic conductivity is defined as the rainfall minus outflow rate at steady-state (figure 6). Because each scenario reached steady-state outflow rates, the effective hydraulic conductivity could be compared to the expected steady-state weighted saturated hydraulic conductivity calculated from the different overland flow areas of the Urban element. The weighted hydraulic conductivity is calculated by converting the infiltration capacity in mm/hr to cubic meters for each of the overland flow areas of the element. Conversion to a volumetric rate is necessary so that contributing volumes can be subtracted out when overland flow areas that receive input from upslope have higher infiltration capacities than the rainfall rate.

Subdivision Level: Verification of the model for the La Terraza subdivision (figure 3) was conducted using observed rainfall and runoff data collected from July 2005 through September 2006 (Kennedy, 2007). Rainfall was measured by four recording rain gauges, with areal average rainfall event totals ranging from 2 to 35 mm (events less than 2 mm were not used). Runoff,

both into and out of the La Terraza subdivision, was measured by v-notch weirs. Runoff events that overtopped the outlet weir were excluded, giving a high-quality data set of 47 events.

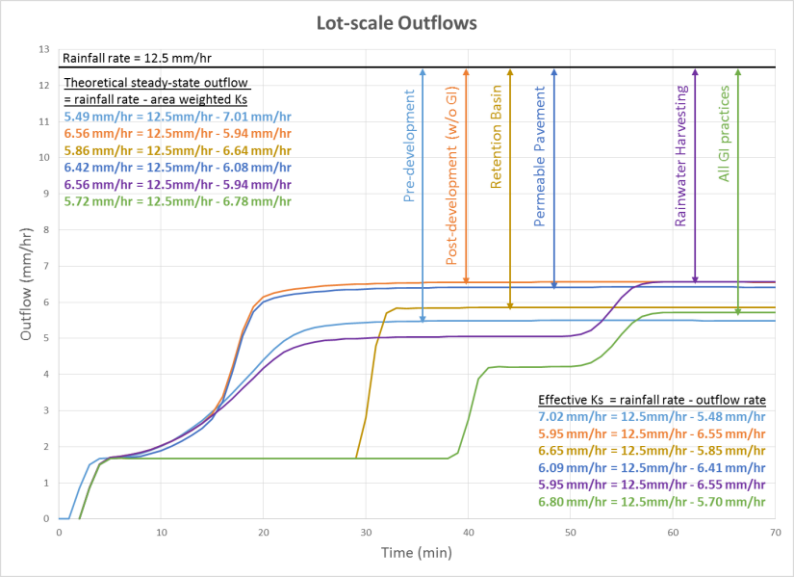

Figure 6 Hydrographs illustrating effective hydraulic conductivities for lot-scale testing.

The parameter file created by AGWA was modified to incorporate some of the parameters used by Kennedy (2007) as well as the measured inflows from the adjacent undeveloped watershed. The altered parameters included the interception and Manning n values, and street slopes were reduced from 0.02 to 0.01 to better reflect the values measured by Kennedy (2007). Initial soil saturation values for each event were also obtained from Kennedy (2007).

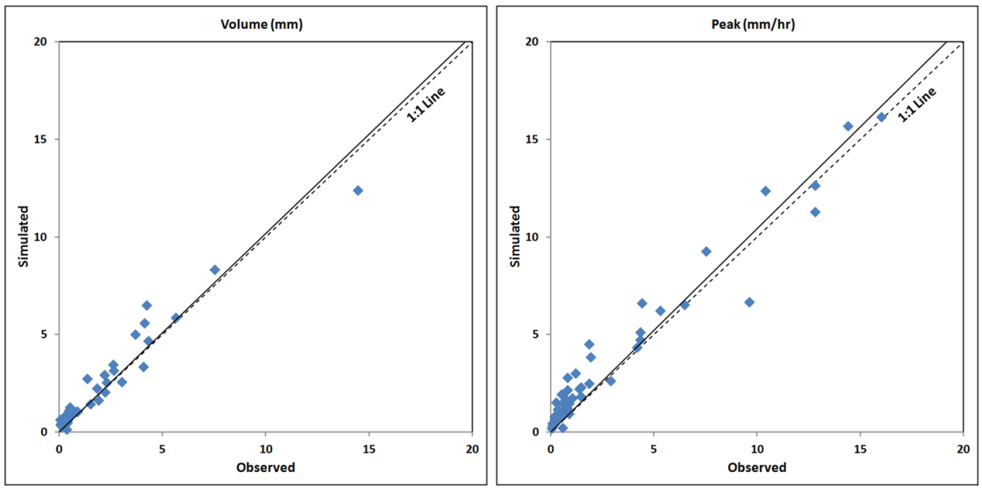

Figure 7 Simulated versus observed event runoff volume (mm) and peak flows mm/hr (n = 47) for July 2015 through September 2006 for the La Terraza subdivision.

The total event runoff volumes and peak flow rates for the 47 simulated events compared to measured values are shown in figure 7. Both volumes and peaks yielded Nash-Sutcliffe

efficiencies (coefficients of determination) greater than 0.9, with very little tendency to over or under predict the observed values. This test provides assurances that with high-quality rainfall-runoff observations, the AGWA GI tool can realistically simulate the effects of subdivision-scale development for multiple lots and streets within a larger watershed with upslope contributions from a natural, undeveloped sub-catchment. Ideally, a development containing GI features with high-quality rainfall-runoff observations could be located to provide real world testing of the AGWA GI tool. Until such data becomes available, this test coupled with the successful lot level testing described in the prior section, provides a measure of confidence in the ability of the AGWA GI tool to simulate the selected GI features in arid and semiarid areas at the lot-, subdivision-, and small catchment-scale.

LIMITATIONS AND ISSUES

Limitations of the KINEROS2 model are discussed in Goodrich et al. (2012). KINEROS2 is currently an event-based model and will not simulate plant water use, soil water movement between events, or track snow accumulation and melt, or subsurface flow. Before simulating an event, it requires an initial estimate of soil moisture. The event-based version precludes modeling of the changes in soil moisture due to drainage, evaporation, and plant water use. This could have an impact when attempting to realistically simulate how water captured by rain harvesting GI practices is drawn down for watering through different weather scenarios. The representation of two-soil layer infiltration available in KINEROS2 has not been implemented within the AGWA GI tool. Unless site specific post-development soils and infiltration data is available this limitation is not viewed as a major shortcoming for the AGWA GI tool.

While KINEROS2 can compute infiltration and route runoff on planar or curvilinear overland flow elements, the Urban GI element is restricted to a planar surface with one slope designated for the non-street components and another slope for the one-half street component. The urban element assumes water flows directly to the street, and the street is assumed to be crowned to allow independent routing of water on each side of the street. Flow from one lot will not cross the mid-line of the street to the other half, so street runoff is uniquely associated with one lot. The Urban GI element in KINEROS2 assumes all of the runoff generated will flow from the back of the lot towards the street. In reality, lot-generated runoff could flow onto adjacent lots. KINEROS2 provides a representation for dead storage, such as a swimming pool or walled yard that effectively traps and holds runoff, however, the AGWA GI tool currently lacks the ability to incorporate this.

If high-quality post construction topographic data from LIDAR were available, it would be possible to further sub-divide a lot into more than one overland flow element coupled with an Urban GI element in these cases. Currently, this is most easily done by altering the KINEROS2 parameter file outside of the AGWA GIS environment, but tools to subdivide elements will be supported in AGWA in the future. This limitation is not seen as a major shortcoming as the primary application envisioned for the AGWA GI tool is for rapid relative change assessments to evaluate the hydrologic response effects of GI features where minor flow path deviations should not have a major effect on the overall assessment of the value of adding GI features.

CONCLUSIONS

The AGWA GI tool was designed and developed to represent retention basins, permeable pavements, and rainwater harvesting systems within the AGWA/KINEROS2 modeling environment. The Urban element in KINEROS2 was modified to provide a realistic representation of individual housing lots and the placement of the GI features noted above. Two new GI tools were developed to spatially prepare parameters for the KINEROS2 Urban GI model element. The Flow Routing tool allows the user to draw flow paths on the map, guiding storm water along platted or post-development drainage paths and to the outlet. This is important as analysis of pre-development topography from nationally or locally available digital elevation model (DEM) data will not typically result in flow paths similar to post-development. Even in urbanized areas with high-resolution DEM data on the scale needed to construct 0.3 m (1 foot) contour intervals, accurate flow paths can often be difficult to discern with automated drainage analysis due to small drainage control features such as curbs and gutters. The GI Design and Placement tool allows the design and placement of retention basins, permeable pavements, and rainwater harvesting systems at each lot in a subdivision. Additionally, various combinations of GI placements can be designed and simulated for an entire subdivision. Three output types are provided by the AGWA GI tool, i.e. infiltration, runoff, and accumulated runoff. Comparisons using these outputs can be made between pre-development and post-development with or without GI practices.

The hydrologic behavior of GI practices was tested at the lot level by verifying: 1) that event volumes of hydrologic components were balanced properly; and 2) the steady-state runoff rate reflected the independently computed effective hydraulic conductivity. Verification of the model at the subdivision-scale was conducted on the La Terraza subdivision using a high-quality set of observed rainfall and runoff data. Simulated runoff volumes and peak flow rates yielded high Nash-Sutcliffe efficiencies (>0.9) and very little bias compared to the observed data. Based on these tests, the AGWA GI tool performed as expected.

At present the AGWA GI tool only focuses on hydrology. Some limitations mentioned related to KINEROS2 will be addressed when the continuous version is available, which includes plant growth functionality and biogeochemistry (K2-O2; Massart et al., 2010). Once integrated into AGWA, the continuous version of KINEROS2 will enable simulation of numerous water quality effects of GI practices. The AGWA GI tool can be a used to inform planning decisions related to urban development and storm water management on lot-, subdivision-, and small catchment-scales. This information will be useful in understanding the expected differences in storm water runoff between neighboring developments or natural environments. In traditional post-development urban environments, the increase in storm water runoff can negatively impact downstream natural resources. GI features have the potential to mitigate those effects by achieving pre-development runoff volumes.

Abstract The Enbridge Line 6B pipeline release of diluted bitumen into the Kalamazoo River downstream of Marshall, Michigan, U.S.A., in July 2010 was one of the largest oil spills into freshwater in North American history. A portion of the oil interacted with river sediment and submerged requiring the development and implementation of new approaches for detection and recovery of oil mixed with river sediment. Hydrodynamic and sediment transport modeling became an integral part of containment and recovery operations for decision support about the potential fate and migration of submerged oil and oiled sediment. Three models were developed for the U.S. Environmental Protection Agency to cover a range of spatial scales of interest to onsite operations. Two-dimensional (2D) hydrodynamic and sediment transport models from the Environmental Fluid Dynamics Code and the sediment bed model SEDZLJ[1] were used to simulate potential resuspension, migration, and deposition of submerged oil and oiled sediment along a 38-mile reach of the Kalamazoo River affected by the oil from Marshall to Kalamazoo. An algorithm was added to SEDZLJ to represent three additional particle size classes of oil-particle aggregates (OPAs) with a range of sizes, specific gravities, and settling velocities. Field and laboratory experiments and flume tests were done to support the numerical modeling of OPAs. A three-dimensional hydrodynamic model was developed to simulate hydrodynamics and OPA tracking through Morrow Lake, the most downstream impoundment. This model incorporated wind and dam operations into high and low flow, lake drawdown, and containment simulations. Finally, a 2D unstructured grid model, HydroSed2D, was used to simulate flows and sediment transport along 1- to 2-mile segments of the Kalamazoo River around islands and through side channels and backwater areas that are particularly prone to submerged oil deposition.

Integrated models could be developed quickly due to the availability of information and services combined with spill response operations that included: bathymetry and topography data, field-based geomorphic mapping of submerged oil, and discharge measured at U.S. Geological Survey streamflow gauges. Modeling results were included in a multiple-lines-of-evidence approach that was used by the Federal On-Scene Coordinator and operations staff for decision-making related to assessment and recovery of submerged oil, as well as net environmental benefit analysis. Similar modeling approaches will likely be useful for future oil spills in riverine environments.

BACKGROUND

The Enbridge Line 6B pipeline release of diluted bitumen (dilbit) into the Kalamazoo River downstream of Marshall, Michigan in July 2010 was one of the largest freshwater oil spills in North American history (Fig. 1). Only the 2004 Delaware River (Philadelphia) spill of about 265,000 gallons of heavy crude oil (U.S. Coast Guard, 2005) and the nearly 800,000 gallon spill of diesel fuel into the Monongahela River, near Pittsburgh in 1988 (Clark and others, 1990) are comparable in size to the 843,000 gallon release reported by Enbridge from Line 6B (http://www.epa.gov/enbridgespill/). The spill happened during a flood with a 4 percent exceedance probability (Hoard et al., 2010). Much of the floating oil was recovered quickly following the spill using conventional methods such as surface containment, absorbent boom, vacuum trucks, and drum skimmers (Dollhopf et al., 2014). However, the remaining oil mixed with river sediment, submerged, and deposited along 38 miles of the river, requiring the development and implementation of new approaches for detection and recovery of submerged oil and oiled sediment (Dollhopf et al., 2014). These approaches included the development of integrated hydrodynamic models to better understand and predict the fate and transport of the residual oil and its association with sediments over the range of environmental conditions encountered as a consequence of changes in river flow and spill response operations.

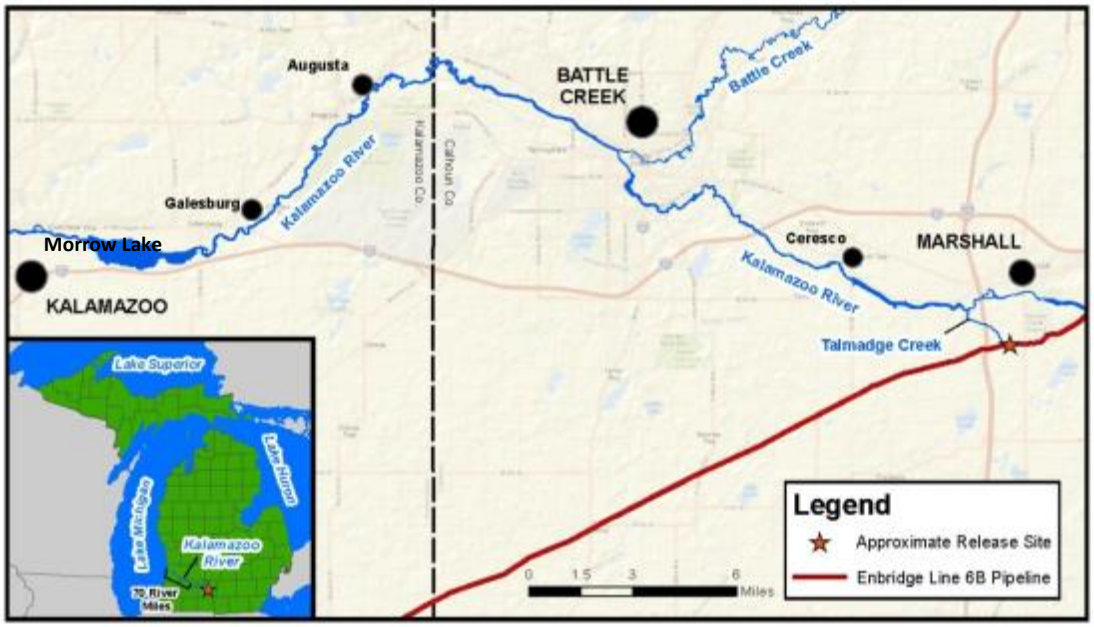

Figure 1 Location map of the Kalamazoo River affected by the July 2010 Enbridge Line 6B oil spill.

Hydrodynamic modeling originated with Enbridge in 2011 to help answer operational questions about the resuspension and downstream deposition of remaining submerged oil under different river flows scenarios and whether the oil could migrate past the most downstream impoundment, Morrow Lake (Enbridge Energy, L.P., 2012a, b). River flows in the Kalamazoo River can quickly increase by an order of magnitude, ranging from summer low flows of about 300 ft^3/s to rainfall or rain-snowmelt related runoff flows of greater than 3,000 ft^3/s. A set of hydrodynamic and sediment transport models using the 2-dimensional (2D) Environmental Fluid Dynamics Code (EFDC) was developed by Tetra Tech for Enbridge in 2011-12 to simulate river water levels, flows, velocities, shear stresses, sediment loads, and erosion and deposition patterns and rates along the 38 miles of the oil-affected Kalamazoo River (Enbridge Energy, L.P., 2012a, b).

A main assumption of the Enbridge modeling was that the transport characteristics of silt-sized sediment could be used as a surrogate for submerged oil. This assumption was based on the consistent spatial association of the remaining submerged oil with fine-grained soft sediment in slow-moving depositional areas of the river (Dollhopf et al., 2014) (Fig. 2). The Enbridge models were rapidly developed (within 3 months) using available data including topography from light detection and ranging (lidar) flown along the oil affected river corridor in 2011, and bathymetry from thousands of elevations associated with sediment poling assessments (agitation of river sediment using an aluminum pole with an 8-in diameter metal disc) for submerged oil (Enbridge Energy, L.P., 2012a). Data sets from two recently constructed HEC-RAS models for the upper and lower portions of the oil affected reach (Hoard et al., 2010; AECOM, 2011a, b; U.S. Army Corps of Engineers, Hydrologic Engineering Center, 2002, 2010) also were used for model setup and calibration. Discharge data from U.S. Geological Survey (USGS) gauging stations provided upstream and downstream boundary conditions as well as model calibration and validation comparisons. Water levels and oil marks collected by Enbridge and the U.S. Environmental Protection Agency (EPA) provided additional validation data.

Figure 2 Photos from the Kalamazoo River: (A) Oiled soft sediment in the vicinity of the Ceresco impoundment in 2012 and (B) typical oil sheen and globs on the water surface near soft sediment deposits in the Battle Creek Millponds in 2013.

Starting in 2013, a team of scientists and modelers continued the hydrodynamic and sediment transport modeling for EPA by updating the Enbridge models with additional data. Efforts were focused on expanding simulations using additional spatial scales and operational considerations including containment and water-level drawdowns in impoundments. The physical properties of the oiled sediment, including its persistence in the environment, were also reassessed in terms of the original representation of submerged oil as being transported with silt particles in the models. Repeated visual observations of spontaneously releasing globs from agitation of sediment during poling assessments, observations of oil globs in sediment cores, and ultraviolet epi-fluorescence microscopy of oil and sediment mixtures indicated that the oiled sediment was likely in the form of oil-mineral aggregates, similar to those that readily form in marine environments (Lee, 2002; Lee et al., 2011; Lee et al., 2012; Dollhopf et al., 2014). Aggregates were renamed oil-particle aggregates (OPAs) for the Kalamazoo River in recognition that a portion of the particulate matter is composed of organic as well as mineral particles. With the addition of the new field and laboratory data, a new set of sediment classes representing typical OPAs for dilbit in the Kalamazoo River were added to an existing sediment transport model. Updated and new models were developed to help answer operational considerations for continued recovery of submerged oil in the Kalamazoo River through the 2014 dredging efforts (Dollhopf et al, 2014).

The objectives of the 2013-14 EPA models are summarized in the following questions:

- Where and under what streamflow conditions will the remaining submerged oil and oiled sediment resuspend, transport, and settle along the river?
- What will happen to the remaining submerged oil and oiled sediment after dredging the impoundments and sediment traps?
- Will more submerged oil migrate into Morrow Lake and what conditions will allow it to pass through Morrow Dam?
- What are the effects of containment and recovery strategies on the migration potential of remaining Line 6B submerged oil?

This paper describes the design and framework of EPA's integrated modeling approach for simulating the fate and transport of submerged oil and OPAs in the Kalamazoo River following the 2010 Enbridge Line 6B release of dilbit. Whereas the final results of the modeling effort were not available for release at the time of this writing (October 2014),updated and new model results were used as they became available, during the decision-making process for remaining oil in the river in the Fall of 2012 through 2014.

THE KALAMAZOO RIVER

The Line 6B pipeline release happened in a wetland adjacent to Talmadge Creek 2 miles upstream of its confluence with the Kalamazoo River near Marshall, in Calhoun County Michigan (Figure 1). The drainage area of the Kalamazoo River near Marshall is 449 mi^2 and more than doubles in size at the downstream end of the oil-affected reach near Comstock with a drainage area of 1,010 mi^2 in large part because of the addition of Battle Creek, a tributary with a drainage area of 241 mi^2. The downstream end of the oil-affected reach is approximately 70 miles upstream of the river's confluence with Lake Michigan. The Kalamazoo River experiences a continental climate with about 32 in. of precipitation and over 40 in. of snowfall annually. Average July temperatures are 72^o F and January temperatures are 24^o F. Surficial geology mainly consists of glacial outwash composed of sand and gravel, as well as medium to coarse textured glacial till (Monaghan and Larson, 1984). Soils have mainly sandy loam textures (U.S. Department of Agriculture, 1994).

The oil-affected reach between Marshall and Kalamazoo has three impoundments – Ceresco, the Mill Ponds near the City of Battle Creek, and Morrow Lake. Flows are minimally affected by power plant releases at Marshall, on Battle Creek, and at Morrow Dam. The width of river varies between about 75 and 200 ft and is generally wide with a width/depth ratio of 40 and a gentle slope of 0.06 percent (3.14 feet/mile) (Tetra Tech, 2011). Water depths range from about 1 to 4 ft. The bottom is composed of gravel, cobble and boulders in the main channel in riffles and thick deposits of organic-rich muck in impoundments. Aquatic vegetation is abundant in summer months. The floodplain of the river is almost completely forested wetland which gives the suspended and bottom sediment a relatively high organic matter content, on the order of 20 percent or more. The river contains many islands, bars, and oxbows. Deposition of submerged oil associated with the Line 6B release occurred along channel margins, backwaters, side channels, oxbows, and in impoundments. Resuspension of submerged oil and settling downstream was evident in repeated poling assessments following floods (Dollhopf et al., 2014).

MODELING DESIGN AND FRAMEWORK

The updated modeling efforts encompassed three main modeling types for simulating submerged oil and oiled sediment transport resuspension, migration, and settling in areas of the river with continued issues with submerged oil: (1) a 2D EFDC model (Hamrick, 1992) of the 38-mile oil-affected reach of the Kalamazoo River; (2) a 3D EFDC model (Hamrick, 1992) for Morrow Lake that accounted for wind and subsurface withdrawals at Morrow Dam; and (3) nested sub-models of enhanced sediment traps using HydroSed2D (Zhu, 2011). These three models, with updated sediment transport algorithms and sediment properties, were needed to address questions at the appropriate spatial scales being asked by operational response staff. It was necessary to have a multidisciplinary modeling team for this work including expertise in heavy oil and sediment transport to be able to develop new algorithms for OPA resuspension, migration, and settling. The USGS, GRTusa, and Weston, Inc. provided coordination, oversight, and direction for the new models, as well as direct and rapid communication with operations staff and the Federal On-Scene Coordinators (FOSCs). They also worked with Tetra Tech and reviewed the 2012 Enbridge model. LimnoTech, Inc. updated the 2D EFDC model. The U.S. Army Corps of Engineers (USACE) developed the OPA algorithm that was coupled to SEDZLJ and conducted onsite SEDFLUME tests (Perkey et al., 2014). The University of Illinois Ven Te Chow Hydrosystems Laboratory (VTCHL) developed the 3D EFDC model, the HydroSed2D model, and conducted *in situ* flume tests and laboratory experiments for OPA. Oil experts from the New Jersey Institute of Technology, and the Canada Offshore Oil, Gas and Energy Research Centre at the Bedford Institute of Oceanography (COOGER) guided laboratory experiments and flume tests and overall modeling approaches.

The modeled flows encompassed a range of flow conditions (Table 1). The updated 2D EFDC models overlapped with two flow simulations included in the Enbridge model for comparison purposes. For the floods, the peak flow associated with the July 2010 flood during the oil spill had a 4-percent probability of the event being equaled or exceeded in any given year for the Marshall USGS streamflow gauge and a 20-percent probability downstream of the Battle Creek confluence (Hoard et al., 2010). The April 2013 high flow also had an exceedance probability of 20 percent, and had corresponding velocity measurements and suspended sediment samples. For the October-November 2011 high base flow period, these flows were equaled or exceeded 20 percent of the time over the period of record and the time period was chosen that overlapped with velocity measurements. The July 2013 low flow was included to represent depositional conditions in the river with flows being equaled or exceeded 50 percent of the time over the period of record. The July 2013 low flow also was chosen to examine the potentially erosional effects in Morrow Lake during low flow from the bottom draw turbines at Morrow Dam. The August 2012 low flow period was used to simulate containment effects on flows when there were corresponding velocity measurements. Lastly, mean daily flows from July-October and November-January from the Kalamazoo River near Battle Creek streamflow gauge were used for simulations of water level drawdowns in Morrow Lake to assist in decision making on whether to dredge oiled sediment in Morrow Lake delta or excavate in the dry.

Table 1 Types of models and in-common flow scenarios for 2D EFDC, 3D EFDC, and HydroSed2D. [H, hydrodynamic; S, sediment transport; PT, particle tracking; O, Oil-particle aggregate transport]

Model Description	Jul 2010 Oil spill flood	Oct-Nov 2011 High base flow	Aug 2012 Low flow	Apr-May 2013 flood	Jul 2013 Low flow	Flood 1-percent exceedance probability	Mean daily Jul-Oct, Nov-Jan
2D EFDC	H[1]	H[1], S[1], O		H	H, S		H[2]
3D EFDC			H[3]	H, PT	H, PT		H[2]
HydroSed2D				H	H	H, S	

[1]Updated simulations for comparison with the Enbridge model.
[2]Simulated Morrow Lake drawdown.
[3]Containment added in Morrow Lake delta.

The Enbridge 2D EFDC model was assembled from new and existing bathymetric and topographic data collected up through the fall 2011 (Enbridge Energy, L.P., 2012a, b). Boundary conditions were established using available streamflow data at five USGS gauges along the Kalamazoo River and its tributaries between Marshall and Comstock. Suspended sediment concentration and particle size data were not available for the streamflow gauges in the modeled reach and had to be assembled from a larger geographic area of representative locations on upstream and downstream streamflow gauges on the Kalamazoo River and on adjacent streams. Some sediment transport parameters were estimated from existing published literature. Bathymetry data were generated from poling assessment data points, combined with surveyed longitudinal profile points, single beam survey of Morrow lake bathymetry conducted in September 2010, channel cross sections measured for the HEC-RAS modeling, and flood inundation mapping. For floodplain topography, 1-ft contours were generated from the 2011 Enbridge lidar data used in the HEC-RAS modeling and flood inundation mapping for the entire area within the 100-yr floodplain boundary (AECOM, 2011a, b). Banklines for the riverine grid were drawn in a geographic information system (GIS) from November 2011 aerial imagery raster files at a scale of 1:100. Streambed characteristics for particle sizes were applied to the grids from 2011 surficial core data assigned to specific geomorphic mapping units and supplemented with substrate types recorded in poling assessments.

The updated 2D EFDC hydrodynamic-sediment transport model was compared with the Enbridge model, as well as used to run new simulations for 2013 high and low flows. The updated model was run with the Sandia National Labs version of EFDC (SNL-EFDC), which incorporates the sediment transport algorithms of SEDZLJ (Jones and Lick, 2001) instead of the standard sediment transport module included in the Enbridge model. Similar to the Enbridge model, the updated model had a domain of the entire oil-affected reach of the Kalamazoo River and consisted of two base grids, one for in-channel flows, called the riverine grid, with a boundary fitted curvilinear-orthogonal horizontal grid network, and another for out-of-bank flows, called the floodplain grid, with a finer-scaled Cartesian grid network with cells of approximately 15 x 15 m. The Cartesian grid network was needed for simulating overland flood flows beyond the sinuous channel. The sediment transport and OPA simulations were run only using the riverine grid. The updated 2D EFDC hydrodynamic model provided flow inputs and

checks for the HydroSed2D models and overall checks with the 3D EFDC model for the upstream delta portion of Morrow Lake.

The domain of the 3D EFDC model (Hamrick, 1992) was Morrow Lake and its dam (Fig. 1). The model incorporated wind data and a 3D view of the gates and turbines at Morrow Dam. This was important to consider because the turbines withdraw a substantial amount of flow, especially during low flow conditions. It was thought originally that outflows from the updated 2D EFDC model would serve as inflows for the 3D EFDC model at the upstream end of Morrow Lake; however, measured water levels at the upstream end of Morrow Lake were used instead because it was thought that measured water elevations were more quantitative for upstream boundary conditions than simulated flows. The 3D EFDC hydrodynamic model provided simulations of the effects of a water level drawdown in Morrow Lake on velocity and bed shear stresses in the upstream delta area. A simplistic design of subsurface containment curtains in Morrow Lake delta were also explored for a July 2012 low flow period that had corresponding velocity measurements along the containment curtains.

The HydroSed2 model code was previously developed at the VTCHL (Liu et al., 2008; Zhu, 2011). The model was chosen to run simulations at a subset of enhanced sediment traps at mileposts (MP) along the spill-affected reach of MP 10.4, MP 10.5, MP 14.75, and MP 21.5 because its unstructured triangular mesh could be detailed enough to represent complex river geomorphology of backwaters (MP 10.4, 10.5), side channels and islands (MP 14.75), and meander cutoffs and oxbows (MP 21.5). An example sediment transport run was included for MP 14.75 and part of the Mill Ponds impoundment.

Common outputs for all models included maps of velocity magnitudes and bed shear stress for the hydrodynamic models. Results from the hydrodynamic models were felt to be the most robust because of the relative wealth of water level, velocity, and discharge data available for calibrations and validation. Initially, velocities of less than 30 cm/s were associated with submerged oil depositional areas and a critical bed shear stress for erosion of 0.4 Pa was used as a conservative estimate of areas where erosion was likely.

Sediment transport runs were more time consuming and had less validation data. Keeping this in mind, fewer runs were done for the 2D EFDC and HydroSed2D models. Typical output included maps of net erosion and deposition. For the 3D EFDC model, less time was spent on sediment transport and instead a Lagrangian particle-tracking model was developed for OPAs.

At the time of this writing (October 2014), documentation for the individual models (2D EFDC, 3D EFDC, HydroSed2D, OPA algorithm) were in the technical review stage. By the time of the SEDHYD 2015 conference, the documents should be available to the public. Some of the datasets that made these models possible to develop relatively quickly for submerged oil and OPAs are highlighted below.

UPDATED DATA SOURCES

The Enbridge models were calibrated in the Spring 2012 to discharge, water surface elevation, and velocity using USGS data from streamflow gauges and other measurements collected by Enbridge and the USGS in 2010-2011 (Enbridge Energy, L.P., 2012a, b). Erosion and sedimentation rates and sediment loads could not be calibrated or validated because no sediment data were available; however, historical suspended sediment data were used from an upstream streamflow gauge at Albion, Michigan and outputs were visually checked against depositional

areas mapped in the geomorphic surfaces unit maps. Model sensitivity analyses were performed on several input parameters to assess how small variations might affect model outputs. Results from these analyses indicate that the models were most influenced by flow and bathymetry and that more data were needed for these and for sediment transport characteristics.

The three new sets of models included major updates of bathymetry, floodplain topography, tributary flow inputs, dam configurations and ratings, channel roughness, and suspended sediment characteristics from data collected in 2012-14 (Table 2). Inclusion of wind data in the 3-D model was important because the majority of Morrow Lake is less than 6 ft deep, which allows for wind to establish strong vertical circulation cells with upwellings and downwellings. The stage/discharge curve was developed for Morrow Dam with the help and experience of the dam operators.

Table 2 Selected major updates in data inputs and calibration for the U.S. Environmental Protection Agency updated 2D EFDC, 3D EFDC, and HydroSed2D models.

Data Type	**Description**
Grids	2D EFDC grids same as Enbridge model, new grids for 3D EFDC and HydroSed2D
Bathymetry and HEC-RAS	Based on multiple sources – poling assessments, surveyed elevations and cross sections, acoustic surveys. Updated with additional data collected in 2012-13, including new HEC-RAS cross sections. Redeveloped bathymetry raster melded with topography at banklines.
Floodplain topography	New county lidar. Redeveloped topography raster.
Tributary flow inputs	Tributary flows redistributed based on drainage area
Dam configurations	Configurations for all dams updated, including dam geometry. Headwater elevations and 3-part stage/discharge rating curve were need for the powerplant operations at Morrow Dam.
Channel roughness	Roughness recalibrated using additional stage and velocity data
Suspended sediment concentration and particle size	Concentration/discharge curves updated with suspended sediment data collected at five U.S. Geological Survey streamflow gauges during six events 2012-14.

Even though there were major data gaps and the Enbridge 2D EFDC model had to be constructed quickly, preliminary model results for flow, water levels, velocity, and shear stress were carefully considered by operations staff. The models helped to verify areas of the river that likely changed from depositional during lows to erosional during high flows. The models also were used for prioritizing and verifying the depositional characteristics of enhanced sediment traps during a range of flows (Mahajan et al., 2013).

Recent developments in remote sensing made it possible to construct detailed, complex hydrodynamic models for a long stretch of the river relatively quickly. High-resolution lidar data were available for constructing detailed topography of the floodplain. High-resolution survey-grade global positioning systems were used to collect the geospatial coordinates of several thousand poling assessment points, which could be used for bathymetry. Powerful and organized onsite GIS capabilities made it possible to construct detailed and complex maps on a daily basis. Acoustic/sonar methods, combined with survey-grade GPS, were used to collect reliable and detailed velocity (e.g., stationary and transect data) and discharge measurements.

SEDFLUME AND IN SITU FLUME TESTS

In 2012, there was a lack of quantitative data that could be used for sediment transport model calibration and validation including oiled sediment and OPAs. River bed substrate was represented in the Enbridge model with selected sediment core data from 2011 applied to mapped geomorphic surface units with simplified sediment types (Enbridge Energy, L.P., 2012a). For the updated models, the Enbridge database was supplemented with additional data derived from sediment cores collected in 2012, onsite SEDFLUME tests of nine cores by the USACE (Perkey et al, 2014), and onsite *in situ* flume tests at five sites by the VTCHL (report in draft at time of this writing) in 2013.

The onsite flume-style erodibility tests were done in three general areas—the Mill Ponds, the downstream end of Morrow Lake (SEDFLUME only), and the upstream delta area of Morrow Lake (Perkey et al., 2014). Most of the tests were done to represent the cohesive layered organic-rich silt and fine sand deposits in Morrow Lake delta with moderate to heavy oiling conditions. *In situ* flume tests were done at a subset of the SEDFLUME core locations.

The two flumes measure potential erosion in different ways, making the results complimentary. The mobile SEDFLUME measures gross erosion rates with depth in a core at various shear stresses, as well as physical properties specific to vertical layering. The *in situ* flume tests measured erodibility of the near-surface sediment over a larger area than that of a single core. The *in situ* flume estimates bed shear stress and net erosion rates based on the mass of sediment eroded at a range of discharges which complements the SEDFLUME test results.

These tests were also done in areas that had repeated agitation toolbox techniques done as part of 2011 submerged oil recovery efforts (Dollhopf et al., 2014). Using a combination of results from these tests, literature values, and hydrodynamic results, bed layer properties of particle size, wet bulk density, critical shear stress for erosion, and erosion rates were generated for the updated 2D EFDC SEDZLJ model.

LABORATORY PROPERTIES OF OIL-PARTICLE AGGREGATES

Laboratory experiments and flume tests were done by VTCHL in 2013-14 to specifically characterize and quantify the weathering characteristics of Cold Lake Blend dilbit and the properties of OPAs formed by its subsequent mixing in the presence of Kalamazoo River sediment. The properties of interest for OPAs included the shape and arrangement (Fig. 3), oil droplet size, oil density, number of oil droplets in an OPA, size of OPA, density of OPA, settling velocity, and critical shear stress to entrain OPAs. The first laboratory tests were to weather the diluent from the bitumen while tracking oil mass loss and oil density and viscosity over a range of temperatures found in the Kalamazoo River. The results from these tests confirmed that weathered Cold Lake Blend remained positively buoyant at room temperature, similar to test results by Belore (2010).

The size distributions of oil globules within OPAs and the OPAs themselves were tested with an orbital shaker run at a range of mixing energies while held at room temperature. The globule size is a function of mainly the viscosity of the oil and amount of turbulence, which is commonly characterized with the turbulent kinetic energy dissipation rate. To form OPAs, the weathered bitumen was mixed in the shaker with Kalamazoo River sediment, and the mixing energy, time, sediment type, and sediment concentration were varied. Photography was used to capture the

size of the large globules and a Laser In-Situ Scattering and Transmissiometry (LISST) instrument was used for the small globules.

The OPA also was examined under an ultraviolet epi-fluorescence microscope using similar techniques as those used by Lee et al. (2012) and Ma et al. (2009). Preliminary results from these tests indicate that the OPAs generated in the laboratory tests were composed of complexly shaped aggregates of oil globules ranging from about 10 to 100 μm with attached particles of about 10 μm or smaller. The most common OPA type observed in the photomicrographs were the single and multiple droplet aggregates as illustrated in Figure 3A; solid-type aggregates were observed when unconventional mixing conditions were implemented.

Annular flume experiments were run to determine the critical bed shear stresses associated with re-entrainment of the OPA from the bed into the water column. In addition, a settling column was used to measure OPA settling velocities.

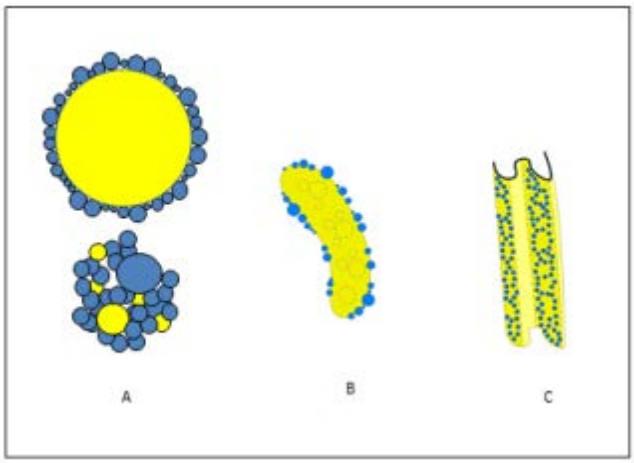

Figure 3 Types of oil-particle aggregates: (A) single and multiple droplet aggregate, (B) solid aggregate of large, usually elongated mass of oil with interior particles (dashed blue circles), and (C) flake aggregate of thin membranes of clay aggregates that incorporate oil and fold up (modified from Stoffyn-Egli and Lee, 2002). Blue color represents particles and yellow represents oil.

Results from these tests were used, along with other field data, for characterizing OPA properties in SEDZLJ and 3D EFDC particle tracking models. Within these models, the OPA maintains a stable form. Future models could be developed from these data to simulate the mechanisms responsible for the formation and breakup of OPAs in freshwater riverine environments.

DEVELOPMENT OF AN OIL-PARTICLE AGGREGATE ALGORITHM

A preliminary simple algorithm for OPAs was developed by the USACE for inclusion in the Kalamazoo River SEDZLJ model. The algorithm represents oiling conditions in the river in 2012, after formation of OPAs. The algorithm uses existing data from other studies of OPAs (Lee et al., 2012), onsite observations from poling assessments and cores, and preliminary results from VTCHL experiments and flume tests. Three groups of OPAs have been included in the model, in recognition that there are likely multiple sizes and densities of oil globules and OPAs in the riverbed. The groups, which are considered substrate classes in SEDZLJ, range from a large 2-mm single oil globule with a 10-μm silt coating to more complex OPAs with multiple smaller globules and diameters of 31 μm and 100 μm. Densities range from just greater than the density of freshwater for the large oil globule with silt coating (1.034 g/cm^3) to somewhat

heavier and close to the density of organic matter for the OPAs (1.511 g/cm^3). Settling velocities range from 0.2 to 20+ mm/s, depending on the amount of oil relative to the size of the aggregate. A major assumption is that the OPAs stay intact, i.e., they do not breakup or disaggregate, during model runs. The bed layering in SEDZLJ required data on the mass fraction of OPA and its size, the density of the OPA, and erosion rate of each layer. The Kalamazoo River streambed from the 2012 Enbridge model was updated with SEDFLUME core data to obtain layer properties, and then further overlaid with 2012 oiled areas of the river to estimate properties of OPAs. The simplified transport algorithm for OPAs is a start for future modeling of OPA formation, transport, and deposition.

SUMMARY AND CONCLUSIONS

Multiple-scale hydrodynamic and sediment transport models were successfully developed in a rapid fashion to address operational questions regarding the fate and transport of submerged oil associated with the July 2010 Enbridge Line 6B spill. Preliminary hydrodynamic models covering several miles of river could be constructed quickly because of the relatively large amount of quickly collected bathymetry and topographic data during response operations and available discharge data at existing USGS streamflow gauges. An organized geographic information system allowed the daily addition of data that was made available immediately across a common platform for sharing inputs and results among models. Due to the length of the cleanup time, the 2012 Enbridge model was updated with more data on bathymetry, velocity, water levels, dam operations, suspended sediment, and streambed conditions. Results from the 2012 and updated models were part of a multiple-lines-of-evidence approach that was used by the Federal On-Scene Coordinator for decision-making related to assessment and recovery of submerged oil, as well as net environmental benefit analysis.

The updated models fill a niche in simulating submerged oil transport and fate, in that they are the first of their kind to model oil-particle aggregates (OPAs) in a riverine freshwater environment. It is hoped that the modeling approach used for the Kalamazoo River will be useful if future oil spills occur in similar freshwater environments and that characteristics of OPAs can be applied to lacustrine hydrodynamic models as well. Rivers in the Midwestern U.S. have characteristics conducive to formation, deposition, and resuspension of OPAs including suspended sediment in the water column (especially during floods), shallow depths, wide channels, relatively low gradient, abundant impoundments, and turbulent flows. These characteristics will likely result in the need for submerged oil recovery and oiled-sediment cleanup for both light and heavy crude oil spills, and a closer look at the ecological risks and potential benefits of physical oil dispersion mediated by the presence and availability of suspended particles.

Abstract: The Automated Geospatial Watershed Assessment tool (AGWA) is a watershed modeling tool that supports the parameterization and execution of several distributed hydrologic models, KINEROS2, RHEM (Rangeland Hydrology and Erosion Model), and SWAT (Soil & Water Assessment Tool version 2000 and version 2005) in the following GIS environments: ESRI ArcView 3.x, ESRI ArcMap 9.x, and ESRI ArcMap 10.x. KINEROS2 is an event-based rainfall-runoff model that is physically-based, representing interception, infiltration, surface runoff, sediment detachment, sediment transport, and sediment deposition processes for overland and channel flow. For a more detailed description of AGWA and KINEROS2, including their histories, see Goodrich et al. (2015; these proceedings) and their respective websites (www.tucson.ars.ag.gov/agwa and www.tucson.ars.ag.gov/kineros). This demonstration will showcase the capabilities of both AGWA and KINEROS2 in a variety of applications, scenarios, and use-cases.

AGWA supports the parameterization and execution of hydrologic models for watershed modeling efforts by performing the following tasks: watershed delineation; watershed discretization into discrete model elements; watershed parameterization; precipitation definition; model simulation creation; model execution; and model results visualization (Figure 1). Watershed delineation uses a filled, hydrologically correct DEM and derived flow direction and flow accumulation with a user-defined outlet to create a watershed boundary. Watershed discretization subdivides the watershed into model specific elements based on the user's model selection and stream network definition choice. Watershed parameterization assigns area-weighted topographic, soils, and land cover parameter estimates to the model elements. Precipitation definition creates individual storm event files for KINEROS2 or continuous, daily precipitation aggregates for SWAT that drive the models. Model simulation creation creates the model input files required to execute a simulation. Model execution runs the model in a command prompt window. Finally, model results visualization imports the model results into tabular format that can be associated with and displayed on the model elements in the GIS.

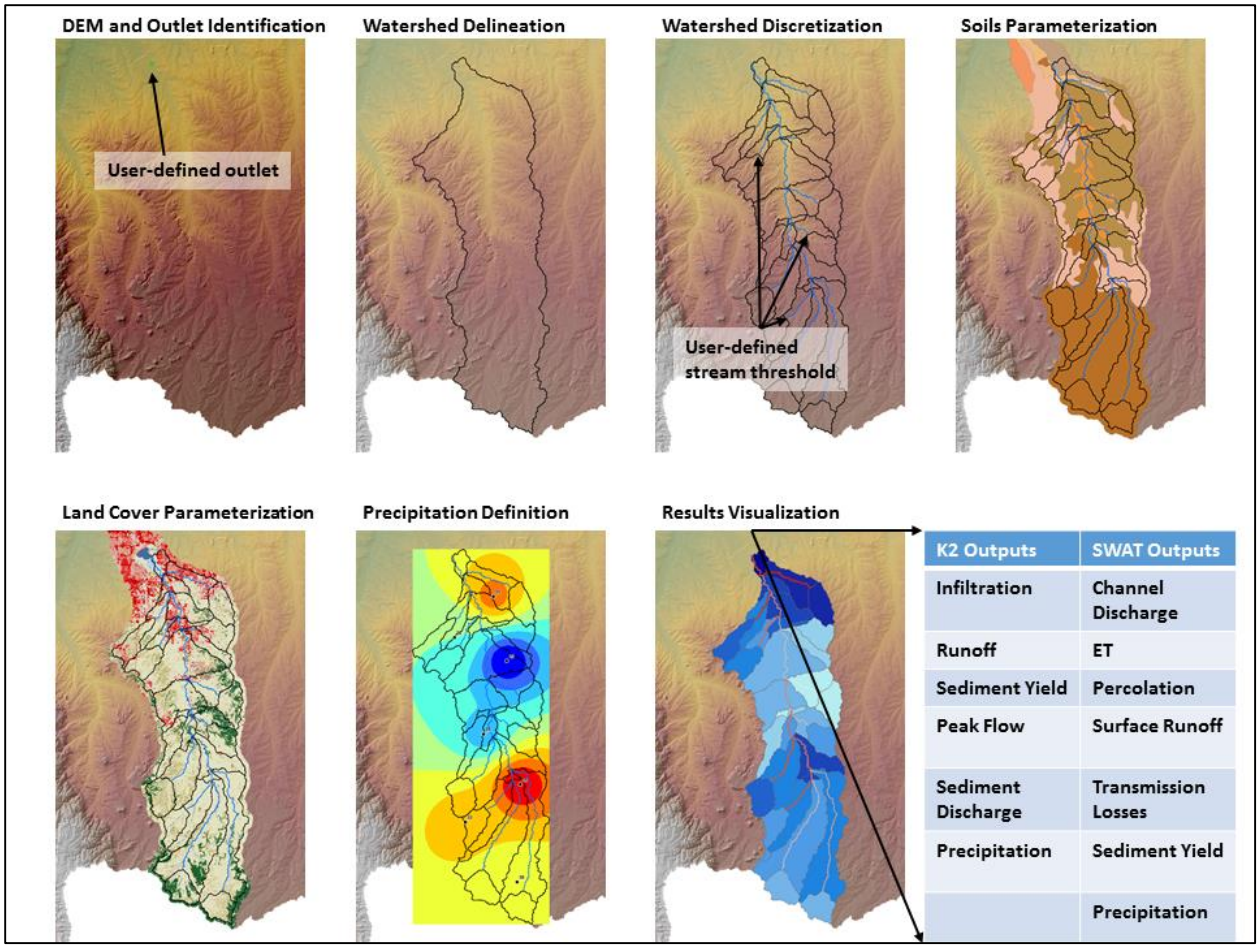

Figure 1 The required steps in AGWA to perform a watershed assessment. A DEM is used to delineate the watershed, subdivide it into model elements, and parameterize the elements in conjunction with the soils and land cover layers. Precipitation drives the model and model results are imported and visualized in the GIS.

The AGWA demonstration will feature the seven general AGWA steps. In addition, it will highlight some advanced features/functionality recently added to AGWA, including: an area-of-interest group delineation tool for delineating watersheds within a defined boundary (political, management, administrative, etc.); batch simulations; batch parameterizations; hillslope sub-discretizations; additional stream network definition methodologies utilizing a flow length threshold, flow accumulation threshold, or an existing stream network; rapid-post fire watershed assessments and report generation; use of dynamic erosion formulations in the RHEM (Rangeland Hydrology and Erosion Model) model; and incorporation of Low Impact Development (LID) features in the KINEROS2 model.

DEMONSTRATION OF THE WATER EROSION PREDICTION PROJECT (WEPP) INTERNET INTERFACE AND WEB SERVICES EXTENDED ABSTRACT

Abstract: The Water Erosion Prediction Project (WEPP) model is a process-based FORTRAN computer simulation program for prediction of runoff and soil erosion by water at hillslope profile, field, and small watershed scales. To effectively run the WEPP model and interpret results additional software has been developed. Software external to WEPP includes user interfaces, databases of model parameters and software to provide translation to WEPP input formats along with spatial mapping and graphical software to present modeling results. Recent WEPP projects at the USDA-ARS National Soil Erosion Research Laboratory (NSERL) have included web-based user interface development. Providing access to the WEPP modeling resources using a web browser allows easy access for users and a central point for any model or data updates. In addition to web browser interfaces WEPP model services are made available through representational state transfer (REST) web services. The WEPP REST software services allow additional web sites or applications to be developed that make use of the WEPP technology.

This presentation will demonstrate the current WEPP internet GIS and hillslope interfaces available from servers at the NSERL. How to use the WEPP REST web services will also be demonstrated.

INTRODUCTION

The Water Erosion Prediction Project (WEPP) model is a process-based FORTRAN computer simulation program for prediction of runoff and soil erosion by water at hillslope profile, field, and small watershed scales. The inputs to the WEPP model consist of text files with parameters for climate, soils, topography/slope and land use management. Watershed simulations also include input files that describe the channel parameters and connectivity. Creating the WEPP input files and presenting model results are handled by separate user interface programs. When WEPP was first released in 1995 the intent was that DOS file building interface programs would be replaced with more user-friendly interfaces. Additional desktop interfaces have included support for Microsoft Windows (Flanagan, et al. 1998) and the GeoWEPP extensions to ArcGIS (Renschler, 2003).

Web-based applications of the WEPP hillslope and watershed models are available from the WEPP NSERL website at: http://milford.nserl.purdue.edu/. The US Forest Service has also developed specialized web-based applications of WEPP for forest conditions available at: http://forest.moscowfsl.wsu.edu/fswepp/ (Elliot, 2004). Web-based interfaces allow the model to be used by groups with different expertise levels by simplifying the user interfaces. For full access to all model inputs for research purposes the desktop version of WEPP and interface are still available. In addition to the WEPP interfaces available through browsers, web services have been developed. These allow additional interfaces to be developed while still taking advantage of having the model simulations and data centrally located. The WEPP web services have been designed to be REST compatible. This allows the most number of client application types to use the services since information is transferred in common formats such as XML or JSON using HTTP methods (Rodriguez 2008).

This extended abstract describes three web-based technologies that have been developed to make complex science within the WEPP model more usable by managers, scientists, students and the general public.

WEPP INTERNET HILLSLOPE MODEL

The WEPP hillslope model requires four types of input files to be setup to run a simulation. These include the climate input, slope characteristics, soil information and management input (Flanagan and Livingston,1995). The online WEPP interfaces use the CLIGEN model to generate daily climate data required by the model (Nicks and Gander, 1994). In the simple hillslope interface the slope inputs are entered directly on the web page. Soil data are read from local WEPP soil files stored on the server or can be accessed using the NRCS soil data access for SSURGO data (NRCS, 2011). The management data can be read from local WEPP management files stored on the server or converted from RUSLE2 (Revised Universal Soil Loss Equation version 2) management data.

WEPP produces extensive outputs that include spatial soil loss down the profile and also daily outputs of model variables. This information can be shown graphically in model output pages. Figure 1 shows a hillslope simulation page with inputs on the left panel and a brief summary of the model outputs on the right panel.

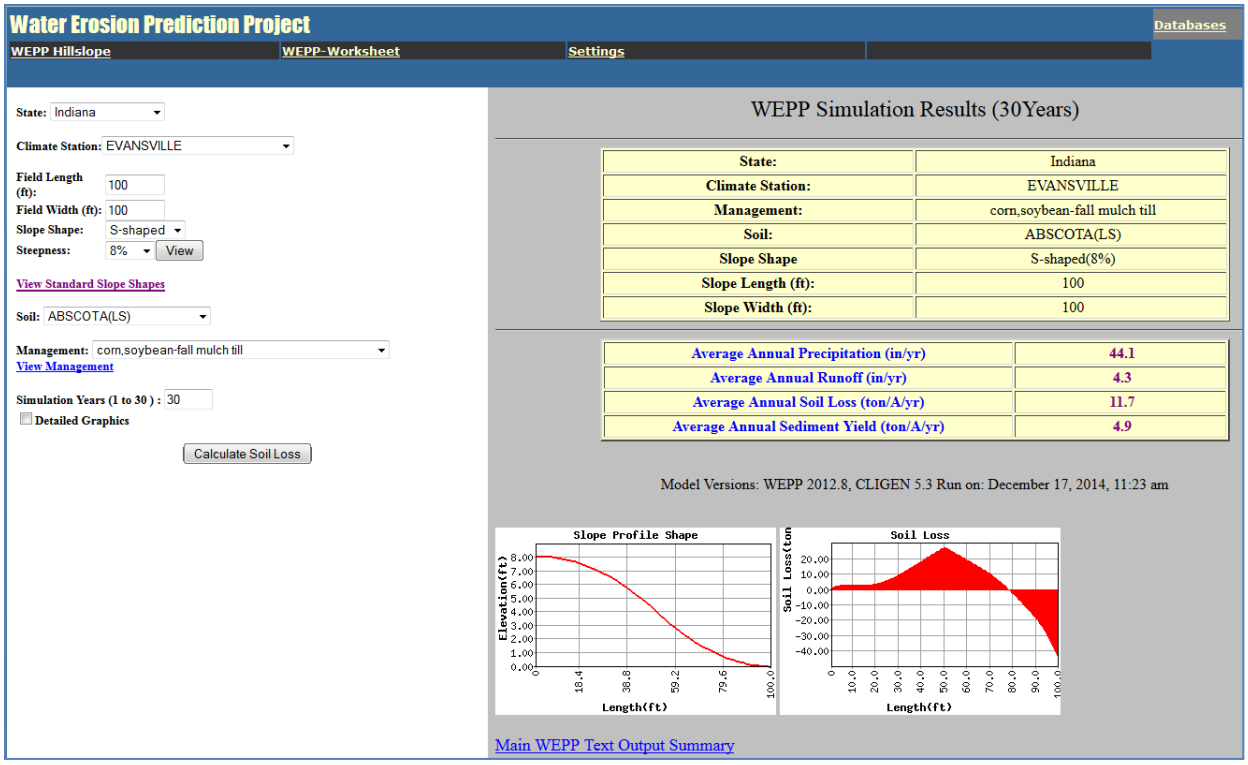

Figure 1 WEPP hillslope model simulation. Inputs are chosen from simple choice lists.

The web server is comprised of a Ubuntu Linux system running the Apache 2 web server. The server side software includes PHP scripts and custom C++ programs to setup, run and process outputs from the WEPP model.

WEPP INTERNET WATERSHED MODEL

The WEPP watershed model internet interfaces use a DEM to determine a channel network and watershed subcatchments. The TOPAZ model is used to delineate the channel network and subcatchment areas within a watershed (Garbrecht and Martz, 1997). The interface uses Google Maps for base map images and overlays modeling results from TOPAZ or WEPP as additional layers. Figure 2 shows an area with the TOPAZ calculated channel network overlaid on the Google Maps Physical layer.

Figure 3 shows the same area after an outlet point has been selected and the watershed delineated from that location. The input files for WEPP simulations are prepared using the area delineated by TOPAZ, and involves extracting WEPP soil parameters from the SSURGO soils data, using the USGS National Landcover data to determine management inputs and using the USGS DEM to determine the slope profile inputs to WEPP. Climate inputs can be adjusted by using the PRISM gridded data (PRISM Climate Group, 2004) if the area of interest has different weather characteristics than the nearest station in the Cligen database.

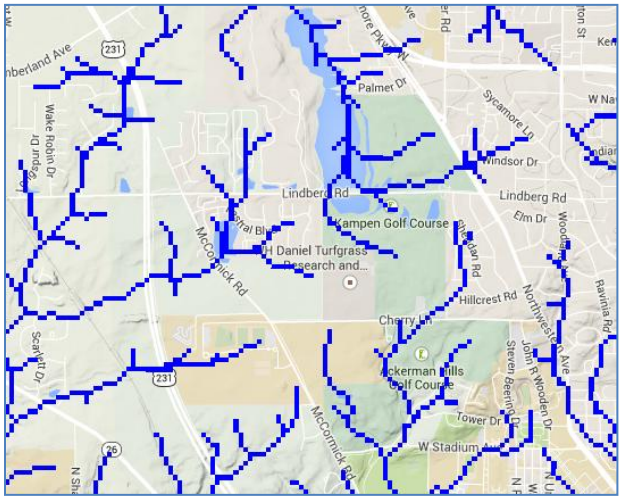

Figure 2 Channel delineation from TOPAZ model.

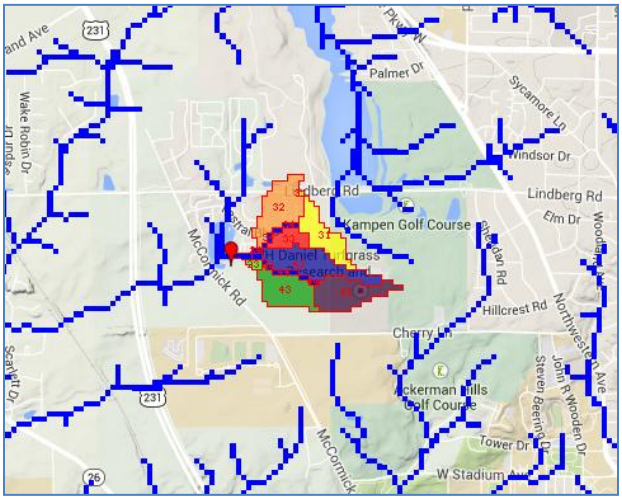

Figure 3 Watershed delineation using the TOPAZ model.

The online WEPP watershed interface supports two types of simulations: flowpath and representative hillslope (Cochrane and Flanagan, 1999; Flanagan et al., 2013). In the flowpath method each flowpath in the watershed is simulated as a WEPP hillslope profile. The spatial soil loss determined on each flowpath can be output as a GIS layer as shown in Figure 4. Flowpath simulations may take hundreds or thousands of WEPP simulation runs to cover a watershed. No channel routing is currently performed when applying the flowpath method.

The representative hillslope method simulates one hillslope per subcatchment and includes channel routing. This method takes much less computing resources than the flowpath method, however the results are not as detailed at the subcatchment scale. The watershed simulation does include channel processes so that offsite effects of runoff and sediment leaving the watershed can be evaluated. Figure 5 shows the GIS output layer for a representative hillslope run. Color shading indicates areas of higher erosion above the tolerable soil loss in red, 3 t/ha/yr in this example, to areas below the tolerable soil loss in shades of green, while areas of deposition are shown in yellow in Figures 4 and 5.

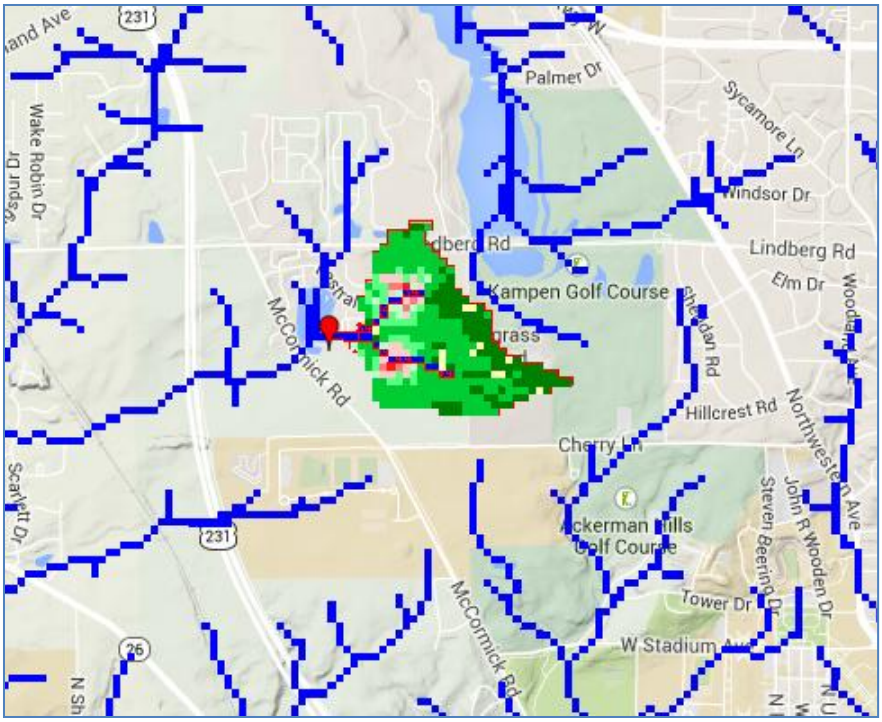

Figure 4 Flowpath output

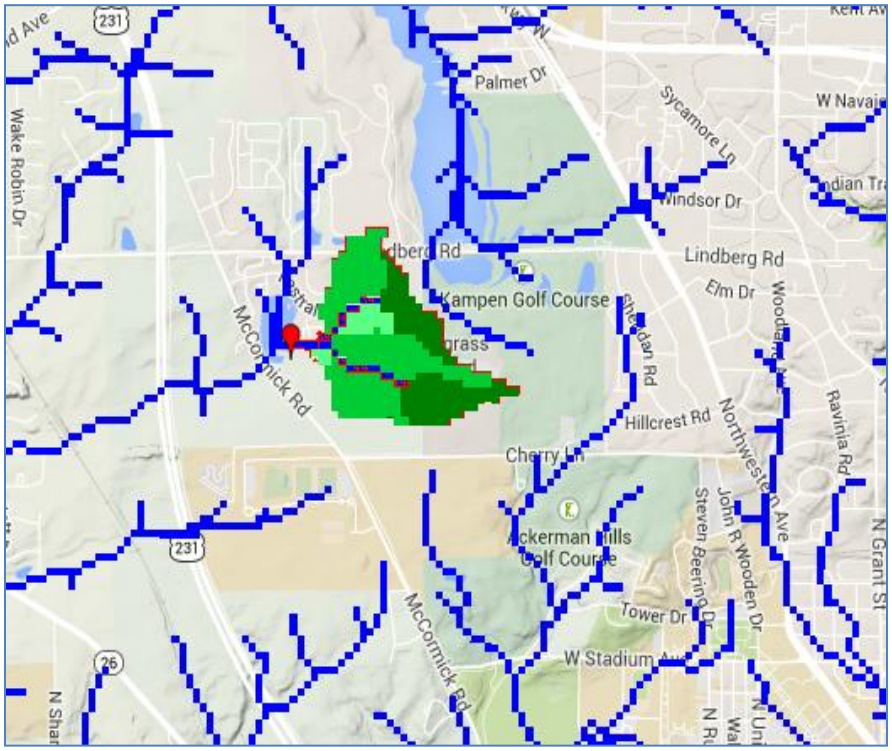

Figure 5 Representative hillslope output

Similar to the WEPP hillslope interface the web server is comprised of a Ubuntu Linux system running the Apache 2 web server. The server side software consists of PHP scripts and custom C++ programs to setup, run and process outputs from the WEPP model (Frankenberger et al., 2011). In addition, the OpenLayers JavaScript library is used to display GIS data on the client machine. Google Maps background images are used in the application. The server also uses the MapServer application to provide GIS functions for raster and vector data.

WEPP REST WEB SERVICES

Although the existing web-based interfaces are useful they are limited by what interfaces are available on the web servers. Changes to the interfaces require coordination with developers, or rehosting the WEPP model, data and web pages on a different server. This makes it difficult to develop specialized interfaces or integrate the model with other web-based tools. RESTful web services allow communication with software services using the standard HTTP protocol. This allows the data and modeling processing to reside in one server environment and the user interface to reside on a different server website, Windows application or mobile app. The WEPP web service categories are summarized in Table 1.

Table1 WEPP REST services

Climate Data for CLIGEN	WEPP Model Runs
WEPP soils from SSURGO	TOPAZ Model Runs
Management Data, local or RUSLE2	DEM Grids for WEPP Watershed Runs
CLIGEN Model Runs	TOPAZ outputs for WEPP Watershed Runs

The client application that uses the services can be written in any language. Below is an example using the command line curl program to request all the Cligen stations in Indiana. The URL can also be entered into a browser.

```
curl -i -H "Accept: application/json" -X GET
http://milford.nserl.purdue.edu:8080/wepprest/d/climate/cligen/IN
```

The return information is in JSON format:

```
[
    {
        "id": "IN120177.PAR",
        "lon": -85.6800003,
        "name": "ANDERSON QUARTZ PLT",
        "lat": 40.0999985
    },
    {
        "id": "IN120676.PAR",
        "lon": -84.9499969,
        "name": "BERNE",
```

```
        "lat": 40.6699982
    }...
```

The following example makes a 10 year Cligen run for a station in Indiana. This request is slightly different from the previous request. The URL includes the Cligen version to run along with the station id and output file. An extra file is also passed that includes additional Cligen parameters.

```
curl -H "Content-Type: application/json" -X POST -d
@runcligen.txt
"http://milford.nserl.purdue.edu:8080/wepprest/m/climate/cligen/4
.3/IN122660/test123"

# contents of runcligen.txt:
{
  "years" : 10,
  "type" : "continuous",
  "interp" : "None"
}
```

The next request reads the model output from the Cligen run. In this URL the run identifier and particular output file are included.

```
curl -i -H "Accept: application/octet-stream" -X GET
http://milford.nserl.purdue.edu:8080/wepprest/m/climate/cligen/te
st123/output.cli
```

An example Windows WEPP hillslope application was developed in C# to test the WEPP web services. This application runs on the Windows desktop but does not install any WEPP related programs or files. Instead it uses the WEPP web services to setup and run simulations. Figure 7 shows the climate selection panel which uses the Cligen services data to plot locations in Bing maps.

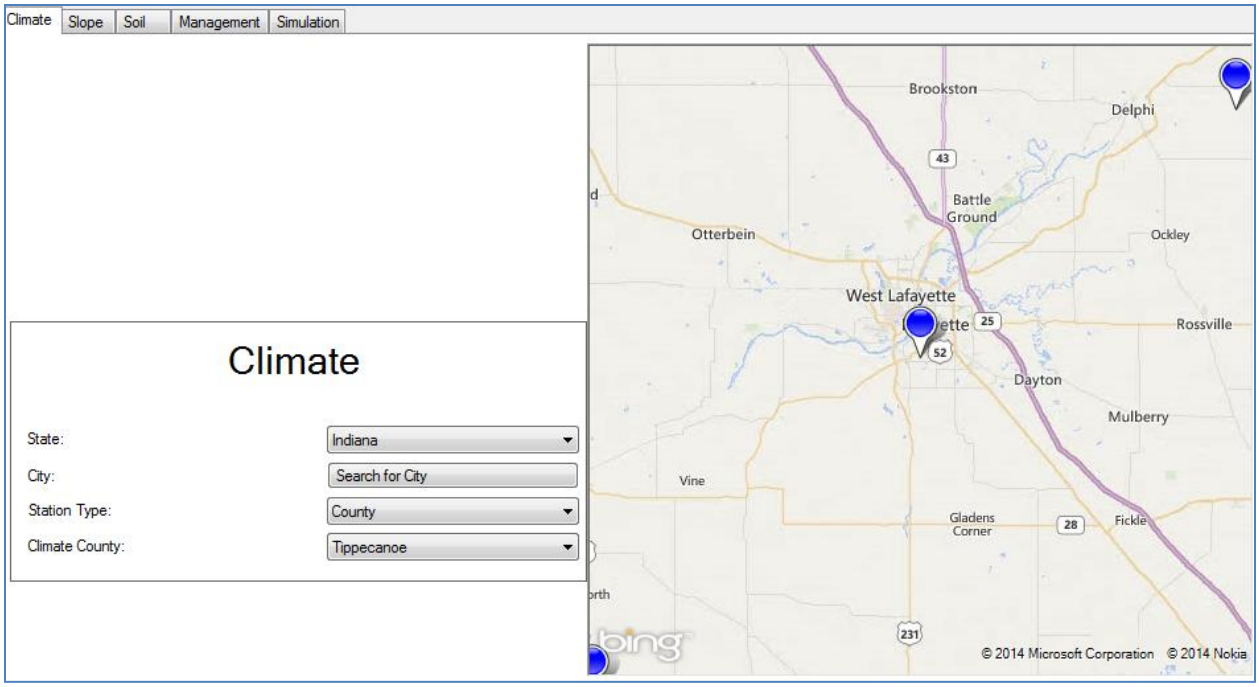

Figure 7 Climate location selection for a WEPP run.

Figure 8 shows the soil window which formats data returned from requesting WEPP soil data from the web service. By requesting SSURGO data the web server is also communicating with the NRCS soil data access web services to get the requested WEPP soil parameters.

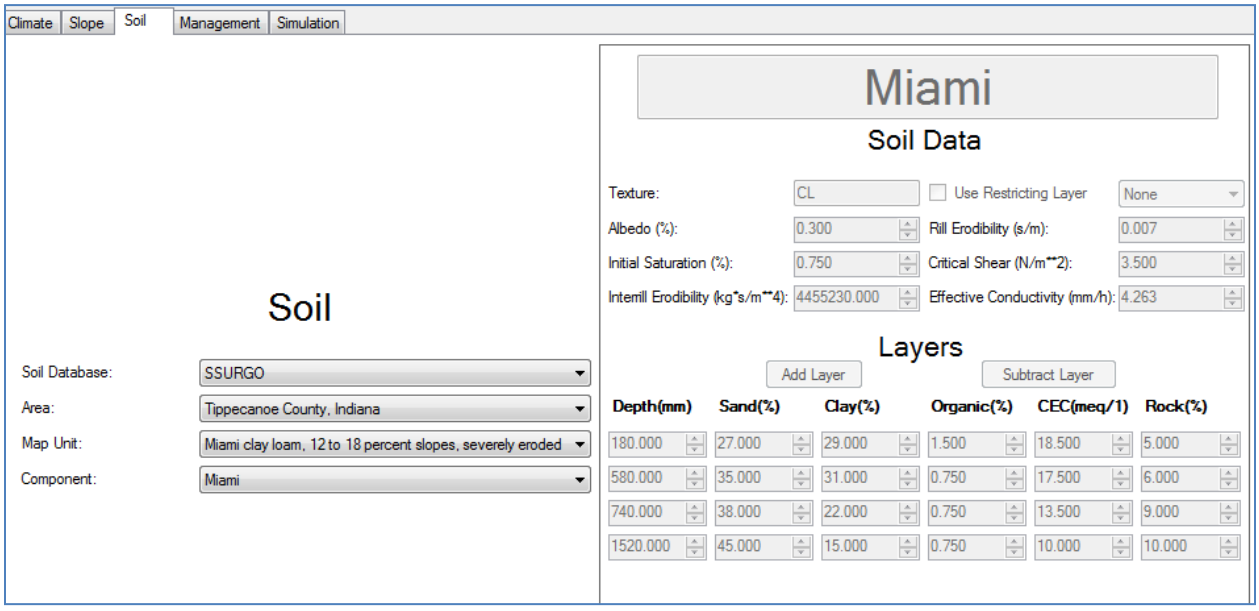

Figure 8 Soil selection for a WEPP run.

The management selection is made by first requesting a list of managements that apply to the area of simulation. A default list of WEPP managements along with a list of RUSLE2

managements is returned and displayed. The RUSLE2 management database has over 20,000 records. If a RUSLE2 management is selected the data are translated to WEPP format. Figure 9 shows the list of managements for Indiana.

After the management is selected the number of years is input and the WEPP hillslope model run. A brief output is displayed. The input files for the run are displayed on the right with additional output data and graphs available. Figure 10 shows the WEPP output page.

Future work involving WEPP internet applications involves expanding the web services application programming interface (API) to allow more of the model functionality to be available. Other data sources relevant to WEPP modeling, such as NASS land cover and more detailed DEM's will be included. In addition, the NRCS Cloud Services Innovation Platform (CSIP) implements a set of web services for NRCS models and data (David et al., 2013). WEPP is being integrated into the CSIP platform. Having WEPP compatible with CSIP will allow WEPP to be used for NRCS conservation planning. The expanding CSIP infrastructure will also allow more WEPP model simulations than the current server environment.

Figure 9 Management selection for a WEPP run.

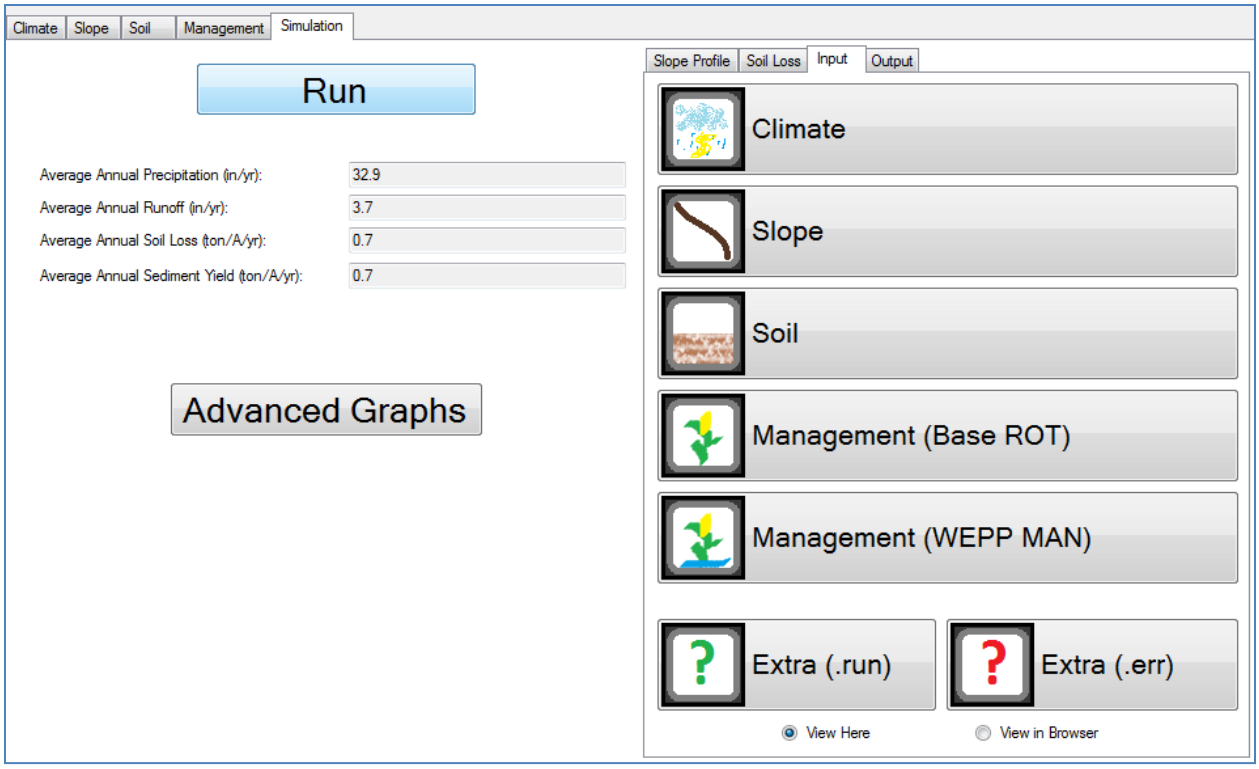

Figure 10 WEPP model results and links to input files used in the simulation.

SUMMARY

The WEPP web-based interfaces allow users to more easily apply the model to single hillslope and watershed simulations. Although the existing web-based interfaces are useful they are limited by what interfaces are available on the web servers. Changes to the interfaces require coordination with developers, or rehosting the WEPP model, data and web pages on a different server. The REST services for WEPP allow the model to be integrated into new internet, desktop or mobile applications without having to include model programs and databases since the model and data reside on servers. Accessing the model through the web services allows for more flexible development of WEPP related applications.

MODELING OF A NON-PHYSICAL FISH BARRIER

Marcela Politano, Research Engineer, IIHR – Hydroscience & Engineering, The University of Iowa, Iowa City, IA, marcela-politano@uiowa.edu; Ezequiel Martin, Assist. Research Scientist, IIHR – Hydroscience & Engineering, The University of Iowa, Iowa City, IA, juan-martin@uiowa.edu; Yong Lai, Hydraulic Engineer, Technical Service Center, Bureau of Reclamation, Denver, CO, ylai@usbr.gov; Merlynn Bender, Hydraulic Engineer, Technical Service Center, Bureau of Reclamation, Denver, CO, mbender@usbr.gov; Dave Smith, Research Ecologist, US Army Corps of Engineers, Vicksburg, MS.

Abstract: Non-physical barriers (NPBs) are used to deter fish from entering an undesirable pathway without restricting flow. NPBs are commonly comprised of a bubble curtain, low-frequency sound, and hi-intensity light-emitting diode (LED) Modulated Intense Lights (MILs). In this study a 3D numerical model was developed to predict bubble, sound and light fields in the vicinity of an NPB. A Boussinesq approach was used to account for the reduction of density in the zones where bubbles are present. A simplified diffusive model for the sound intensity was developed. Two methods are proposed for light, one for high attenuation/scattering conditions based on P-N models and the other for low scattering conditions based on the superposition of analytical solutions for elementary one-dimensional cases. To validate the solvers, several experiments were simulated. A sample model application to a simplified NPB located in Georgiana Slough in the Sacramento River is presented and discussed.

INTRODUCTION

Non-physical barriers (NPBs) use behavioral stimuli such as bubbles, low-frequency sound, and high-intensity light-emitting diode (LED) Modulated Intense Lights (MILs) to deter fish from entering undesirable locations. The sound is concentrated within the bubble curtain due to the difference in the velocity of sound of water and air to prevent sound saturation. Lights projected onto the bubble curtain improve visibility for fish swimming in the direction of the curtain. This NPB arrangement is typically referred to as a Bioacoustic Fish Fence (BAFF).

The migration of juvenile salmonids in the San Joaquin and Sacramento Rivers is of great environmental interest due to decline of native species. Fish diversion into the Delta may result in delayed migration, elevated risk of predation, exposure to poor water quality conditions, and mortality in pumping facilities. The California Department of Water Resources (CDWR) and the U.S. Bureau of Reclamation (Reclamation) proposed to use a NPB to reduce the diversion of juvenile salmonids from the Sacramento River into the interior and south Delta. The effectiveness of NPBs in deterring fish is variable, depending on the location, barrier geometry, and river flows. NPB can also have unintended effects, such as increased predation upstream and downstream of the barrier. All the above increase the environmental risk requiring site specific study and evaluation. In this study a numerical model for a NPB was developed to better understand the effect of the barrier on the Sacramento River hydrodynamics and support the design and operation of a NPB to deter and direct fish movement.

NUMERICAL MODEL

In this study, we first developed the model equations to simulate the bubbles, sound and light fields. The model equations were then implemented into the open source code OpenFoam (Weller et al. 1998). OpenFoam is a collection of C++ libraries, based on object oriented programming, designed for continuum mechanics applications. A new solver, pisoFoamBLS, which includes simplified models for predicting bubbles, sound and light fields near a non-physical fish barrier, was developed based on the code pisoFoam using a modular approach. Several studies related to implementation of different solvers in OpenFoam may be found in the literature (Hussein 2009, Kassem et al. 2011, Flores et al. 2013, among others) and repeated herein.

MODELING OF BUBBLES

Mathematical Modeling: A bubbly flow, i.e., a discrete gas phase in a continuous fluid, is formed in bubble curtains. As illustrated in Figure 1, bubbles injected in an initially quiescent medium induce a motion in the liquid similar to that observed in buoyancy-induced flows. Three distinct zones can be observed in a bubble curtain:

1. The primary bubble zone: where bubbles accelerate as they detach from the nozzle
2. The plume zone: where bubble breakup and coalescence prevail to form the plume

3. The free bubble zone: where the dynamic process of breakup and coalescence have reached an equilibrium and bubbles rise without significant size change

Measurements of gas volume fraction, bubble frequency and chord length by Castillejos and Brimacombe (1987) indicate that bubble breakup in the plume zone predominantly occurs near the injection location. Close to the free surface, the bubble velocity decreases as liquid moves tangent to the free surface, which enhances coalescence and promotes larger bubble sizes.

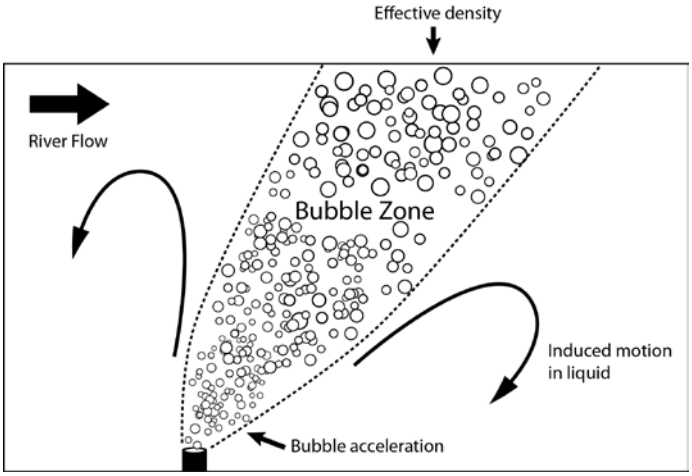

Figure 1 Induced liquid motion for a bubble curtain in a river

Most of bubble plume models found in the literature are intended for the free bubble zone region. The current modeling effort is based on the model presented by Buscaglia et al. (2002). The authors used a two-fluid approach assuming an incompressible mixture gas-liquid phase. In this approach, the Navier-Stokes equations are restored, significantly simplifying the formulation. The main advantage of this model is that an equation for the gas phase is included and therefore the shape of the bubble zone can be predicted. Future model improvements such as inclusion of a bubble size distribution, breakup and coalescence, bubble dissolution, bubble compression, bubble induced turbulence, etc., can easily be incorporated into the model using this formulation. Following Buscaglia et al. (2002), density differences are neglected except where they appear in the term multiplied by the acceleration due to gravity resulting in:

$$\nabla \cdot \vec{u}_m = 0 \tag{1}$$

$$\rho_l \frac{\partial}{\partial t}\vec{u}_m + \rho_l \nabla \cdot \left(\vec{u}_m \vec{u}_m\right) = -\nabla P + \nabla \cdot \left[\tau_m^{\mathrm{Re}} + \tau_m\right] + \rho_m \vec{g} \tag{2}$$

Equations (1) and (2) can be solved to compute pressure and velocity of the mixture phase with any single-phase CFD solver adding a source term in the momentum equation $\vec{S}_m = -(\rho_l - \rho_g)\alpha \vec{g}$. In this study an isotropic turbulence model $k-\varepsilon$ was used for turbulence closure. The gas velocity was obtained from the momentum equation for the gas phase. Inertia, gravity force and viscous shear stresses are significantly smaller than liquid-gas interfacial forces due to the small density and viscosity of the gas phase and are usually neglected. In this particular application, drag is the most important interfacial force and lift and virtual mass can be neglected resulting in:

$$-\nabla\left(P + \frac{2}{3}k\right) + \frac{3}{8}\frac{C_g^D}{R}\vec{u}_r\left|\vec{u}_r\right| = 0 \tag{3}$$

In a bubble curtain, bubble size can change due to breakup, coalescence, mass transfer and pressure variations. In this study, an equation for the bubble number density was used:

$$\frac{\partial N}{\partial t} + \nabla \cdot \left[\vec{u}_g N\right] = \frac{\nu^t}{Sc}\nabla^2 N_g \tag{4}$$

The bubble volume at a given position can be calculated from $v_b = \frac{P_c}{P}\frac{4}{3}\pi R_c^3$, where P_c and R_c are the pressure and radius at the injection point. The bubble zone can be determined using the gas volume fraction, which can be obtained from the mass conservation equation for the gas phase $\alpha = \frac{4}{3}\pi R^3 N$.

Model Comparison with Experiments: The model was used to simulate an experiment by Grevet et al. (1982) in which a water-filled cylindrical tank was agitated by a gas bubble stream, and compared against velocity data measured inside the tank. The modeled tank radius, R, was 0.3 m and the water height, H, 0.6 m. Bubbles were injected into the quiescent liquid through an orifice of 0.0127 m (0.5 inch) at a flowrate of 205 cm3/s. Only one fourth of the tank was simulated to reduce grid size and computational time. Symmetry boundary conditions were used on the sides. Grid size was approximately 105 nodes. Since bubble velocities were not measured, it is assumed that bubbles enter the domain at their terminal velocity. Reasonable agreement was found between model predictions and experimental data for three axial positions (Figure 2). As rising bubbles leave the injector, they generate an inward flow at the left bottom side of the tank. The bubble stream then generates an upward flow in the center of the tank and a large clockwise vortical structure at the upper right side, with negligible radial velocities. The rising bubble velocity is terminated at the free surface and the liquid vertical moment is converted to horizontal flow. The horizontal flow is blocked by the tank wall and is redirected downward along the side wall. The model is considerably less accurate near the walls, but since wall interaction is not important in a bubble curtain, grid refinement was not performed to capture the velocity profile near the walls. The proposed model assumes one variable bubble size. Implementation of a bubble size distribution is expected to improve model accuracy. Figure 3 shows the gas volume fraction distribution in the tank. For the low gas volume fraction injected, bubbles concentrated in the core of the tank, rise almost uniformly in a nearly straight line. Near the injector, bubble velocity increases due to the upward liquid flow in the center of the tank. This local increase of the liquid velocity causes a reduction of the gas volume fraction. Conversely, bubble velocities are reduced near the free surface resulting in a local increase of the gas volume fraction.

MODELING OF SOUND

Mathematical Modeling: The acoustic field in a domain can be represented by an equation of acoustic energy conservation:

$$\frac{\partial W}{\partial t} = -\nabla \cdot \boldsymbol{I} - D \tag{5}$$

where W is the acoustic energy and $\boldsymbol{I}$ the acoustic energy flux. The last term in the RHS represents dissipation effects. In this study a method was developed to deal with the strong changes in fluid properties introduced by the presence of the bubble barrier as well as the multiple surfaces that partially absorb the sound signals at the boundaries. The diffusive equation used in architectural acoustics was identified as a viable candidate to fulfill these requirements. A Fick's law-type relation is postulated between the energy flux and the energy density, $\boldsymbol{I} = -\boldsymbol{D_W}\nabla W$, which adapted to give a dependence of the dissipation on W rather than $\boldsymbol{I}$, transforms the conservation equation for sound energy to:

$$\frac{\partial W}{\partial t} = -\nabla \cdot (\boldsymbol{D_W}\nabla W) - \alpha_W^2 |\boldsymbol{D_W}| W + S_W \tag{6}$$

where a general distributed source term S_W has also been included. A new parameter, an anisotropic diffusion coefficient $\boldsymbol{D_W}$, has been introduced, for which modeling is required. The expression for the dissipation term is such that the exponential decay of a plane wave in an isotropic media is recovered. Following Picaut (2002), absorption is modeled as a boundary condition. Picaut et al. (1999) proposed a diagonal tensor related to length-scale of domain for the diffusion coefficient:

$$\frac{D_{xx}}{\ell_x} = \frac{D_{yy}}{\ell_y} = \frac{D_{zz}}{\ell_z} = D_{3D} \tag{7}$$

with the diffusion proportional to sound speed ($D_{3D} \sim c$). Eq. (6) is a standard diffusion equation for which solution methods are well established and can be readily implemented in OpenFoam. Certain features of the sound field are lost by using this approach, such as the appearance of interference patterns and the rapid evolution of the sound field that can be found with the ray tracing method. However, it is questionable that those features are of significant importance for the current application, as it is expected that the cases of interest will be quasi-steady in both bubble-encapsulated and non-encapsulated sound fields as the fluid velocity is much smaller than the speed of sound, and the sound source are non-pulsating in time.

A set of linear attenuation coefficients and speed of sound data for bubbly flows presented by Silberman (1957) were used in this study.

Model Comparison with Experiments: The data presented by Würsig et al. (2000) represent one of the few reported field experiments with useful, albeit scarce, data for model validation. Sound levels produced by a pile-driving hammer in shallow waters were measured with and without a bubble curtain designed to mitigate the sound. Measurements of background noise are also available, but there is no measurement of sound levels near the source or inside the bubble curtain area. A slab geometry with an average depth of 8 meters was simulated. In Figure 4, the measured data on April 26, 1996 is shown along with the simulated results. The authors reported an overall sound level for frequencies spanning 100 Hz to 25.6 kHz, as well as results for the different one-octave bands. Notable differences in attenuation by the bubble curtain occur for the different frequencies, but it was found that the reported average trend for all frequencies is consistent with the results for low frequencies (as the sound intensity is largest for the 400 Hz octaves), and a representative frequency of 400Hz was chosen to perform the simulations. A uniform source for the background noise and an additional source near the coordinates' origin were obtained. The relationship between the wall attenuation coefficient and the diffusion parameter was established using the expression proposed by Silberman (1957). An extremely low value of Dyy /Drr = 1.6x10-4 was found from the experimental data, and as shown in Figure 4, the predicted decay matches well with the data. Finally, a mean gas volume fraction was estimated from the reported flow rate, assuming a terminal bubble velocity and a corresponding plume spreading angle. The resulting bubbly region is a ring, 25 m in diameter and 0.5 meter in thickness, with an estimated gas volume fraction of 0.02. It is reported that the resulting attenuation by the bubble barrier is about 3 to 5 dB, which agrees well with the estimated attenuation. The simulations required a smaller value of gas volume fraction to match the data of 0.003. When experimental data become available, further simulations and analyses should be performed to identify the reason for this discrepancy.

MODELING OF LIGHT

Mathematical Modeling: Calculations of light intensity can be extremely resource-intensive and are typically done using Monte Carlo simulations; or are based on semi-analytical approximations to an integro-differential equation. The latter approach was used in this study. The fundamental equation describing the light field in a continuous media is called the radiative transfer (RT) equation. The RT conservation equation balances the changes of spectral radiance (L) in a given direction with the processes that can modify it: absorption, scattering and emission. The attenuation of the beam is given by the absorption, defined by the absorption coefficient $a_{\mathrm{E}}(x,\lambda)$ times the radiance and all the scattering out of the beam direction that can be approximated as $-b_{\mathrm{E}}(x,\lambda)L$, with bE the average of the volume scattering function. The elastic (i.e., without a change of wavelength) scattering for other directions into a given direction constitutes a source and is represented as an integral that accounts for all the contributions over all possible 4π solid angle directions to a given one. Finally, emission may correspond to an actual source or due to inelastic scattering from other wavelengths, and can be expressed as a general source sE, per steradian. The complete RT equation can be written as (Mobley, 2001):

$$\Omega\nabla L(\boldsymbol{x},\theta,\varphi,\lambda) = -c_{\mathrm{E}}(\boldsymbol{x},\lambda)L(\boldsymbol{x},\theta,\varphi,\lambda) + \int_{4\pi} L(\boldsymbol{x},\theta',\varphi',\lambda)\beta_s(\boldsymbol{x},\theta',\varphi',\theta,\varphi,\lambda)d\Omega' + s_{\mathrm{E}}(\boldsymbol{x},\theta,\varphi,\lambda) \quad (8)$$

with β_s is the angle dependent volume scattering function and c_{E} the sum of a_{E} and b_{E}. Eq. (8) contains both an integral on the solid angle and spatial derivatives which can be very difficult to solve explicitly. In this study, the scalar irradiance, *E*, obtained by integration of *L*, was used. Extensive literature exists on different methods implemented to solve Eq. (8). In this study, two methods were implemented. A superposition of elementary solutions is proposed when scattering effects are not important and a P-1 model for high attenuation and/or scattering.

Certain apparent optical properties such as the diffuse attenuation coefficient can be approximated as a function of intrinsic properties for certain simple cases (Kirk, 2003; Kirk, 2006). Two simple solutions for the scalar irradiance can be found for planar and point sources by simple integration of Eq. (10):

$$E(z) = E_0\exp(-Kz) \quad (9)$$

$$E(r) = \frac{r_0^2}{r^2}E_0\exp(-Kr) \quad (10)$$

In the superposition of elementary solutions method, multiple elementary solutions are automatically combined to produce a light field that approximates the solution of RTE:

$$\nabla\cdot(\mathbf{u_E}E) = S_{\mathrm{E}} - KE \quad (11)$$

where $S_{\mathrm{E}} = 4\pi s_{\mathrm{E}}$, and *K* is the diffuse attenuation coefficient. To recover the solutions presented before (Eqs. 9 and 10), a dimensionless vector field is defined as $\mathbf{u_E}$ = (0,0,-1) for a plane source emitting in the z negative direction and $\mathbf{u_E} = \mathbf{e_r}$ the radial unit vector for the point source case. By presenting the solution as a result of a numerical integration it is possible to introduce more complex geometries and also variability of the attenuation factor, which can be calculated independently of the solution. With this simple scheme it is possible to reproduce background illumination due to natural daylight as a plane source, as well as including the stroboscopic lights of the barrier as point sources.

P-N models use a diffusive representation of the RTE, and as such its range of validity is for conditions with high attenuation and/or scattering (Sazhin et al., 1996). In general, P-N models are based on the expansion of the solution to RTE in orthogonal series of spherical harmonics. For the P-1 model only the first and third terms of the series are kept resulting in:

$$-\sum_{i=1}^{3}\frac{\partial}{\partial x_i}\frac{1}{3(a_{\mathrm{E}}+b_{\mathrm{E}})}\frac{\partial L^{(0)}}{\partial x_i} = 4\pi s_{\mathrm{E}} - a_{\mathrm{E}}L^{(0)} \quad (12)$$

Attenuation and absorption coefficients available in USEPA (2000) and Mobley (2001) as a function of water molecules, chlorophyll, inorganic matter and colored dissolved organic matter were used.

For a bubbly flow, the effect of the bubbles in the attenuation of light must also be considered. For most cases, it can be assumed than the bubble's radius R is much larger than the wavelength of the incident light. This condition is known as the geometric optic limit, for which both the geometric approximation and the Mie theory of scattering will predict the same far-field solution for the interaction of a plane wave and a single large sphere (Randrianalisoa and Baillis, 2014). It is a good assumption to neglect the absorption within the bubble and only consider the scattering contribution (Shamoun et al., 1999). For multiple scatters, the interaction between particles can be neglected if the characteristic spacing between particles is large compared to both the wavelength and the particle radius. In that case, the scattering characteristics can be obtained as a summation of the individual contributions. The resulting extinction coefficient due to bubbles is $c_{\mathrm{b}} = \frac{3}{4}\frac{\alpha}{R}$:

In this study reflections at the boundaries from the original sources were implemented using a cosine emission law.

Model validation: Some simple geometries were run to validate the implemented models and to highlight the differences between the two models. Unfortunately, no data for controlled bubbly flows were identified that could be simulated, other than some information on attenuation coefficients that was already included in the modelling process. The dimensionless irradiance field for two point sources in a closed cavity were simulated. First reflections are possible in the bottom boundary only. The model predicts the irradiance reduction with the radial distance shown in Eq. (10) (Figure 5). Total irradiance shown on the left frames is the summation of incidente (middle frame) and reflected (right frame) irradiances. This case shows the feasibility of representing the modulated intense lights (MILs) for the fish barrier as the solution of superimposed single point sources.

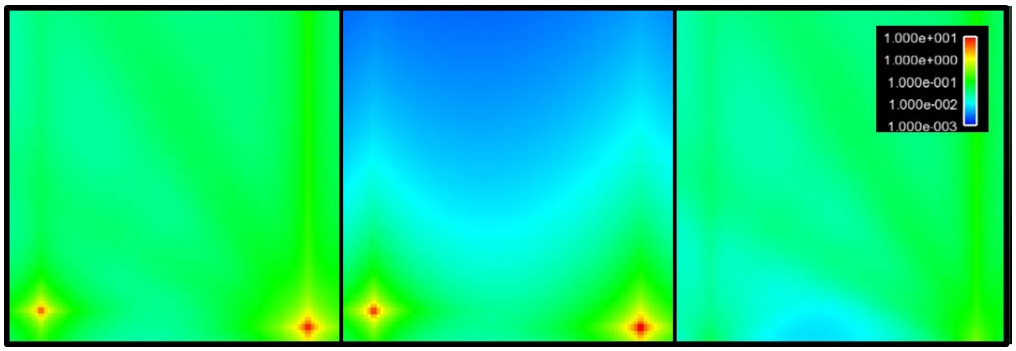

Figure 5 Total irradiance (left), incidente (middle) and reflected (right) from two point sources near the bottom of a cavity

The focus of the validation of the P-1 model was to demonstrate the effect of bubbles on the distribution of the irradiance. Figure 6 shows the basic profile for the case where no bubbles are present. As expected, the irradiance decays radially from the source with an equivalent diffuse attenuation coefficient $K = (3a_{\mathrm{E}}c_{\mathrm{E}})^{1/2}$. Two possible boundary conditions are shown in Figure 6 for the boundary closest to the source, the partial reflective condition (left frame) and full reflective conditions (right frame). As expected, the latter results in larger values for E, but given the rapid decay of the irradiance most differences between the two cases are localized to the region immediate to the source and very close to the boundary.

The deformation of the radial pattern due to the presence of a bubble curtain is shown in Figure 7. The extension of the curtain is shown with dashed lines. Several values of gas volume fraction with fully reflecting boundary were considered. The main effect of the bubbles is to concentrate the light field into a smaller region and with a larger maximum value for E. The distribution of the light field varies radically depending on whether the light source is contained in the bubble curtain, in which case very little illumination escapes the curtain, or whether the source is placed near the curtain, in which case bubbles act as a reflector.

SIMULATION OF A NON-PHYSICAL FISH BARRIER

Simplified Georgiana Slough: A main channel with two bifurcations and a non-physical fish barrier upstream of the smallest stream was simulated to test the capability of the proposed model to predict the flow field and bubble, sound and light fields in the vicinity of a fish barrier (Figure 8). The geometry of the Georgiana Slough in the Sacramento River was used (McQuirk and Reeves, 2012). Since bathymetric information was not available a constant water depth of 9.1 m was used. This value was selected based on information of underwater sound measurements that were taken between 2.9 m to 14.6 m (McQuirk and Reeves 2012). In this paper a simulation using typical conditions in the Sacramento River upstream of the Georgiana Slough is presented. Flowrates upstream and downstream of the curtain were 334 m3/s and 132 m3/s, respectively. Small bubbles of 0.8 mm (0.03 inch) diameter were injected at the bottom of the river at a pressure of 1.91 105 Pa and at 25 oC. The diffusion coefficient was set using Eq. (12), with constant D3D = 0.1cwater, lz=10 m and lx=ly=200 m, a mixed boundary condition was imposed on the bottom and the side walls, and release conditions at the surface. Sound sources operating in the range 5-600 Hz with a mean sound level of 152 dB re 1□Pa were installed in the field near Georgiana Slough (McQuirk and Reeves, 2012). A far field value (~200 m) of about 110 dB re 1□Pa was reported. In this study, nineteen sound projectors were located immediately downstream of the bubble barrier and each projector was modeled as a constant source of acoustic energy density of 0.01 W/m. Four lights sources of 10 W/m3 were included upstream of the bubble barrier.

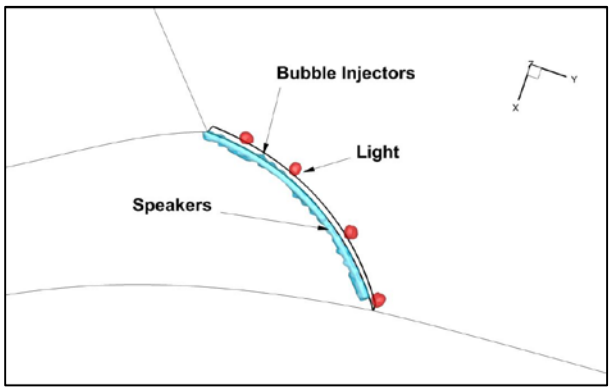

Figure 8 Simulated fish barrier

Figure 9 shows slices near the river bed (a), in the mid plane (b) and at the free surface (c). Vectors were interpolated in an equally-spaced structured mesh to enhance visualization. Bubbles significantly modify the flow pattern near the curtain. Two phenomena affect the gas volume fraction distribution; the most important is the buoyancy that drives bubbles toward the free surface and the other is the downstream convective transport by the river. The latter is significant at high river velocities and can be noted downstream of the curtain where the plume is directed towards the left bank. Upstream of the curtain and at small depths, the liquid velocity reverses direction due to the horizontal surface flow created when the plume reaches the free surface.

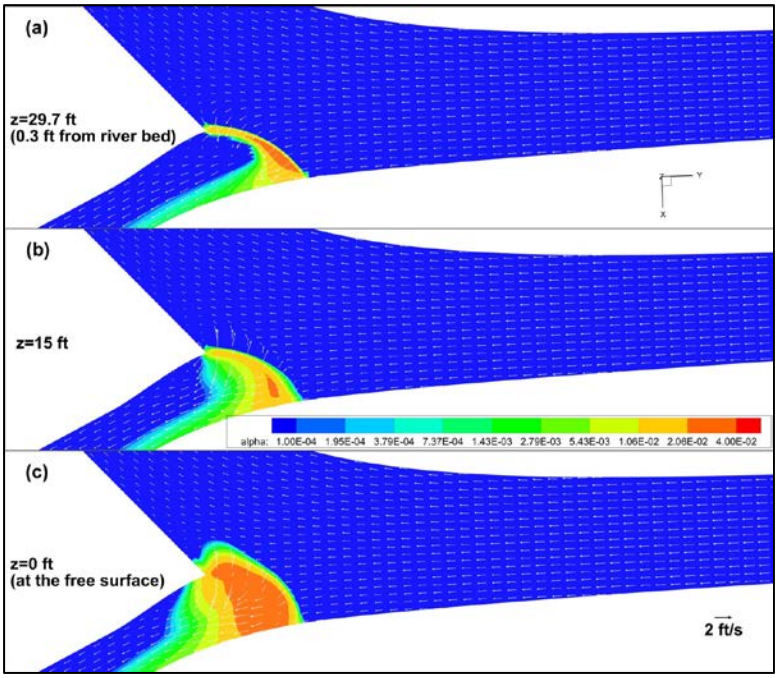

Figure 9 Gas volume fraction and velocity vectors at (a) 9 m (29.7 ft), (b) 4.5 m (15 ft) and (c) 0 m (0 ft)

Figure 10 shows flow characteristics near the bubble curtain. The frames in the top and middle show gas volume fraction isosurfaces and distribution of gas volume fraction at slices through the middle of the channels, respectively. Bubbles are transported away from the plume center by the strong surface current induced by the gas phase. The gas distribution and flow pattern are not symmetric relative to the bubble plume center due to the geometry and convective transport by the river flow. Streamlines colored by velocity magnitude in the bottom frame show back flow near the inner wall of the larger branch towards the bubble curtain.

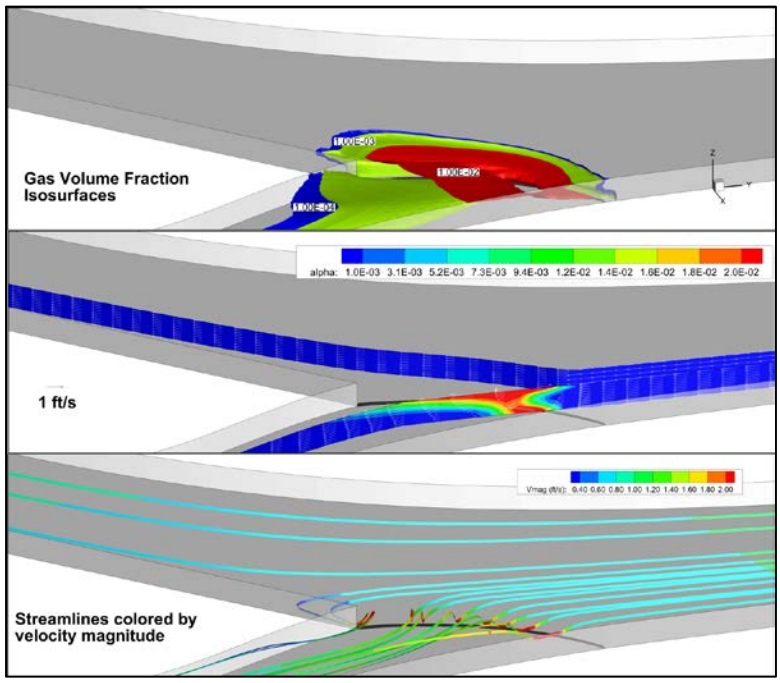

Figure 10 Gas volume fraction isosurfaces (top), gas volume fraction distribution in each river branch (middle), and streamlines colored by velocity magnitude (bottom)

Figure 11 shows the gas distribution and recirculation zones generated by the bubble curtain. As the bubble plume rises through the water column it entrains ambient water inducing two recirculating zones. Near the injector, the gas volume fraction is reduced as bubble velocity increases due to entrained liquid into the plume. On the other hand, near the free surface, the gas volume fraction increases for two phenomena, one is the increment in bubble volume due to decompression and the other is the reduction of liquid vertical velocity near the free surface. Note that since slip velocity increases with bubble size, a larger relative velocity is expected near the free surface. However, this effect is less important than the reduction of liquid velocity by the free surface.

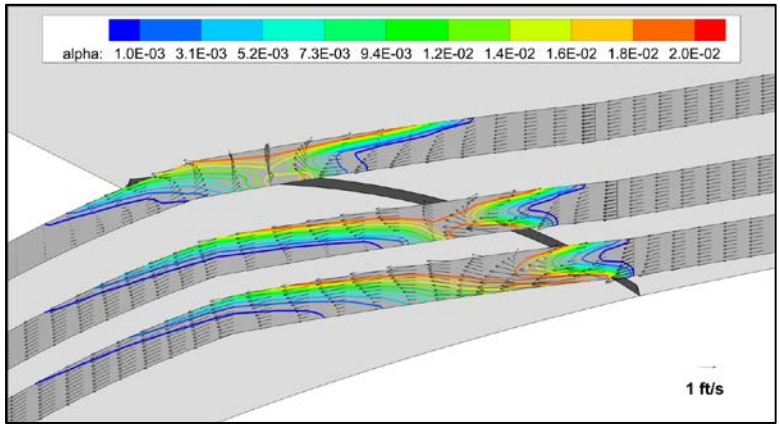

Figure 11 Gas volume fraction and velocity vectors near the bubble curtain

Figure 12 shows isosurfaces of sound energy. Bubbles encapsulate the sound within the fish barrier. However, some differences in the level of sound are observed due to increased sound attenuation by bubbles transported near the outer wall along the smaller channel.

Figure 13 shows the irradiance generated by the high-intensity LED MILs predicted with the superposition of elementary solution method (a) and P1 model (b). Light scattering and absorption by the bubbles results in an appreciable concentration of light within the fish barrier.

CONCLUSIONS AND FUTURE DIRECTIONS

Numerical models for predicting the hydrodynamics, bubble, sound, and light distributions near a non-physical fish barrier were developed. The models were implemented using a modular approach in the open source code openFoam. A Boussinesq approach was used to account for the reduction of density in the zones where bubbles are present. The effect of the bubbles on the sound and light fields were considered through attenuation coefficient models found in the literature. Simple geometries were simulated to validate the implementation of the models. Model results for a non-physical fish barrier located in a bifurcation similar to Georgiana Slough indicate that the bubble plume has a strong effect on the flow pattern near the barrier. The resulting large-scale recirculations and increased accelerations near the barrier are expected to influence fish migration route. Sound and light are strongly coupled with the bubble plume. Bubbles effectively encapsulate both sound and light within the barrier region. According to the model, the effectiveness of bubbles to attenuate sound depends on the position of the speakers relative to the bubble plume. Since the bubble plume location depends on the induced liquid movement as well as downstream transport by the river, optimal location of speakers is a function of the river flowrate and gas injection rate through the diffusers.

Additional research needs to include a full set of experimental data and monitoring near a fish barrier, at several river and barrier operational conditions, for better quantification of important variables. Examples include measurements of gas volume fraction, bubble size, river depth, liquid velocities, and sound and light fields. The complex three-dimensional nature of the problem will require measurement stations at several transects near the barrier. This is essential to fully validate and improve the developed numerical tool and identify areas where future modeling effort should focus.

RIVERWARE DEMONSTRATION

EXTENDED ABSTRACT

David Neumann, Senior Research Assistant, Center for Advanced Decision Support for Water and Environmental Systems, University of Colorado, Boulder, CO, david.neumann@colorado.edu
Edie Zagona, Director, Center for Advanced Decision Support for Water and Environmental Systems, University of Colorado, Boulder, CO, zagona@cadswes.colorado.edu;

RiverWare is a river and reservoir modeling tool used by water managers, planners, consultants, utilities, researchers and stakeholders for forecasting and scheduling reservoir and hydropower operations, water rights and water accounting, developing and evaluating alternative operating policies and planning new projects. Developed by the University of Colorado Center for Advanced Decision Support for Water and Environmental Systems (CADSWES) with sponsorship of the Tennessee Valley Authority, the Bureau of Reclamation and the U.S. Army Corp of Engineers, RiverWare simulates the hydrologic response of a river/reservoir system given inflows and multi-objective operating policies. This demonstration will show how the object-oriented models are constructed from the palette of objects and linked together to form a river system network as shown in Figure 1.

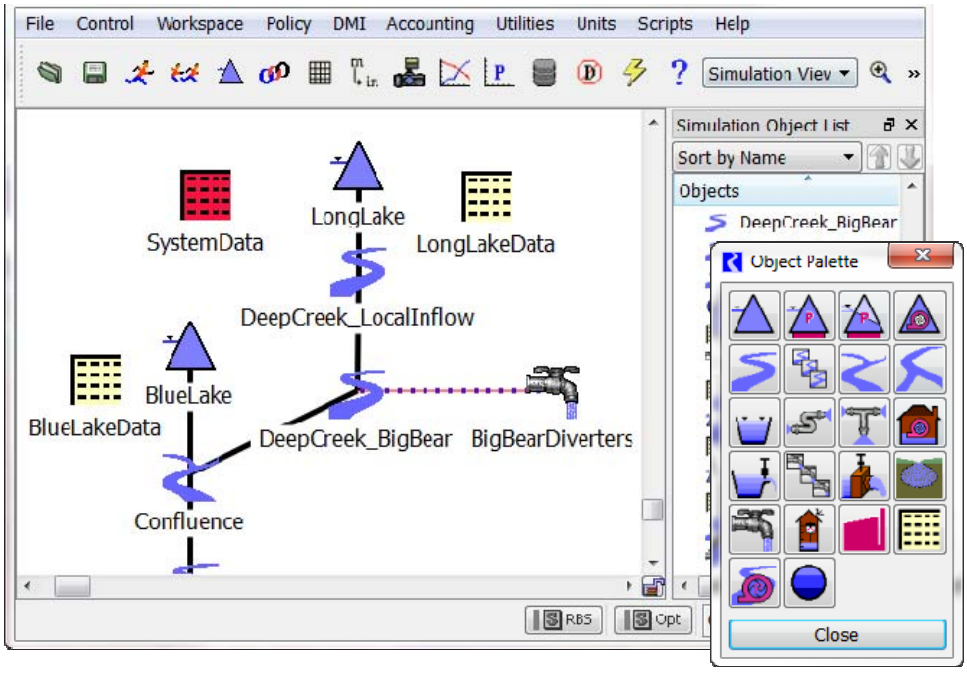

Figure 1 RiverWare Workspace and Object Palette

Simulation demonstrations will include hydrologic processes in rivers and reservoir, consumptive uses and return flows, distribution canals, groundwater interaction and pumping, pipe flows, hydropower and pumped storage, inline pumping and hydropower plants. A water quality module tracks salinity, temperature and dissolved oxygen throughout the system using

ether a simple well-mixed or layered/discretized approach. In the demonstration, we will show how to model the salinity and flow interaction of the surface water with groundwater including inflows from surface water (including point sources), pumping, deep aquifer brine inputs, evaporation, and evapotranspiration.

The rulebased simulation solution is driven by prioritized, logical rules that represent the multi-objective operating policies such as flood control, water supply, environmental flows and hydropower production. We'll show how to create and execute these policies, using them to produce operating schedules, manage flood events or evaluate alternatives for EIS analysis. RiverWare also models water ownership and can perform water accounting calculations – we'll demonstrate how agencies use RiverWare for prioritized water allocation, to operate with rules based on water ownership, and to perform after-the-fact legal accounting.

The optimization solution is driven by prioritized goals that represent policy constraints and objectives. We'll demonstrate how utilities use RiverWare's pre-emptive linear goal programming to optimize hydropower production while meeting water management constraints.

We'll show how data can be easily loaded into RiverWare from various sources using the input Data Management Interface (DMI) which allows data to be automatically loaded from text files, Excel spreadsheets, HEC DSS files, HDB database or any other database.

We will demonstrate RiverWare's many utilities for viewing, analyzing and visualizing data including a fully featured plotting utility, outputs to HTML model reports and tabular series slot reports, pie charts, and tea cup diagrams. There are many options for exporting data from RiverWare including the output DMIs to any database, direct export to Excel, HEC DSS, and HDB. We'll show how to export RiverWare results to netCDF files and files that can be used directly in the Tableau Software for data processing, analysis, and visualization.

RiverWare's multiple run management utilities can be used to automate thousands of runs, and produce probabilistic outputs, or to perform yield studies. This concept of running many runs can be further structured using the RiverWare Study Manager and Research Tools (RiverSMART). This tool automates a planning study by organizing and running scenarios of hydrologic inputs, demand inputs and policy sets and then provides utilities to analyze and compare the results from these scenarios. Using this approach, water managers can run proposed operating policy changes through climate change hydrologies to analyze impacts and compare alternatives. We'll show how to define a RiverSMART study, generate scenarios, simulate the scenarios and then post process the results of either scenarios or sets of scenarios. We'll describe and show the various plugins that can be used within RiverSMART including the R plugin, the GPAT graphs plugin, and the Hydrology Simulator plugins.

RiverWare's script utility can be used to automate many of the processes that are performed on a day to day basis. Scripts contain actions which execute a process in RiverWare. For example, a script that load a ruleset, import observed data from a database, configure initial conditions, make a run, and generates output plots. Scripts are run from a configurable Script Dashboard, as shown in Figure 2, in which model operators can also view and change key decision variables. We will demonstrate how scripts and dashboards can be used to simplify modeling processes.

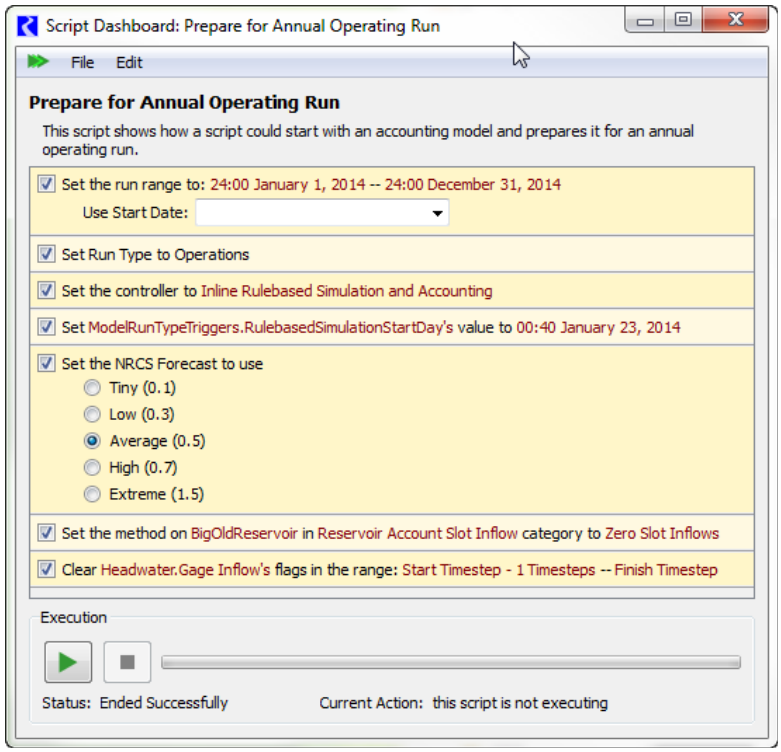

Figure 2 RiverWare Script Dashboard

RiverWare is integrated into the U.S. Army Corp of Engineers Corp Water Management System (CWMS). Further, it is integrated as a component of multiple Flood Early Warning Systems (FEWS) developed by Deltares. This integration allows for tighter coupling of RiverWare with other modeling tools for real time operations and management.

RiverWare's easy-to-use graphical user interface, statistical post-processing, script management, spreadsheet-view of data, direct database connection configurations, and powerful diagnostic and analysis utilities will complement as we show examples of the application of RiverWare to numerous river basins. Free evaluation versions of the software with demo models will be given to interested visitors.

RVR MEANDER – A TOOLBOX FOR RIVER MEANDER PLANFORM DESIGN AND EVALUATION

Eddy J. Langendoen, U.S. Department of Agriculture, Agricultural Research Service, National Sedimentation Laboratory, Oxford, MS, eddy.langendoen@ars.usda.gov; Davide Motta, AMEC, Philadelphia, PA, davide.motta3@gmail.com; Jorge D. Abad, Department of Civil and Environmental Engineering, University of Pittsburgh, jabad@pitt.edu; Marcelo H. Abstract: Restoring the meandering planform or spatial variability of historically meandering streams that have been channelized or highly disturbed is one of the most difficult aspects in river restoration. River planform and cross-sectional geometry are the result of complex interactions between flow, boundary materials, and channel morphology. Hence, simple methods based on the reference-reach concept or hydraulic geometry relationships have often failed to produce long-term, stable meander reaches without additional bank protection. More sophisticated river meander models use empirical relations to calculate rate of channel migration, limiting their applicability as they do not explicitly account for the physical properties of the floodplain soils. The RVR Meander platform merges the functionalities of: the first version of RVR Meander developed by the University of Illinois, which is based on the classical meander migration model of Ikeda, Parker and Sawai; and the streambank erosion algorithms of the channel evolution computer model CONCEPTS developed by the US Department of Agriculture. It is written in C++ language and is composed of different libraries for preprocessing, hydrodynamics, bank erosion, migration, filtering, plotting, and I/O. It runs as a stand-alone application on Windows and Linux operating systems or as a plugin for ESRI's ArcMap software. RVR Meander has been used to model the migration of various rivers in the US and abroad.

INTRODUCTION

The ongoing modification and resulting reduction in water quality of U.S. rivers have led to a significant increase in river restoration projects over the last two decades (Bernhardt et al., 2005). The increased interest in restoring degraded streams, however, has not necessarily led to improved stream function. Palmer and Allan (2005) found that many restoration projects fail to achieve their objectives due to the lack of policies to support restoration standards, to promote proven methods and to provide basic data needed for planning and implementation. Proven models of in-stream and riparian processes could be used not only to guide the design of restoration projects but also to assess both pre- and post-project indicators of ecological integrity.

One of the most difficult types of river restoration projects concern reconstructing a new channel, often with an alignment and channel form different from those of the degraded pre-

project channel. Recreating a meandering planform to provide longitudinal and lateral variability of flow and bed morphology to improve in-stream aquatic habitat is often desired. Channel meander planform is controlled by a multitude of variables, for example channel width to depth ratio, radius of curvature to channel width ratio, bankfull discharge, roughness, bed-material physical characteristics, bed material transport, resistance to erosion of the floodplain soils, riparian vegetation, etc. Therefore, current practices that use simple, empirically based relationships or reference reaches have led to failure in several instances, for example a washing out of meander bends or a highly unstable planform, because they fail to address the site-specific conditions (e.g., Kondolf, 2006).

Recently, progress has been made to enhance a physically- and process-based model, RVR Meander, for rapid analysis of meandering river morphodynamics with reduced empiricism. For example, lateral migration is based on measurable physical properties of the floodplain soils and riparian vegetation versus the driving forces of the river hydrodynamics. The model can also be used in a Monte Carlo framework to statistically describe the long-term evolution of the meander planform. RVR Meander has been used to evaluate migration rates of restored meandering streams and bends on the Big Sioux River, SD and Trout Creek, CA at engineering time scales. It has also been used to assess the uncertainty and risk associated with the alignment of the meandering low-flow channel of the planned diversion of the Red River of the North around the metropolitan area of Fargo, ND and Moorhead, MN. The RVR Meander model and example applications are presented in the below sections.

RVR MEANDER

The current RVR Meander platform (Motta et al., 2012; http://rvrmeander.org/) extends the capabilities of the original version of RVR Meander (Abad and Garcia, 2006) by merging it with the stream-bank erosion submodel of CONCEPTS (Langendoen and Simon, 2008). The original version employed the classical migration approach (CMA) of Ikeda et al. (1981), who linearly related the local rate of meander migration to the near-bank velocity using a migration coefficient. RVR Meander is composed of modules to simulate hydrodynamics, bed topography, bank erosion, and migration of meandering rivers. It is available as a plugin for ArcGis versions 9.3.x and 10.x.

Hydrodynamics and Bed Topography: The model for hydrodynamics and bed topography implemented in RVR Meander is analytical and obtained from linearization of the two-dimensional depth-averaged Saint Venant equations. It follows the approach first developed by Ikeda et al. (1981) and adopts the secondary flow correction derived by Johannesson and Parker (1989), who introduced an "effective centerline curvature" that lags behind the local channel curvature and determines the transverse bed slope through a coefficient of proportionality named scour factor. Important model assumptions are: spatially- and temporally-constant channel width; bed topography is only a function of channel planform; and spatially-constant friction coefficient.

Bank Erosion and Meander Migration: In the physically-based meander-migration approach (PMA) in RVR Meander developed by Motta et al. (2012), simulated bank retreat is controlled

by the resistance to hydraulic erosion and the occurrence of cantilever and planar failures (Langendoen and Simon, 2008).

Hydraulic erosion requires that the local boundary shear stress exceeds the critical value to detach bank material, and is modeled with an excess shear stress relation. An average erosion distance is computed for each layer comprising the composite bank material. The shear stress acting on each of the bank material layers is obtained by scaling the shear stress at the toe, which is the bed shear stress at the bank computed with the linear hydrodynamic model, using the hydraulic radius of the flow area impinging on the layer.

Cantilever failure is the collapse of an overhanging slab of bank material formed by preferential retreat of more erodible underlying layers or simply by the erosion of the bank below the water level with respect to its upper, unsaturated portion. The occurrence of cantilever failure, for the case of shear collapse mechanism (Thorne and Tovey, 1981) considered here, is simply determined from geometrical considerations, once an undercut threshold is exceeded. The undercut threshold is defined as the ratio of bank material cohesion to unit weight. Mass failures along planar slip surfaces are analyzed using a limit equilibrium method in combination with a search algorithm to find the failure block configuration with the smallest factor of safety (Langendoen and Simon, 2008). Factor of safety is the ratio of available shear strength to mobilized shear strength, and when smaller than one the bank is unstable. The method accounts for the effects of pore-water pressure on bank material shear strength, confining hydrostatic pressure provided by the water in the channel, and can automatically insert tension cracks if the upper portion of the failure block is under tension.

Input Data Requirements: Because RVR Meander is intentionally a simplified 2D model it inputs are limited. The main physical input parameters are: (1) design or bankfull discharge; (2) channel dimensions such as width, depth, and slope; (3) channel centerline to determine channel curvature; (4) valley slope; (5) channel boundary roughness; (6) scour factor; (7) bank profiles; and (8) resistance to erosion properties of the bank soils, i.e. erodibility and shear-strength parameters.

Software: The RVR Meander model can be executed in two modes (Figure 1): (1) as a stand-alone version from the command line in MS Windows or Linux; and (2) through a graphical user interface that is a plugin for ESRI's ArcMap 9.3.x or 10.x software. The compute engine is the same for both modes. The software, its manuals, and tutorial files can be downloaded at the URL http://rvrmeander.org.

The stand-alone version requires four input files: (1) "testdata.txt," pairs of easting and northing coordinates of the initial channel centerline; (2) "valley.txt," pairs of easting and northing coordinates of the valley centerline; (3) "prototype.cfg," general parameters for simulation; and (4) "InitialSectionProperties.dat," initial configuration of channel banks (shape and bank-material properties) for physically-based approach for meander migration. The ArcMap plugin uses the same input files, which are however prepared within ArcMap. The output files for the standalone version are designed to be post-processed using such software as Tecplot and MS Excel. The ArcMap plugin generated files can be directly viewed inside ArcMap with the

exception that the current version does not support "Bank geometry output," and needs plotting software such as MS Excel to view this output.

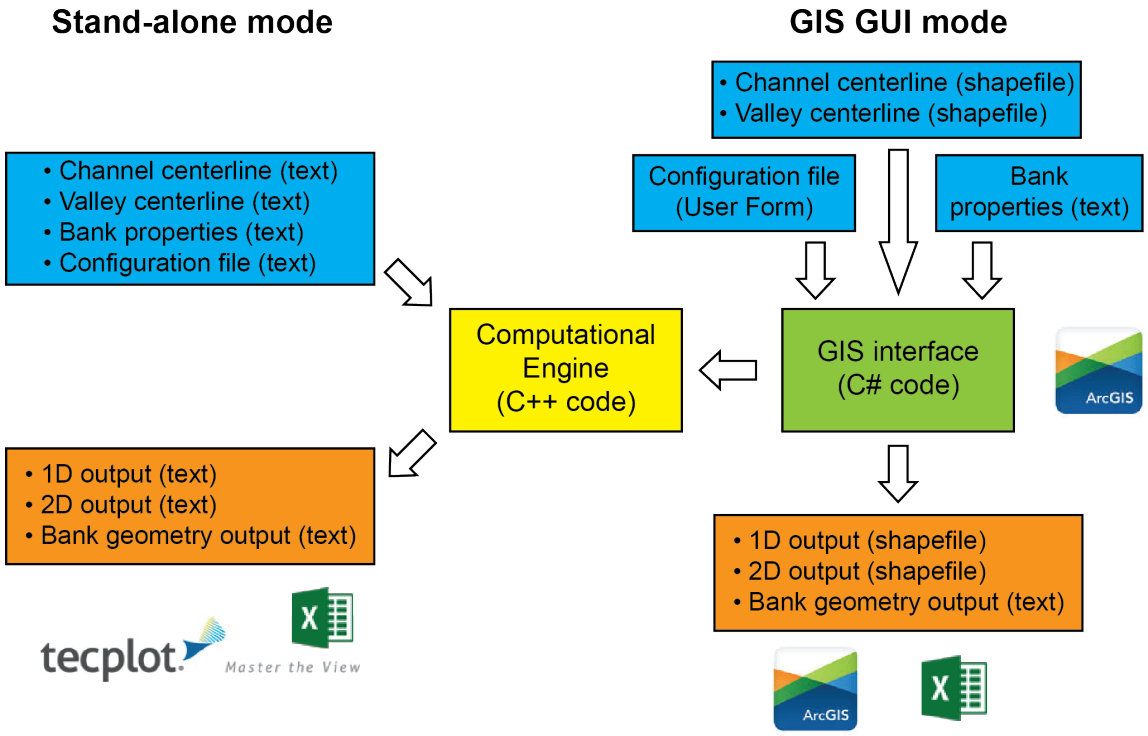

Figure 1 RVR Meander software is available as a stand-alone program for MS Windows and Linux operating systems and as a plugin for ESRI's ArcMap.

APPLICATIONS

Mackinaw River, Illinois: The performance of the proposed approach was tested for a reach on the Mackinaw River in Tazewell County between the towns of South Pekin and Green Valley, Illinois. The average width of the study reach is 38 m, valley slope is 0.47 m/km, and effective discharge is 62 m^3/s. The migration of the centerline between 1951 and 1988 was simulated with RVR Meander using both CMA (migration coefficient calibrated as $3.3x10^{-7}$) and PMA. Bank retreat in the physically-based method was assumed to be caused by hydraulic erosion only, and the critical shear stress τ_c =9 Pa (measured critical shear stress is approximately 8 Pa).

Figure 2 compares the centerline migration obtained with the classical migration-based and the physically-based approaches. The channel centerline simulated using PBA agrees well with that observed away from the boundaries of the model reach. The channel centerline simulated using CMA is similar to that obtained by PMA for the upstream part of the study reach. However, CMA significantly overestimates the channel centerline migration, both in terms of meander amplitude and downstream translation, along the downstream part of the study reach.

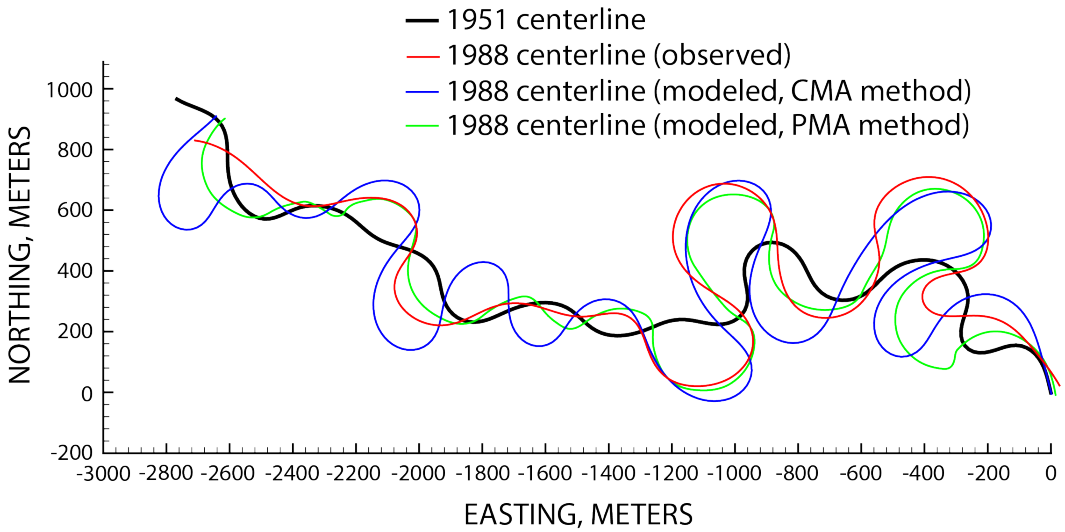

Figure 2 Comparison of observed and modeled centerline migration between 1951 and 1988 of a reach on the Mackinaw River, Illinois, USA. Flow is from right to left.

Big Sioux River, South Dakota: RVR Meander was used to assess potential erosion zones for a 34-km long reach on the Big Sioux River between Dell Rapids and Sioux Falls, South Dakota. The reach is fairly sinuous with an average sinuosity (ratio of channel length over valley length) of 1.6. The average channel top width and depth are 40.5 m and 2.2 m, respectively. The average channel slope is 0.4 m/km, and valley slope is 0.66 m/km. The 1.5-year return period discharge is 57.5 m^3/s, which is assumed to represent the bankfull discharge. The Manning *n* roughness coefficient is 0.052. A scour factor of 7 produced a transverse bed slope similar to that observed. The bed material is sand dominated with the median bed material grain size along the study reach varying between 0.03 and 7.0 mm with a mean value of 1.4 mm. Bank material is cohesive except for the sediments/soils at depth, which consist of sands and gravels. The upper cohesive layer primarily comprises erodible loam and sandy loam soils, but percent clay is found as high as 55%.

Figure 3 shows an example 11 meander bends with large simulated shear stresses near the outer bank. The plotted shear stress distributions were normalized by the reach-averaged shear stress representing uniform flow conditions. RVR Meander simulated high shear stresses at 45 unprotected bends that may potentially lead to enhanced migration rates. Sixteen of these bends have exhibited significant migration between 1991 and 2012, and should be targeted for construction of bank protection works. Eleven of these bends are located along a section of the Big Sioux River where several meander bends were cutoff between 1937 and 1991, which has resulted in increased bank erosion rates due to the channel adjustment caused by the local channel shortening and consequent increased gradient.

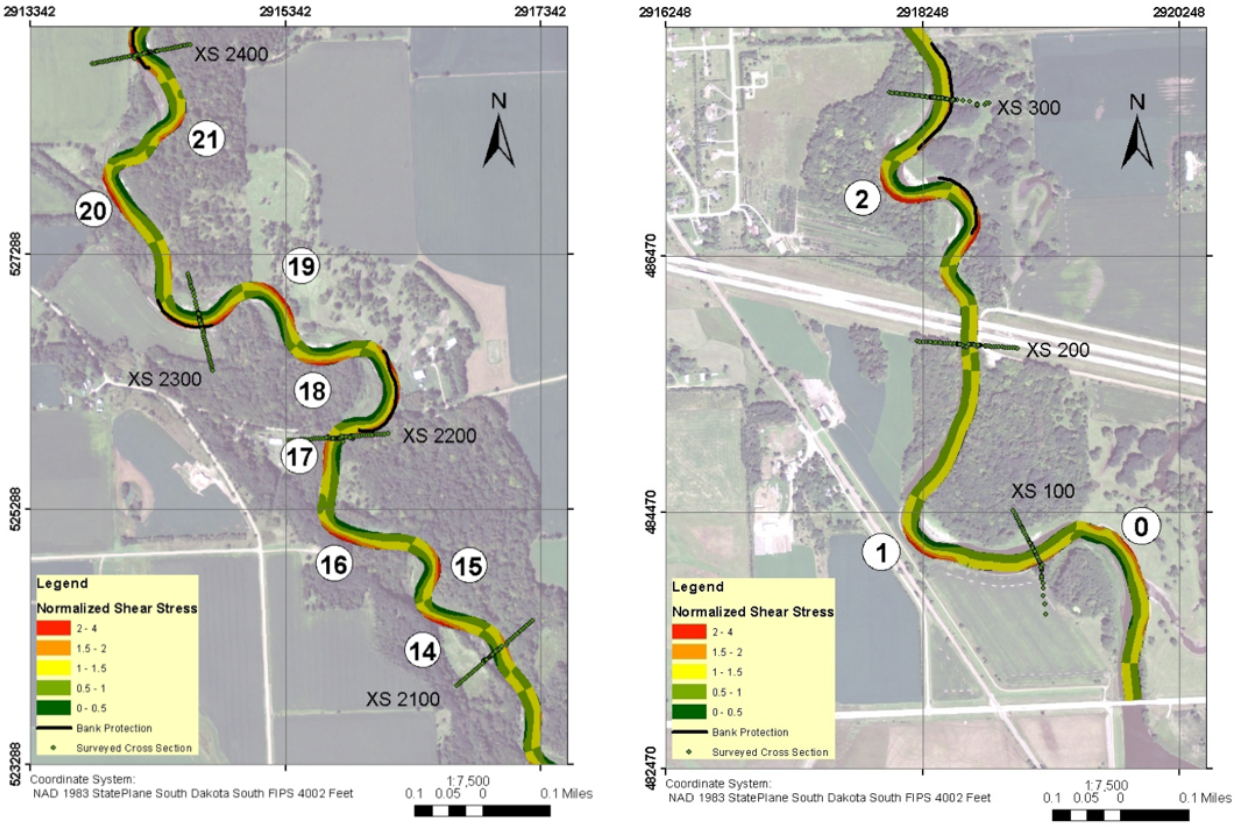

Figure 3 Example locations of large near-bank bed shear stresses simulated by RVR Meander along selected reaches of the Big Sioux River between Dell Rapids and Sioux Falls, South Dakota. Flow is from top to Bottom

Meander Belt Width Analysis, Red River Diversion, North Dakota: The Fargo-Moorhead Metropolitan Area Flood Risk Management Project seeks to prevent flooding of the cities of Fargo, North Dakota, and Moorhead, Minnesota by constructing a 36-mile diversion channel to the west of the metropolitan area. Included in the project plans is a low-flow channel (LFC) with a meandering planform (initial target sinuosity was 1.5) to provide enhanced aquatic habitat to mitigate the loss of approximately 5.5 miles of Lower Rush and Rush River reaches cut off by the diversion. An analysis of flow and sediment conveyance determined the LFC top width at 100 feet. The bottom width of the main diversion channel was set at 300 feet.

RVR Meander was used to determine if a meandering planform of the LFC was feasible given these widths. A Monte Carlo approach was followed, which facilitates risk analysis—in this case, calculating the probability that the meander belt will expand beyond the constraints of the diversion channel, given different conditions (e.g., planform configurations, resistance-to-erosion of boundary materials, channel aspect ratios, construction sequence). For example, only a limited number of soil samples could be collected along the planned course of the diversion (samples from more readily accessible locations were used as substitutions). For each design, a 1000 simulations were conducted over 50- or 100-year periods. The planform was generally sine-generated, and the cross-sectional shape was trapezoidal. We used the 1.5-yr return

discharge as the design discharge. Planform width, sinuosity, and dominant wavelength were the parameters that were assessed (see Figure 4).

The Monte Carlo simulations indicated that the LFC meander belt would generally have a tendency to narrow over time. Of factors considered, the initial wavelength had the largest impact on LFC migration; initial amplitude was also seen to be important. Other parameters such as the channel side slopes and bottom width, however, did not appear to significantly impact meander belt width over the life of the project. Also of note were simulation results for a phased construction scenario — assuming that construction of the diversion channel downstream of the Lower Rush River was completed first. These results suggested that in the first 10 years following phased construction, the change in meander belt width would be very small.

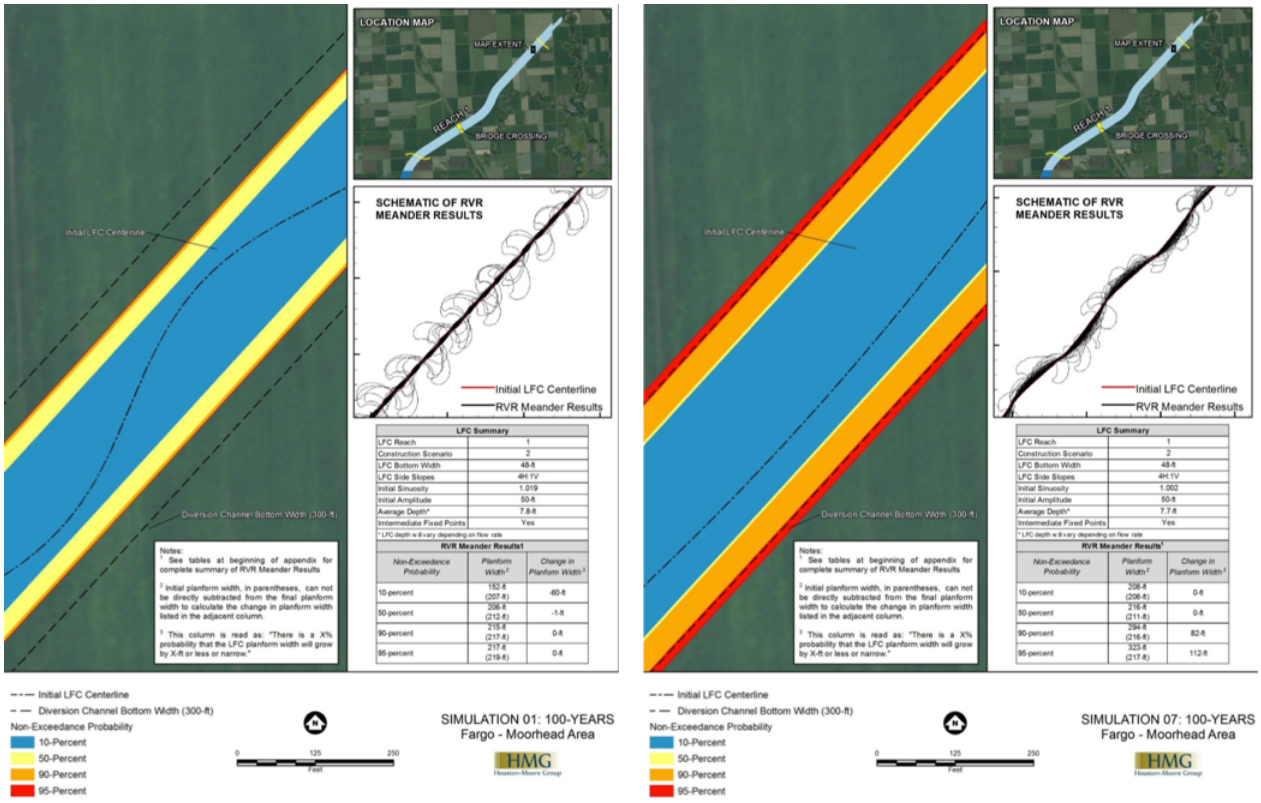

Figure 4 Example results of probabilistic meander belt width analysis of the LFC of the Red River, North Dakota, are presented using non-exceedance contours. (Left) meander planform with an initial sinuosity of 1.02 that tends to straighten. (Right) meander planform with an initial sinuosity of 1.002 that tends to increase its sinuosity and planform width; there is a 10% probability that the LFC will migrate into the diversion sidewall.

WINDAM C EARTHEN EMBANKMENT

INTERNAL EROSION ANALYSIS SOFTWARE

Karl Visser, PE; Hydraulic Engineer; USDA-NRCS; National Design, Construction, and Soil Mechanics Center; Fort Worth, Texas; karl.visser@ftw.usda.gov;
Ronald D. Tejral, PE; Agricultural Engineer; USDA-ARS; Hydraulic Engineering Research Unit; Stillwater, Oklahoma; ronald.tejral@ars.usda.gov;
Mitchell L. Neilsen, PhD, Professor of Computing and Information Sciences, Kansas State University; Manhattan, Kansas; neilsen@k-state.edu

Abstract: Two primary causes of dam failure are overtopping and internal erosion. For the purpose of evaluating dam safety for existing earthen embankment dams and proposed earthen embankment dams, Windows Dam Analysis Modules C (WinDAM C) software will simulate either internal erosion or erosion resulting from an overtopping event. WinDAM C models erosion failure of a homogeneous embankment. Future expansion includes non-homogeneous embankments, and embankment protection analysis.

The four essential functions of the software are:

1. Hydraulically routes one input hydrograph through, around, and over a single earthen dam.
2. Estimates internal erosion and potential breaching of an earthen embankment dam.
3. Estimates erosion of the earthen embankment caused by overtopping of the dam embankment.
4. Estimates auxiliary spillway erosion in up to three earthen or vegetated auxiliary spillways.

The user imports an inflow hydrograph into WinDAM C and selects either internal erosion analysis or overtopping analysis.

Regarding internal erosion within the earthen embankment, the user sets the elevation and initial size of the internal erosion conduit. WinDAM C initially assumes a horizontal, rectangular conduit shape. The internal erosion conduit grows larger as flow erodes embankment material. The erosion may breach the embankment and drain the reservoir.

Since the research has been completed, United States Department of Agriculture (USDA) and Kansas State University (KSU) are currently verifying and validating a working version of WinDAM C, which should be released for external evaluation and testing in 2015.

INTRODUCTION

Windows Dam Analysis Modules (WinDAM) is a modular software application to analyze earthen embankments during internal erosion and overtopping. Recently released for testing and evaluation by the dam safety community, WinDAM B (USDA, et al. 2012) includes erosional failure of a homogeneous embankment through overtopping and release of stored water. The alpha version of WinDAM C, currently under development, includes analysis of internal erosion. Future planned development includes non-homogeneous embankments. The US Department of Agriculture – Agricultural Research Service (USDA-ARS), US Department of Agriculture – Natural Resources Conservation Service (USDA-NRCS), and Kansas State University (KSU) are working jointly to develop this software.

For nearly seventy years, the USDA-NRCS has partnered with landowners, municipalities, conservation districts and other sponsors to construct more than 11,000 rural flood control dams. These structures provide $1.5B in annual benefits by providing flood control, municipal and rural water supplies, irrigation water, wetland habitat, and recreation among others. Many of these aging dams were designed with a 50-year service life, and time takes a toll on these structures. Sediment pools fill and encroach upon the flood detention volume. Structure components deteriorate, and hazard creep occurs in urbanizing areas that were once rural cropland areas. As a result, the consequences of dam failure must be considered when evaluating and prioritizing these structures for rehabilitation since the structures may no longer meet NRCS design criteria (USDA, 2005).

Overtopping and internal erosion are the primary causes of dam failures, with each mode attributed to a roughly equal number of failures (Foster, Fell and Spannagle 1998). For a given dam, one (or neither) mode may be more likely. For example, many of the storage reservoirs in arid West have large volumes relative to inflow and are managed such that overtopping is very unlikely. The US Bureau of Reclamation (USBR, 2011) names internal erosion of embankments (or their foundations) as the number one cause of dam failures in the western US. WinDAM C, when completed, will estimate breach erosion of an earthen dam through one of two modes: internal erosion through the embankment or overtopping the embankment. This document describes the WinDAM model currently being developed to examine internal erosion. The model is currently at the alpha stage of development undergoing verification and validation testing by the developers. It is anticipated that additional testing by the dam safety user community will also be required.

WINDAM C CAPABILITIES

Purpose of Software: The essential functions of WinDAM C software are threefold:

- Hydraulically route (level pool routing) one inflow hydrograph through, around, and over a single earthen dam.
- Estimate auxiliary spillway erosion in up to three earthen or vegetated auxiliary spillways.
- Estimate erosion of the earthen embankment caused by internal erosion or by overtopping of the dam embankment.

Since WinDAM C does not include any hydrology component, the user must create the reservoir inflow hydrograph in other software, such as WinTR-20 (USDA-NRCS, 2009) or SITES (USDA-NRCS, 2015). The user can import the hydrograph or paste the hydrograph points into the user interface. The user has the flexibility to choose the hydrologic software most suitable for analysis of site conditions.

Internal Erosion of Homogenous Earthen Embankment: WinDAM C models the dam embankment as a homogenous earthen material. Many USDA-NRCS dams are homogenous earthfill, so the WinDAM C model applies. If applied to zoned embankments, the suggested approach is to consider material and geometry that will dominate the process. For computational purposes, the earthen embankment fits into a simplified, rectangular-shaped valley (Figure 1) with vertical abutments and level valley floor.

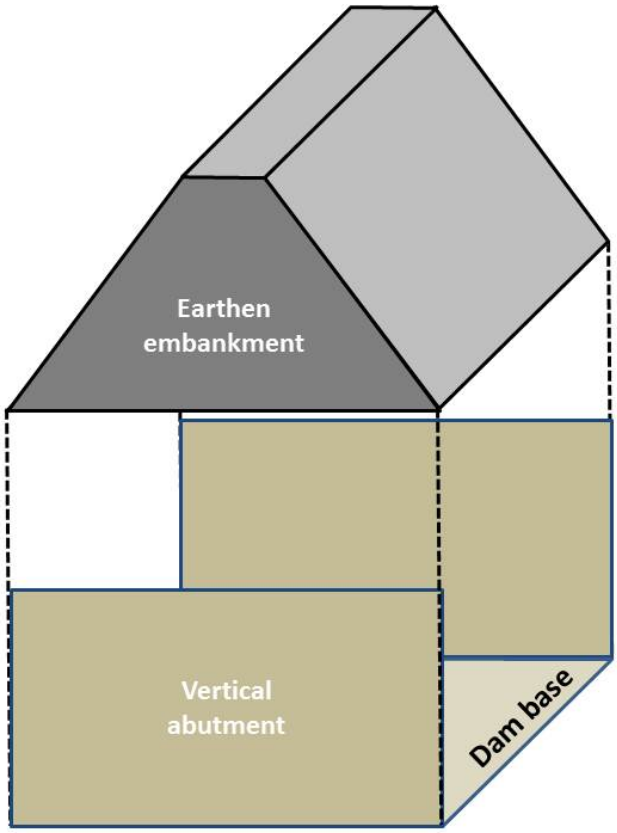

Figure 1 Homogenous earthen embankment in rectangular-shaped valley

Initial Internal Erosion Conduit: For a WinDAM C internal erosion analysis, the user specifies the initial size and location of the internal erosion conduit. To simplify the analysis, the conduit is horizontal—there is no slope in the upstream-downstream direction through the embankment, as shown in Figure 2. The conduit is assumed to be rectangular. The user must specify the

initial conduit dimensions—width and height. The user must input the initial elevation of the conduit invert, as well as the lateral stationing between the left and right abutment.

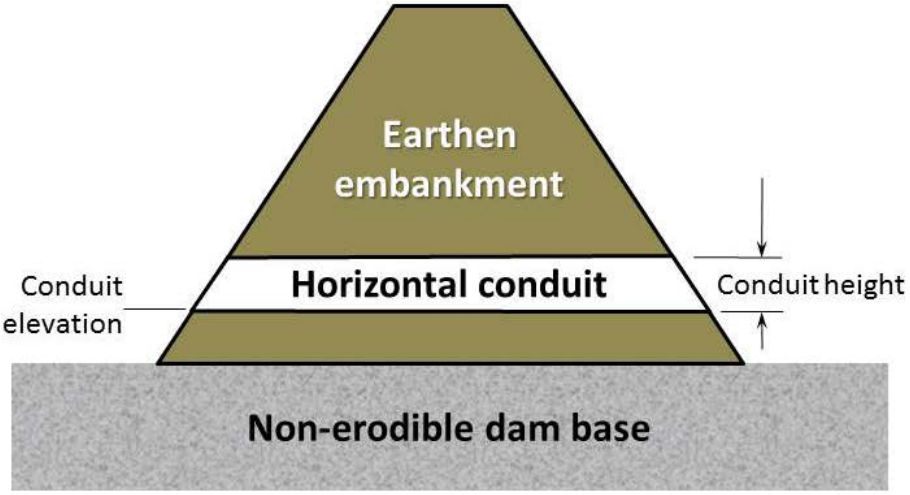

Figure 2 WinDAM C internal erosion horizontal conduit profile

In WinDAM C the left and right abutments are considered to be non-erodible and vertical, as shown in Figure 3. The embankment foundation, or dam base, is non-erodible and level. The dam crest profile is defined as a series of user-entered points (Figure 3).

The internal conduit erodes laterally until it reaches an abutment, as shown in Figure 3. The conduit also erodes vertically between the dam crest profile and the dam base. As long as some portion of the conduit is flowing full and the shear stress is sufficient to erode the embankment material, the conduit expands in all four directions equally. Once conduit erosion reaches one of the embankment boundaries (abutment, dam base, or dam crest), expansion/erosion in that direction stops.

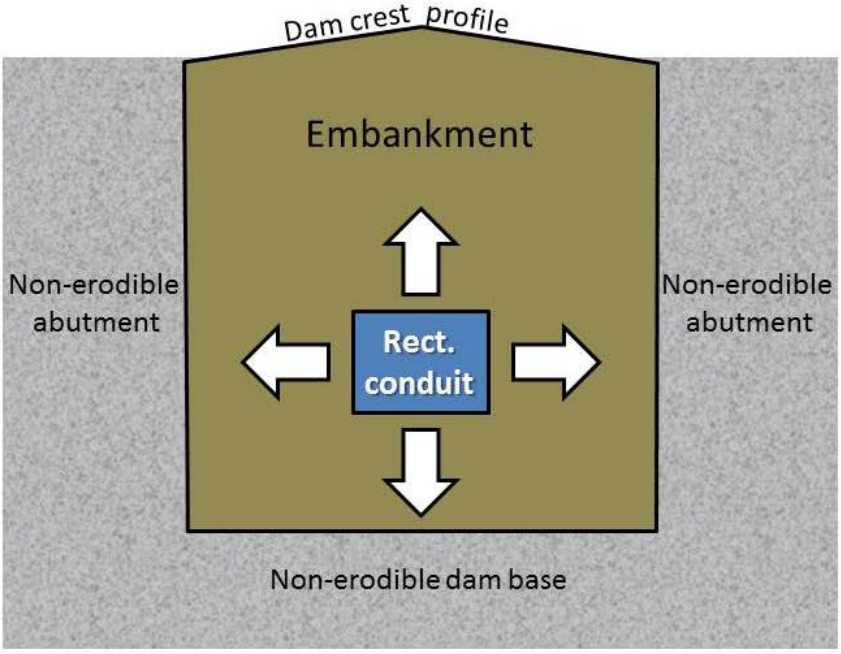

Figure 3 WinDAM C conduit cross-section looking upstream

Erosion Processes: Two erosion processes are simulated. The conduit enlarges concentrically due to shear detachment (laterally and vertically in a conduit simplified as having a rectangular cross section); classically this is the only process associated with internal erosion. However, development of a headcut at the outlet and subsequent advance of that headcut also play an important role in breach by internal erosion in some instances, so this process is also modeled.

At the beginning of each time step, the model computes the shear stress produced by flow passing through the rectangular internal erosion conduit. In instances where conduit is full for less than entire length, a backwater curve and resulting average shear stress along conduit length are computed. If the average shear stress is greater than the user-specified critical shear stress, then the amount of erosion is estimated and the conduit expanded accordingly for the next time step.

In addition to simply expanding the internal conduit laterally and vertically, WinDAM C also checks to see if a headcut will form at the downstream invert of the conduit (Figure 4). After this headcut has formed, headcut advance and deepening is computed for each time step using the user-prescribed erosion model (Table 3). This process is simulated much like that of a headcut formed in overtopping with important distinction that width is controlled by the conduit.

Transition from Internal Conduit Erosion to Breach Erosion: Once this headcut reaches the upstream face of the embankment the internal conduit has become an open breach and flow

transitions to breach flow. At this point, lateral expansion of the breach is the same as with overtopping flow conditions.

In the early stages of internal erosion, the conduit is usually stable regardless of support by hydrostatic water pressure. As the conduit enlarges, the support provided by water becomes critical. There are three cases when the roof of the conduit is considered to be stable:

1. The conduit is flowing full over the entire length of the conduit.
2. The conduit is flowing full over some part of the conduit length.
3. When flow transitions to free surface flow along the entire length of the conduit and the conduit width is less than twice the overburden height (vertical distance from the dam crest to conduit roof).

As the breach progresses and reservoir drains the roof of the internal erosion conduit will collapse. WinDAM C considers the conduit roof collapsed for these two cases:

1. Erosion of the roof reaches the dam crest profile
2. Free surface flow along the entire conduit length and the conduit width is more than twice the vertical distance from the dam crest to the roof.

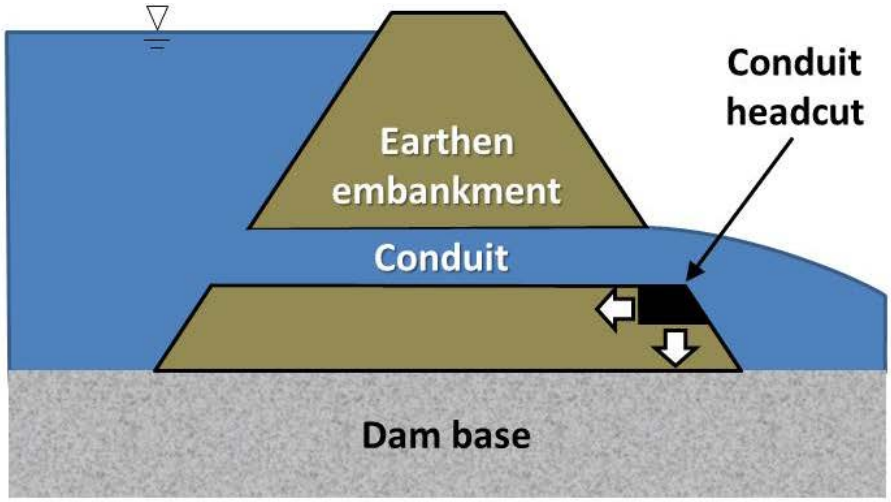

Figure 4 Conduit headcut

Negligible Internal Conduit Erosion Cases: There are cases where the resulting internal erosion is negligible. These possible cases include:

- Elevation of internal erosion conduit is above maximum water surface in the reservoir, which results in no flow in internal erosion conduit.
- Insufficient time or flow to produce meaningful erosion because the generated stress does not exceed the soil critical stress by sufficient time or amount.

- Highly erosion-resistant embankment materials may not generate shear stresses greater than the soil critical stress.

Overtopping Breach Erosion: If the user selects overtopping erosion analysis in WinDAM C, flow through the breach depends on the eroded breach area and the driving head based on the reservoir water surface, breach elevation, and any downstream tailwater. The four stages of the overtopping breach are described in Table 1.

Table 1 Four stages of WinDAM overtopping breach

Stage 1	Surface protection on downstream embankment slope fails. Headcut forms on downstream face of dam at low point in the crest profile.
Stage 2	Headcut advances through the crest to upstream embankment slope. Breach is initiated when the headcut enters the upstream crest and begins to lower the hydraulic control.
Stage 3	Headcut continues to advance into the reservoir pool releasing stored water.
Stage 4	Headcut continues to widen as reservoir drains following local removal of the embankment in the breach area.

Modeling Flow Through Embankment Cracks: Earthen embankments are susceptible to cracking from seismic activity or from desiccation in arid regions. As an overtopping erosion event, the only way to evaluate a crack is to input the crack in the dam crest profile. WinDAM overtopping erosion analysis was not developed for such evaluation and is not appropriate for several reasons. First, crest width in WinDAM is a constant and WinDAM evaluates both stress and erosion strictly from a depth perspective rather than considering the extremely steep profile segments as walls. Second, overtopping is considered on a one-dimensional, unit-discharge basis.

However, analyzing a crack, even one that extends to the dam crest, as an internal erosion event may be appropriate if the user develops a thorough understanding of the computational model and interprets inputs and results accordingly. Cracks have been associated with internal erosion (Bonelli et al., 2006) (Fell et al., 2003). The geometry of a crack can be more correctly approximated in an internal erosion simulation in WinDAM C. However, the research program and software were not undertaken to address the early stages of breach development represented by narrow cracks. Users should recognize model constraints and interpret results accordingly, e.g.

- WinDAM C assumes turbulent flow through the internal conduit, whereas flow through narrow cracks may be laminar flow.

- WinDAM C embankment materials properties do not change during the analysis. Over a sufficiently long period of time, flow within small cracks may saturate portions of the embankment and alter its resistance to erosion.

Interaction Of Erosion And Hydraulics: The hydraulics and erosion are coupled for the embankment breach analysis. In other words, a larger breach in the embankment lets more flow pass through the embankment breach during the next time step. Erosion prediction is relatively straightforward in the homogeneous earth embankment.

Erosion prediction in the auxiliary spillway, however, is much more complex than in the homogenous earth embankment. Hydraulics and erosion are not coupled in the auxiliary spillway because the erosion model only includes information on the weakest unit width subsurface materials in the auxiliary spillway. As a result, WinDAM C does not have the data to estimate the lateral expansion in the auxiliary spillway. Erosion computations in the auxiliary spillway stop when the headcut reaches the upstream edge of the level crest of the auxiliary spillway.

WINDAM VERSIONING

Research is ongoing for future enhancements to WinDAM software, as shown in Table 2. USDA and KSU are currently verifying and validating a working version of WinDAM C, which should be released for evaluation and testing in 2015.

Table 2 WinDAM Versioning

Version	Existing Capabilities or Future Enhancements
WinDAM A+ (2008)	Embankment overtopping analysis (Slope protection evaluation: no embankment erosion analysis)
WinDAM B (2011)	Homogenous fill embankment overtopping and erosion analysis
WinDAM C (2015)	Internal erosion prediction through homogenous fill embankment
WinDAM D (proposed)	Potential failure initiation at toe, berms, and groins. Alternative embankment slope protection materials (i.e. blocks, reinforced vegetation)
WinDAM E (proposed)	Zoned fill embankment overtopping erosion prediction

INPUT DATA

The auxiliary spillway materials in WinDAM C are described with the same data inputs as in SITES (USDA-NRCS, 2015).

WinDAM C requires the user to input one flow hydrograph. This hydrograph input is similar to the SITES input procedure. SITES gives the user the option to input hydrology through a watershed model, but WinDAM C only allows hydrology input through a single hydrograph. Various design hydrographs will require a different WinDAM C run for each hydrograph.

WinDAM C may be run with or without embankment breach evaluation. When breach evaluation is desired, the earthen embankment must be described so WinDAM C can model either internal erosion or overtopping erosion. The user specifies the embankment slope protection: vegetation, rock riprap, or no cover. The dam embankment crest and slope dimensions are also input.

For the breach analysis option, the user selects one of two headcut models: Temple/Hanson Energy model or Hanson/Robinson Stress Model (Hanson, et al. 2011). The WinDAM C erosion prediction models are designed for estimating erosion of typical NRCS earthen embankments composed of fine-grained, cohesive materials, where the dominant erosion process is the formation, advance, and deepening of a headcut. The soil parameter inputs for each model are listed in Table 3.

Table 3 WinDAM C Erosion Model Soil Inputs

Model	Hanson/Robinson Stress Model	Temple/Hanson Energy Model
Input Parameter *(Units)*	Erodibility (ft/hr)/(lb/ft^2)	Erodibility - (ft/hr)/(lb/ft^2)
	Critical Shear Stress (*lb/ft^2)*	Critical Shear Stress – (*lb/ft^2)*
	Undrained Shear Strength (*lb/ft^2)*	Advance coefficient - *(ft/hr)/(ft/s^3)*
	Total Unit Weight (*lb/ft^3)*	

All four input parameters in the Hanson/Robinson stress model can be measured. In addition this model is recommended for tall dams (> 50 ft high). Since the advance coefficient parameter in the Temple/Hanson cannot be measured directly, most users select the Hanson/Robinson stress model.

A WinDAM C internal erosion analysis covers a few hours or days. The WinDAM model does not account for wetting or drainage of embankment soils during the erosion analysis. Therefore, the material properties of the embankment soil do not change over the period of the breach analysis.

Generally, the outflow from dams is controlled primarily by the hydraulic features of the dam—principal spillway and auxiliary spillway. For these dams where backwater effects are not significant, a single downstream tailwater elevation is sufficient. However, some dams have downstream hydraulic features such as levee or road embankments that impose significant and dynamic backwater effects. WinDAM C incorporates a tailwater rating table to simulate how the outflow from the dam varies with downstream capacity. This backwater is used when analyzing the auxiliary spillway flow, but is not yet utilized when computing the auxiliary spillway erosion.

OUTPUT

WinDAM C has three forms of output; the initial summary screen the user sees upon completion of a valid run, ASCII text output files, and numerous graphical plots. WinDAM C has multiple text output files to describe the expected performance of the embankment and multiple auxiliary spillways. The current list of available output plots in WinDAM C are listed below.

- Conduit/Breach Width
- Dam Cross-section
- Dam Crest Profile
- Conduit Width/Height
- Headcut Advance
- Headcut Position
- Hydrographs

- Reservoir Surface Area
- Reservoir Storage Volume
- Reservoir Water Surface
- Maximum Overtopping / Breach Discharge
- Maximum Overtopping Head
- Overtopping Stress
- All Discharge Ratings
- Auxiliary Spillway Ratings
- Principal Spillway Rating
- Tailwater Elevation
- Tailwater Rating

A sample of the Headcut Advance plot is shown in Figure 5.

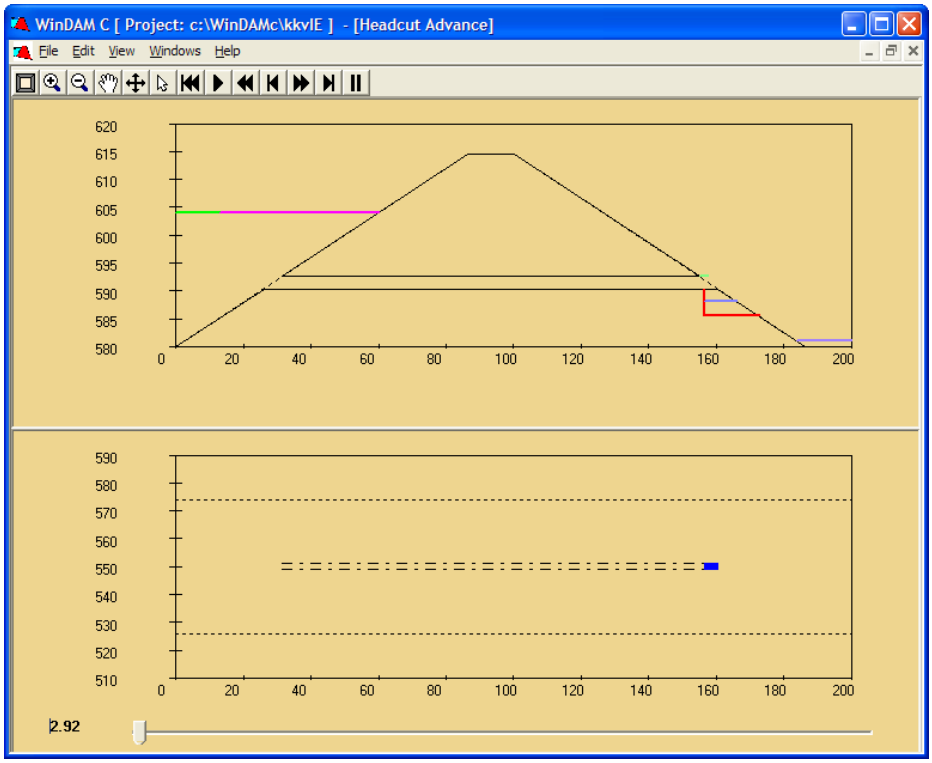

Figure 5 Sample WinDAM C headcut advance plot. Top half is dam cross-section. Bottom half is plan view.

INITIAL MODEL VALIDATION

Four different internal erosion tests on earthen embankments have been conducted at the ARS Hydraulic Engineering Research Unit in Stillwater, OK. Qualitatively, the WinDAM C predicted erosion matches the prototype erosion. The tests indicate that critical shear stress is a key parameter for initiation of erosion and particle detachment, especially for low-head dams (R. Tejral, personal communication, 2014).

CONCLUDING REMARKS

This report contains a preview of the internal erosion modeling capability being developed for WinDAM C. In addition, attention was given to capabilities already available to WinDAM B users—analysis of auxiliary spillways and overtopping breach. WinDAM software download and answers to frequently asked questions can be found at http://go.usa.gov/8Oq.

INTRODUCTION

WinTR-20 model is a storm event surface water hydrologic model applied at a watershed scale. The model assists in hydrologic evaluation of flood events for use in the analysis of water resource projects. It can be used to analyze current watershed conditions as well as assess the impact of proposed changes made within the watershed. Multiple storms (or rainfall frequencies) can be analyzed within one model run. A summary table for all storms within the run can be produced. Direct runoff is computed from watershed land areas resulting from synthetic or natural rain events. The runoff is routed through channels and/or impoundments to the watershed outlet.

WINTR-20 CAPABILITIES

Primary Purposes of Software:

- The WinTR-20 model is the heart of the system and performs the rainfall-runoff and watershed routing calculations.
- The Data Converter transforms oldTR-20 input data to the new input format accepted by the WinTR-20 model.
- The HEC-RAS Reformatter transforms HEC-RAS output profile data to WinTR-20 Stream Cross section data.
- The National Oceanic and Atmospheric Administration (NOAA) Atlas 14 rainfall data converter import NOAA data into WinTR-20 (csv or text files).
- The Northeast Regional Climate Center (NRCC) rainfall data converter imports NRCC data to WinTR-20 (text files).
- WinTR-20 generates inflow hydrographs to import into WinDAM software (filename.hyd) based on NRCS Technical Release 60 (TR-60) criteria.

WinTR-20 version 3.10.00 has been released and is available for download.

COMPUTER DEMONSTRATION

A computer will be set up with WinTR-20 version 3.10.00 to demonstrate use of the software. Experts will be available to answer questions.

SOFTWARE AVAILABILITY

The WinTR-20 system, documentation, and training material may be downloaded at no expense from http://go.usa.gov/KoZ . Questions may be directed to the WinTR-20 support team e-mail address: NRCS-TR20@usda.gov .

2011 MORGANZA CONTROL STRUCTURE TAILBAY SCOUR DEVELOPMENT & SEDIMENT DISTRIBUTION

T. (Jerry) Shih, Ph.D., P.E., U.S. Army Corps of Engineers, New Orleans, Louisiana,
Tzenge-Huey.Shih@usace.army.mil
Suchen Chien, U.S. Army Corps of Engineers, New Orleans, Louisiana,
Suchen.Chien@usace.army.mil

Abstract Completed in February 1954, the Morganza Control Structure (MCS) is a very unique Mississippi River flow diversion structure. When the forebay stage reaches 56.0 feet design height, the MCS is capable of diverting 600,000 cubic feet per section (cfs) water. Since completion, the MCS has been used to divert the flood water twice.

The first operation was started on April 17, 1973. The 1973 diversion caused significant scour at the MCS tailbay. As a remedy to protect the MCS tailbay from future scour, a reinforced concrete plunge pool was built in 1977. The second operation was started on May 15, 2011, but significant scour occurred again and promulgated even further downstream.

Six multi-beam surveys were performed between May 17 and June 6, 2011 to monitor the scour development. Each survey showed new scour holes and the development of original findings. The most severe scour holes were approximately 30 feet lower than their original elevations. Scour holes were un-watered in April 2012 and a Terrestrial LiDAR survey was performed on June 23, 2012. According to the survey results scour holes continued to develop after June 6, 2011, but they were not as severe as those in the early operation.

In May 2011, USGS performed a preliminary sediment deposition survey. Daniel Kroes et al. found that an estimated 326,000 cubic yards of dense soil were scoured away immediately downstream of the structure. The scoured soil became approximately 571,000 cubic yards of loose sediment and was deposited at least 30 miles from the MCS. If sediment that was deposited in the forebay and the sediment that came through the structure are included, the deposited sediment could be as high as 2 million cubic yards.

USACE's Engineering & Research Development Center (ERDC) was asked to perform an investigational study using a physical model as it is better than the numerical model for this type of rehabilitation experiment. After 18 months of repair and construction, successfully completed in March 2014, the MCS is now ready and capable of passing the project flood.

Based on ERDC's modeled results, three principle reasons caused the 2011 MCS tailbay scouring: (1) little to no tailwater immediately behind the structure (2) benchmarked headwater stage had been increased since the structure was constructed in 1954 and (3) only some of the 125 gates were used to pass the flood waters.

Lessons learned from both 1973 and 2011 operations and ERDC's physical model experiment are that tailwater conditions are critical for the stilling basin design and energy dissipation calculation, operation needs to be maintained no more than the maximum headwater design stage, and gate operations are extremely important to minimize and prevent tailbay scour.

INTRODUCTION

Completed in February 1954, the Morganza Control Structure (MCS) is a very unique Mississippi River flow diversion structure. The MCS forebay and the Mississippi River are separated by a three-mile long potato ridge. The waters of the Mississippi River can flood the MCS forebay when the stage is above elevation 43.0 feet NGVD29. When the forebay stage reaches 56.0 feet design height, the MCS is capable of diverting 600,000 cfs water.

The structure has 125 gate bays and is 3,906 feet long. Each gate bay has a crest weir with a top elevation of 37.5 feet NGVD29, and on top of the crest weir is a two-leaf (upper and lower panel) gate. According to the current MCS water control manual, a gate shall be either fully opened or closed to divert sufficient floodwater from the Mississippi River to avoid unacceptable stress along the main stem of the Mississippi River. At the toe of the weir's downfall, there are two rows of baffle blocks installed on the stilling basin floor to dissipate the energy of the floodwaters passing through the structure. The floor and end-sill wall of the 86 feet long stilling basin is at elevation 29.0 and 32.0 feet NAVD29, respectively. Behind the end-sill wall, there is an 80 feet long extended derrick stone apron installed parallel to the structure as shown in Figure 1.

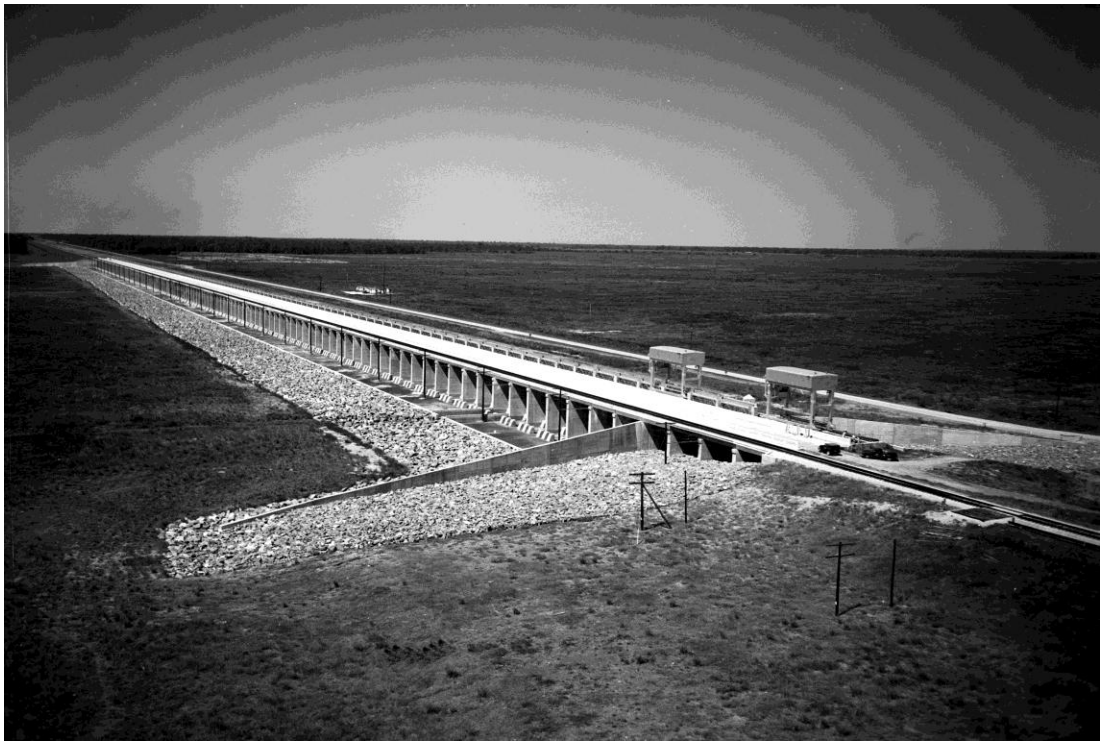

Figure 1 The Morganza Control Structure (MCS) in 1954

The operation of the MCS is based on a Mississippi River and Tributaries flood damage risk reduction feature called "Project Flood" to prevent riverine flood stages from (1) exceeding the approved flow line, i.e. encroachment on freeboard requirements, (2) limiting flows to design discharge of 1,500,000 cfs between MCS and Bonnet Carre Spillway, and (3) limiting flow below the Bonnet Carre Spillway to the design flow of 1,250,000 cfs.

1973 OPERATION

Since completion, the MCS has been used to divert the flood water twice. The first operation was started on April 17, 1973. The operation was not triggered by the Mississippi River flow rate, but by the vulnerability of the Atchafalaya River primary diversion facility, the Old River Control Structure. At the peak stage, 46.0 feet, approximately 210,000 cfs were diverted by the MCS. The 1973 diversion caused significant scour at the MCS tailbay. As a remedy to protect the MCS tailbay from future scour, a reinforced concrete plunge pool was built in 1977 as shown in Figure 2.

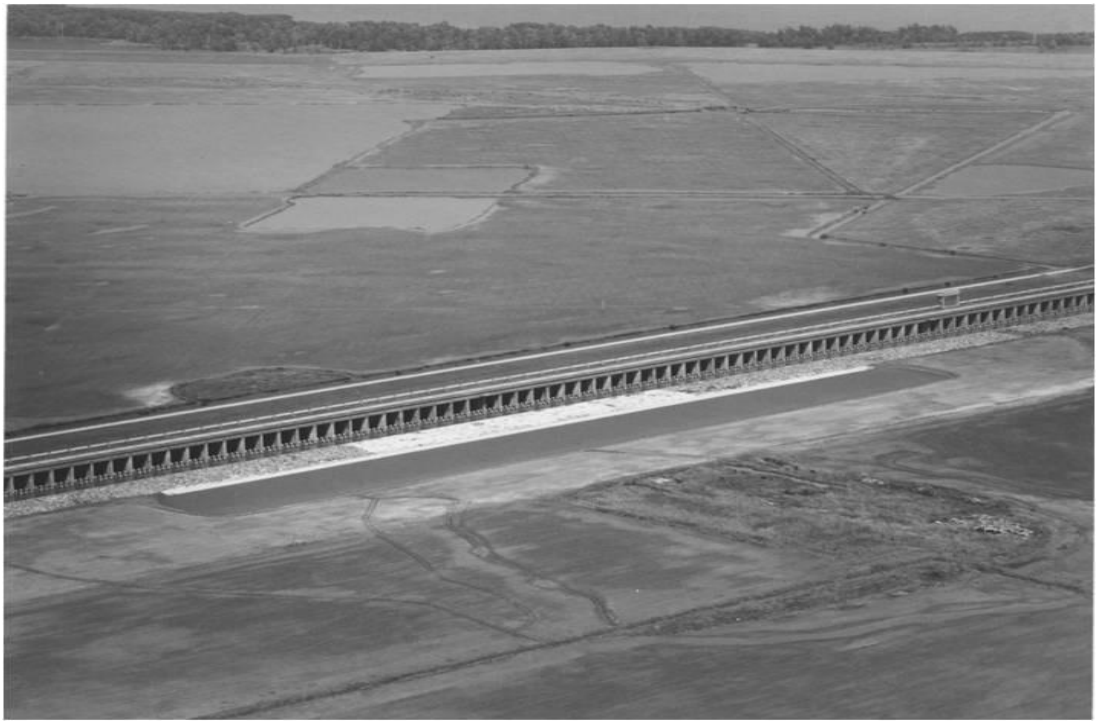

Figure 2 The MCS with Plunge Pool in 1976

The pool is located downstream of the derrick stone apron, between Gates 42 and 86, which had a Vertical (V)/Horizontal (H) =1/10 concrete paved front slope and a V/H=1/4 back slope. The plunge pool bottom was partially lined with concrete and riprap with a bottom elevation of 19.0 feet NGVD29. The horizontal distances of concrete and riprap varied from 90 feet to 110 feet and 10 feet to 30 feet, respectively. The front and back slopes met with ground elevations at 31.0 feet and 32.0 feet NGVD29, respectively. The repair made in 1977 was believed to be sufficient in preventing future scour.

2011 SCOUR DAMAGES

The second operation was started on May 15, 2011. While the operation in 2011 was successful, significant scour occurred which promulgated even further downstream. During the 2011 flood

fight, even though the highest forebay stage was 59.6 feet, the maximum diversion flow rate was only 185,000 cfs because fewer gates were used in 2011 than in 1977.

Severe scour located downstream of the MCS was observed by the operation manager on May 16, 2011 because scour indicators embedded five feet below the ground were missing. Since the MCS could be vulnerable if scour holes extended back toward the structure, a survey was immediately ordered to investigate the scour development at the MCS tailbay.

Six multi-beam surveys were performed between May 17 and June 6, 2011 to monitor the scour development. They were May 17, 2011; May 18, 2011 (plunge pool south only); May 19, 2011 (plunge pool only); May 20, 2011, May 26, 2011 (no plunge pool); and June 6, 2011. Each survey showed new scour holes and the development of original findings. The most severe areas were at the vicinity of the plunge pool downstream, which were approximately 30 feet lower than their original elevations. The scour development was obtained by using the "Fledermaus" program to compute and plot ground elevation changes between surveys. Scour damage that developed between June 6, 2011 & May 17, 2011 is presented in Figure 3. Major scour that developed between two referenced dates were downstream of the plunge pool, especially at areas located at two extruded corners, which were close to 27.5 feet in difference.

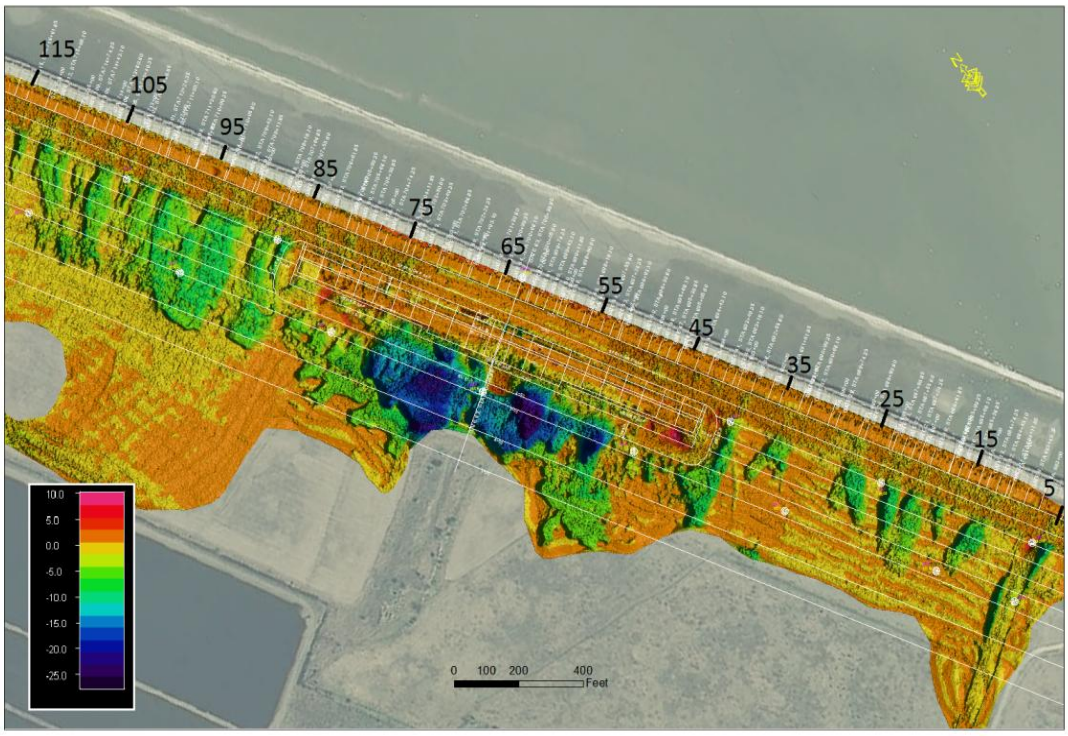

Figure 3 Scour Damage Developed between June 6, 2011 & May 17, 2011

Scour damage that developed between June 6, 2011 & May 18, 2011 (south plunge pool only) are presented in Figure 4. Major scours developed between two referenced dates remained downstream of the plunge pool, especially at areas located at two extruded corners. It seems like there was not much scour development from May 17, 2011 to May 18, 2011.

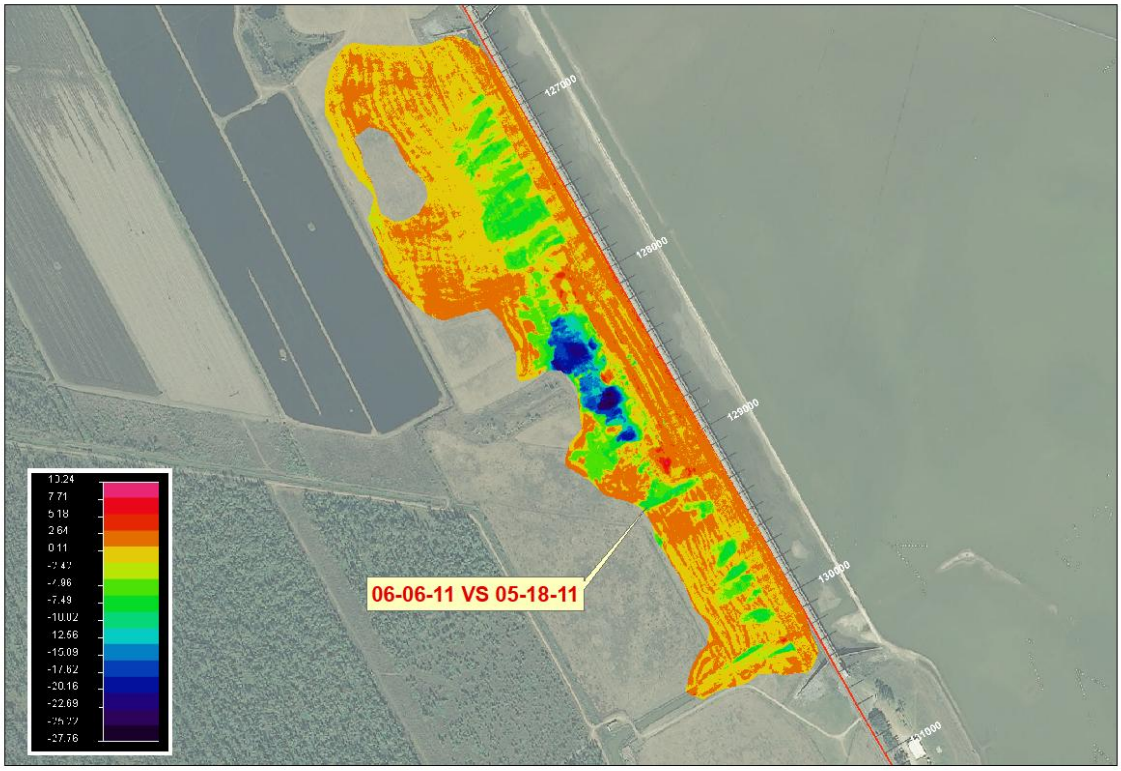

Figure 4 Scour Damage Developed between June 6, 2011 & May 18, 2011

Contours plotted according to May 17, 2011 survey, and scour (elevation difference) contours that developed between May 20, 2011 and May 17, 2011; May 26, 2011 and May 20, 2011; as well as June 06, 2011 and May 26, 2011 are presented in Figure 5. Survey results concluded that the tailbay terrain was changing continuously while the MCS was in operation. All surveys showed that major scour areas were downstream of the plunge pool, especially at areas located near two extruded corners.

The multibeam survey performed on June 6, 2011 showed that scour holes were created at almost all of the tailbay for a distance as far as 600 feet away from the structure. The worst scour area was at the immediate downstream of the plunge pool, which had elevations lower than 10 feet NAVD88. At the plunge pool's two extruded corners, elevations were close to 3 feet NAVD88, which mean approximately 30 feet of ground earth was scoured away from its location. Presented in Figure 6 is the survey performed on June 6, 2011.

The generated scour maps helped tremendously with gate operation exercise during the 2011 operation. Since the MCS middle gates faced plunge pool, the 2011 flood fight used middle gates more frequently. The MCS gate opening frequencies during the 2011 flood fight are presented in Figure 7.

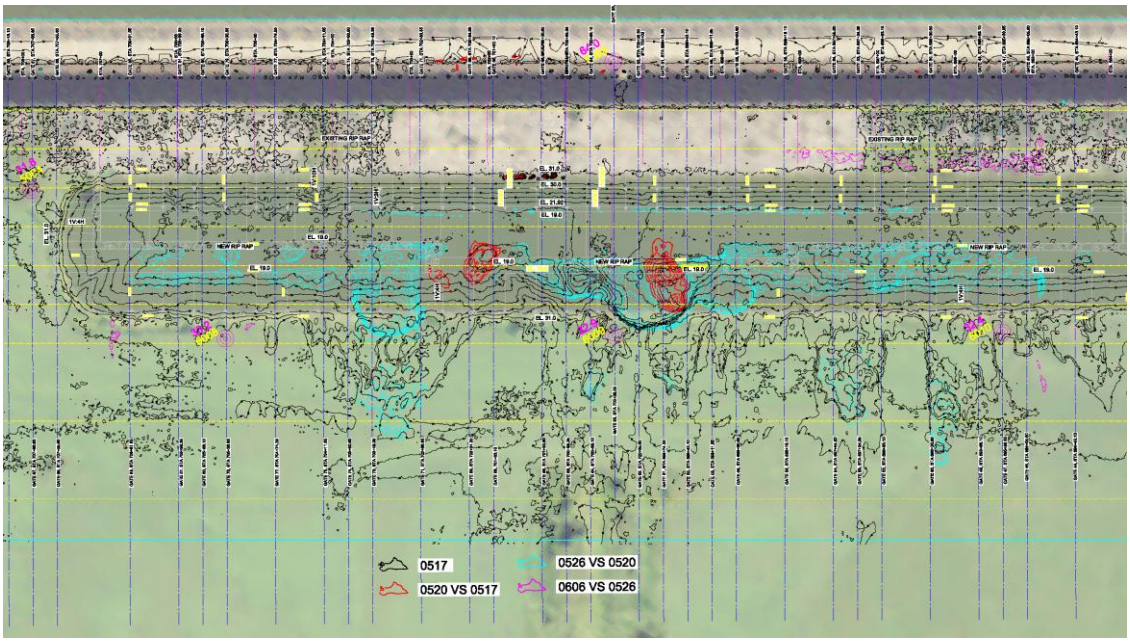

Figure 5 Scour Damage Developed between Two Adjacent Surveys

Figure 6 Multibeam Survey Performed on June 6, 2011

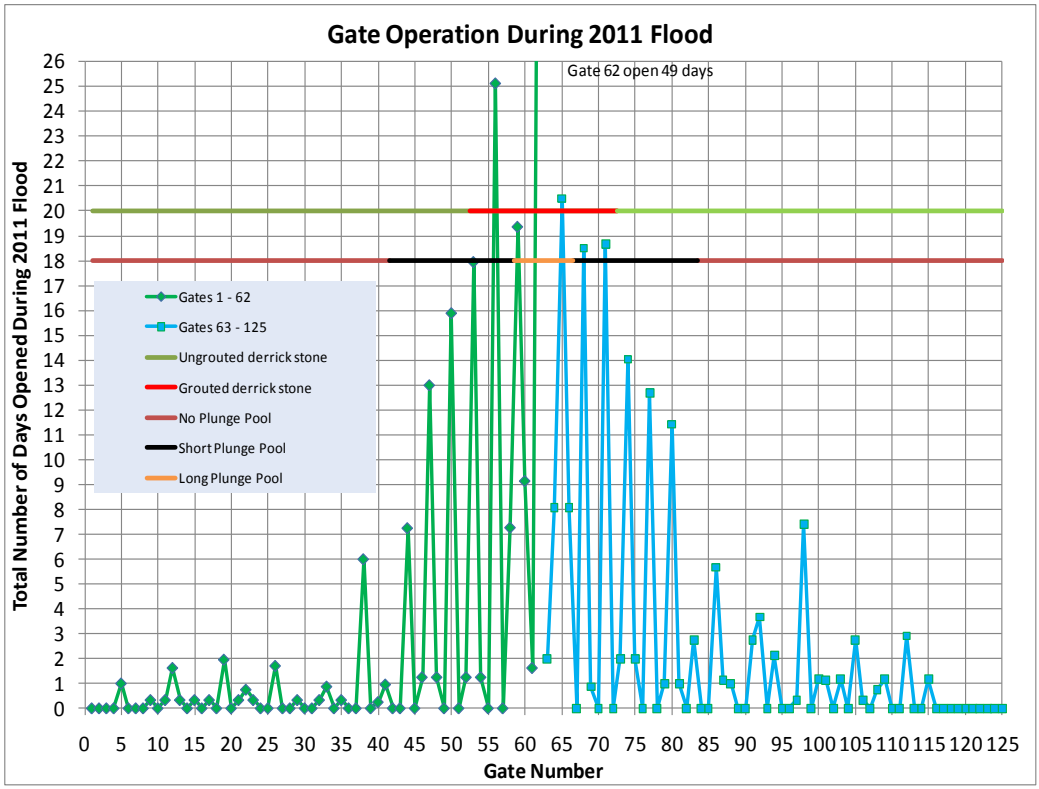

Figure 7 MCS Gate Opening Frequencies during the 2011 Flood Fight

2012 TERRESTRIAL LIDAR SURVEY

In April 2012, the U.S. Army Corps of Engineers (USACE) New Orleans District (MVN) un-watered the scour holes to inspect the undermining damage to the concrete slab at the bottom of the plunge pool and to perform a topographic survey. Figure 8 depicts the scour profile plotted downstream of each operated gate bay. Assuming no further development after the last dated 2011 operation, July 7, 2011, the tailbay contour should be the same as a June 23, 2012 Terrestrial LiDAR survey. The MCS tailbay scour development from June 6, 2011 to the last date of operation is presented at Figure 9. After June 6, 2001 operation scour damages were 2 feet or less, with the exception of a few small areas.

After the plunge pool was un-watered, scour damages can be found as shown in Figures 10 and 11. Several rocks as heavy as 6,000 pounds were carried away from the derrick stone apron. Some were carried away as far as 600 feet downstream on top of a rising hill. Nine out of 15 MCS tailbay buoys were missing after the 2011 operation.

MCS TAILBAY REPAIR

USACE's Engineering & Research Development Center (ERDC) was asked to perform an investigational study using a physical model as it is better than the numerical model for this type of rehabilitation experiment. The investigation had four specific purposes: (1) to develop a scour protection plan for the plunge pool gate bays (2) to develop a scour protection plan for the non-plunge pool gate bays (3) to update the 1951 discharge rating curve to include a higher headwater, actual crest design, and actual pier design information and (4) to use the study findings to update the MCS gate operation sequence to reduce/eliminate the scour damage seen in 1973 and 2011.

To meet the primary project goal of having the MCS fully repaired by the 2014 flood season, the construction phase of the repair work was executed by the New Orleans District (MVN) in three consecutive phases, each occurring upon completion of its respective physical model experiment. The repair and construction materials (mainly riprap stone) were hauled from pre-approved quarries along the upper Mississippi River via barges to an off loading site along the west bank of the Mississippi River near the town of Morganza. The material strength, stability, slopes and protection of critical sections replicated the conditions tested by the model. After 18 months of repair and construction, successfully completed in March 2014, the MCS is now ready and capable of passing the project flood.

Presented in Figure 12 is a MCS physical model in 1:22 scale. A MCS physical model with plunge pool experiment is presented in Figure 13.

Figure 12 MCS Physical Model in 1:22 Scale

Figure 13 MCS Physical Model with Plunge Pool Experiment

SEDIMENT DEPOSITION AFTER 2011 OPERATION

In May 2011, USGS performed a preliminary sediment deposition survey. Daniel Kroes et al. (2014) found that an estimated 326,000 cubic yards of dense soil were scoured away immediately downstream of the structure. The scoured soil became approximately 571,000 cubic yards of loose sediment and was deposited at least 30 miles from the MCS. If sediment that was deposited in the forebay and the sediment that came through the structure are included, the deposited sediment could be as high as 2 million cubic yards.

An estimated sediment distribution caused by the 2011 operation is presented in Figure 14.

CONCLUSIONS

Based on ERDC's modeled results, three principle reasons caused the 2011 MCS tailbay scouring: (1) little to no tailwater immediately behind the structure (2) benchmarked headwater stage had been increased since the structure was constructed in 1954 and (3) only some of the 125 gates were used to pass the flood waters.

Lessons learned from both 1973 and 2011 operations and ERDC's physical model experiment are that tailwater conditions are critical for the stilling basin design and energy dissipation calculation, operation needs to be maintained no more than the maximum headwater design stage, and gate operations are extremely important to minimize and prevent tailbay scour.

AN APPROXIMATION OF THE SEDIMENT BUDGET FOR THE TOMBIGBEE RIVER AND THE MOBILE RIVER BASINS

John J. Ramírez-Avila, Assistant Research Professor, Civil and Environmental Engineering Department, Mississippi State University, Mississippi State, MS, jjr149@cee.msstate.edu; William McAnally, Emeritus Professor, Mississippi State University, Mississippi State, MS, McAnally@ngi.msstate.edu; Sandra L. Ortega-Achury, Research Associate, Civil and Environmental Engineering Department, Mississippi State University, Mississippi State, MS, sandraortega@cee.msstate.edu

ABSTRACT

A sediment budget is an accounting of the sources and disposition of sediment as it travels from its point of origin to its eventual exit from a drainage basin. Sediment budgets are important in defining the dynamic behavior of a river system. The Mobile River Basin covers two thirds of the state of Alabama and portions of Mississippi, Georgia, and Tennessee. It is the fourth largest basin in the United States in terms of flow volume and is the sixth largest river system in the U.S. in terms of area. The lower Mobile Bay is a designated national estuary under the EPA's National Estuary Program. The Mobile Bay and the rivers draining into it support major uses with national implications which include the Tennessee-Tombigbee Waterway, the Port of Alabama, various commercial fisheries, large industry, tourism and recreation, and abundant development. Surface water in the Tombigbee River and Mobile River Basins generally meet Federal and State drinking water standards and guidelines for protection of aquatic life. However, water quality conditions along both river basins have been reported to be adversely affected by urban and agricultural activities, as indicated by elevated concentrations of sediments, nutrients, pesticides, and other organic compounds and biological communities commonly exhibit signs of environmental stress. A study was performed to develop a sediment budget for the Tombigbee River Basin and the Mobile River Basin. A two tier analysis was developed to determine the annual sediment changes along the Tombigbee River Basin and the Mobile River Basin. Results indicate that important sedimentation processes are occurring on the impoundments distributed along the Tombigbee River Basin and the Alabama River Basin, which receives waters from the Cahaba River, Coosa River, and Tallapoosa River. Higher rates of sediment along the lower part of the Tombigbee River Basin could be related to the occurrence of river bank instability processes between the Demopolis and the Coffeeville Dams on the Tennessee-Tombigbee Waterway. Total sediment loads at the entrance of the Mobile River ranged from 0.8 to 18.75 Mg yr^{-1}. Changes on morphological and hydrodynamic processes below the diversion of the Mobile River in two distributaries can be favoring sedimentation processes along the lower part of the basin and the Mobile Bay. Assessment of a sediment budget in the Mobile River Basin is important to increase the scientific understanding of sediment behavior and distribution within the basin, as important factors that influence water quality trough the basin itself, the Mobile Bay and the Gulf of Mexico.

INTRODUCTION

A sediment budget is an accounting of the sources and disposition of sediment as it travels from its point of origin to its eventual exit from a drainage basin (Stream Systems Technology Center, 2004). Sediment budgets are important in defining the dynamic behavior of a river system (Sharp, 2007). Knowledge of stream and watershed characteristics is important for understanding natural processes and problems associated with watershed management and stream restoration. Sediment production and deposition have been linked to variations in fluvial sediment transport. In many lowland rivers, a major part of sediment is transported in suspension.

The Mobile River is the sixth largest river basin in the United States and the fourth largest in terms of flow (Figure 1). The water resources on the Mobile River Basin (MRB) are influenced by an array of

natural and cultural factors, which impart unique and variable qualities to the streams, rivers, and aquifers and provide abundant habitat to sustain the diverse aquatic life in the basin (McPherson et al., 2003). Surface water in the Mobile River Basin generally meets Federal and State drinking water standards and guidelines for protection of aquatic life. However, water quality conditions are adversely affected by urban and agricultural activities, as indicated by elevated concentrations of nutrients, pesticides, and other organic compounds, and biological communities commonly exhibit signs of environmental stress (Atkins et al., 2004). Approximately 70% of the MRB is covered by forest and silviculture is the largest industry. Logging and other silviculture activities can significantly contribute high rates of sediment from erosion and runoff.

Assessment of a sediment budget in the MRB is important to increase the scientific understanding of sediment behavior and distribution within the basin as important factors that influence water quality trough the basin itself, the Mobile Bay and the Gulf of Mexico. A study was conducted to provide an estimate of sediment inflows, outflows and deposition along different sites within the Tombigbee River Basin (TRB) and the Mobile River Basin (MRB). Results from the two tier analysis approach considered to determine the annual sediment changes along the Tombigbee River Basin and the Mobile River Basin are reported.

Description of the Study Area

The MRB encompasses 113,185 km^2 along the states of Mississippi, Alabama, Tennessee and Georgia (Figure 1A). The western part of this basin, which is the sixth largest river basin in the United States, is comprised of the TRB (35,674 km^2) and the Black Warrior River (BWR - 16,280 km^2). The eastern MRB is drained by the Alabama River (ARB- 58,726 km^2) which receives waters from the Cahaba River, Coosa River, and Tallapoosa River. The Mobile River is formed by the confluence of the Alabama and Tombigbee Rivers, near Vermont, AL. Downstream from the confluence, the Mobile River flows about 48 km to the south before splitting into several distributaries (Johnson et al., 2002). After flowing across a deltaic plain, these distributaries discharge into the Mobile Bay, which discharges into the Gulf of Mexico (Figure 1B).

The mean annual flow in the MRB is about 1760 $m^3 s^{-1}$. The Alabama and Tombigbee Rivers contribute about 52 and 48% of the flow, respectively (Atkins et al., 2004). Mean annual runoff and precipitation generally are uniform throughout the MRB, with a highest precipitation amount typically occurring in the northeast part and southern area of the basin. Streamflow in the MRB is highly regulated by upstream impoundments. Around 1,020 km^2 of impoundments are extended along the entire basin, some of them constructed for hydroelectric generation and flood control purposes; other series of navigable impoundments were created by completion of the Tennessee Tombigbee Waterway to connect the MRB with the Tennessee River drainage in northeast Mississippi. As a result of this regulation, natural season flow patterns in these tributaries have been altered, with moderated peaks and low flows downstream from the impoundments. Water quality is affected by sediment and nutrients that are trapped in the impoundments and contribute to eutrophication, algal blooms, low oxygen levels and fish killing (Atkins et al., 2004).

Water quality agencies have identified numerous causes and sources of surface water impairment in the MRB. The complex combination of natural (e.g. physiography, geology, soils, climate, hydrology and ecology) and human factors (e.g. built impoundments, land use changes, mining) within the MRB are considered the principal influences on water quality (Johnson et al., 2002).

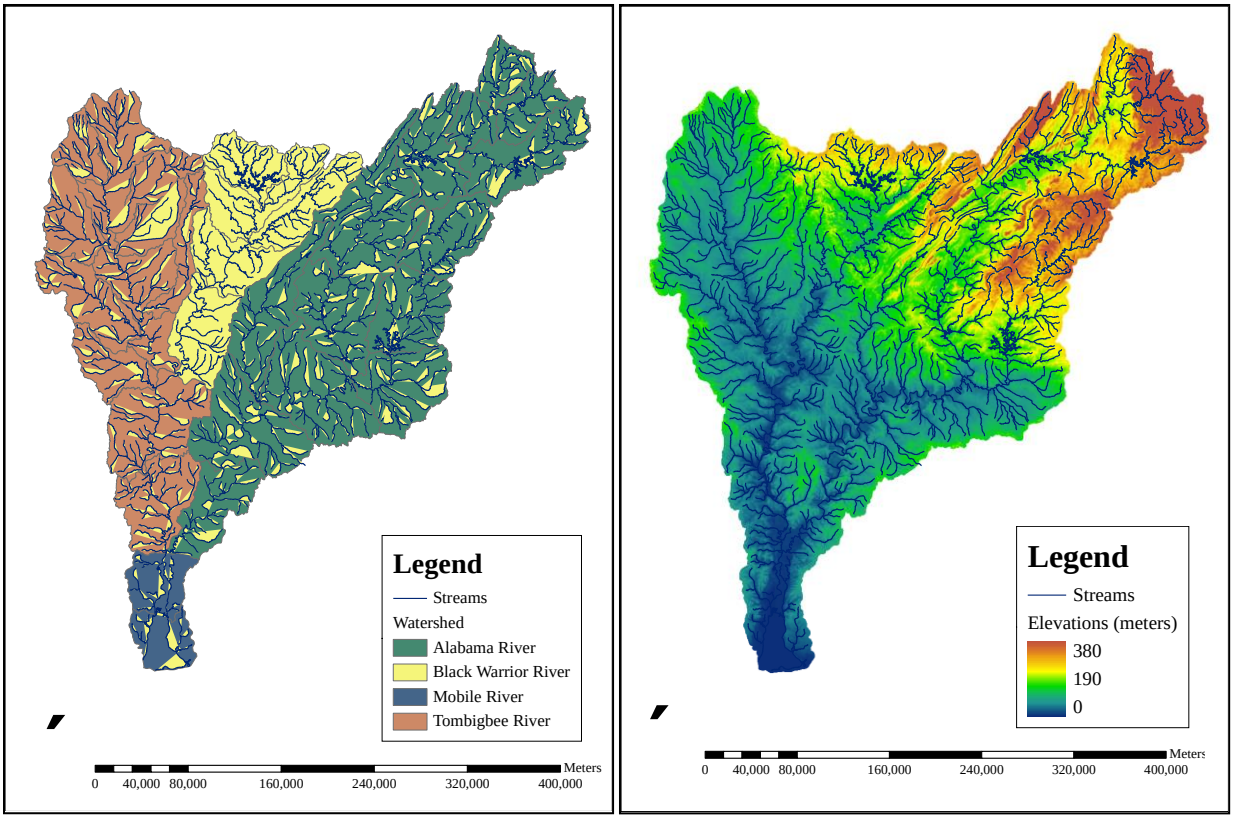

Figure 1. A) Mobile River Basin and principal Subbasins B) Topography in the Mobile River Basin.

METHODS

The development of the sediment budget for the TRB and the MRB included the application of a two tiered analysis, based on the proposed sediment budget template developed by Sharp (2007). Initially, data from USGS stations within the MRB in the form of suspended sediment concentrations, suspended sediment loads, instantaneous flow, daily average flow and peak flow were collected. All available data from 1975 to 2010 for all the USGS gauging stations involved in the present study were used. Table 1 presents the USGS stations where data were collected.

All the USGS stations within the Upper Tombigbee River (HUC 03160101), the Middle Tombigbee River (HUC 03160106) and the Middle Tombigbee River-Chickasaw (HUC 03160201) subbasins were evaluated to provide an estimate of sediment inflows, outflows and deposition in the TRB (Figure 2). Results of the sediment budget developed by Sharp (2007) for the Aberdeen Pool were setup as the initial sediment load input for the upper subbasin (HUC 03160101). The sediment load at the outlet of each subbasin was considered as the total sediment load entering the next segment downstream. USGS stations within the same subbasin but not located on the Tombigbee River were used to determine the contribution of flow and sediment loads from tributary watersheds. The entire sediment load of a tributary watershed considered both, accounted and unaccounted areas. The upstream section within a watershed or subbasin contributing at the location of a USGS station was part of the accounted area. The section between the location of a USGS station and the mouth of the watershed, the outlet of a subbasin or a specific location within a subbasin (e.g. entrance of a lake) was considered as the unaccounted area. The sediment load of the accounted area of a watershed or subbasin was divided by its extension providing calculations of mean daily (Mg d^{-1} km^2) or mean annual (Mg yr^{-1} km^2) sediment yield for Tier 1 and Tier 2, respectively.

The unaccounted area of a subbasin or a tributary watershed was considered to have similar sediment yield than the sediment yield observed at the upstream area contributing to a USGS station.

A sediment rating curve (expressed as Equation 1), which represents the relationship between suspended sediment discharges (Q_s) and the stream or river flow (Q), was developed for the entire dataset within a specific subbasin. The development of the sediment rating curves were the base of both of the tiered analyses, and were used to determine the sediment load generated by each tributary watershed, subbasin or upstream area contributing to a lake.

$$\mathbf{Q_s = aQ^b} \qquad \text{Equation 1}$$

where
Q_s is the suspended sediment discharge (Mg d^{-1}), Q is the observed instantaneous flow (m^3 s^{-1}), and *a* and *b* are regression parameters.

The Tier 1 analysis implements basic principles to create an initial sediment budget by determining suspended sediment (SS) loads and yields at the magnitude of the effective discharge, also known as bankfull discharge ($Q_{1.5}$). A flow frequency distribution was generated from the annual maximum peak flow series at each USGS station by using the model PKFQWin (Version 5.2). The $Q_{1.5}$ was calculated from the generated flow frequency distribution (Figure 3, annual exceedance probability=0.6667).

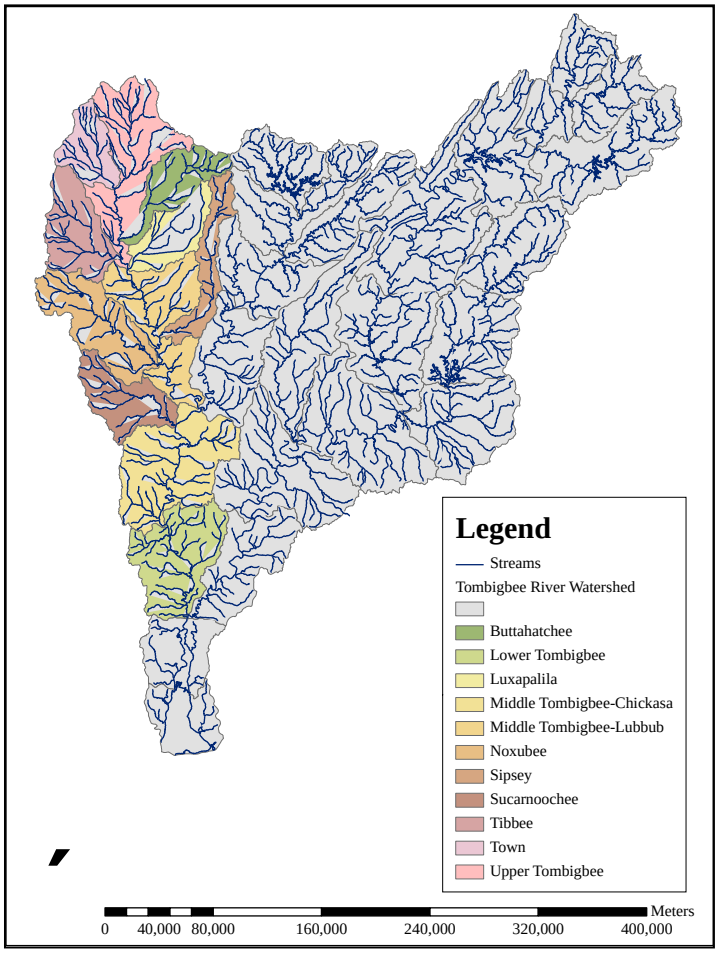

Figure 2. Tombigbee River Basin and subbasins

The SS load and daily SS yield at the $Q_{1.5}$ was obtained for each USGS station by using the sediment rating curve developed for each subbasin. Changes on sediment load (erosion or deposition) caused by the presence of an impoundment (e.g. lake) were evaluated by determining a sediment mass balance, which determines amounts of sediment entering the lake, dredging and sediment loadings from the lake.

Tier 2 analysis is a second stage where annual sediment discharges for each station are estimated using its mean daily flow data series. For this study, flow data series ranged from 1974 to 2010, when available. The sediment rating equation of each site was used to calculate mean daily SS load values (Mg d^{-1}) from the mean daily flow (m^3 s^{-1}). The mean daily SS loads were added for each complete calendar year to provide an annual SS load (Mg yr^{-1}). A mean annual SS load was generated by averaging annual sediment loads from 1974 to 2010. Once each station has a calculated annual SS load, a SS yield (Mg yr^{-1} km^2) was estimated for the contributing area where each station was located. Ungaged areas located downstream of a USGS station were considered to have similar sediment yield that gaged areas, when both areas were located within the same hydrologic unit (watershed) and flow was not routed through a downstream impoundment (dam).

The Tier 2 considers bed load as a percentage of the SS load. The bed load can be estimated as the 20% of the SS load for locations without the presence of an impoundment, or locations representing the influent of an impoundment. A lower value of 5% can be considered to calculate effluent flows from any impoundment in this study.

More extended and detailed information about the conceptualization and methodology used to develop a tiered sediment budget analysis is described by Sharp (2007) and Ramirez-Avila (2011).

RESULTS

Annual sediment loads and yields were calculated based on a two tiered analysis for each USGS station within the TRB, the BWR and the lower Alabama-Coosa-Tallapoosa River Basin (ACT) with enough available sediment and flow dataset. The annual SS load estimations based on the Tier 1 and Tier 2 analyses for four subbasins within the TRB and for the outlets of the BWR and the lower ARB are presented in Tables 2 and 3.

Calculated deposition rates at the Columbus Lake were 10.2 and 3.4 millions Mg yr^{-1} of sediment using the Tier 1 and Tier 2, respectively. The Tier 1 deposition rate for the Aliceville Lake was 407,200 Mg yr^{-1} while the Tier 2 estimation described that the system is balanced when no dredging is performed. For the mass balance estimations reported dredging rates of 100,000 Mg yr^{-1} and 127,000 Mg yr^{-1} (McAnally et al., 2004) were considered for the Columbus and Aliceville Lake, respectively.

The sediment load from the BWR, a mixed land use basin, represented only 9% of the sediment load entering to the Mobile River. The relatively low sediment load from this area reflected the influence of impoundments upstream of the subbasin's outlet. Similar observations in the reduction of sediment loads from this subbasin were reported by McPherson et al. (2003).

For both methods of analysis, the Middle Tombigbee River-Chickasaw was the subbasin with the higher annual sediment yield (Mg km^{-2} yr^{-1}) within the TRB. Two important structures (Demopolis and Coffeeville Locks and Dams) are located within this subbasin, which could be the key to explain the significant increase in sediment loads occurred between the inlet and the outlet of this area. According to Bankhead et al., (2008) a considerable amount of widening (up to 85 m between 1974 and 2003) has occurred along the length of the Tombigbee River within this subbasin. During their research, areas of high bank erosion were more commonly observed in certain locations with a spatial trend being seen between the dams established in this subbasin. Downstream of Demopolis Dam bank erosion rates were low, but increased up to 3 m yr^{-1} along the following 48 km from the dam. Downstream of this length, trends of bank erosion decreased towards Coffeeville Dam, with bank erosion increasing again a few kilometers upstream of the dam. Below Coffeeville Dam, bank erosion rates were high, and then decreased downstream along the following 64 km.

The annual SS load entering the Mobile River after the junction of the Tombigbee/Warrior system with the Alabama River just north of the city of Mobile, AL was estimated as 34 million of Mg and 5.4 million of Mg for the Tier 1 analysis and Tier 2 analysis, respectively. Downstream from the confluence, the Mobile River flows about 48 km to the south before splitting into the Tensaw River and the Mobile River. A USGS station is located on each branch few kilometers after the diversion. The observed reduction in the cumulated magnitude of the SS load for both Tier analyses (Tables 2 and 3) was evidenced after estimating the individual load on each station. This reduction (deposition) can be caused by the individual occurrence or the combination of three factors: i) the changes on flow velocity caused by the diversion of the Mobile River; ii) the minimum change of channel slope and the meandering path of the branches from the diversion to their outlet into the Mobile Bay; and iii) the probable deposition on areas along the deltaic plain during high flow events.

The extension of the entire ACT represented the 53.1% of the total area contributing to the Mobile River; however, in both analyses the SS load contribution from this basin was 1.8 times smaller than the SS loaded by the Tombigbee/Warrior system. The observed lower sediment loads along the ACT could be attributed to the presence of a significant number of highly regulated impoundments constructed for hydroelectric generation and flood control processes.

For each tiered analysis, a linear relationship between the area of the watersheds and subbasins within the TRB and the BWR and the estimated SS load was determined (Figures 4 and 5). The best fitting observed when using the Tier 1 for estimations can be explained because the SS load variability depends only from the magnitude of the bankfull discharge ($Q_{1.5}$) after being determined a unique rating curve for each subbasin. For sediment load estimations based on the Tier 2, the change in the mean daily flow on each station along the different years the rating curve was routed (generally from 1974 to 2010) was the factor that affected the reduction in the linear fitting of the dataset.

Although the Tier 2 analysis used the same USGS flow gages that the Tier 1 analysis, the use of daily flow events provides a closer approximation to the natural flow conditions (Sharp, 2007). The occurrence of flows similar to or higher than the bankfull discharge is different for each watershed and subbasin. In the performance of an ongoing study, the same authors of this study found that flows with magnitude similar to, or above the bankfull discharge represented only the 15% of the entire flow records for the Buttahatchie River in Mississippi. This condition determines that the application of the Tier 1 generates a significant overprediction of the rate of sediment yield by a specific watershed and/or sediment deposited on specific locations (e.g. Columbus Lake on this study), and further analysis is necessary to perform a more accurate estimation of sediment loads when limited flow data is available.

Considering the application of the Tier 2 as the more accurate method to determine the sediment flux along the different watersheds and subbasins into the MRB, a total sediment load ranging from 0.8 to 18.75 million Mg yr^{-1} is expected to enter the Mobile River after the junction of the Alabama and the Tombigbee Rivers (Table 4). Further analysis is needed to determine the rate of reduction of the SS load and the total load of sediment along the distributaries below the Mobile River diversion. When comparing the similar range of dates (2004 to 2010) between the loads at the entrance of the Mobile River and the distributaries the trend to reduce the magnitude of the loads is consistent.

Table 2. Estimation of annual suspended sediment load for different subbasins within the Mobile River Basin based on Tier 1

Subbasin	Drainage Area* (km^2)	Area Contribution (%)	Annual Suspended Sediment Load at $Q_{1.5}$ (Mg yr^{-1})	Suspended Sediment Load Contribution+ (%)

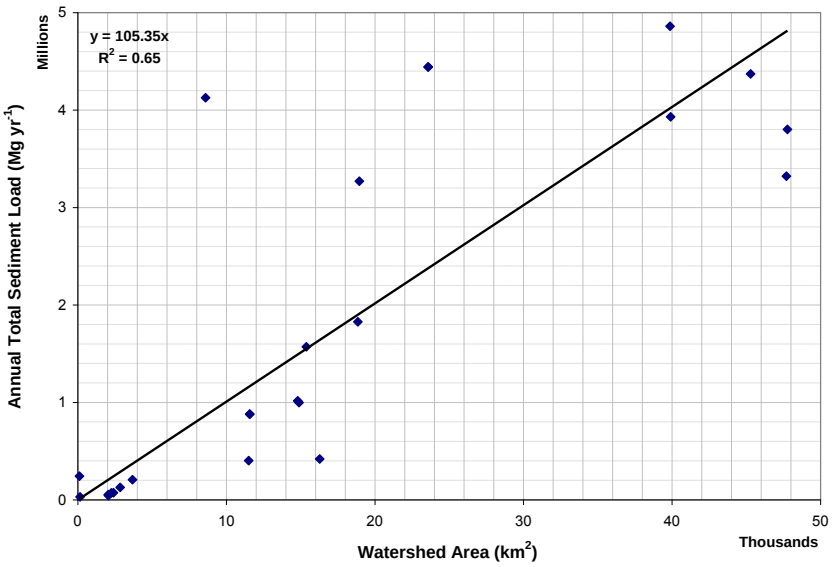

Figure 5. Relation between watershed area and Tier 2 estimated annual suspended sediment load.

CONCLUSION AND RECOMMENDATION

Results from the sediment budget analysis of TRB and the MRB evidenced that the system is contributing significant amounts of sediment to the impoundments. It was also observed that the system is experiencing an important process of sediment deposition along the lower part of the MRB. Based on sediment contributions from the upstream basin, which could range between 0.8 and 18.75 millions Mg yr^{-1}, the sediment deposition along the lower part of the MRB ranges between 0.1 and 2.85 millions Mg yr^{-1}. Since the availability of data is limited for the lower part of the Basin and the Bay, where sediment concentration is different due to changes in morphological and hydrodynamic processes, further analysis is needed and the collection of data would be an initial step to facilitate the process. As discussed in the analysis of sediment trends along the upstream basins and the changes on sediments behavior below the Mobile River diversion, the Tier 2 appears to be a reasonable procedure to determine the loads and the

trends of sediment processes along the entire watershed. The authors expect to develop a more detailed analysis along the Alabama River Basin to generate more important insights in the behavior of sedimentation processes along the Mobile River Basin.

Abstract

The Middle Truckee River is currently listed by the California State Water Resources Control Board as being impaired by excessive sediment. Water quality is of particular concern because the river is habitat for two federally-listed fish species, cui-ui (*Chasmistes cujus*) and Lahontan cutthroat trout (*Oncorhynchus clarki henshawi*). The Lahontan Regional Water Quality Control Board (Lahontan Water Board) has developed a Total Maximum Daily Load (TMDL) for suspended-sediment concentration to attain sediment-related water quality objectives in the Middle Truckee River, the segment of the Truckee River extending from the outflow of Lake Tahoe at Tahoe City to the California-Nevada state line near Farad, California. A four year study (WY 2011–WY 2014) was conducted to: a) document suspended-sediment loads; b) evaluate the relationship between streamflow, suspended-sediment concentration, turbidity, and suspended-sediment transport rates, and; c) evaluate changes in these relationships over time in response to land management, sediment control strategies, and other implementation measures outlined in the TMDL. Note that The Water Year (WY) begins on October 1 and ends on September 30 of the named year. Water year 2014 began on October 1, 2013 and ended on September 30, 2014.

Cold Creek, Donner Creek, and Trout Creek were monitored in the Town of Truckee, California. Cold Creek is largely undeveloped with a history of logging, road-building, and railroad infrastructure, Donner Creek is heavily urbanized, and Trout Creek is a mix of open space with lightly developed suburban/recreational land uses. Additional monitoring was initiated on the mainstem of the Middle Truckee River across two years (WY 2013 and WY 2014) at two stations located upstream and downstream of the tributaries and used to evaluate significance of these tributaries in delivering suspended sediment to the Truckee River.

Monitoring, analysis and computations have been used to characterize suspended-sediment production and delivery (i.e. yields and loads) at each of the six stations and compare suspended-sediment loads between watersheds and across all years and calculate contributions from each tributary to the mainstem. We also have compared suspended-sediment loads and load durations to a regulatory target set forth in the Middle Truckee River TMDL.

At four of the six stations, we calculated suspended-sediment loads using two methods: 1) establishing relationships between instantaneous suspended-sediment transport rates and

instantaneous streamflow ("streamflow-suspended sediment rating curve"), then applying that relationship to the near-continuous streamflow record, and; 2) establishing relationships between instantaneous suspended-sediment concentration and turbidity ("turbidity-suspended sediment rating curve"), and applying that relationship to the near-continuous turbidity and streamflow records. In the absence of a continuous-logging turbidity meter at the remaining two stations, loading was calculated using only the streamflow-based rating curve method.

The initial year of monitoring (WY 2011) was much wetter than average, with significantly above average snowpack and a longer than normal runoff period. The following three years constituted one of the driest three-year periods on record. A range of runoff and sediment-delivery events occurred during the period, and can generally be classified as rain-on-snow, rain-on-ground, summer thunderstorms, or spring snowmelt. Our conclusions can be summarized as follows:

- Comparison of results between two computational methods suggests that a continuous record of turbidity is better able to capture discrete events or more accurately assess changes in loading during an event, thereby providing more accurate estimates of daily and annual suspended-sediment loading.
- Suspended-sediment load duration curves for turbidity-based loads (15-minute data) can be used to evaluate if streams met regulatory targets or water quality guidelines for the watershed.
- Comparisons of streamflow-based sediment rating curves to historical data were used to evaluate improvements or further degradation; these data currently do not indicate reductions in loading to the Middle Truckee River over time.
- In WY 2013 and WY 2014, Cold Creek, Donner Creek, and Trout Creek delivered 27 and 19 percent of the total suspended-sediment load in the Middle Truckee River, respectively. These subwatersheds only represent 5 percent of the total watershed below Lake Tahoe.
- In all years, Donner Creek delivers higher loads and yields (loads normalized by watershed area) when compared to Cold Creek and Trout Creek. These results appear to reflect the urban nature of the subwatershed, with high hydrologic connectivity between impervious surfaces and the stream.

EFFECTS OF BEDLOAD SAMPLER NETTING PROPERTIES ON HYDRAULIC AND SAMPLING EFFICIENCY

Abstract Bedload samplers with coarse nets let small particles pass through the net, while samplers with fine nets have various problems capturing fine and coarse gravel bedload. Using samplers with nets of different mesh sizes may facilitate capture of a wider range of bedload particle sizes. However, preliminary evidence suggests that sampled transport rates are influenced by mesh size as well as by other net properties that tend to change with mesh size. Hence, a user would need to know and adjust for those differences before combining transport rates sampled with different mesh-width nets. To further investigate effects of netting properties on flow hydraulics and sampled transport rates, this study compares water throughflow and gravel transport sampled with two different mesh-size nets attached to non-flared bedload traps. One bag is a flexible, non-precision net with a 3.6 mm mesh width, the other bag is a stiff 1.18 mm precision mesh. The 1.18 mm net had a slightly better throughflow as long as the net remained empty, attributable to its slightly larger percent open area. Adding a substantial—but not uncommon—volume of 10 liters of organic material to the 1.18 mm net retarded and ponded the approach flow considerably because the organic material accumulated at the end of the cylindrical net where it blocked throughflow from exiting. The funnel-shape taken by the 3.6 mm net let most of flow exit shortly behind the bedload traps entrance, while captured solids traveled along the net bottom towards the bag end. The segregation of exiting flow from the accumulated material avoided major blockage of flow. In the 1.18 mm precision net, two hydraulic effects combined: higher through-flow for empty nets and compromised throughflow as organic material starts to accumulate at higher flow and transport. As a result, the 1.18 mm net sampled higher transport rates than the 3.6 mm net at low flow, while the 3.6 mm net sampled higher rates at higher flow.

INTRODUCTION

Coarse-bedded mountain streams transport a wide range of bedload particle sizes from sand to cobbles, but most bedload samplers can capture only a limited range of particle sizes. The sampler opening sets the upper limit of collectable particles, while the mesh width sets the lower limit. Large opening samplers with a large volume collection bag or basket and a coarse mesh of 4 to 25 mm collect only coarse particles, such as basket (Nanson 1974) or net-frame samplers (Bunte 1996, Whitacker and Potts 2007a,b), bedload traps (Bunte et al. 2004, 2007, 2008, 2010 a and b) or hanging baskets (Rickenmann et al. 2012). Those samplers provide satisfactory measurements of medium and coarse gravel or cobble transport rates but yield no information on transport of sediment finer than the mesh width. Samplers intended to capture coarse sand and

fine gravel typically have 0.2 to 0.5 mm mesh width bags. However, sand and fine organic particles quickly clog those bags, and the approximately 5-liter volume bag attached to small pressure difference samplers fill quickly when transport rates are high. Clogging and filling limit a sampler bag's water through-flow rates and sampling efficiency (Druffel et al. 1976; Johnson et al. 1977; Beschta 1981, 1983). Sampling times are typically kept to 2 minutes or less to avoid mesh clogging and bag overfilling, but if sampling times are too short to integrate over the natural fluctuations of bedload transport rates (Gomez et al. 1989; Turowski 2011) transport rates are overestimated when transport is low and underestimated when transport is high (Bunte and Abt 2005, Singh et al. 2009). Increasing both mesh and bag size alleviates the fast clogging and bag filling (Beschta 1981, 1983; O'Leary and Beschta 1981), and the subsequently higher throughflow rates increase sampled bedload rates. However, for a flared sampler body that is designed to have a hydraulic efficiency > 1 to compensate for the retardation of flow velocity in the fine-mesh and small-volume bag, increasing hydraulic and sampling efficiency via a coarser and larger bag to mitigate clogging might overcompensate.

Considering the limited range of particle sizes that can be representatively captured with a specified sampler body and bag, capturing a wider range of bedload particle sizes seems to require combining samples collected with nets of different mesh diameters. However, transport rates sampled using nets with different mesh widths differ (Beschta 1981, 1983; O'Leary and Beschta 1981). Furthermore, differences in mesh width are tied to changes in other net properties such as thread width, mesh shapes, and net stiffness, all of which can further affect hydraulic efficiency. An example of how the relation between mesh width and thread width affects a net's throughflow capacity is given below.

The percent open area A_o is a measure that relates the mesh opening width w to the thread width d in woven nets, or to the width of the knitted strands surrounding mesh openings in knitted nets, respectively (Figure 1a). Bunte and Swingle (2009) attached various nets with opening sizes of 0.5 to 3.6 mm to bedload traps, measured flow depth at the entrance of bedload traps deployed in a gravel/cobble bed stream, and showed that ponding of the approach flow increased with

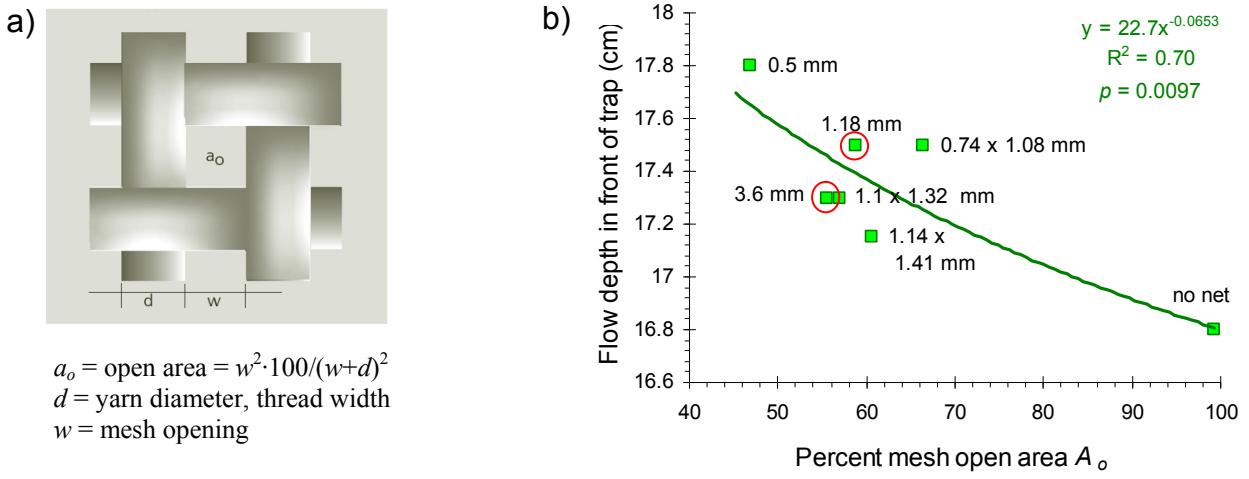

Figure 1: Schematic diagram of netting dimensions (from www.Sefar.com; slightly altered) (a). Negative relation between upstream ponding of flow and a net's percent open area A_o. Numbers next to data points indicate the mesh opening width w; note that not all meshes are square. The two circled nets were used in this study (a).

deceasing percent mesh open area A_o (Figure 1b). Scatter in the relation of ponding vs. A_o is attributed to concomitant netting properties such as being knitted vs. woven which determines mesh shapes and netting stiffness and whether mesh and net shapes change with increasing flow.

If throughflow rates, and hence sampled transport rates, differ between nets, then samples from different nets cannot be combined without first quantifying how those nets affect the sample outcome. However, systematic studies on how different nets affect sampled transport rates are rare. In this study we compare upstream flow hydraulics and sampled bedload rates between a 3.6 mm and a 1.18 mm mesh-width net attached to bedload traps with non-flared openings. Of the nets tested by Bunte and Swingle (2009), the 1.18 mm net was attractive because it would extend the size range collectible in bedload traps to coarse sand and pea gravel, while the square and precise mesh shape should give a precise lower limit of sampled particle size, and the sturdy nylon material suggested durability. The 0.5 mm nylon precision net was not included in this study because of its known propensity for immediate clogging and ponding (Bunte and Swingle 2003).

METHODS

Properties of the two study nets The 3.6 mm mesh-width net is knitted in a hole-pattern from thin, lightly twisted nylon yarn and is the original netting with which bedload traps were designed. This non-precision netting—called knotless Raschel (www.deltanetandtwine. com) and used for catfish farming—is very stretchable (and hence handles well). Mesh holes have a parallelogram shape when being gently stretched at low flows but become almost square when being fully stretched at moderate flows (Figure 2a). The bag, sewn as a cylinder, stretches to a funnel shape when subjected to flow (Figure 2b). The 1.18 mm mesh-width net is precision netting woven from 0.36 mm diameter nylon monofilament thread (www.Sefar.com). This netting is relatively stiff and unstretchable (Figure 2c), and the square mesh shape and the sewn cylindrical net shape are retained at all flows (Figure 2d). Both nets are about 1.2 m long. Properties of the two nets are summarized in Table 1.

Table 1: Characteristics of the two netting materials tested with bedload traps.

Netting material	Formal description	Open mesh width w (mm)	Width of thread or strand d (mm)	Ratio w/d	Open area A_o (%)	Smallest collectable 0.5 phi size class (mm)
hole-pattern knitted from thin, twisted nylon yarn, non-precision	Raschel 210d/9	3.6 - 5 based on stretching	1.23	2.9	56	4
Square mesh woven from nylon monofilament, precision	Sefar 06-1180/59	1.18	0.36	3.3	59	1.41

Field site The field comparison was carried out during snowmelt runoff at Fool Creek, a small step-pool mountain stream near Fraser in central CO. The reach-averaged gradient is 0.044 m/m, channel width is 1.3 m. The surface D_{16}, D_{50}, and D_{84} particle sizes are 12, 52, and 122 mm; 2% of the surface particles are smaller 2 mm and 11% and smaller 8 mm. The channel has a plane-bed morphology with low steps at the site, but turns to step-pool morphology about 10 m upstream. In the step-pool reach, the stream has carved a tortuous path around numerous large woody debris (LWD) pieces and created miniature forced bars. Storage and release of sediment around those semipermeable LWD dams causes highly variable transport rates.

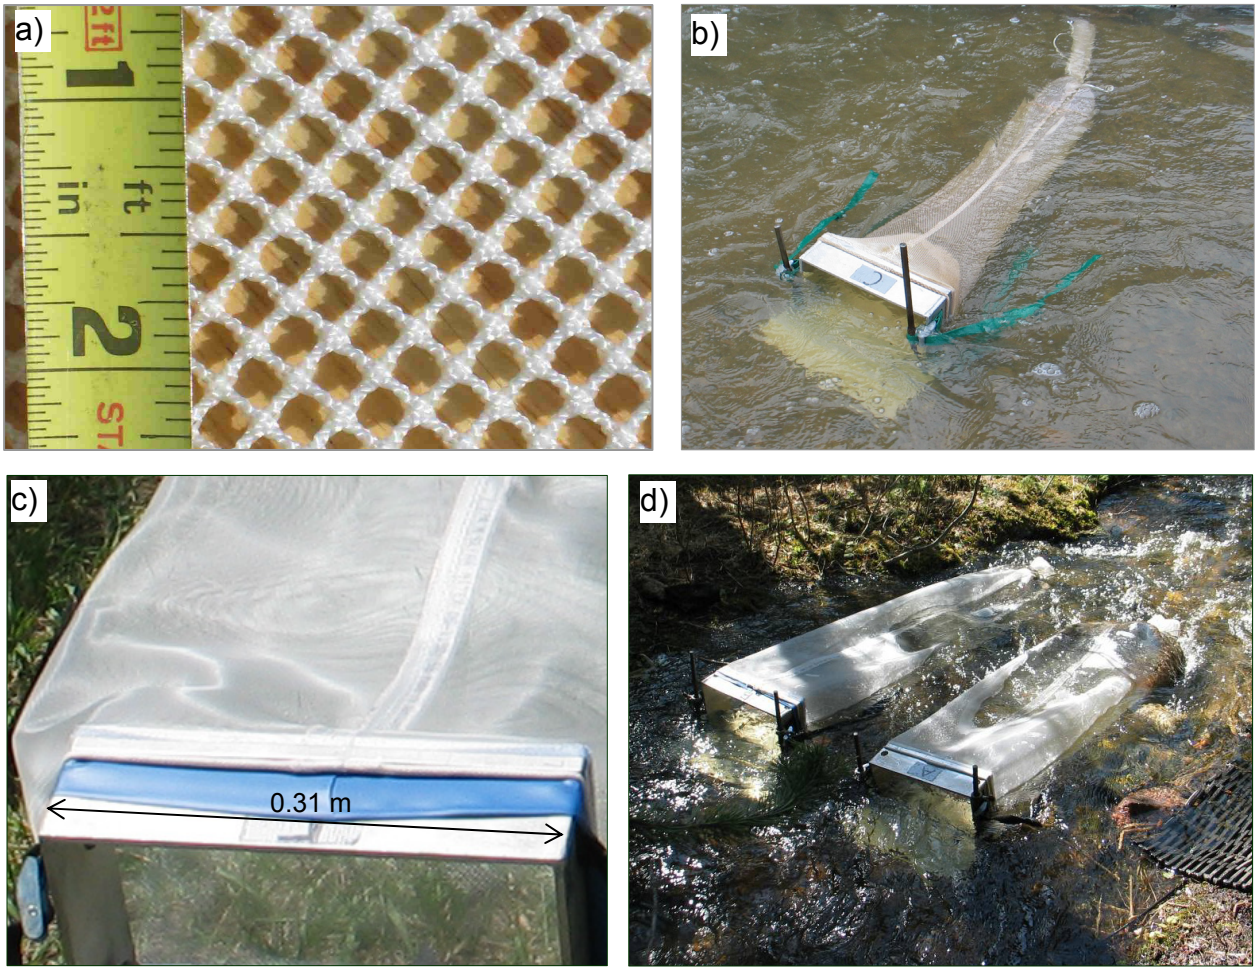

Figure 2: Detail of the 3.6 mm knitted nylon Raschel non-precision netting as the material is stretched to pull the meshes open into almost square shapes (a). The net—attached to a bedload trap—stretches to a funnel shape when subjected to flow (b). Detail of the 1.18 mm precision net woven from monofilament thread (c). The unstretchable 1.18 m nets—attached to bedload traps—retain a square mesh and cylindrical bag shape in all flows (d).

Bedload sampling Bedload traps have a 0.2 by 0.3 m frame to which a sampling net is attached. To cover the lateral variability of bedload transport, two bedload traps were installed next to each other on the channel bed, which resulted in a 0.2 m trap spacing, much tighter than the 0.8 to 1.2 m distance typically kept between neighboring bedload traps in wider streams. A set of two bedload traps with either the 3.6 mm (Figure 3a) or the 1.18 mm netting attached (Figure 3b) was alternately deployed for one-hour sampling times. When the 1.18 mm net visibly started to bulge at about 50% bankfull flow, sampling time was reduced to 30-40 minutes. Bedload samples were collected in flows of 20 to 80% of bankfull.

Data pairing To compare transport rates between the two netting materials, samples from both nets were sorted into data pairs collected no more than an hour apart. On some occasions, transport rates from two consecutive samples collected with the same net were averaged before pairing. In order to plot samples with zero transport, they were assigned a transport rate of 1E-6 g/s which is more than an order of magnitude less than the smallest sampled rate.

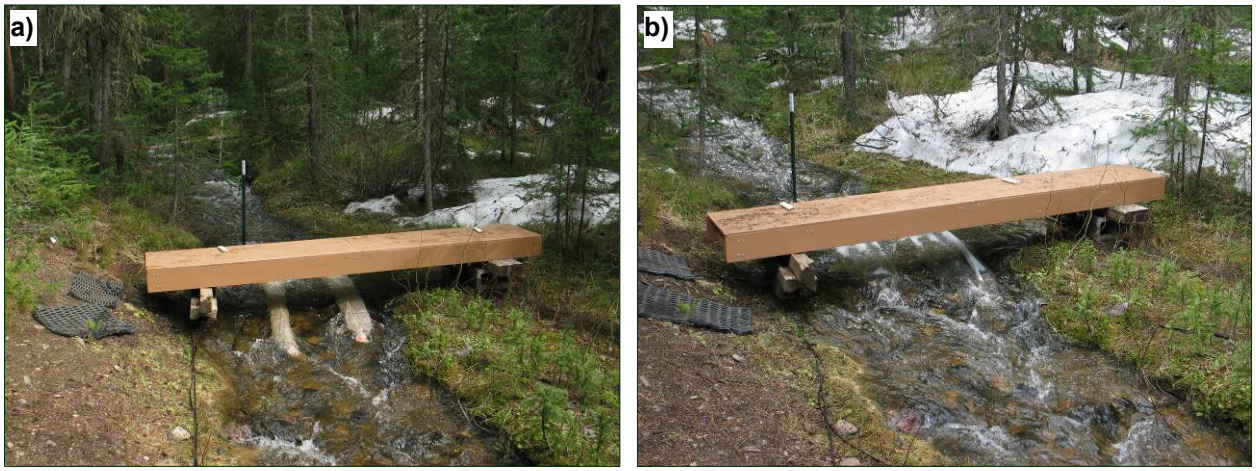

Figure 3: Fool Creek bedload sampling cross-section with footbridge and two bedload traps installed: the original 3.6 mm mesh width nets (a) and 1.18 mm precision nets (b).

Measurements of flow depth and velocity Flow depth as well as the mean vertical flow velocity at 0.6 of the flow depth was measured at distances of 0, 0.15, 0.305, and 0.61 m in front of the ground plates along the center line of the two traps with either the 3.6 mm or the 1.18 mm net attached. Flow depth was measured with a ruler and flow velocity with a Marsh-McBirney electromagnetic current meter. Depth measurements have an error of approximately 5 mm; the error in the velocity measurements was not estimated. The operator moved on a footbridge and a wooden plank placed across the stream in order not to disturb the flow. Pieces of tape on the upstream and downstream sides of the plank marked the measuring locations of 0.305 and 0.61 m in front of the traps. Flow depth and velocity were measured for three conditions: 1) at the bare ground plates with no trap installed, 2) with traps installed but empty, and 3) with traps to which 10 liters of organic material (mostly scales of conifer tree cones) had been added. The amount of organic material typically collected in Rocky Mountain streams in 1-hr bedload trap samples ranges from less than 0.1 to more than 20 l over a highflow season (Bunte et al. 2015, poster session, this volume). A 10-l volume—substantial, though not uncommon—fills about 20% of the net's volume. The measurements were repeated on two different days with flows of 0.17 and 0.20 m^3/s (57 and 67% Q_{bf}) and resulted in 48 individual measurements of flow depth and of flow velocity per net and day, a total of 192 measurements. At a discharge of 0.17 m^3/s, flow depth approached the upper rim of the sampling frame at the right trap and reached to about 75% of the frame height on the left trap. At a discharge of 0.2 m^3/s, flow started to overtop the upper rim of the right trap and reached to about 80% of the frame height on the left trap.

RESULTS AND DISCUSSION

Analysis of flow hydraulics in front of bedload traps

Effect of bedload trap presence on upstream flow hydraulics Compared to a bare ground plate, presence of a bedload trap generally caused ponding which increased the upstream flow depth and reduced the vertical mean flow velocity. The addition of organic material to the net further increased ponding, and retarded flow as shown in all plots of Figure 4. However, the degree of ponding and retardation, and the upstream extent of these effects, are determined not only by the netting properties, but also by the local flow hydraulics.

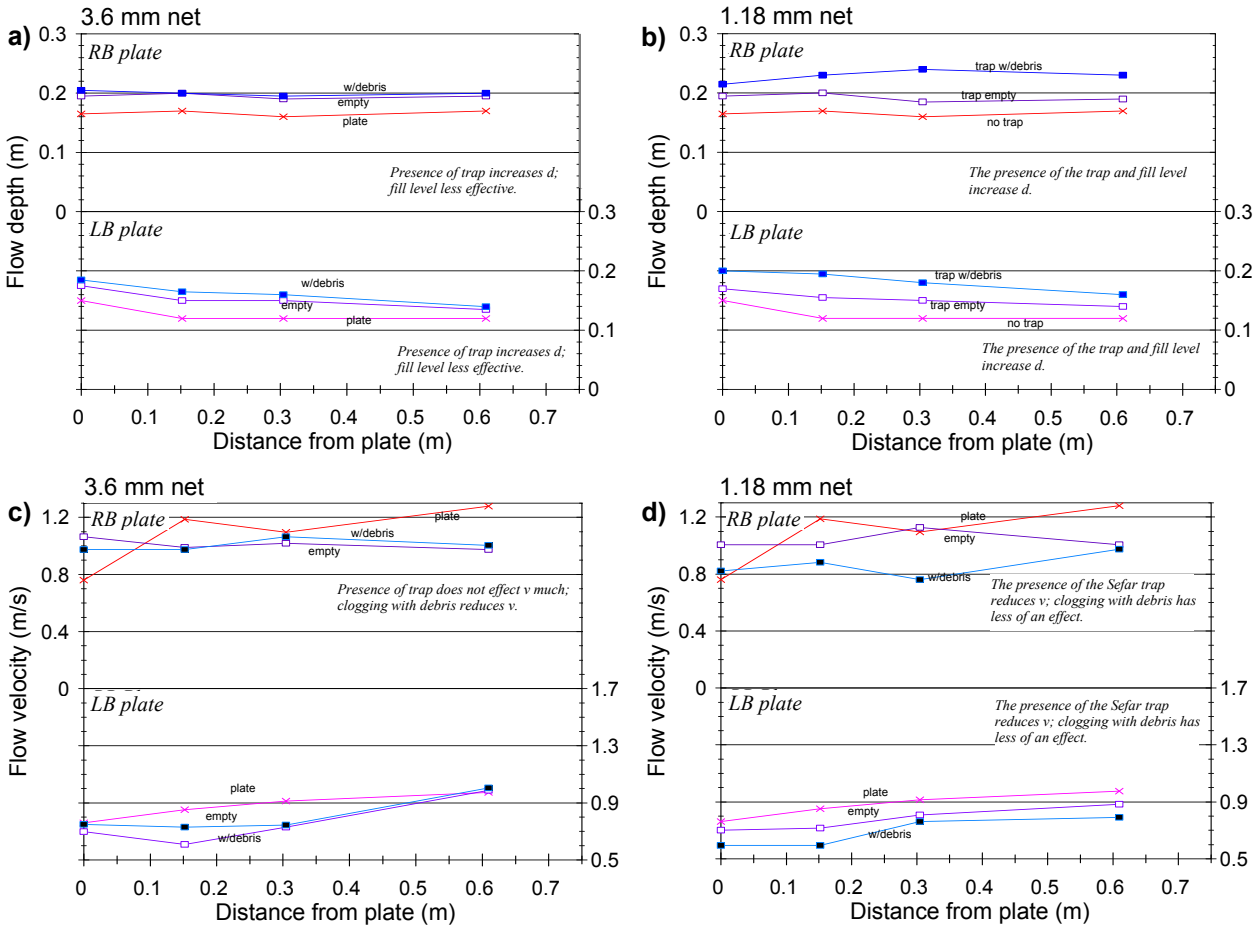

Figure 4: Flow depth (a, b) and mean flow velocity at 0.6 *h* (c, d) measured at a discharge of 0.17 m^3/s at four locations in front of the right and left bedload traps fitted with the 3.6 mm net (a, c) and the 1.18 mm net (b, d). Reddish lines refer to bare ground plates with traps removed. Purple lines refer to empty traps, and bluish lines to traps filled with 10 liters of organic debris.

For example, flow was deeper and faster at the RB plate and overtopped the RB trap, while 25% of the LB trap height protrudes through flow. There may also be hydraulic interference be-tween the two traps due to their close spacing. In order to integrate over local effects and focus on the general effects exerted by the netting properties, this study averaged the measurements of flow depth and flow velocity over all four longitudinal locations and over the left and right traps.

Average ponding and reduction in mean flow velocity For the two sampled flows of 0.17 m^3/s (Figure 4) and 0.20 m^3/s (not shown because patterns are very similar to those at 0.17 m^3/s), empty traps fitted with the original 3.6 mm net increased flow depth in front of the traps by about 18% and 20%, respectively, compared to the flow depth measured over the bare ground plates. The addition of 10 liters of organic material produced only a minor increase in flow depth for the 3.6 mm net (Table 2). Compared to flow depth on the bare plates, bedload traps with organics raised flow depth by 23%. Traps with empty 1.18 mm nets increased flow depth similarly by 18% for the lower flow and to slightly more (22%) at the higher flow. In contrast to the 3.6 mm traps, the 10 liter of organics added to the 1.18 mm nets increased flow depth by an additional 19 and 15% such that compared to the bare plates, traps with organics increased flow depth by 40%.

The response of retardation of flow velocity is similar to that of ponding (Table 2). Again, compared to the bare ground plate, an empty trap with a 3.6 mm mesh reduced the mean flow velocity by 10 and 13% at the two flows, and adding the organic material retarded the flow just slightly more. Empty traps with 1.18 mm nets reduced mean flow velocity a few percent less than empty 3.6 mm nets (about 7 and 10%), possibly due to the slightly higher open area of the 1.18 mm net (59%) compared to the 3.6 mm nets (56%). However, the added organic material reduced flow velocity in the 1.18 mm nets by another 15% in both flows, while the effect of organic material in the 3.6 mm nets was again minor.

Table 2: Average effect of empty and filled bedload traps fitted with the original 3.6 mm and the 1.18 mm nets on upstream flow depth and mean flow velocity at two discharges Q.

	Empty trap *vs*. no trap		Added 10 l of org. mat. *vs*. empty trap		Trap with 10 l of org. material vs. no trap	
	Q = 0.17 m^3/s	Q = 0.2 m^3/s	Q =0.17 m^3/s	Q = 0.2 m^3/s	Q = 0.17 m^3/s	Q = 0.2 m^3/s
Percent increase in flow depth						
Orig. 3.6 mm nets	18.3	20.7	4.3	1.6	23.4	22.7
1.18 mm nets	17.9	22.4	19.1	14.8	40.4	40.6
Percent decrease in flow velocity						
Orig. 3.6 mm nets	- 9.5	- 12.9	2.4	- 3.2	-7.4	-15.7
1.18 mm nets	- 7.4	- 10.3	- 14.7	- 15.0	-21.0	-23.7

The pronounced effect of captured organic material on flow ponding and retardation in the 1.18 mm precision nets is caused by the stiffness of the net material which makes the net retain its cylindrical shape at all flows. Organic material that enters the net accumulates along the upper back part of the bag, where most of the water would otherwise exit, and obstructs water through-flow (Figure 5a, c). A similar response was observed at a 0.5 mm precision net that bulged and ponded flow within minutes of deployment in low to moderate flow (Bunte and Swingle 2003), suggesting that fine-meshed, stiff precision nets should not be used when organic material is in motion. The original 3.6 mm bedload trap net, by contrast, stretches to a funnel shape, and most of the flow exits the net just shortly behind the trap frame (Figure 5b). Organic material and bedload is directed to travel along the bottom of the net, and both accumulate in the narrow net end (Figure 5d) where solids do not have much effect on flow hydraulics near the trap entrance.

Comparison of fractional transport rates At the lowest transporting flows when small gravel particles were just starting to move, the non-precision 3.6 mm net collected either no particles or lower rates of the 4 - 5.6 mm size class than the 1.18 mm net (Figure 6a). The nominal 3.6 mm mesh size probably lets flat particles of the 4-5.6 mm size class pass when meshes still have a parallelogram shape before they are fully stretched by flow. Adding to the particle escape is the fact that the first 4 – 5.6 mm bedload particles in motion also tend to be the flatter and less voluminous specimens of the size class. At higher flows when meshes are fully stretched and almost square, the 3.6 mm net is believed to capture particles of the 4-5.6 mm size class representatively.

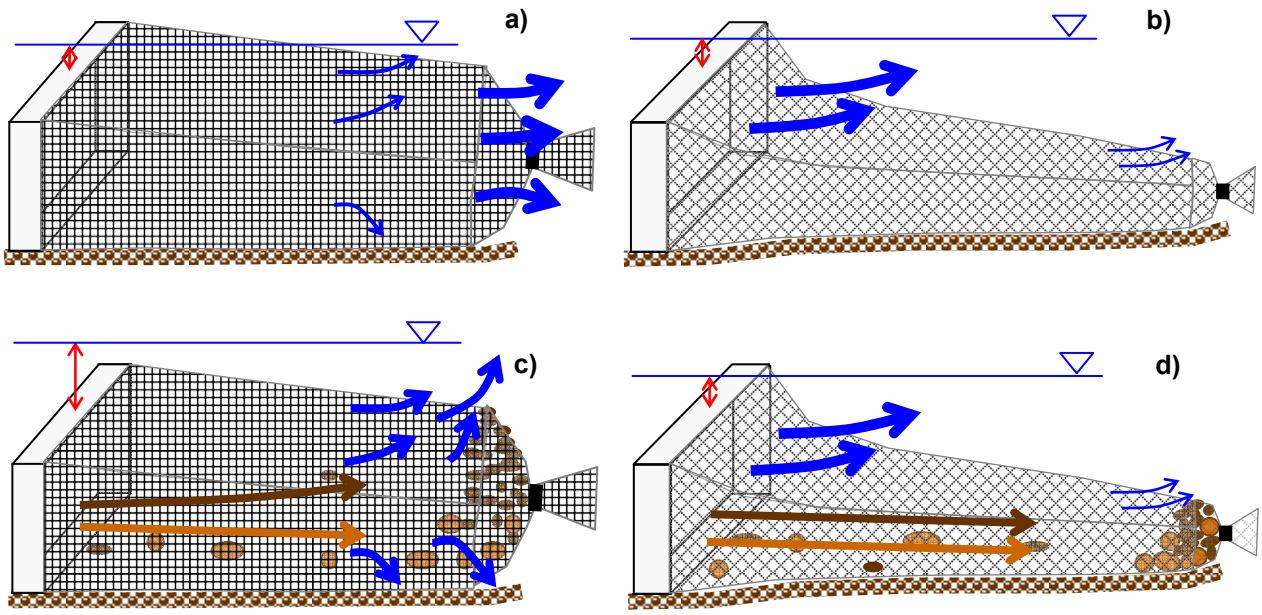

Figure 5: Sketches of flow and solid transport through the 1.18 mm precision net (a) and through the stretchable 3.6 mm Rachel (b) in the absence of organic material. Organic material added to the nets accumulated in the net end and blocked the exit of flow in the stiff 1.18 mm net (c) but not in the flexible, funnel-shaped 3.6 mm net (d). Blue arrows indicate water through-flow, dark brown arrows indicate the path of organic material, beige arrows indicates the bedload path.

At low transport, the 3.6 mm net often contained no 5.6 - 8 mm particles (Figure 6b), while the 1.18 nets had captured one or several. Similar observations held for the 8 - 11.2 (Figure 6c) and the 11.2 - 16 mm size class (Figure 6d). As suggested by the measured flow velocity, the 1.18 mm net with a 59% open area retarded throughflow less at very low flows than the 3.6 mm net with a slightly lower open area of 56%. Thus, absent high organic concentrations, the 1.18 mm net performed better at lower flows. At moderate transport rates, both nets collected all size bed-load fractions at similar rates, i.e., within a factor of about ±4 of each other, given Fool Creek's fluctuating transport. At the highest sampled transport rates, the 3.6 mm net tended to collect higher transport rates than the 1.18 mm net in all size fractions.

Ratios of transport rates collected with the two nets

Ratios of transport rates collected in the 3.6 mm vs. the 1.18 mm net for fractional and total bed-load transport (excluding zero samples) plotted vs. discharge (Figure 7a) show that the 1.18 mm net yields higher transport rates than the 3.6 mm net at the lowest flows, which is expected because the 1.18 mm net has a slightly higher percent open area and retards flow slightly less than the 3.6 mm net (Table 2). As discharge exceeds about 0.21 m^3/s (70% of bankfull flow), the 3.6 mm net started collecting higher rates than the 1.18 mm net for all particle size classes. The switch is attributed to the capture of organic material typically transported in Rocky Mountain streams during snowmelt runoff, and with increasing flow those organics comprise increasingly larger proportions of the solid transport (Bunte et al. 2015, this volume). Captured organic material accumulates in the bag ends where it blocks flow from exiting the 1.18 mm nets. As a consequence, the 1.18 mm nets start to bulge at their downstream ends (Figure 7b), pond, and retard flow at the net entrance, and decrease sampling efficiency.

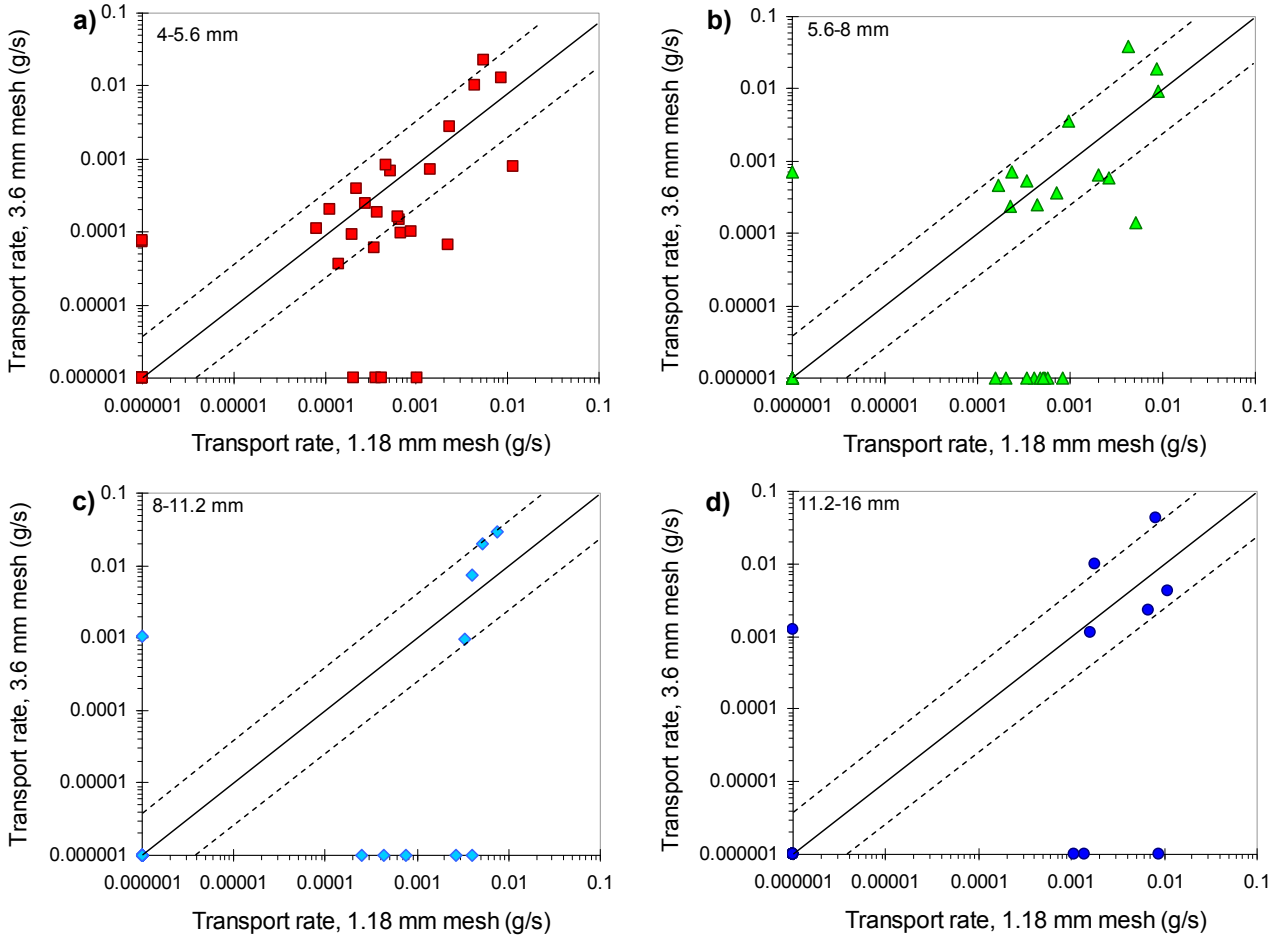

Figure 6: Pair-wise comparison of fractional transport rates collected with the two bedload trap nets. Samples that do not contain a particle were assigned the transport rate of 0.000001 g/s and plotted along the x- and y-axes. The solid diagonal line is the 1:1 line. Stippled lines indicate a factor 4 range above and below the 1:1 line.

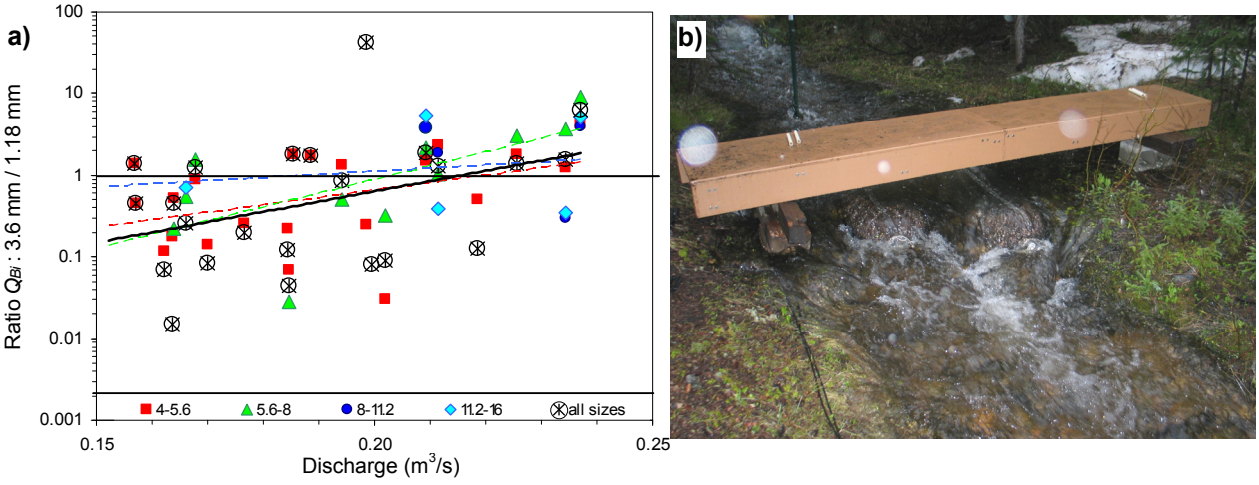

Figure 7: Ratios of transport rates collected in the 3.6 mm vs. the 1.18 mm net for fractional and total bedload transport (a). The 1.18 mm precision nets bulge when the start capturing organic material and pond water upstream (b).

SUMMARY AND CONCLUSION

- The study shows interactions between different netting properties and how they affect flow ponding and retardation, throughflow, and sampled transport rates.

- Hydraulic and sampling efficiency differs between nets of different mesh width even though both netting materials have percent open areas that are not very different.

- Netting stiffness affects hydraulic and sampling efficiency. Stiff nets that retain a near-cylindrical bag shape at all flows are prone to throughflow blockage by organic material, and respond with bulging, ponding, and retardation of flow, as well as with a reduction in sampled transport rates. Flexible nets segregate the paths of water throughflow and solid transport in the net such that solids accumulate where they have much less effect on hydraulic and sampling efficiency.

- At low flows, the 1.18 mm net measured higher transport rates of fine gravel particles with fewer zero samples than the 3.6 mm net. Both nets approach similar transport rates in moderately high flows (70% of bankfull), but in higher flows, the 3.6 mm yields higher rates than the 1.18 mm net. This switch in sampling efficiency between the two nets has implications on sampled gravel transport relations which increase more steeply with flow (i.e. the bedload rating curve slope) if the 3.6 mm net is used rather than the 1.18 mm net.

- The study showed that responses of hydraulic and sampling efficiency to netting properties are complex. Hydraulic efficiency is a response to the combined effects of the percent open area of the mesh, increasing flow, the shape taken by the net in flowing water, and net clogging and blockage which typically intensify with higher flow, higher transport rates of organic material, and longer sampling time.

Acknowledgements We are grateful to Rico Thueler, the executive vice president of the Sefar company who sent us free of charge 10 yards of the Sefar netting material (06-1180/59) when the desired netting (06-1140/66) was not available. We thank Mark Dixon, Lucas Herman, Laurie Porth, Sandra Ryan and Kelly Elder (USDA Forest Service, Rocky Mountain Research Station) for project support. Field experience by Gustavo Merten (Univ. of Minnesota) who successfully used bedload traps with a mosquito net attached initiated this study and encouraged us to analyze the effects of a net with a 1 to 2 mm mesh width for sampling coarse sand and pea gravel. We are grateful to John Potyondy (USFS ret.) and the USFS Stream Team who provided us with the opportunity for further field testing of bedload traps.

Abstract: Sediment is one of the most significant pollutants to lakes and streams in Minnesota. Various measures have been used to represent sediment as an impairment of water quality. The Minnesota Pollution Control Agency and its partners have completed many Total Maximum Daily Loads for turbidity given the numeric criteria for turbidity in Minnesota's water quality standards (WQS). Much effort was expended in dealing with the variability in the measurement of turbidity and the development of total suspended solids (TSS) surrogates for the turbidity standards. The MPCA has recently adopted regional TSS water quality standards to replace the turbidity water quality standards to lessen the uncertainty present in the measurement of turbidity. TSS criteria were developed given the extensive dataset present for TSS even though we know that TSS is an incomplete measure of sediment in streams and rivers. A partnership with United States Geological Survey (USGS) has given Minnesota resource agencies the opportunity to evaluate the relationships between TSS and suspended sediment concentrations as well as to explore the use of surrogate technologies for SSC, conduct bedload monitoring, and evaluate dimensionless sediment rating curves in stream geomorphology assessments. While these evaluations have provided a more robust approach, on-going efforts will be required to fully characterize sediment in Minnesota's rivers and streams.

INTRODUCTION

Various parameters have been used to describe sediment suspended in water. The MPCA has traditionally used total suspended solids as a measure of the sediment suspended in water. It has also used turbidity and Secchi tube depths as measures of sediment in water. The USGS typically uses SSC as their measure of suspended sediment. The following text describes how the four parameters are being used in Minnesota.

TURBIDITY

Minnesota was one of only a few states that adopted numeric criteria for turbidity in its water quality standards. The turbidity WQS for warm and cold water streams were 25 and 10 NTU, respectively. The basis for the numeric criteria is not clear based on a review of the primary documents used in the development of early state water quality standards (Appendix B, MPCA,

2007). The lack of clarity in the development of the standard along with changes in the technology used to measure turbidity over time and variable responses of material in water to light passage made for many uncertainties in the application of the turbidity water quality standard (WQS) in assessing streams for impairment and completing TMDLs.

Sadar (1998) describes the development of turbidity measurement technologies with their similarities and differences. For a period of time around the development of the WQ criteria guidelines, various turbidity units, including JTU, ppm, NTU and even 'turbidity units' or no units, were used in the literature. Federal Water Pollution Control Administration (1968) and U.S. Environmental Protection Agency (1976) contained references to many of these units. The resulting documentation for Minnesota's numeric criteria for turbidity was silent on the method and units used in establishing the criteria.

As MPCA staff began evaluating data for TMDLs, differences in the data became evident. An initial comparison of turbidity measurements grew out of overlapping temporal data sets obtained from Hach 2100A and Hach 2100P meters in two monitoring programs at sites near Lock and Dam #3 on the Mississippi River. Definite differences in the data were apparent over similar monitoring periods (Figure 1) even though the sampling was not completed on the same days. A second comparison of turbidity data came from turbidity measurements made by two laboratories on split samples for a river remote sensing project in 2004. Samples were collected at several sites spread across the southern half of Minnesota. A plot of the data (Figure 2) shows the difference between NTU and NTRU values as measured by Hach 2100A and Hach 2100AN meters, respectively. Based on a regression analysis of the data, a surrogate value for the water quality standard for turbidity of 25 NTU was estimated to be 39 NTRU. The variability in turbidity data lead to extended discussions about the appropriate measure of turbidity to apply to the numeric criteria, differences in turbidity data resulting from the use of different meters, and differences in the relationships of turbidity and suspended solids across Minnesota.

TOTAL SUSPENDED SOLIDS

As the state water quality agency, the MPCA has traditionally used total suspended solids as its measure of sediment suspended in water. The development of this use is likely the result of the focus of the USEPA and state water quality agencies on point source pollution and wastewater treatment. Gray et al. (2000) presents information from various editions of standard laboratory methods published by the American Public Health Association, American Water Works Association, and Water Pollution Control Federation (1946, 1971, 1976, and 1985) that describes the application of TSS through the years with the transition to its application to natural waters in the 1976 edition.

TSS is a water quality parameter that is widely used as a measure of the suspended particles in rivers. It is often used as a measure of the amount of inorganic sediment suspended in water, although it also includes the organic suspended material present in water. As a measure of suspended sediment, TSS concentrations provide an indication of water quality condition for use in evaluating aquatic life use support. The TSS methods in Minnesota most often involve a simple grab sample from the stream, followed by lab analysis where a subsample is used to determine a concentration.

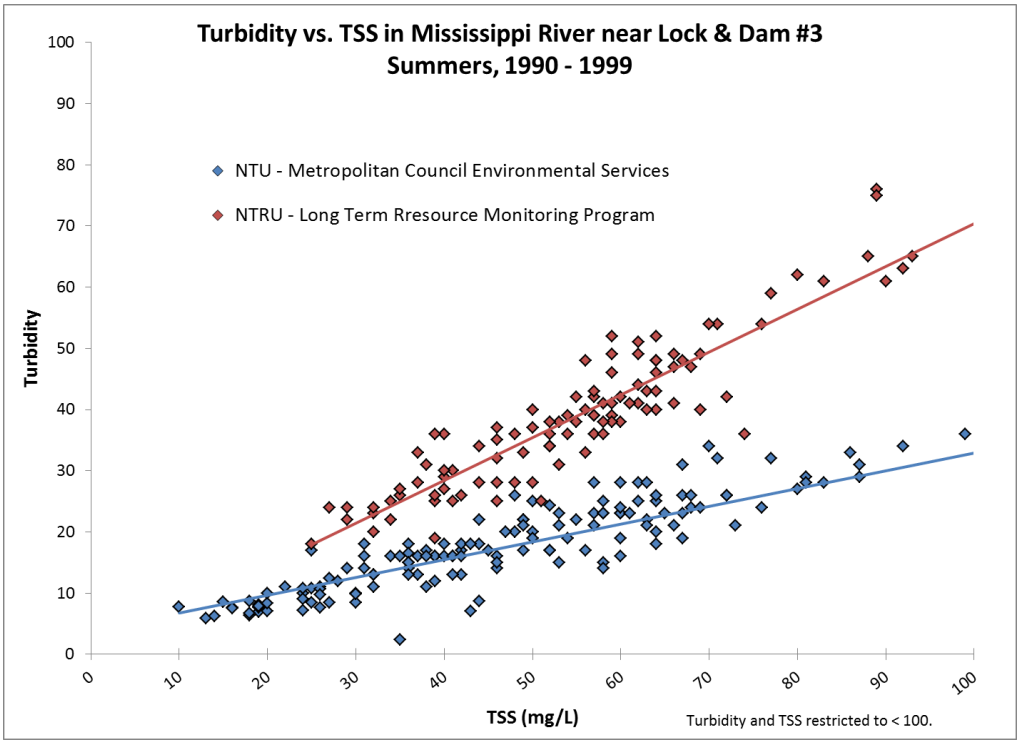

Figure 1 Comparison of turbidity data from different meters versus TSS concentrations.

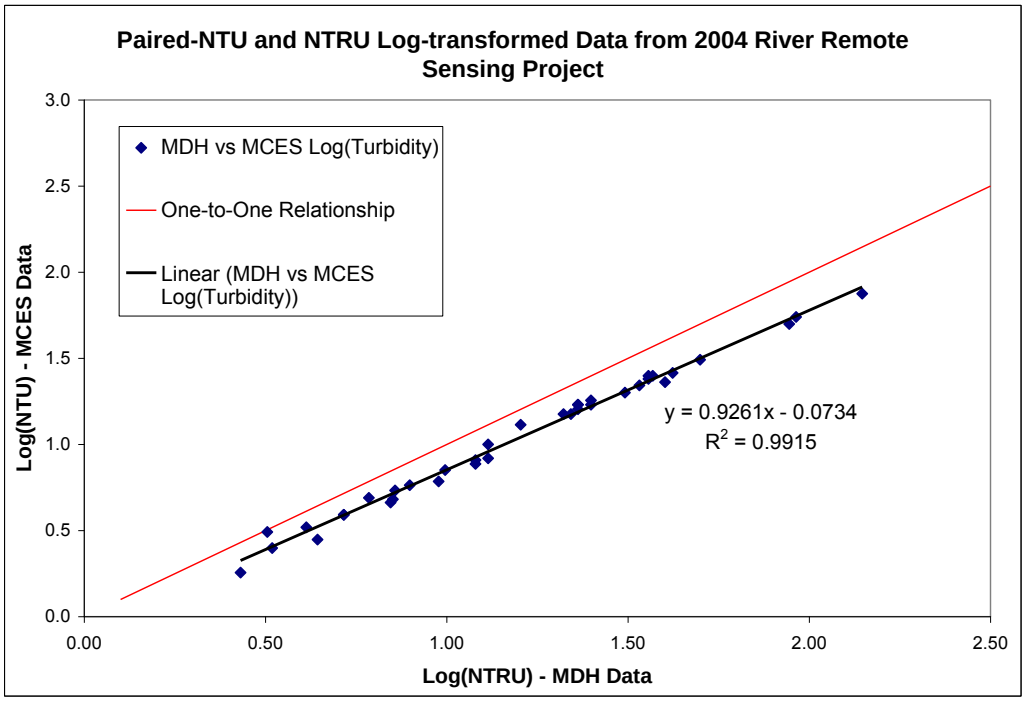

Figure 2 Relationship between paired turbidity data from different meters.

The use of TSS relative to water quality standards and TMDLs in Minnesota developed with the need to complete TMDLs for the turbidity WQS. Given that turbidity is not a measure of mass in a volume of water (concentration), a concentration surrogate had to be established in order to calculate loads for TMDLs. The use of TSS as the state's measure of particulates suspended in water and the correlation of TSS to turbidity lead to the primary use of TSS in turbidity TMDLs (MPCA 2007). The TMDL protocol (MPCA 2007) provided guidance for the development of the surrogate concentrations using simple linear regression. It noted that individual relationships should be developed for each impaired stream reach unless data analysis demonstrated that a whole stream, watershed, or region provided an equivalent result.

As the recognition of the variability in turbidity measurements and the factors causing that variability grew, the MPCA began evaluating the potential for replacing the turbidity WQS. Using two data analysis efforts, the MPCA developed proposed amendments to Minnesota water quality standards (Minn. Rule 7050) that included regional and time components for TSS (MPCA 2014). Relationships between fish and macroinvertebrate data and TSS concentrations were evaluated using quantile regression and changepoint analysis. The statistical methods are relatively new tools being used to identify threshold concentrations and establish numeric criteria to protect aquatic life. The second analysis effort involved the development of TSS frequency curves for "reference" or "least-impacted" streams in the state (Markus 2011).

Proposed TSS criteria were developed for three regions of the state for warm water aquatic life use based on a combination of major watershed and aquatic ecoregions and statewide for cold water aquatic life use. The criteria also provide temporal considerations of elevated TSS concentrations during snowmelt and storm events by indicating that the standards are not to be exceeded more than 10 percent of the water samples collected in the period, April through September. In addition, site specific water quality standards were developed for the mainstems of the Red and lower Mississippi Rivers. The statement of need and reasonableness (SONAR) required in Minnesota's rulemaking process noted that the TSS criteria would provide a transition from a statewide turbidity standard to regional standards, better connection of the water quality variable to biotic response, and more direct TMDL load calculations (MPCA 2014a). The TSS criteria were adopted following the state's rulemaking process in June 2014; however, final review and approval by EPA is still pending as of mid-January 2015.

The MPCA established the Watershed Pollutant Load Monitoring Network (WPLMN) to provide a long-term network of monitoring sites across the state to obtain spatial and temporal pollutant load information from Minnesota's rivers and streams. The WPLMN uses TSS as its measure of the sediment suspended in water. Annual and average pollutant loads, yields, and flow weighted mean concentrations are computed for each site using FLUX32 software (MPCA 2014b). Figure 3 shows the flow weighted mean concentrations for TSS for the major watershed sites in Minnesota from 2007 – 2011.

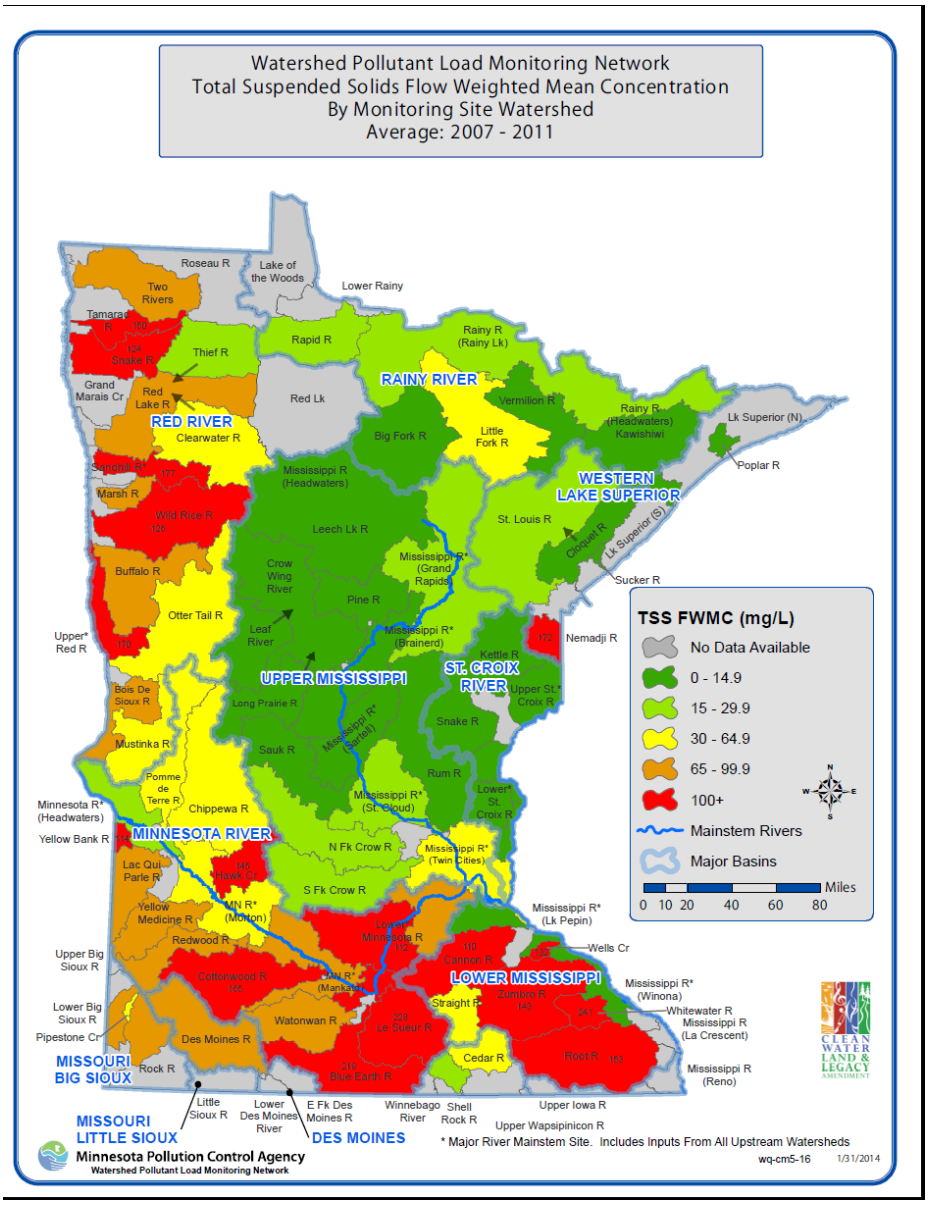

Figure 3 Flow-weighted mean concentrations of TSS by major watershed in Minnesota.

SUSPENDED SEDIMENT CONCENTRATION

Suspended sediment has been sampled by USGS at various times and locations in Minnesota. The first SSC data in Minnesota dates back to the late 1800s. Suspended-sediment concentration (SSC) samples were collected at several sites in the 1970s and 1980s as part of a focus on developing a national dataset for use in evaluating suspended sediment. Tornes (1986) compiled and analyzed the suspended sediment data in Minnesota from 1960 to 1981. SSC sampling decreased in Minnesota after the 1980s paralleling decreases at a national level. With a few exceptions, SSC monitoring was reduced to a single daily sediment station on the Minnesota River at Mankato.

A cooperative effort between the MPCA and USGS renewed a SSC monitoring effort in 2007. The monitoring network was designed to improve the understanding of fluvial sediment transport relations through systematic sampling of SSC, TSS, and turbidity in selected Minnesota rivers. SSC monitoring was deemed important given that TSS concentrations have often been found to be significantly different from corresponding SSC (Gray et al. 2000). With these differences and the great influence of sediment on water quality impairments, MPCA staff believed that it was important to characterize differences between TSS and SSC in identifying the sediment processes affecting aquatic life.

The establishment of the sediment monitoring network provided the opportunity to continue the state's progress in addressing sediment-related impairments. Although the MPCA has moved toward establishing a water quality standard for TSS, a more complete understanding of the whole amount of sediment moving in streams and rivers is needed. The results of the current study through 2011 showed that the average TSS concentration was significantly different from the corresponding SSC for each of the seven rivers sampled (Figure 4). The overall average for the seven sites combined indicated a 50 percent difference in concentration (Ellison et al. 2014). Characterization of the differences between TSS and SSC is needed to provide estimates of the total suspended sediment being transported in Minnesota's rivers in addition to the total suspended solids load provided through the use of TSS in the MPCA's statewide load monitoring program. The data and relationships established will allow better calibration of the sediment component of the HSPF watershed models being completed for each 8-digit HUC watershed in Minnesota, improved identification and characterization of the sediment stressors affecting fish and macroinvertebrates in the MPCA's stressor identification process, the incorporation of the unmeasured sediment component in TSS in sediment transport studies, and identification of best management practices needed to control excess sediment. SSC and bedload data have also been collected in a related project to evaluate the use of dimensionless sediment rating curves in stream geomorphology assessments.

The current monitoring effort has transitioned from evaluating the differences between TSS and SSC to developing hydroacoustic techniques for continuous SSC following the work of USGS and others. The use of hydroacoutics as a surrogate for SSC present an opportunity to provide sediment data that is more accurate and less costly than traditional sampling and analysis techniques (Landers 2010). The study will work to incorporate the latest developments by USGS and others in the work to develop standard procedures for the use of hydroacoustic technology.

SECCHI TUBE

Secchi tube measurements through Minnesota's volunteer stream monitoring program provide a fourth measure of sediment in water. It is an indirect measure of the amount of dissolved and suspended material in water. The Secchi tube forms the foundation of the MPCA Citizen Stream-Monitoring Program (CSMP). The CSMP is part of the volunteer water-monitoring program in Minnesota. The CSMP began in 1998 with the goal to provide individuals an opportunity to get involved in a simple, yet meaningful stream monitoring program. The Secchi tube is a modified transparency tube that is designed to function like a traditional Secchi disk used in lake monitoring (MPCA 2011). 358 CSMP volunteers monitored almost 500 sites in 2013. The transparency data are entered into the MPCA's water quality database and is used in conjunction

with turbidity and TSS data in assessing the water quality condition of Minnesota's streams (MPCA 2013).

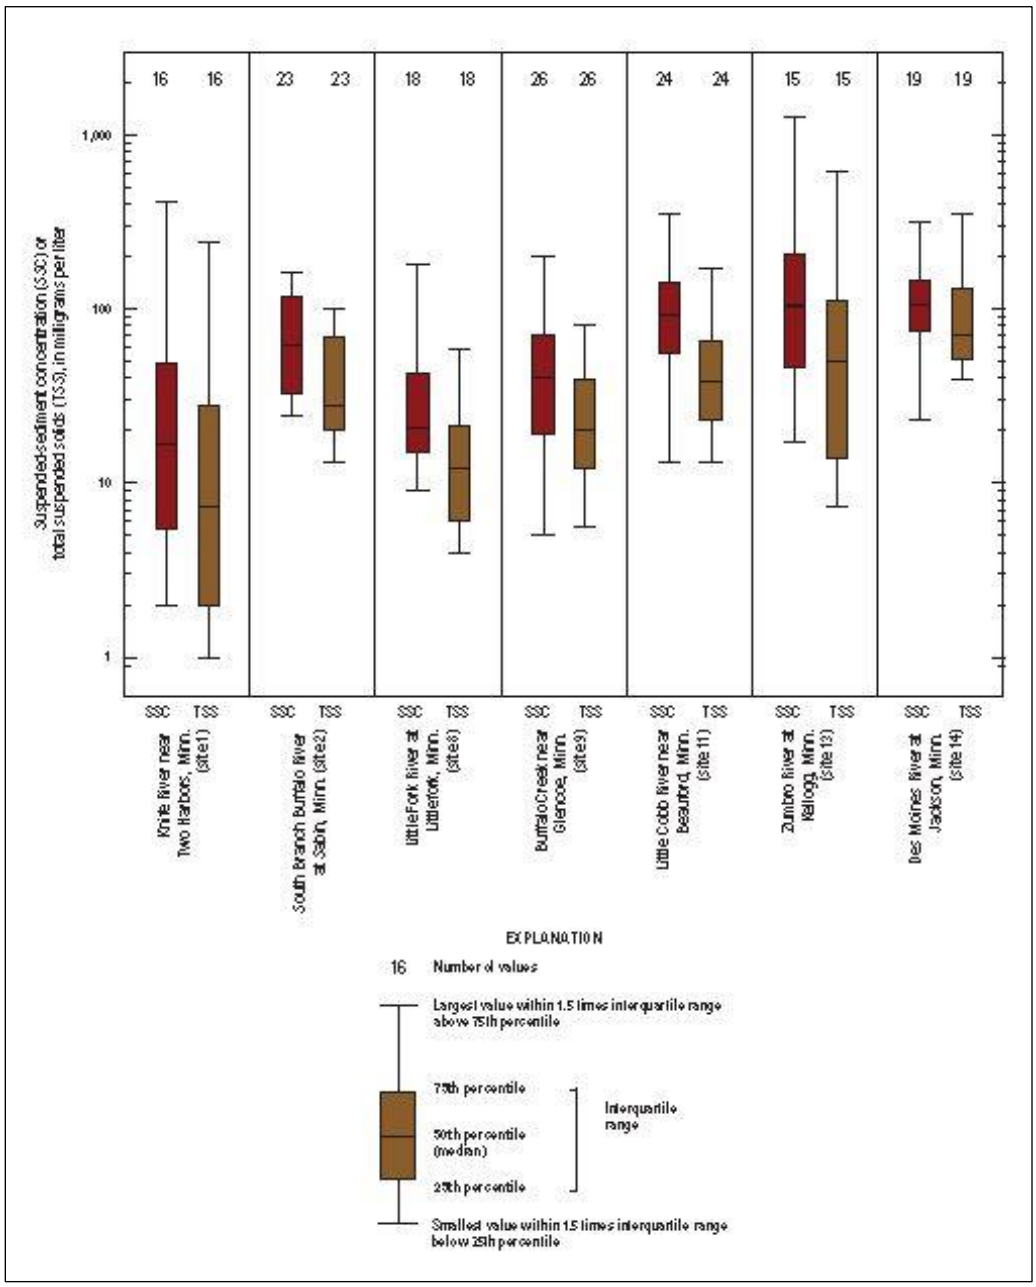

Figure 4 Suspended-sediment concentrations and total suspended solids for selected sites in Minnesota, 2007 through 2011 (from Ellison et al. 2014).

DATA APPLICATIONS

Various measures of sediment have been used in Minnesota. The use of each has its own positive and negative aspects. The use of turbidity will switch from being a numeric water quality standard to more of a surrogate for sediment issues. TSS will provide an improvement to

Minnesota's water quality standards by providing a parameter with units of concentration and mass, incorporating an explicit exceedance interval, and shifting to a direct measure of sediment. Watershed models are being developed for each major watershed in Minnesota using the Hydrological Simulation Program – FORTRAN (HSPF) computer model. The models will simulate the surface hydrology and water quality of Minnesota's 81 major watersheds. Calibration of the model requires the use of available water quality data. The model calibration for sediment relies primarily on TSS data. HSPF predicts sediment output as concentrations of clay, silt, and sand. Calibration requires that assumptions be made regarding the particle sizes of the sediment in the water and that sampled by TSS.

Sediment budgets provide an accounting method for sediment entering, leaving, and stored in a landscape unit, accounting for the sediment sources and disposition (Phillips, 1986; Reid and Dunne, 1996). Sediment budgets have been developed using various types and amounts of data. Early sediment budgets were completed by Beach (1994) and NRCS (1994, 1996, and 1997). Barr Engineering Company (2004) completed a project for the MPCA evaluating the sediment data available for the Lower Mississippi River Basin in Minnesota. Wilcock (2010) describes the most recent sediment budget work done to identify and quantify the sources of fine sediment in the Minnesota River Basin. An integrated sediment budget for the Le Sueur River Basin was completed as part of this work (Gran et al. 2011). A similar project for the Greater Blue Earth River Basin is scheduled for completion in 2015. With the exception of limited SSC and bedload data, the sediment budgets have had to rely on TSS data.

The addition of SSC and bedload monitoring through the cooperative agreement with USGS provides the opportunity to provide a more direct calibration of the watershed models, complete more comprehensive sediment budgets, and identify specific stressors affecting aquatic life. The best approach, which to date has not been fully implemented, would be to utilize a sediment budget approach incorporating improved monitoring techniques for suspended and bedload materials and to concurrently assess both stream geomorphology and the biotic community. Such an effort cannot be done for every watershed in the State, but it would be beneficial to have it in selected watersheds. Knowledge about the sand-sized particles along with the fines in suspended sediment is especially important in making connections between impaired aquatic life, habitat, and sediment sources and transport processes.

ONLINE MODELING TOOLS ASSIST IN EVALUATING POSTFIRE FLOODING AND EROSION RISK

Peter Robichaud, Research Engineer, USDA Forest Service, Rocky Mountain Research Station, Moscow, Idaho, probichaud@fs.fed.us; William Elliot, Research Engineer, USDA Forest Service, Rocky Mountain Research Station, Moscow, Idaho, welliot@fs.fed.us; Erin Brooks, Assistant Professor, University of Idaho, Moscow, Idaho, ebrooks@uidaho.edu; Marianna Dobre, Post-doctoral Fellow, University of Idaho, Moscow, Idaho, mdobre@uidaho.edu; Dennis Flanagan, Research Agricultural Engineer, USDA Agricultural Research Service, National Soil Erosion Laboratory, West Lafayette, Indiana, Dennis.Flanagan@ars.usda.gov; James Frankenburger, Information Technology Specialist, USDA Agricultural Research Service, National Soil Erosion Laboratory, West Lafayette, Indiana, James.Frankenburger@ars.usda.gov

Abstract: Postfire assessment teams need erosion modeling tools to quickly assess the risks of elevated runoff and sediment delivery to infrastructure and water resources. Major advancements in our knowledge of postfire assessments, risk analysis and erosion control treatment effectiveness have improved our ability to understand the consequences and outcomes that occur in the postfire environment. Disturbed areas often increase overland flow connectivity degrading water quality and water resource. We have developed accessible and easy-to-use Water Erosion Prediction Project (WEPP) based online models to help forest land managers predict postfire runoff, soil erosion and sediment delivery from disturbed forests and rangelands. These models, the Erosion Risk Management Tool (ERMiT), Disturbed WEPP and the Peak Flow Calculator allow users to vary climate, soil texture, local topography, vegetation, and surface cover (burn severity, management activities, etc.). ERMiT is more appropriately used by land managers to predict the probability of postfire sediment delivery for a given storm for hillslopes left untreated and hillslopes treated mulch, seeding, or erosion barriers. The latter model aids in decisions of where, when, and how to apply postfire mitigation treatments. Disturbed WEPP predicts annual runoff and sediment yields from young and old forests, following wildfire, grazing, and timber harvest disturbances. These tools are also available as ERMiT Batch and Disturbed WEPP Batch allowing users to vary input parameters and efficiently compare results in simple spreadsheet output tables. The Peak Flow Calculator allows users to quickly determine peak discharge rates for small watersheds. Online GIS-WEPP BAER Interface is the most recent addition to our suite of user-friendly model platforms. Local topographic, soils, fire effects and climatic variables are seamlessly incorporated into the WEPP Watershed model with point-and-click area selection using online mapping services. These easy to access and easy to use tools assist in making the best use of limited rehabilitation resources and assessing fire effects on soils in conjunction with local climate and watershed characteristics.

INTRODUCTION

Land management issues related to wildfires and postfire response have become more prominent as the frequency of large wildfires has increased. Resource managers are concerned with both the direct effects of the flame front and the postfire consequences. Postfire peak runoff and erosion can be orders-of-magnitude larger than prefire values due to the loss of surface cover and fire-induced changes in soil properties (Moody et al. 2013). Direct and indirect fire effects impact

larger numbers of people as source water for municipal water supplies and community developments are encompassed by areas increasingly at risk for wildfire (Miller et al. 2011).

ONLINE MODELING TOOLS

Many of our postfire erosion models (http://forest.moscowfsl.wsu.edu/fswepp/; Figure 1) were developed as part of a suite of tools (http://forest.moscowfsl.wsu.edu/BAERTOOLS/) for use by Burned Area Emergency Response (BAER) teams. The models are fully open to the public and there are no costs associated with their use allowing both public and private specialists access to the same tools. Behind the interfaces, the Water Erosion Prediction Project (WEPP) Model, a distributed physically-based hydrology and erosion model (Flanagan and Nearing 1995; Laflen et al. 1997), is the server-based "engine" that processes inputs and creates outputs based on the Forest Service WEPP interfaces.

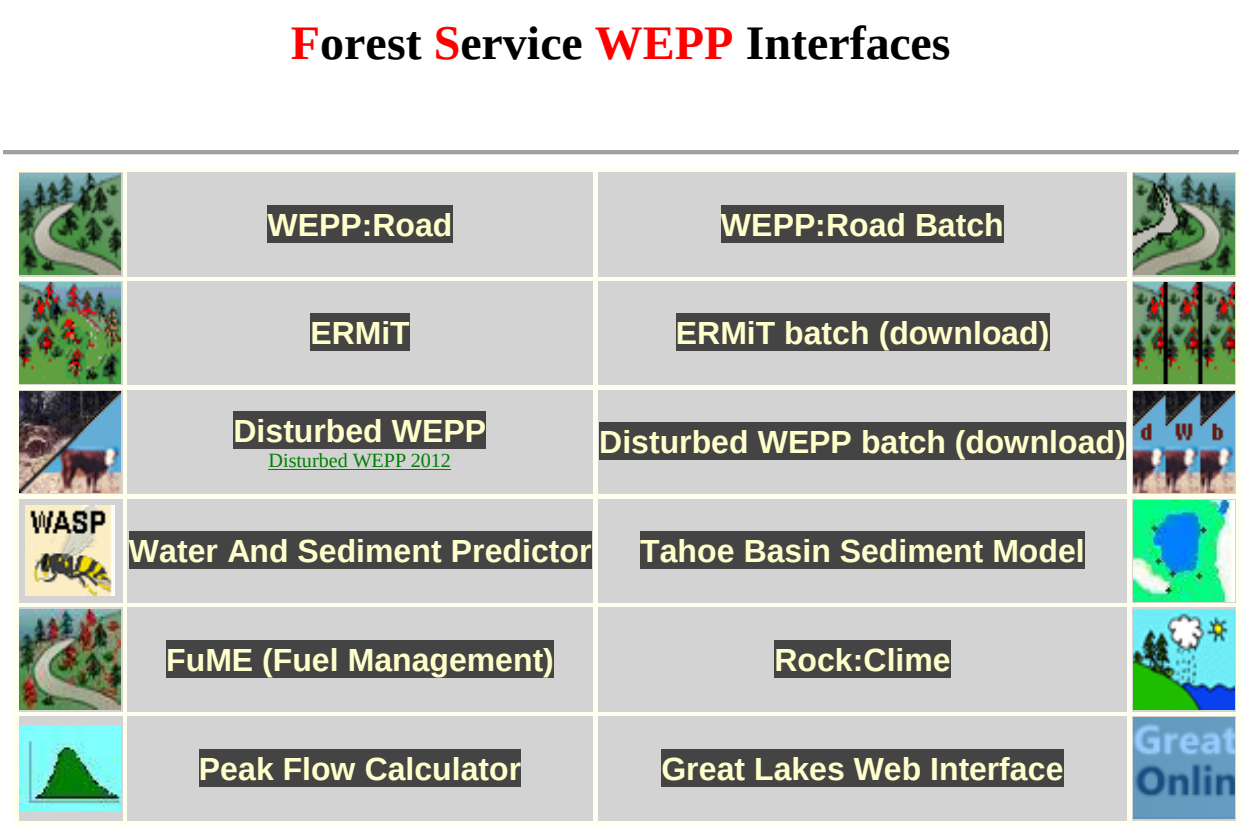

Figure 1. Online web page for accessing Forest Service WEPP models (http://forest.moscowfsl.wsu.edu/fswepp).

ERMiT: The Erosion Risk Management Tool (ERMiT) predicts the probability of a given depth of runoff and sediment yield from a single rainfall or snowmelt event on unburned, burned, and recovering forest, range, and chaparral hillslopes (Robichaud et al. 2007a; b). ERMiT provides a distribution of single event erosion rates with the likelihood of their occurrence. ERMiT also predicts the sediment yields following mulching, seeding, and installing of log erosion barriers (Figure 2).

Sediment Delivery					
Probability that sediment yield will be exceeded 35 % go	Event sediment delivery (ton ac^{-1})				
	Year following fire				
	1st year	2nd year	3rd year	4th year	5th year
Untreated	10.63	4.73	2.1	1.06	0.25
Seeding	10.63	2.87	1.82	1	0.25
Mulch (0.5 ton ac^{-1})	2.97	2.22	2.1	1.06	0.25
Mulch (1 ton ac^{-1})	2.06	1.83	2.1	1.06	0.25
Mulch (1.5 ton ac^{-1})	2.02	1.75	2.1	1.06	0.25
Mulch (2 ton ac^{-1})	1.97	1.73	2.1	1.06	0.25
Erosion Barriers: Diameter 0.7 ft Spacing 65 ft go ?					
Logs & Wattles	7.75	4.21	1.71	0.84	0.15

Figure 2. ERMiT output screen showing various treatment effect on sediment delivery.

Disturbed WEPP: Disturbed WEPP predicts annual erosion rates for forest and rangeland hillslopes (Elliot 2013). Disturbed WEPP can simulate a variety of management scenarios, including the effects of wildfire, fuel treatments, timber harvest, and regeneration. The output includes mean annual runoff, erosion rate, sediment yield, and the probability of these occurring.

Peak Flow Calculator: Our online interface to the Natural Resource Conservation Service (USDA-NRCS) Curve Number method is used to estimate stream peak flow from small burned watersheds. The rainfall and runoff amounts predicted by ERMiT, other computer programs, or reported in the literature can be used to estimate a curve number for a selected land use condition, which in the case of fire is generally related to the soil burn severity.

ERMiT and Disturbed WEPP Batch Spreadsheet Tools: Downloadable batch spreadsheet tools for the ERMiT and Disturbed WEPP interfaces are available (http://forest.moscowfsl.wsu.edu/fswepp/batch/bERMiT.html; http://forest.moscowfsl.wsu.edu/fswepp/batch/dWb.html). The model runs are carried out on our server, but input scenarios and processing of results are done on the user's computer with spreadsheet software. These spreadsheets allow users to run ERMiT or Disturbed WEPP for multiple hillslopes simultaneously. Drop down menus and copy/paste features facilitate the process of filling out the input worksheet(s).

Online GIS-WEPP BAER: We have developed new beta-release tool that uses the open-source MapServer© online GIS in conjunction with WEPP spatial analysis procedures to allows users to conduct watershed analysis without the need to have a GIS program on their computer or the need to reformat data sets (Frankenberger et al. 2011). The interface uses Google Map images and TOPAZ analysis to define a watershed for simulation with WEPP, based on the USGS seamless DEM. The post-fire burn severity map is the primary input to define the spatial extent

of the fire which is used in conjunction with the soil layer, the vegetation layer, and DEMs (Frankenberger et al. 2011; Flanagan et al. 2013). These interfaces do not require advanced GIS skills, such as the downloading and preprocessing of topography, soils, or land cover databases.

Abstract: The Potamology Model (PotaMod) was developed for mobile-bed modeling using the Sediment Impact and Analysis Methods (SIAM) model within HEC-RAS. PotaMod allows for updating of hydraulics in response to erosion and sedimentation. The SIAM component of HEC-RAS is a sediment budget tool that compares annualized sediment reach transport capacities to supplied sediment and identifies reaches of overall sediment surplus or deficit. SIAM uses a reach-averaged approach; thus, PotaMod follows with bed-elevation and grain-size distribution adjustments on a per-reach basis in response to sediment transport. PotaMod uses SIAM sediment-transport output data for a given series of hydrologic events to update grain-size distributions and HEC-RAS cross-section elevations for each reach. Specifically, PotaMod uses the local sediment balance output of SIAM to determine depths of aggradation or degradation for each reach, and it uses the sediment balance by grain size output to determine adjustments to grain-size distributions for each reach. PotaMod was used to simulate 100 years of sediment transport in the Long Creek Watershed located in Mississippi. The watershed includes a seven-mile reach of the Long Creek and five miles of the Caney Creek tributary. Thalweg profiles and reach-based changes in bed elevation, local balance by grain size, and grain size distributions were computed for each year.

INTRODUCTION

For projects that implement modifications to reduce watershed-sediment loads, analyzing system-wide sediment process linkages is imperative to ensure there are no negative impacts in other parts of the watershed. The Sediment Impact and Analysis Methods (SIAM) model was developed to evaluate watershed- and reach-scale sediment processes through integration of watershed-scale sediment continuity concepts and stream rehabilitation and management. SIAM is a reach-based 1-D continuity model that compares annualized sediment transport capacities to supplied sediment and identifies reaches of overall sediment surplus or deficit. SIAM results can be mapped to illustrate potential imbalances in a channel network to help identify design or remediation needs. (Little and Jonas, 2010)

In 1985, the Delta Headwaters Project (DHP), formerly the Demonstration Erosion Control (DEC) Project, was initiated with the primary objective of providing channel stability and reducing delivery of sediments to downstream reservoirs, flood-control channels, and wetlands (Hudson, 1997 and Watson et. al., 1997). SIAM was originally developed as part of the DHP and is currently embedded in the Army Corps Hydrologic Engineering Center River Analysis System (HEC-RAS) as a hydraulic design function. SIAM can be used as a screening tool for

assessing multiple rehabilitation alternatives during the reconnaissance and feasibility phases of a project (Martin et al., 2010).

The Potamology Model (PotaMod) application was developed for mobile-bed modeling using the SIAM hydraulic design function in HEC-RAS. PotaMod allows for updating of hydraulics in response to erosion and sedimentation. SIAM uses a reach-averaged approach; thus, PotaMod follows with bed-elevation and grain-size distribution adjustments on a per-reach basis in response to sediment transport. PotaMod uses SIAM sediment-transport output data for a given series of hydrologic events to update grain-size distributions and HEC-RAS cross-section elevations for each reach. Specifically, PotaMod uses the *local sediment balance* output of SIAM to determine depths of aggradation or degradation for each reach, and it uses the *sediment balance by grain size* output to determine adjustments to grain-size distributions for each reach.

As a reach-based mobile-boundary model, PotaMod has a critical advantage compared to cross-section based mobile-boundary sediment-transport models. It has the capability to simulate several years of mobile-bed sediment transport in a relatively short time period. Simulation computations are significantly shorter than cross-section based models due to reach-based sediment transport calculations and adjustments. Also, bed elevation and grain-size distribution adjustments are made after simulating a full hydrograph with varying flows and flow durations. As a point of comparison, for the Long Creek model discussed near the end of this paper, the 100-year simulation with 13 reaches and 139 cross sections completed in 10.1 minutes.

PotaMod can be used to evaluate the impacts of rehabilitation and management alternatives over a long period of time with updated hydraulic conditions allowing insight into potential changes in channel stability. Along with the benefits, PotaMod has the following limitations:

- computations are based on reach-averaged properties;
- adjustments to cross-section elevations and grain size distributions are made at the reach scale;
- adjustments to cross-section elevations and grain size distributions are made after a simulated duration of the input hydrograph;
- model assumes no limitation on bed-material supply; and
- computations are steady state and one-dimensional.

MODEL INPUTS

PotaMod works with an existing HEC-RAS SIAM model. Therefore, all inputs for a HEC-RAS and SIAM project are required to use the application. Additional required inputs include:

1. Calibration data for each reach
    a. *Local Balance Calibration Criteria*
        i. *Calibration adjustment factor* – a multiplier applied to SIAM computed sediment transport.
        ii. *Max aggradation or degradation value* – a maximum value given as a rate in ft/yr.
        iii. *Negligible aggradation or degradation value* – given in units of ft.

b. *Representative flow depths*– used for computing adjustments to grain-size distributions. Three options are provided: reach-averaged hydraulic depth, reach-averaged maximum cross-sectional flow depth, and a user-defined depth. All depths are given in ft.
c. *Minimum wash load criteria* – user can choose a criterion from a list of grain-size categories or user may choose to have no minimum wash load criterion.

2. Number of iterations to perform – program uses the duration curve provided in the SIAM input to determine simulation period.

MODEL CALCULATIONS

Once a simulation is initiated, PotaMod executes HEC-RAS and then SIAM. Subsequently, PotaMod uses the *local sediment balance* and *balance by grain size* data from the SIAM output and updates both cross-section elevations and grain-size distributions for each SIAM reach. This section details how the model calculates changes in cross-section elevations and grain-size distributions.

Cross-Section Elevation Adjustments for SAIM Reaches: Using the *local sediment balance* SIAM output for each reach, HEC-RAS cross sections are adjusted on a per-reach basis. The following provides an outline of how the program computes changes in cross-section elevations and how those changes are applied to a series of cross sections within a SIAM reach:

1. *Local sediment balance* output from SIAM is adjusted using the *local balance calibration factor.*

2. Adjusted local balance is converted from tons to volume of bed material using a unit weight of 95 lbs/ft^3 for the bed material.

3. The volume of bed material is divided by the reach length and the reach-averaged channel bankfull width to obtain a channel-elevation adjustment for the entire reach: depth of aggradation, d_A or depth of degradation, d_D. Reach lengths are determined as the difference between the upstream-most and downstream-most river stations within a defined SIAM reach *plus* one-half of the distance between the upstream-most cross section within the reach and the adjacent cross section upstream of the reach *and* one-half of the distance between the downstream-most cross section within the reach and the adjacent cross section downstream of the reach. Eq. 1 provides the mathematical expression used for computing reach lengths:

$$L = (Sta_{US} - Sta_{DS}) + 0.5(Sta_{Ad-US} - Sta_{US}) + 0.5(Sta_{DS} - Sta_{Ad-DS}) \quad \text{Eq. 1}$$

where L is the reach length (ft); Sta_{US} is the upstream-most river station within a SIAM reach (ft); Sta_{DS} is the downstream-most river station within a SIAM reach (ft); Sta_{Ad-US} is the river station adjacent to the SIAM reach on the upstream end (ft); and Sta_{Ad-DS} is the river station adjacent to the SIAM reach on the downstream end (ft).

For SIAM reaches that have only one cross-section, the reach length is computed using Eq. 2:

$$L = 0.5\left(Sta_{Ad-US} - Sta_{US}\right) + 0.5\left(Sta_{DS} - Sta_{Ad-DS}\right) \qquad \text{Eq. 2}$$

Further, for computing reach-averaged channel bankfull widths, individual cross-section bankfull widths are determined as the distance between the defined left-bank station and right-bank station within each HEC-RAS cross section.

If the depth of degradation or aggradation is less than the user-defined negligible tolerance, no adjustment is made to the cross-section elevations within that reach. Otherwise, computed reach elevation adjustments are converted to a degradation or aggradation rate by dividing by the simulation period (units of ft/time). If the degradation or aggradation rate is greater than the user input limiting rate, the depth of degradation or aggradation is set to the limiting value for that reach.

4. Cross-section elevation data points within the bankfull width are identified for each cross section using the defined left-bank and right-bank stations from HEC-RAS data.

5. Identified cross-section points within the bankfull width are adjusted by the computed depth of aggradation or degradation.

Grain-Size Distribution Adjustments for SIAM Reaches: Using the SIAM output for *local sediment balance by grain size*, grain-size distributions (GSD) are adjusted for each SIAM reach. Initially, PotaMod develops a GSD for aggradation or degradation from the *local sediment balance by grain size* SIAM output data for each reach. Subsequently, PotaMod determines whether aggradation or degradation occurred from the *local balance*. For aggradation, an aggradation GSD is developed from the aggraded particle sizes and any degraded particle sizes are neglected. For degradation, a degradation GSD is developed from the degraded particles sizes and any aggraded particles sizes are neglected.

Case of Aggradation If the depth of aggradation is greater than the user-defined negligible depth of aggradation for a given reach, a new bed-material GSD is computed using a weighted average with the computed aggradation GSD and the previous bed-material GSD. A volume-based averaging method is used where the aggradation GSD is weighted by the depth of aggradation and the previous GSD is weighted by 10% of the representative flow depth. The averaging method is presented in Eq. 3:

$$GSD_N = \left(\frac{d_A}{d_A + (10\%)y}\right) GSD_A + \left(\frac{(10\%)y}{d_A + (10\%)y}\right) GSD_P \qquad \text{Eq. 3}$$

where GSD_N is the bed-material percent-finer value for a given particle-size classification (GSD) for next time-step simulation; d_A is the depth of aggradation determined from *local sediment balance* [L]; y is the representative flow depth assigned as either the reach-averaged

hydraulic depth or maximum reach hydraulic depth[L]; GSD_A is the aggradation GSD determined from *local sediment balance by grain size*; and GSD_P is the GSD for previous simulation. If the depth of aggradation is less than the user-defined negligible depth of aggradation, then no adjustment to the GSD is made for that reach ($GSD_N = GSD_P$).

Case of Degradation If the computed depth of degradation, d_D, is less than the computed mixing depth (10% of the representative flow depth) and is greater than the negligible degradation depth, a new bed-material GSD is computed using a weighted average with the computed degradation GSD and the previous bed-material GSD. A volume-based averaging method is used where the armor layer GSD is weighted by the depth of the armor layer and the previous bed-material GSD is weighted by 10% of the representative flow depth. The averaging method is presented in Eq. 4:

$$GSD_N = \left(\frac{d_{AL}}{d_{AL} + (10\%)y}\right) GSD_{AL} + \left(\frac{(10\%)y}{d_{AL} + (10\%)y}\right) GSD_P \qquad \text{Eq. 4}$$

where GSD_{AL} is the armor layer GSD as determined by Eq. 5; and d_{AL} is the depth of armor layer as determined by Eq. 6 [L].

$$GSD_{AL} = \frac{GSD_P(d_T) - GSD_D(d_D)}{d_{AL}} \qquad \text{Eq. 5}$$

where d_T is the total depth of previous bed material altered ($d_T = d_{AL} + d_D$) as determined by Eq. 7 [L]; GSD_D is the degradation GSD determined from *local sediment balance by grain size*; and d_D is the depth of degradation determined from local sediment balance [L].

$$d_{AL} = d_T - d_D \qquad \text{Eq. 6}$$

$$d_T = d_D Max\left(GSD_D / GSD_P\right) \qquad \text{Eq. 7}$$

If the depth of degradation, d_D, is greater than the computed mixing depth (10% of the representative flow depth), then no adjustment to the GSD is made for that reach ($GSD_N = GSD_P$). Also, if the depth of degradation, d_D, is less than the user-defined negligible depth of degradation, then no adjustment to the GSD is made for that reach ($GSD_N = GSD_P$).

Wash Load Criteria Adjustments for SIAM Reaches: If the *Minimum Wash Load Criterion* is set to "0, None" in the calibration input for a given SIAM reach, the *Wash Load Maximum Class Diameter* for SIAM calculations is adjusted based solely on the updated grain-size distributions. Specifically, the grain-size classification with the largest grain-size diameter where less than 10% of the particles by weight are finer is set as the new *Wash Load Maximum Class Diameter* for the next iteration. If the *Minimum Wash Load Criterion* is set to one of the twenty grain-size classifications in the calibration input, the grain-size classification with the

largest grain-size diameter where less than 10% of the particles by weight are finer is compared to the *Minimum Wash Load Criterion* and whichever is largest is set as the new *Wash Load Maximum Class Diameter* for the next iteration.

MODEL OUTPUTS

PotaMod provides output data for: 1) bed elevations and changes for each iteration; 2) local balance by grain size; 3) reach grain-size distributions; and 4) thalweg profiles for each iteration. The following sections provide details for each type of output data.

Bed-Elevation Data: Bed-elevation output data contain information on changes in bed elevations for each SIAM reach and each iteration. Specifically, the following data are provided: *Reach ID*, *Reach Name*, *Iteration Number*, *Time* (yrs), *Local Balance* (tons), *Bed Elevation Change* (ft), *Cumulative Bed Elevation Change* (ft), *Average Bankfull Flow Depth* (ft), and *Maximum Bankfull Flow Depth* (ft).

Local Balance by Grain Size Data: Local balance by grain size output data contain information on the local balance by grain size for each SIAM reach and each iteration. Specifically, the following data are provided: *Reach ID*, *Reach Name*, *Iteration Number*, *Total Local Balance* (tons), and *Local Balance by Grain Size* (tons). The grain-size classifications are consistent with those used within SIAM, in which there are twenty classifications ranging from Clay to LB (large boulder).

Reach Grain Size Distribution Data: Reach GSD output data contain information regarding the grain-size distribution and wash load index for each SIAM reach and each iteration. Specifically, the following data are provided: *Reach ID, Reach Name, Iteration Number, Wash Load Index,* and *Grain-Size Distribution*. Similar to the *local balance by grain size*, *grain-size distributions* are reported using the grain-size classification system within SIAM. Further, the *Wash Load Index* is given as an integer value between 1 and 20 and directly correlates to the grain-size classifications.

Thalweg Profiles: Thalweg profile output data contain information regarding thalweg elevations for each river station and iteration. Specifically, the following data are provided: *River Reach Name*, *SIAM Reach Name*, *River Station* (ft), *Initial Thalweg Elevation* (ft), and *Thalweg Elevation* for a given iteration (ft).

APPLICATION TO LONG CREEK WATERSHED

Martin et al. (2010) presented SIAM analyses conducted for three of the DHP watersheds: Hickahala Creek, Long and Caney Creeks, and Harland Creek. The baseline SIAM model for the Long Creek Watershed was used as input for PotaMod to evaluate 100 years of sediment transport. The Long Creek Watershed is located in Mississippi and has an area of 39.7 mi^2 (Figure 1). The watershed includes a seven-mile reach of Long Creek and five miles of the Caney Creek tributary. For the SIAM and PotaMod analyses, the watershed was divided into 13 SIAM reaches (Figure 2).

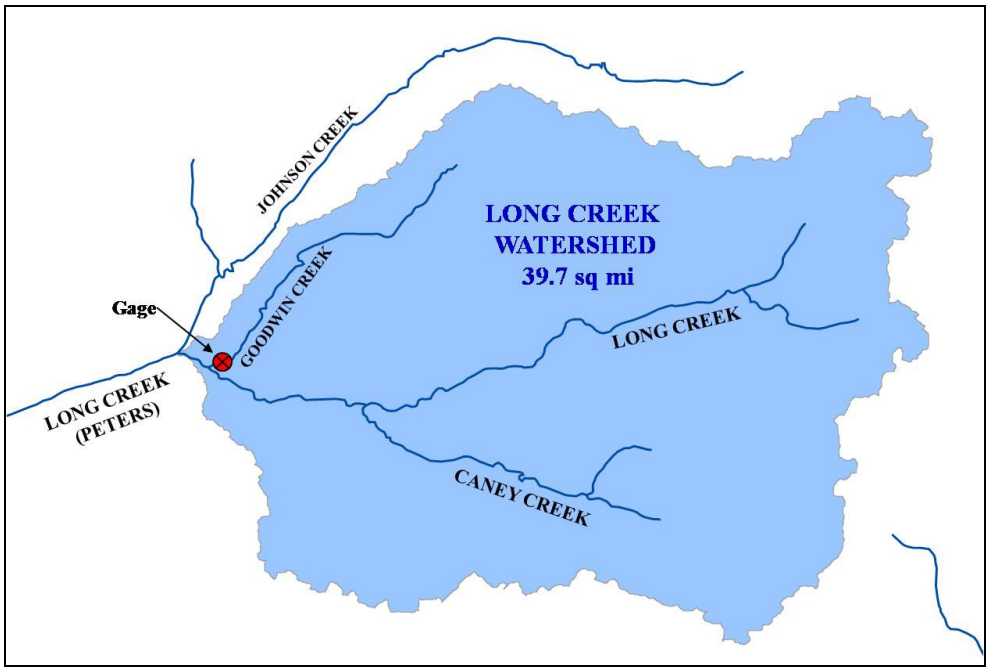

Figure 1. Long and Caney Creek Watershed (Martin et al., 2010)

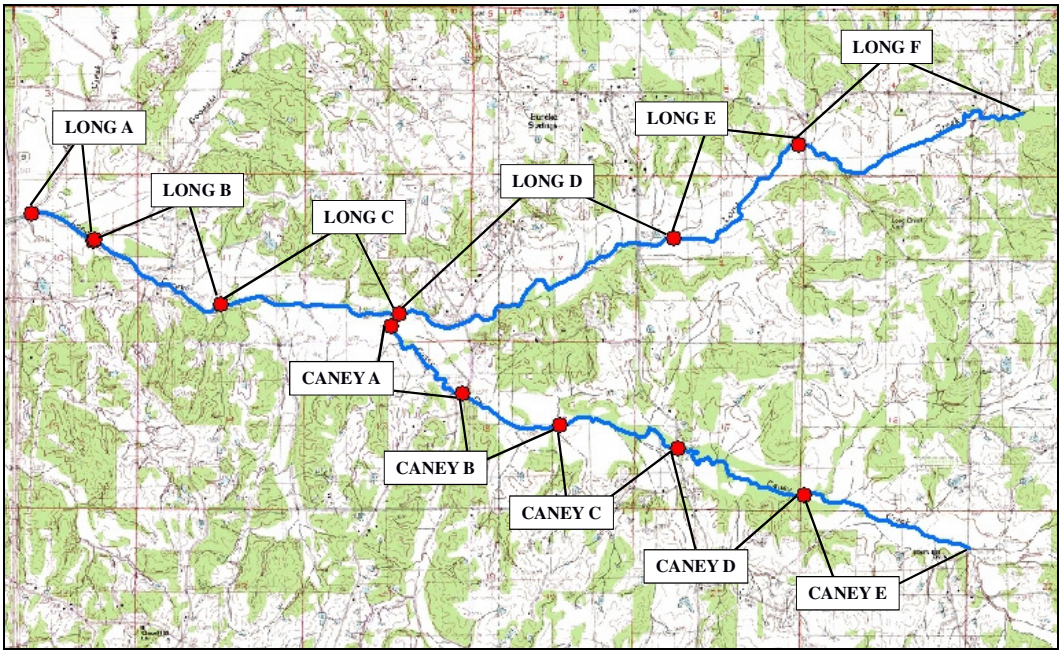

Figure 2. Long Creek and Caney Creek SIAM reaches (Martin et al., 2010)

Results of the Martin et al. (2010) SIAM analysis indicated that the DHP reduced fine sediments delivered from the Long Creek Watershed by 44%. Figure 3 shows pre- and post-project fine-sediment supply (determined from SIAM models) for the Long Creek Watershed resulting from implementing DHP features (bank stabilization and grade control structures).

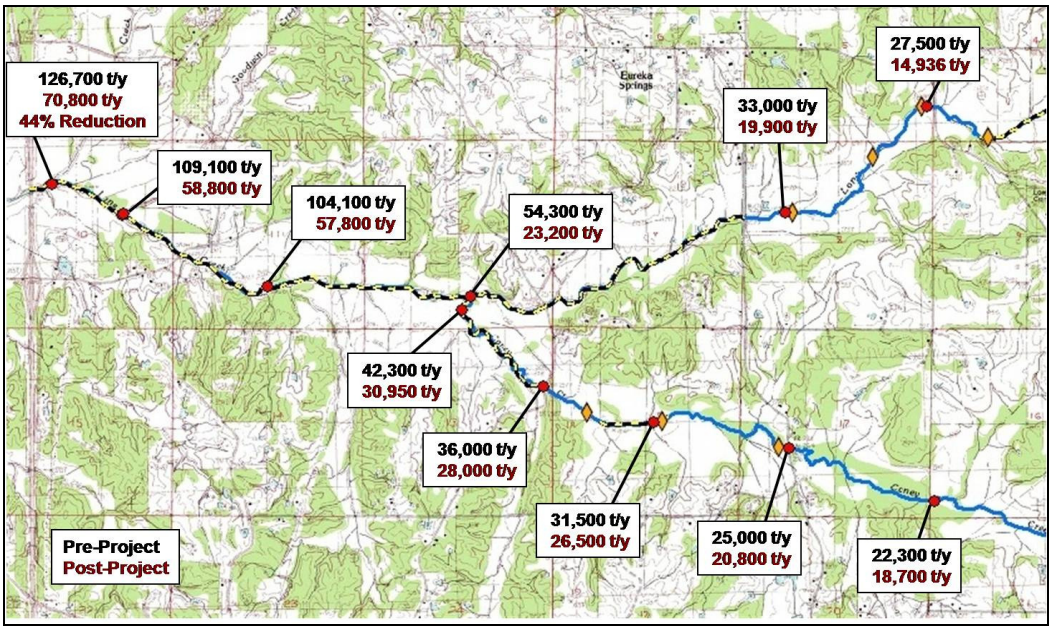

Figure 3. Reductions in fine-sediment supply along Long and Caney Creeks as a result of the DHP features determined from SIAM analysis (Martin et al., 2010)

Model Inputs Reach-based model input parameters are provided in Table 1 The Laursen (Copeland) SIAM transport function was specified for sediment transport computations and a calibration coefficient of 0.01 was used for all reaches. Maximum scour or aggradation rates were set to 0.5 ft/hr for all reaches except for the reaches at the model boundaries. The downstream boundary reach had a limiting aggradation and degradation rate of 0.01 ft/yr and both upstream boundary cross sections had a limiting rate of 0.25 ft/hr. The wash load criteria threshold was set at very fine sand (VFS) meaning that the wash load particle size was not allowed to be less than 0.125 mm. The input parameters were varied to assess the sensitivity of each parameter and the values in Table 1 were used for the model results presented within this paper. The input parameters were not calibrated using field data, as the purpose of this project was to illustrate the model utility of the program and long-term aggradation and degradation data were not available for calibration.

Table 1. Reach-based input parameters

SIAM Sediment Reach Name	Sediment Transport Calibration	Limiting Rate of Agg/Deg (ft/yr)	Mixing Depth Criteria	Initial Representative Depth (ft)	Min Wash Load Criteria
Long A	0.01	0.01	Average	17.6	6, VFS
Long B	0.01	0.5	Average	14.17	6, VFS
Long C	0.01	0.5	Average	13.11	6, VFS
Long D	0.01	0.5	Average	10.56	6, VFS
Long E	0.01	0.5	Average	10.08	6, VFS

SIAM Sediment Reach Name	Sediment Transport Calibration	Limiting Rate of Agg/Deg (ft/yr)	Mixing Depth Criteria	Initial Representative Depth (ft)	Min Wash Load Criteria
Long F	0.01	0.5	Average	9.75	6, VFS
Long USBC	0.01	0.25	Average	8.54	6, VFS
Caney A	0.01	0.5	Average	13.6	6, VFS
Caney B	0.01	0.5	Average	13.17	6, VFS
Caney C	0.01	0.5	Average	9.83	6, VFS
Caney D	0.01	0.5	Average	6.2	6, VFS
Caney E	0.01	0.5	Average	5.44	6, VFS
Caney USBC	0.01	0.25	Average	5.38	6, VFS

USBC = upstream boundary condition.

The one-year hydrograph data used in the model are shown in Table 2. The model computed sediment-transport budgets for the one-year hydrograph using SIAM, then updated bed elevations and grain-size distributions in the HEC-RAS model based on SIAM output data. PotaMod repeated this process 100 times for a total simulation time of 100 years.

Table 2. One-year hydrograph for SIAM calculations

Duration (days)	Discharge (cfs)
104.52	11
28.51	22
26.91	44
26.64	88
35.85	179
40.01	362
42.23	733
35.11	1485
20.94	3007
4.53	6086

Model Results Cumulative bed-elevation changes for reaches in Long Creek and Caney Creek are shown in Figure 4 and Figure 5, respectively. The maximum degradation depth for Long Creek was approximately five feet and it occurred in Long F Reach at the end of the 100-year simulation. The maximum aggradation depth in Long Creek was about one foot and it occurred in Long C Reach after 23 years of simulation. Gradual degradation was the general trend for Long Creek over the 100 years with an average degradation rate of approximately 0.01 ft/yr.

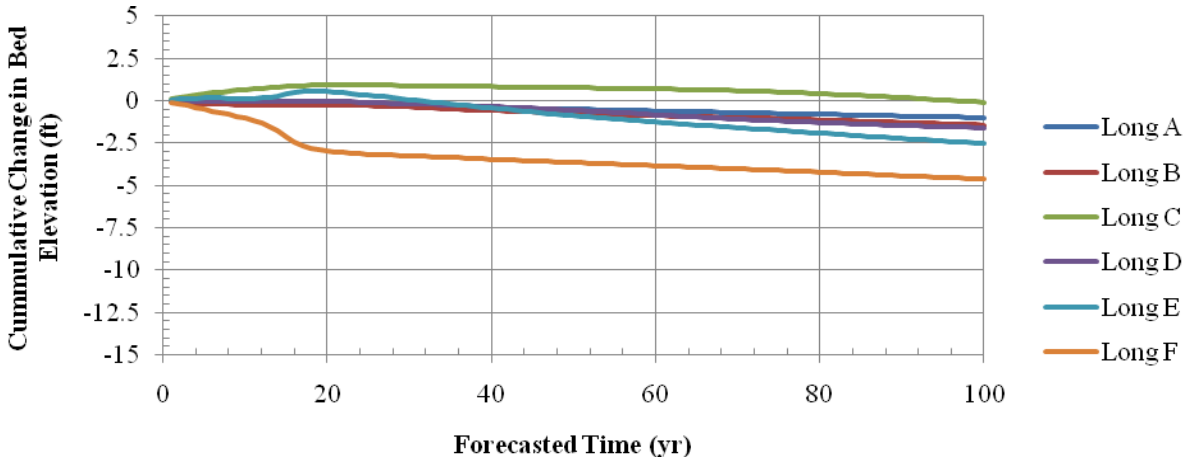

Figure 4. Cumulative bed-elevation change versus model forecasted time for Long Creek reaches

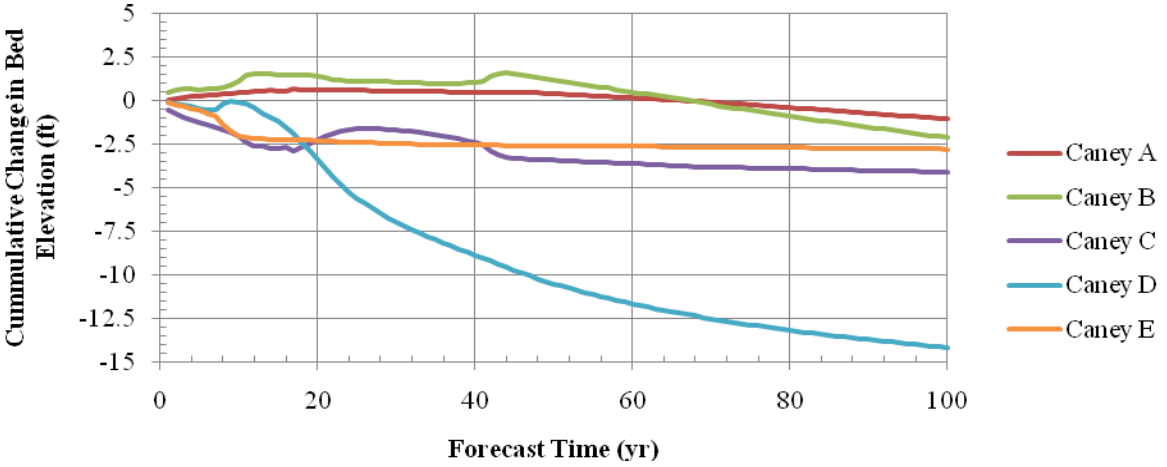

Figure 5. Cumulative bed-elevation change versus model forecasted time for Long Creek reaches

Caney Creek output indicated an overall general trend of degradation; however, the magnitudes were much larger compared to those observed in Long Creek. The maximum degradation depth for Caney Creek was approximately 14 feet and it occurred in Caney D Reach at the end of the 100-year simulation. The maximum aggradation depth in Long Creek was about 1.6 feet and it occurred in Caney B Reach after 44 years of simulation. For Caney Creek, there were significant differences between rates of bed-elevation changes between reaches. Caney D which had the largest projected degradation depth was bound by two reaches that had significantly lower rates of degradation and degradation depths.

Reach-Specific Output Data Modeling results for Long C Reach and Caney C Reach are presented in this section to illustrate the other types of information that are provided in the model output. These two reaches were chosen because they generally encompass the ranges of trends observed in the reaches where there were minimal changes over time in Long C Reach and larger, more pronounced changes for the Caney C Reach. Total local sediment balance versus

time for the two reaches are shown in Figure 6, and grain-size distributions for Long C Reach and Caney C Reach for 1, 25, 50 and 100 years are shown in Figures 7 and 8, respectively.

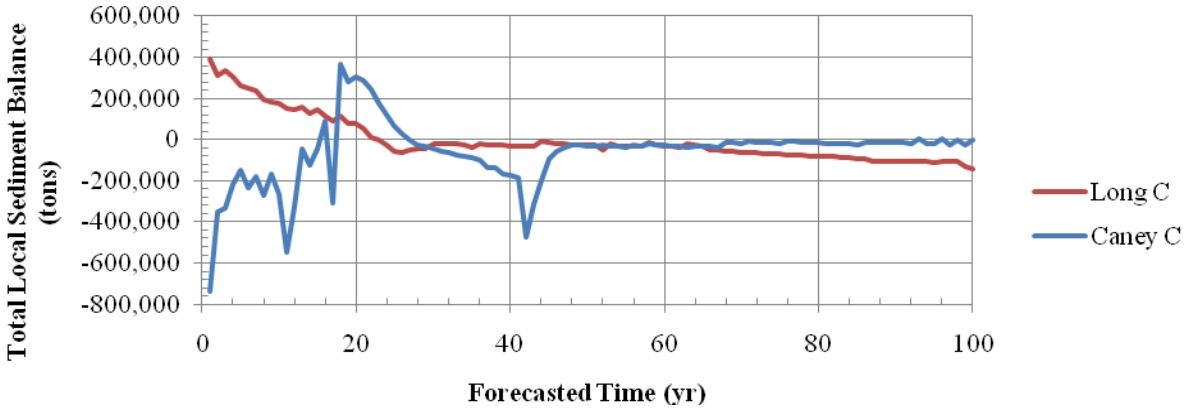

Figure 6. Total local sediment balance for Long C and Caney C reaches.

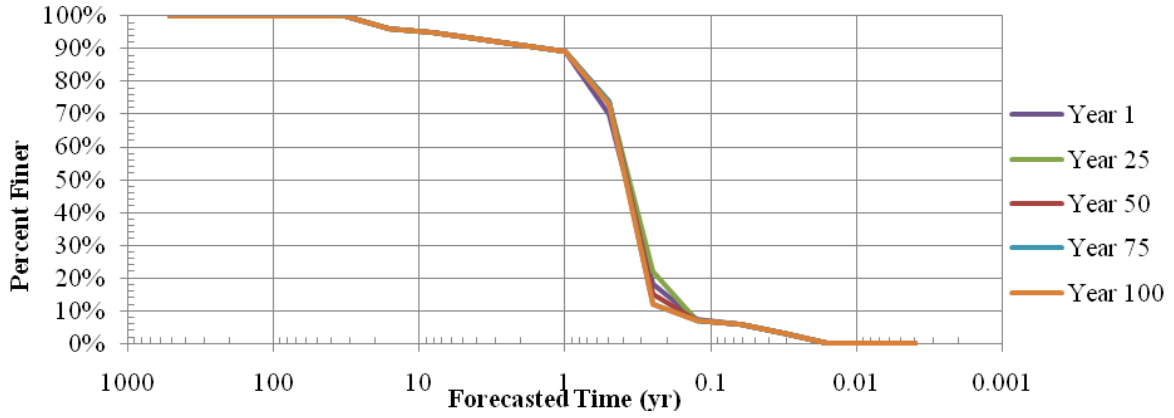

Figure 7. Grain-size distributions for Long C Reach for 1, 25, 50 and 100 years

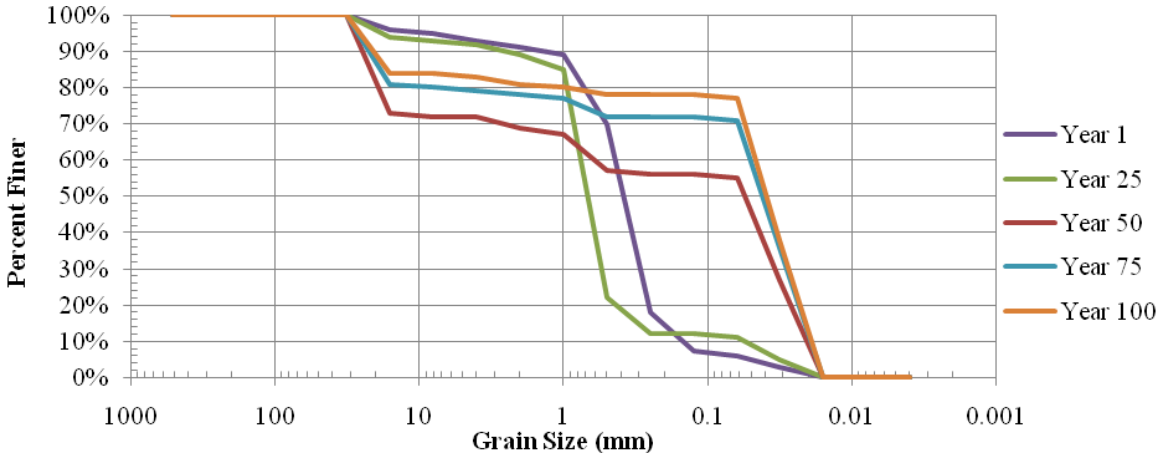

Figure 8. Grain-size distributions for Caney C Reach for 1, 25, 50 and 100 years

SUMMARY

The PotaMod computer application was developed for 1-D mobile-bed modeling using output from the SIAM hydraulic design function within HEC-RAS. PotaMod updates cross-section elevations and grain-size distributions on a per-reach basis to allow updating of hydraulics in response to computed erosion and sedimentation. Specifically, PotaMod uses the *local sediment balance* output of SIAM to determine depths of aggradation or degradation for each reach, and it uses *sediment balance by grain size* to determine adjustments to grain-size distributions for each reach. The PotaMod application has an advantage over other 1-D sediment transport models because it can simulate several years in a relatively short time period. The model can be used to evaluate the impacts of different rehabilitation and management alternatives over a long period of time with updated hydraulic conditions allowing insight into potential changes in channel stability.

PotaMod was used to evaluate 100 years of sediment transport and channel stability in the Long Creek Watershed. The model included 13 SIAM reaches with a total of 139 cross sections. The 100-year simulation required 10.1 minutes to complete. The purpose of this project was to illustrate the utility of the PotaMod application and model results were not calibrated to known bed-elevation changes as those data were not available. Ideally, sediment-transport input parameters would be calibrated with measured field data; however, a relative comparison of model results can be conducted between a baseline condition and different rehabilitation and management alternatives to identify general aggradation and degradation trends within a watershed over time.

ABSTRACT

The prediction of erosion is an important component in the development of land management strategies, particularly where sediment is identified as the cause of water quality impairment. Computational models that predict streambank erosion allow the user not only to quantify the streambank erosion rates and processes along a stream, but also to take subsequent decisions regarding sediment loads reduction, especially when those decisions need to pay special attention to stream channel processes and stabilization of eroding reaches. Streambank erosion processes were hypothesized to be an important mechanism driving sediment supply from the Town Creek Watershed in Mississippi. Field monitoring observations along the main channel of the Town Creek and several of its tributaries have indicated that the incised headwaters can contribute up to 70% of the suspended sediment loads exported by the watershed. Observations also evidenced that annual streambank retreat rates and loads in the Town Creek headwaters could be as high as 2.67 m and 28.5 Mg per meter of stream length, respectively. Thus, streambanks were a significant source of sediments loads to the Tombigbee River and the Aberdeen Pool on the Tennessee-Tombigbee Waterway. The ability of the Conservational Channel Evolution and Pollutant Transport System (CONCEPTS) computer model to predict streambank erosion along the Town Creek Watershed in MS was tested through its application to a 270-m long headwater incised reach. Model predictions over a 13 month period were compared with cross section surveys at 8 transects along the modeling reach. Results showed that CONCEPTS accurately predicted top width retreat and streambank failures in time and magnitude. Results from field monitoring and computational modeling offer important insights into the relative effects of land and streambank erosion on the stream water quality and sediment budget for Town Creek Watershed. Reduction of suspended sediment loads should focus on the attenuation of geomorphic processes and stabilization of reaches and agricultural lands near streambanks at the headwaters within the watershed.

INTRODUCTION

Research along the Town Creek Watershed, MS (TCW) provided evidence that gravitational failure of the incised streambanks located along the northern and western headwaters channels of this watershed was the primary source of sediment loads to the system (Ramirez-Avila, 2011). Monitoring of streambank erosion processes and rates along these unstable channels has documented the occurrence of channel changes, loss of valuable agricultural land, and degradation of stream habitat for fish and other aquatic organisms (Ramirez-Avila, 2010; Ortega-Achury et al., 2009).

Prediction of erosion processes (upland, gully and streambank) is an important component of the development of land management strategies in areas where sediment is identified as the cause of impairment (Staley et al., 2006). Computational models to predict streambank erosion allow the user not only to quantify the streambank erosion rates and processes along a stream, but also to guide subsequent decisions regarding sediment loadings reductions, especially when those decisions need to pay special attention to stream channel processes and stabilization of eroding reaches.

The CONservational Channel Evolution and Pollutant Transport System (CONCEPTS) computer model is a product of continuing research at the US Department of Agriculture, Agricultural Research Service (ARS) National Sedimentation laboratory (NSL) to predict channel adjustment and evolution of incised stream systems. Various studies have been carried out to compare CONCEPTS model predictions of streambed and streambank degradation to field measurements in different areas under diverse scenarios, including studies in the Yalobusha River, MS, Goodwin Creek, MS, Kalamazoo River, MI, Shades Creek, AL, Stroubles Creek, VA and James Creek, MS (Simon et al., 2002; Thomas and Langendoen, 2002; Wells et al., 2007; Simon et al., 2004; Staley et al., 2006; Langendoen and Simon, 2008; Langendoen and Alonso, 2008). Only one of these studies has been carried out within the Ecoregion 65. The study in TCW was the first developed within that Ecoregion that involves comparison of assessed and predicted sediment streambank erosion processes and yields in a short term scenario. The field monitoring dataset includes information on stormflow events, changes in streambank morphology, and characterization of streambank soils and streambed.

Results are presented from the application of the CONCEPTS model to simulate and predict streambank erosion rates along an incised section of a 270 m long reach on the Yonaba Creek, MS, a representative stream segment located at the northern headwaters area of the TCW. The general objective of the study was to assess the performance and capability of the CONCEPTS model to simulate temporal and spatial streambanks changes along the modeled reach. The model evaluation includes: 1) calibration of the CONCEPTS model against existing data detailing streambank changes over the entire reach from February 2009 to July 2009; 2) validation of the model application over the entire reach from August 2009 to March 2010; and 3) development of a sensitivity analysis for CONCEPTS parameters directly related with the prediction of streambank top width retreat, planar failures and fluvial erosion. This paper includes final results from the first two components of evaluation, only.

CONCEPTS Model

The CONservational Channel Evolution and Pollutant Transport System (CONCEPTS) is a computer model developed by the US Department of Agriculture (USDA), Agricultural Research Service (ARS) at the National Sedimentation Laboratory (NSL) in Oxford, MS. The model simulates unsteady one-dimensional flow, graded-sediment transport, streambank erosion and failure processes to predict the dynamic response of flow, and sediment transport to in-stream hydraulic structures (Langendoen, 2000). The CONCEPTS model is a tool designed for the assessment of stream corridor restoration projects. CONCEPTS is composed of three physical processes simulation components: 1) hydrodynamics for unsteady flow hydraulics, 2) mobile streambed dynamics for sediment transport and streambed adjustment, and 3) streambank erosion and channel widening from both hydraulic and geotechnical mechanisms. CONCEPTS is capable of assessing the long term effectiveness of restoration efforts when combined with watershed scale modeling programs as AGNPS or SWAT (Staley et al., 2006).

CONCEPTS simulates open channel hydraulics by numerically integrating the St. Venant equations representing open channel flow. The model uses the generalized Preissman method of

discretization, a forward time finite difference numerical method to approximate the Saint Venant equations. CONCEPTS predicts sediment transport capacity and streambed adjustment through sediment scour and aggradation dynamics by solving the sediment mass conservation equation. A modification of the SEDTRA (Sediment Transport Capacity Predictor) model (Garbrecht et al., 1996) is included into the CONCEPTS model to calculate the total sediment transport by size fraction for a total of 17 pre-defined size classes with a specific sediment transport equation for each one. Channel width adjustments are modeled by CONCEPTS by incorporating the physical process for streambank retreat through hydraulic erosion and gravitational failure. Hydraulic erosion of bank material is calculated by CONCEPTS using an excess shear stress approach for cohesive soils. CONCEPTS also simulates the two most frequent types of streambank failure observed for incised streams with steep banks: 1) planar failure and 2) cantilever failure for heterogeneous cohesive streambank materials (Langendoen, 2000). Based on the shear strength of the streambank soils, a Factor of Safety (FS) is determined for the geometry and the soil properties of the streambank. For the cantilever failure, CONCEPTS determines a FS based on the weight of the overhanging streambank and the shear strength of the streambank soil. Detailed information about the model can be found in Langendoen (2000),

A Java-based Graphical User Iinterface facilitates the model input for CONCEPTS (Figure 1). Three main elements are observed when the interface is opened: the physical data, the channel models, and the run data elements. Detailed information about the model components and the use of the interface to enter information to develop a simulation is found in Ramirez-Avila (2011).

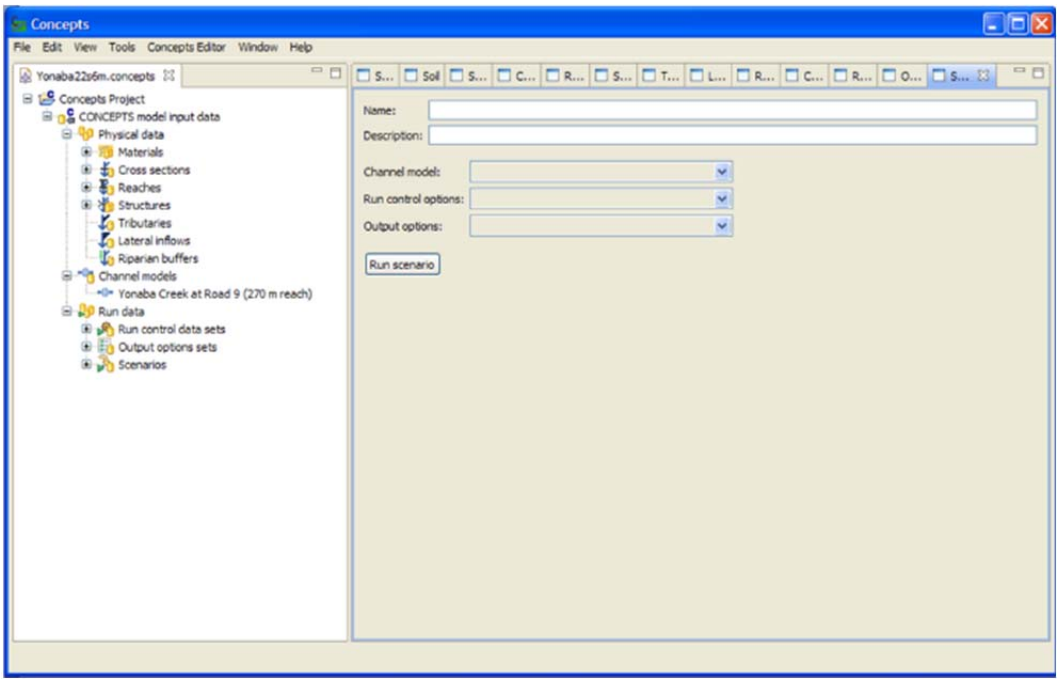

Figure 1. View of the Java Graphical User Interface for the CONCEPTS model

METHODS

Model Setup

The Yonaba Creek reach is a principal tributary of Town Creek located in the northern area of the TCW. The geometry of the 270-m long modeling reach is represented by 8 cross sections (Figure 2). Although the modeling reach is intersected by a bridge along the State Road 9 approximately 50 m below the first cross section, under visual observations its substructure did not contract streamflow or induce deposition or scour so was not included in simualtions. Along the modeling reach, three regions with differing characteristics were identified. First, two cross sections along the upstream sub-reach, which is a straight segment including an 85 m long section with rip rap protection along its entire streambank height.

This segment intersects the State Road 9 bridge. Second, four cross sections along the bendway sub-reach, which evidenced the most significant amounts of streambank erosion and streambank instability. Third, two sections along the downstream sub-reach, which is a straight segment evidencing some streambank gully erosion events, although its geomorphical characteristics did not favor streambank instability processes because of the presence of a berm along its entire length.

Channel Geometry

The eight transects (at river stations 0, 20, 135, 140, 165, 210, and 270 m) along the 270 m modeling reach were periodically surveyed from February 2009 to March 2010. Initial cross sections were surveyed between left to right streambank looking upstream by using a Total Station Positioning System (Leica TSP 1100 Professional Series) in February 13 and 20, 2009. A Real Time Kinematic (RTK) GPS system (TOPCON Hiperlite Plus) was used for the next surveys from May 19, 2009 to March 19 2010. A more detailed description about the cross section surveying performed at this reach was provided in Ramirez-Avila (2011).

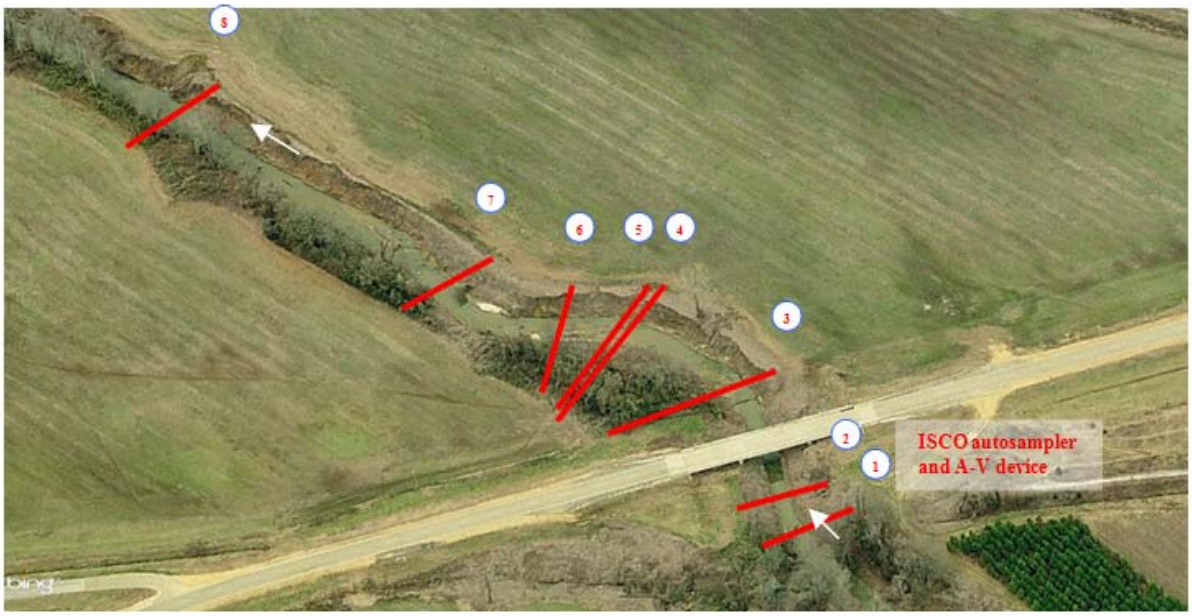

Figure 2. Yonaba Creek study site. Plan view showing the location of surveyed cross sections

Streambank Material Physical Properties

Sampling and testing of streambed and streambank materials for textural composition and geotechnical properties was conducted at the Environmental Laboratory of the Civil and Environmental Engineering Department of Mississippi State University and at the National Sedimentation Laboratory in Oxford, MS. Streambank and streambed materials were analyzed to determine particle size distribution by sieve-hydrometer and by the sieve-pipet method, respectively. Streambed sampling did not show a significant difference in textural composition along the length of the modeling reach. The field observation and particle size analysis results for the streambanks material allows defining representative streambank profiles, including the 85 m segment with rip rap protection.

The modeling reach formed into the spatial distribution of the Jena soil series. The streambank profile along the entire modeling reach is very homogenous. Particle size analysis characterized the entire layers of soils as very fine sandy loam. The soil series description for a typical pedon presents one main layer below the top soil (0.1 m) to a depth of 1.2 m and a second main layer from this depth going deeper than 2 m. Field observations showed an apparently less permeable third soil layer (approximately 5.5 to 6 m depth) and a subsequent gray bottom layer, usually covered by loose material located at the toe of the

streambank produced by streambank failures (Figure 3). Particle size analysis for the deposited material showed a significant reduction in the contents of silt and clay of about 58%.

Streambanks along the modeling reach are very steep. The streambanks at the outer margin (left) of the bendway segment are eroded to near vertical profiles until a failure event produces deposition of loose material at the streambank toe (Figure 3). The angle of the first planar failure of the streambanks (β) was directly related to the friction angle of the streambank material (ϕ') and the initial streambank slope (α) (Equation 1), which was considered homogeneous along the streambank height. Considering the homogeneity of the textural composition along the streambanks height in the modeling reach, the friction angle (ϕ') was determined by evaluating the change in the streambank slope observed after consecutive failure events in the streambanks where it occurred. Initial values for the suction angle (ϕ_b) for each soil were assumed based on their corresponding textural characterization from values suggested by Selby (1993) and Nieber et al. (2008). The cohesion (c') of the streambank soil was considered negligible due to the textural composition of the streambank material, based on the typical values for different materials suggested by Selby (1993) and Nieber et al. (2008).

$$\beta = \left(\frac{\alpha}{2} + \frac{\phi'}{2} \right) \qquad \text{Eq. 1}$$

Figure 3. Representative streambank soil profiles observed along the modeling reach at Yonaba Creek in Blue Springs, MS

The submerged jet test device was used to determine the streambank material soil resistance to hydraulic erosion (Figure 4). The average value of three jet tests conducted at each streambank layer was used for input of τ_c and k_d into the CONCEPTS model. Critical shear stress and erodibility of the streambank material ranged from 0.14 to 11.84 Pa and from 0.76 to 35.8 $cm^3\ N^{-1}\ s^{-1}$, respectively. Coarse grain loose material deposited on the streambank toes presented an average value of 1.12 Pa and 99.41 $cm^3\ N^{-1}\ s^{-1}$ for τ_c and k_d, respectively.

Roughness values (Manning n) were assigned to streambed and streambank sections of each cross section based on in-situ characteristics of the channel (e.g. rip rap protection of streambank, woody vegetation, etc), using the guidelines proposed by Langendoen (2000) and Chow (1959). In general, roughness values for the channel streambed ranged from 0.02 to 0.1 and streambanks from 0.03 to 0.17.

Figure 4. View of the a) jet test device setup, b) jet of water applied on the streambank material, and c) scour generated on the streambank material after a test

Discharge

Hydraulic conditions at the upstream and downstream boundaries of the simulated reach were obtained from observed discharge and stage. A monitoring station consisting of an automatic sampler (ISCO Model 6712) and area velocity flow module (ISCO-750) was setup at the upstream location of the modeling reach from early February 2009 to April 1, 2010. The continuous 15-min hydrographs of all runoff events between February 27, 2009 and April 1, 2010 were used to simulate the hydraulics and morphology of the model reach.

A rating curve (Equation 2) was developed as the downstream boundary condition based on stream velocity and depth profiles measured using a Son Tek flow tracker at cross section #8 (X=270 m) on different dates between August 2008 and June 2009.

$$Q = 3.25 * h^{1.95} \qquad \text{Eq. 2}$$

where Q=Discharge in m^3s^{-1} and h=flow depth in m.

Modeling Assumptions, Calibration and Validation

Although the major amount of the boundary physical properties to evaluate the prediction of streambank erosion processes and rates by using the CONCEPTS model were determined or measured *in situ*, some assumptions had to be made about the data assigned to materials and cross sections within the modeling reach. These assumptions concern sediment loadings, the streambed material resistance parameters, the effective cohesion and the suction angle of the streambanks. CONCEPTS is unable to predict the increased hydraulic forces acting on the left streambank side caused by the helical streamflow pattern in the bendway. Following Langendoen and Simon (2008), the increased shear stresses along the bendway were represented by a reduction in the resistance to erosion of the streambank material in the left streambanks of the sections #3 and #6. Similarly, the presence of a pipe on the lower part of left streambank at the section #5 was represented by a modification in the magnitude of its critical shear stress. Sediment inflows into the study reach were assumed equal to the transport capacity of the streamflow at the section #1 (wash load size class <0.025 mm). No downstream control was established. Processes related with the streambank stability analysis for this simulation included positive pore water pressures, matric suction, confining pressures, and groundwater table dynamics. A number of 5 shear emergences and a block retention time (time needed by flow to remove failed material deposited on the streambank toe) of 15 days were selected. From field observations, the maximum tension crack depth in the streambank stability analyses was determined as 1.7 m.

The calibration scenario included the analysis of hydraulics and streambank stability processes for the entire modeling reach from February 22, 2009 to June 30, 2009. The validation scenario was setup from July 1, 2009 and ended in March 19, 2010. A sensitivity analysis was performed to evaluate the effect of the critical shear stress, erodibility, friction angle and cohesion of the streambank material, streambank roughness and block retention time on the sediment loads and streambank failure events. Results from the sensitivity analysis are reported in Ramirez-Avila (2011).

RESULTS

The 15-min time series of modeled and observed streamflow values at the downstream end of a 270 m long reach along the Yonaba Creek in Blue Spring, MS, are shown in Figure 5. The calibrated modeled time series agreed very well with the observed streamflow time series. A minimum rational change in the initial input value of the determined friction angle (ϕ') for the streambank material was necessary to improve the model accuracy during the calibration phase.

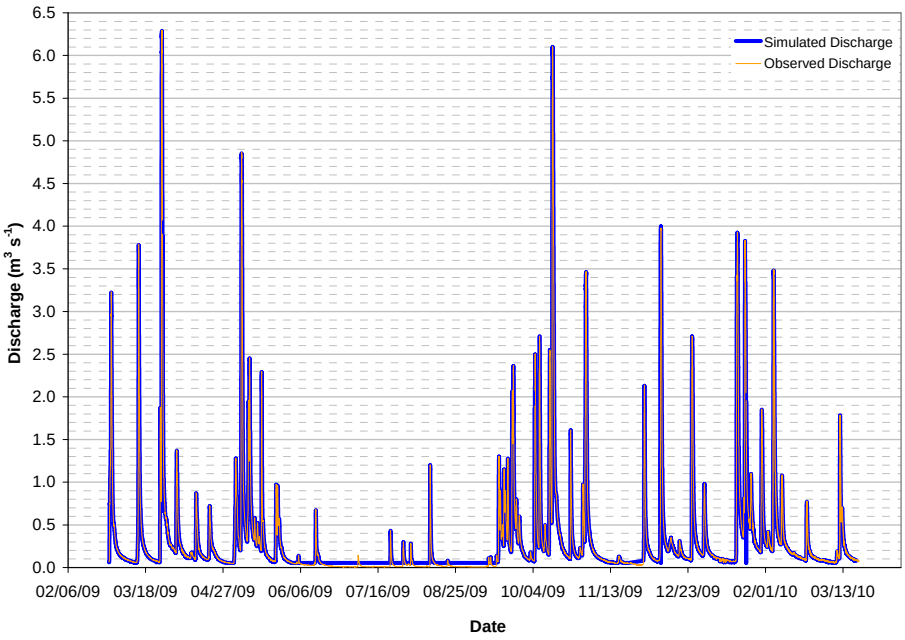

Figure 5. Observed and simulated streamflow discharge for a 270 m long modeling reach along the Yonaba Creek in Blue Springs, MS

Factor of Safety and Streambank Instability

The time series of the computed Factor of Safety (Figure 6) allows visualizing the time of occurrence of a planar or a cantilever failure event during continuous changes in streamflow depths. Along the FS time series, a FS=0.987 during the stormflow event that started in February 26, 2009, and a FS=0.975 during the successive stormflow events that started in March 25, 2009, were observed for sections #3 and #6, respectively. In both cases, the streambank presented a planar failure. The stormflow event that induced the planar failure of section #6 did not induce a planar failure on section #3, probably due to the presence of remaining streambank material deposited on the streambank toe after the previous streambank failure. It also could be because only a cantilever failure of streambank material at the streambank toe height occurred.

Figure 6 shows how the factor of safety (FS) for sections #3, #4, #5 and #6 was reduced after the occurrence of the stormflow peak observed in March 26, 2009. The reduction in the FS indicated two processes: 1) the steepening of the streambank caused by the scour of the streambank material from the streambank itself or from deposited loose material near the streambank by fluvial erosion (Langendoen, 2000); and 2) the loss of matric suction relative to the increase in confining pressure along the streambank height caused by the rising stormflow level. When the FS was smaller than 1, a planar failure on the streambank occurred.

Although the FS for Section #6 was reduced below the critical value of 1 just after the occurrence of the stormflow peak, the planar failure occurred only until the stormflow depth felt to a depth where the forces reducing the strength on the saturated streambank were not higher than the confining pressure exerted by the stormflow (for this specific condition h=2.14 m). Once the failure occurred, the FS was increased due to reduction in streambank angle.

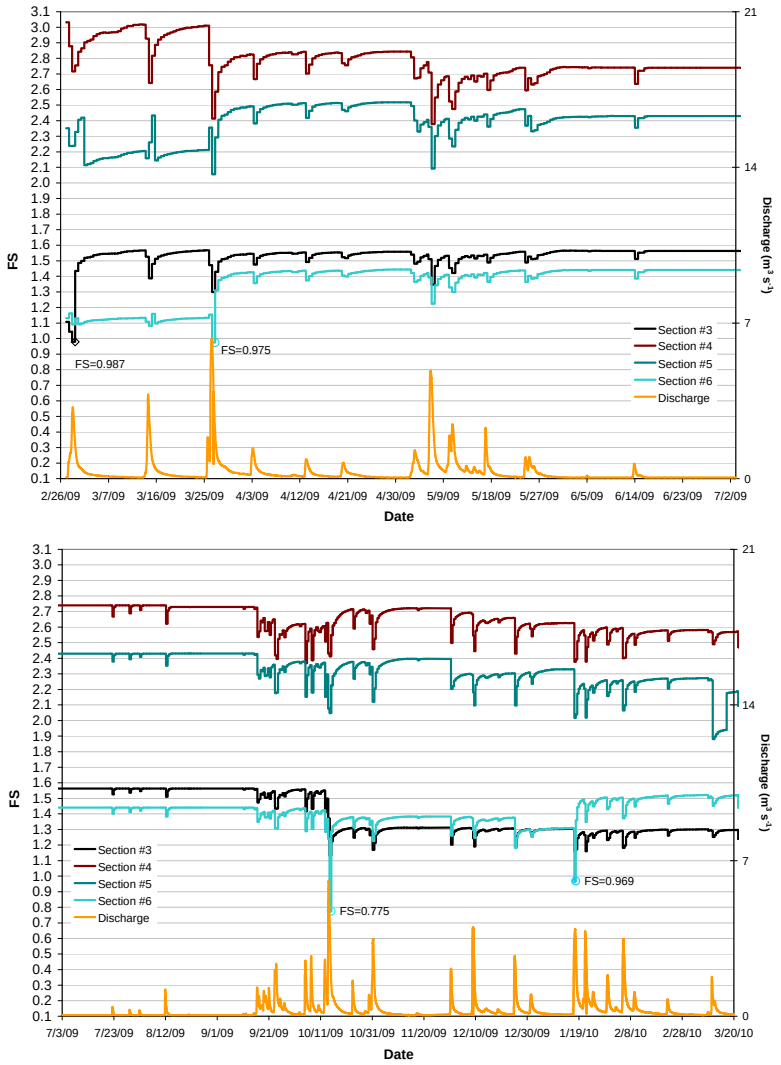

Figure 6. Predicted Factor of Safety (FS) for the left streambanks on a bendway along a 270 m long reach on the Yonaba Creek, MS, between February 22, 2009, and March 18, 2010

Streambank Top Width Retreat

Figures 7 and 8 compare simulated and surveyed cross section changes along the modeling reach obtained during the phases of calibration and validation. The changes in sections #3 and #6 were observed from the surveys performed in May 12, 2009, November 3, 2009, and March 18, 2010, and notes and pictures from field observations confirmed dates when the failures occurred. During the entire simulation, CONCEPTS accurately predicted the stability of the sections upstream and downstream of the bendway segment (Sections #1 #2, #7 and #8). The model adequately predicted in time and magnitude the 1.53 m of streambank top width retreat caused by the planar failure event that occurred on February 28, 2009, on the left streambank of section #3. In general, the simulation of individual planar failures in section #6 was well predicted in time, but the magnitude of the retreat was over-predicted. The 0.89 m of change in the streambank top width observed in March 27, 2009, was slightly over-predicted by 4.5%, but the 0.76 m retreat occurred in January 17, 2010, was over-predicted by 88.2% (Table 1). CONCEPTS predicted a change in FS that reflected a planar failure along the left streambank of section #6 in October 15, 2009, but the model under-predicted by 40.6% the 1.97 m of the top width retreat observed in the survey dated

in November 3, 2009. Overall, the total top width retreats induced by planar failures on section #3 and section #6 were well predicted by CONCEPTS with a difference of 0.02 m and 0.09 m, respectively.

Sections #1, #2 and #7 did not reflect any erosive process from these streambanks, whereas CONCEPTS overestimated the observed streambank erosion in section #8. Both conditions differed from the actual observations due to the inability of CONCEPTS to simulate sediment deposition on the streambank surface. The deposition of sediment on the streambanks surfaces represented at least a 3.5% of difference in the total amount of the actual sediment amount contributed by the streambanks.

Table 1. Observed and simulated changes in top width at the left streambank of two sections along the Yonaba Creek between February and July 2009

Failure Date	Simulated	Observed	Absolute error	Relative Error
Section #3

Positive values = Deposition Negative values (-) = Erosion

-Simulated streambank erosion yield did not include sediment deposited on streambanks surfaces

~Overall cumulated sediment yield ratio across the total amount of gross streambank erosion

+Observed streambank erosion yield included sediment deposited on streambanks surfaces

*Erosion and deposition on section #2 was merely related to exchange of loose material carried by the stormflow events. A net contribution of streambank material was not expected because the streambank was revetted with rip rap

' Estimated only for the cross section

CONCEPTS was able to simulate fluvial erosion and cantilever failures acting at the height of the left toe streambank at section #5, but was not able to replicate the different events of mass wasting which occurred above this height. Total contributions from this section represented around 16.7% of the total streambank erosion observed along the modeling reach. Mass wasting events at section #5 were induced by the scouring effect caused by the streamflow around a 0.75 m diameter corrugated pipe, which collected the concentrated runoff flow from upland. One of these observed events also included pop-out failures that occurred above the pipe height.

It was previously documented that CONCEPTS was very accurate when simulating the total magnitude of planar failures occurring sections #3 and #6. However, simulated total streambank erosion yield and contributions from both sections was overestimated by 1.8 and 1.2 times the observed results, respectively (Table 2). This condition could be caused by the difference in the actual block retention time and the 15-days value used by the model (a higher value for block retention time could not be assigned to the model due to an interruption during the running process attributed to a bug in the block retention routine, which has since been corrected). The block retention time represents the time that the failed loose material stayed on the streambank toe, protecting the streambank from fluvial erosion and streambank

failures, and reducing the amount of sediment yield directly contributed to the streambed and the streamflow after a planar failure. Figure 9 shows how after the first planar failure at section #3, the failed material could stay on the streambank toe during at least 4 more months before being removed by fluvial erosion. It also shows how the streambed received direct contribution from the failed streambank material, changing, among other conditions, the geometry of the cross section and the streambed elevation. The actual change in the streambed was not simulated by CONCEPTS after the first streambank planar failure, and in general during the entire simulation. This condition could also be an important factor affecting the net contribution of the streambank at section #3, as well as the sediment transport analysis along the entire reach. Another factor that could be affecting the total amount of sediment yield by the streambanks could be the magnitude of the soil erodibility parameter determined *in-situ* by jet testing.

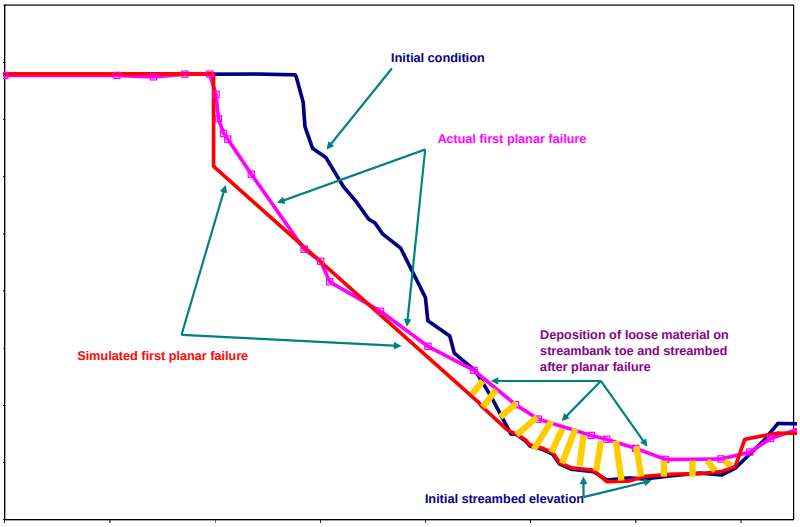

Figure 9. Comparison between actual and simulated planar failure, streambed deposition and erosion of deposited material on the streambank toe at section #3 on Yonaba Creek, MS.

CONCLUSIONS

The ability of CONCEPTS to predict streambank erosion was tested through its application to a 270 m long reach along the Yonaba Creek in Blue Springs, MS. Model predictions between February 2009 and March 2010 were compared with cross section surveys on 8 transects along the modeling reach. Results showed that CONCEPTS very accurately predicted top width retreat and streambank failures in time and magnitude. CONCEPTS simulation yielded streambank degradation predictions comparable to those observed during the studied period. An annual rate of about 2,000 Mg of streambank retreat was assessed by both methods; field measurements and CONCEPTS modeling. However, CONCEPTS did not account for sediment deposition that occurred on the streambank, a condition that slightly reduced the observed net amount of sediment yield contributed by streambank processes. Streambank gravitational failure was the dominant mechanism inducing streambank erosion for the studied reach. CONCEPTS is unable to simulate tangential flows through the bendway section. Moderate changes in the critical shear stress of streambanks for the cross sections along the bendway represent the increased shear stress generated by stormflows along this section. The presence of a pipe on the lower part of left streambank at the section #5 was represented by a modification in the magnitude of its critical shear stress. However, the model was unable to simulate local streambank retreat caused above the pipe. Although it was not observed or studied in detail, the influence of subaerial erosion processes could be significant in accounting for the total retreat amount during winter.

SEDIMENT AND NUTRIENT TRAPPING ON THE MORGANZA SPILLWAY DURING THE 2011 MISSISSIPPI RIVER FLOOD.

Daniel E. Kroes, Research Ecologist U.S. Geological Survey, dkroes@usgs.gov; Edward R Schenk; Gregory B Noe; Adam J Benthem

The 2011 Mississippi River Flood resulted in the opening of the Morganza Spillway for the second time since its construction in 1954. The opening of the Spillway structure released 7.6 km^3 of water through agricultural and forested lands into the Morganza Floodway and the Atchafalaya River Basin (the Basin). This volume represented 5.5 % of the Mississippi River (MR) discharge and 14% of the total discharge through the Basin during the Spillway operation and 1.1 % of the MR and 3.3% of the Basin 2011 water year discharge. During the release there was a net sediment deposition of 0.77 Tg over the 500 km^2 Morganza Spillway and 0.26 Tg was eroded from behind the Spillway structure. The majority of deposition (63 %) occurred in the Forebay (upstream of the structure) and within 4 km downstream of the Spillway structure with minor deposition on the rest of the Floodway. There was a net deposition of 2,600 Mg of nitrogen (N) and 536 Mg of phosphorous (P), during the diversion and was equivalent to 0.17% N and 0.33% P of the 2011 annual MR load. Deposited sediment (84%) was composed of particles that were finer than 50 μm. Median deposited sediment grain size at the start of the Forebay was 13 μm and decreased to 2 μm 15 km downstream of the Spillway structure. Deposition on the Morganza Spillway was limited by a lack of hydraulic connectivity. There was one source of water whose sediment and nutrient content were rapidly deposited. The reconnection of floodplains via flood control spillways can be an effective means to reduce nutrient loading to eutrophied water bodies, like the Gulf of Mexico.

SEDIMENT CHARACTERISTICS AND SEDIMENT TRANSPORT MODELING FOR THE SAGINAW RIVER NAVIGATION CHANNEL

John Barkach, Great Lakes Environmental Center, Inc., Farmington Hills, MI, jbarkach@glec.com
Carol J. Miller, Professor, Wayne State University, Department of Civil and Environmental Engineering, Urban Watershed Environmental Research Group, Detroit, MI, ab1421@wayne.edu
James Selegean, US Army Corps of Engineers, Detroit, MI and Seattle, WA
Fatemeh Babakhani, Wayne State University, Department of Civil and Environmental Engineering

The Saginaw River is a 22.4-mile-long (36.0 km)[2] river located in mid-Michigan and is formed by the confluence of the Tittabawassee and Shiawassee rivers southwest of Saginaw. It flows northward into the Saginaw Bay of Lake Huron. The watershed area is 6,132 square miles (15,881 km^2) and contains 315 dams. The Saginaw River is an important shipping route for mid-Michigan, passing through the cities of Saginaw and Bay City and is one of Michigan's few inland navigable rivers. To maintain the depth of the navigation channels, the Saginaw River is subject to frequent dredging. Since 1963, the Saginaw River navigation channel has been dredged 81times. A total of 22,967,252 cubic yards of sediment were removed at a cost of $65,721,086.

Prior to removal of sediment, the dredged material is subject to a pre-dredge sediment quality assessment. Since 1967, 15 sediment quality assessments have been conducted by the U.S. Army Corps of Engineers; these sediment samples were collected and tested for a variety of physical and chemical characteristics. In this paper, the sediment quality of the Upper and Lower Saginaw River, as well as Saginaw Bay are presented and discussed in conjunction with sediment transport model assumptions.

In addition, an overview of the extensive sediment transport modeling that has been conducted by the U.S. Army Corps of Engineers is discussed in relationship to the total sediment load that is transported from the Saginaw River to Saginaw Bay. These USACE studies have determined that the total sediment load from the Saginaw River to Saginaw Bay ranges from 238,099 to 280,525 tons/year. Sediment flux to the Saginaw Bay was also estimated using the BQART equation that was developed by Syvitski and Milliman (2007). Using the BQART equation, the total sediment load for the Saginaw River was calculated to be 298,724 tons/year at a mean flow (8,320 cubic feet per second) and is similar to the estimates developed by the USACE. Lastly, during the preparation of this paper, it is apparent that the GIS resources that have been developed the MDEQ and State of Michigan can potentially be used to develop a new equation that can be used for smaller streams (<30 m^3/sec) that dominate the Great Lakes region. These areas of further research are presented in this paper.

SEDIMENT CORE CHEMISTRY IN THE ESCALANTE AND SAN JUAN RIVER DELTAS IN LAKE POWELL, UT, IN 2010-2011

POSTER PRESENTATION

Nancy Hornewer, Hydrologist, USGS, Arizona Water Science Center, Flagstaff Programs, njhornew@usgs.gov.

Robert (Bob) J. Hart, Supervisory Hydrologist, USGS, Arizona Water Science Center, Flagstaff Programs, bhart@usgs.gov.

Recent studies by the U.S. Geological Survey, have documented the presence of trace elements, organic compounds including polycyclic aromatic hydrocarbons, and radionuclides in sediment from the Colorado River delta in Lake Powell, UT and from sediment in some side canyons in Lake Powell, Utah and Arizona (Hart and others, 2004 and 2005). The fate of many of these contaminants is of significant concern to the resource managers of the National Park Service at Glen Canyon National Recreation Area because of potential health impacts to humans and aquatic and terrestrial species. The U.S. Geological Survey completed sediment-core sampling in 2010, in the San Juan River and Escalante River deltas in Lake Powell, Utah, to help the National Park Service further document the presence or absence of contaminants in deltaic sediment (Hornewer, 2014).

Three sediment cores were collected from the San Juan River delta in August 2010 and three sediment cores were collected from the Escalante River delta in September 2011. Sediment from the cores was subsampled and composited for analysis of major and trace elements. Fifty-five major and trace elements were analyzed in 116 subsamples and 7 composited samples for the San Juan River delta cores, and in 75 subsamples and 9 composited samples for the Escalante River delta cores. Six composited sediment samples from the San Juan River delta cores and eight from the Escalante River delta cores also were analyzed for 55 low-level organochlorine pesticides and polychlorinated biphenyls, 61 polycyclic aromatic hydrocarbon compounds, gross alpha and gross beta radionuclides, and sediment-particle size. Additionally, water samples were collected from the sediment-water interface overlying each of the three cores collected from the San Juan River and Escalante River deltas. Each water sample was analyzed for 57 major and trace elements.

Most of the major and trace elements analyzed were detected at concentrations greater than reporting levels for the sediment-core subsamples and composited samples. For the San Juan River delta, all elements were detected in each subsample except for rhenium, sulphur, selenium, and tellurium; and all elements were detected in each composited sample except for copper, rhenium, selenium, and tellurium. For the Escalante River delta, all elements were detected in each subsample except for boron, bismuth, molybdenum, rhenium, sulphur, selenium, tin, tellurium, and zinc; and all elements were detected in each composited sample except for rhenium, selenium, and tellurium.

Low-level organochlorine pesticides and polychlorinated biphenyls were not detected in any of the samples. Low-level concentrations of several polycyclic aromatic hydrocarbons were detected in the San Juan and Escalante River deltas but were below reporting levels.

Gross alpha and gross beta radionuclides were detected in both river deltas at concentrations greater than reporting levels for all samples ranging from 8 to 32 pCi/g for gross alpha radioactivity and from 17.1 to 34 pCi/g for gross beta radioactivity. Most of the major and trace elements analyzed were detected at concentrations greater than reporting levels for water samples.

For the water samples, most of the 57 major and trace elements analyzed were detected at concentrations greater than reporting levels in the San Juan and Escalante Rivers. For the San Juan, however, cobalt, cesium, europium, nickel, and thorium were not detected in any of the samples and cadmium, phosphorus, and tin were not detected in 67 percent of the samples. For the Escalante, cobalt, chromium, phosphorus, and tin were not detected in any of the samples and tellurium was not detected in
67 percent of the samples.

SEDIMENT FINGERPRINTING TO DELINEATE SOURCES OF SEDIMENT IN AN URBAN SUB-WATERSHED WITHIN THE CHESAPEAKE BAY WATERSHED

POSTER PRESENTATION

Baker, A.C., Gellis, A.C., Sanisaca, L.G., and Noe, G.B.

The Chesapeake Bay is the nation's largest estuary, its watershed covering 165,800 square kilometers and six states. The Chesapeake Bay is designated under the Clean Water Act as an impaired water body due to degradation by excess sediment and nutrients. Eroded upland sediment contributes to the degradation of the Bay and its tributaries by transporting nutrients and toxic contaminants, burying habitat, and reducing water clarity which diminishes light penetration and subsequently affects submerged aquatic vegetation.

Land management practices are being implemented throughout the Bay watershed to reduce and control sediment erosion and transport. The identification and understanding of sediment sources to fluvial systems and a differentiation between in-stream and upland sources of erosion are important to selecting and implementing the most appropriate management actions. Sediment fingerprinting offers a method for identifying fine sediment sources and their contributions to suspended sediment flux within a watershed. This approach entails the establishment of a minimal set of environmental tracers based on physical and chemical properties that can be used to uniquely define each source in the watershed. Suspended sediment collected under different flow conditions exhibits a composite or fingerprint of these properties that allows them to be traced back to their respective sources.

The sediment fingerprinting approach is being used to help identify sources of suspended sediment to Difficult Run, a tributary to the Potomac River and to the Chesapeake Bay. Difficult Run is located in Fairfax County, VA, in the Piedmont Physiographic Province of the Mid-Atlantic Region of the United States (drainage area of 14.2 km2) (NWIS web). The Difficult Run watershed is an urban watershed crossed by several major highways, and is characterized by forested, urban, and mixed residential and commercial land cover. Potential upland sources of sediment including roads, road-cuts, lawns, and forested areas, and in-stream sources (stream banks) will be evaluated in conjunction with suspended sediment collected from Difficult Run. Preliminary results of this sediment fingerprinting analysis will be presented.

SIMULATING SALINITY CONCENTRATION AT THE COLORADO RIVER BASIN SCALE

POSTER ABSTRACT

James Prairie, Hydrologic Engineer, Bureau of Reclamation, Upper Colorado Region, jprairie@usbr.gov
David Neumann, Water Resource Engineer, Center for Advanced Decision Support for Water and Environmental Systems, University of Colorado, Boulder, david.neumann@colorado.edu
Nicholas Williams, Environmental Engineer, Bureau of Reclamation, Upper Colorado Region, nwilliams@usbr.gov
Edith Zagona, Director, Center for Advanced Decision Support for Water and Environmental Systems, University of Colorado, Boulder, zagona@colorado.edu

The U.S. Environmental Protection Agency (EPA) suggested the development of water quality criteria for salinity in the Basin following passage of the Federal Water Pollution Control Act (Clean Water Act) of 1972. In response, the Basin States formed the Colorado River Basin Salinity Control Forum (Forum) to develop numeric salinity criteria and an implementation plan to ensure compliance while allowing the Basin States to continue to develop their Compact-allocated water. The Forum recommends, the States adopt, and EPA approves the flow-weighted average annual salinity criteria for three locations on the lower Colorado River. The criteria, first established in 1975, are reviewed every 3 years; the latest review was completed in 2014.

Reclamation's long-term planning model, the Colorado River Simulation System (CRSS) implemented in RiverWare, supports the Triennial Review of the flow-weighted average annual salinity criteria in the lower Colorado River and development of a salinity control implementation plan. The framework supporting salinity modeling within CRSS begins with a nonparametric regression model to simulate the natural flow and salt mass relationship coupled with a nonparametric temporal disaggregation model to transfer from an annual to the monthly time step required for the planning model. The planning model integrates the projected natural salt mass with salinity contributed by irrigated agriculture and removed by trans-basin diversion and salinity control projects thereby simulating projected salinity concentrations throughout the Colorado River basin. This framework supports the stochastic methods required to model projected supply variability and determine the associated variability in salinity concentration that is consistent with projected supply variability. This framework is presented and its use in the 2014 Triennial Review is demonstrated.

STATE OF THE PRACTICE OF SEDIMENT MANAGEMENT IN RESERVOIRS: MINIMIZING SEDIMENTATION AND REMOVING DEPOSITS

Cox, Assistant Professor, Parks College of Engineering, Aviation and Technology, Saint Louis University, St. Louis, MO, coxal@slu.edu; Daniel M. Hanes, Professor, Department of Earth and Atmospheric Science, Saint Louis University, dhanes@slu.edu; Lisa G. Chambers, Assistant Professor, Department of Earth and Atmospheric Science, Saint Louis University, chamberslg@slu.edu

Abstract: Sedimentation in reservoirs is becoming more problematic as water storage and supply become increasingly endangered with the aging American infrastructure. Three general strategies for addressing reservoir sedimentation are currently utilized: reduction of incoming sediment yield, minimization of sediment deposition, and removal of sediment from reservoirs. This paper addresses the latter two strategies and their associated management methods. The main management methods associated with minimizing sediment deposition are construction of sediment bypass structures, sediment pass-through (or sluicing), and venting of a sediment-laden density current. The main overall advantage of sediment bypass structures is that they do not interfere with regular reservoir operation; however, the method is difficult to apply, requires careful planning, and cannot be utilized in arid climates where the need for water is high. Sluicing is one of the more often used sediment-management techniques, but depends upon the existing structure of the dam and can cause adverse impacts to the downstream environment if not carefully monitored. Density current venting is seldom-used due to its reliance on the existence and surveying of a density current; however, it has been shown to be effective under certain circumstances. The main management methods associated with removing sediment from reservoirs nearing critical storage loss are flushing and dredging. Drawdown flushing has been studied extensively and has been found to work optimally on narrow, gorge-shaped reservoirs where the water can be fully drawn down. Pressurized flushing is not implemented as often as drawdown flushing as its main purpose is in clearing the area immediately surrounding the bottom outlets of the dam. Flushing generally has more noticeable effects on the downstream ecosystem than sluicing. Dredging, the most often used sedimentation management technique, is also a highly expensive and time-consuming practice, although efficacious when complimented by other methods, particularly for settling basins at the inlet of the reservoir.

INTRODUCTION

America is aging, and its reservoirs are no exception. A report published in 1968 determined that the average annual storage loss of U.S. reservoirs was slightly more than 0.2 percent of the total initial capacity (Dendy, 1968). Though this statistic was not alarming in 1968, after nearly 50 years, about ten percent of the total initial capacity will have been lost due to sedimentation. In fact, the life expectancy of most reservoirs is only 100 to 200 years, and at least 200 of the largest United States reservoirs were more than 40 years old as of 2008 (Baker, et. al, 2008). Figure 1 is a photograph of a dam for floodwater storage in northwest Iowa that was completely silted in from years of soil erosion from land in its watershed.

Figure 1. Dam in northwest Iowa completely silted in and no longer functioning to store floodwaters (Photo by Tim McCabe; Photo courtesy of USDA Natural Resources Conservation Service; Photo by USDA NRCS).

Sediment management is now more than ever a challenge for the current generation (Morris and Fan, 1998). The predicament is further complicated with environmental concerns related to sediment capture and release. Already the effect of dams on American rivers has been so great from an ecologic or hydrologic standpoint that even the predictions of future global climate change impacts are in no way comparable (Graf, 1999). Perhaps the largest problem, however, is the lack of data for the majority of U.S. reservoirs. A report on Kansas reservoirs stated that most of the nearly 6,000 regulated reservoirs do not have bathymetric data, which is essential information for any sediment-management project (Baker, et. al, 2008). This review of the state of the practice of sediment management aims to inventory the feasibility, efficiency, and environmental impacts of various techniques currently in use.

Three main strategies exist for dealing with reservoir sedimentation: reducing incoming sediment yield, minimizing siltation, and removing deposited sediment from reservoirs. Within each of these strategies various techniques present themselves for certain situations. This review will focus on techniques from the latter two of the three aforementioned strategies. Sediment bypass structures, sluicing, and density current venting aim to minimize siltation in reservoirs; and flushing and dredging remove sediment that has settled on the bottom of reservoirs. These techniques battle the issue of sedimentation in reservoirs so that situations such as the one shown in Figure 2 of Lake Red Rock in central Iowa can be prevented or resolved.

MINIMIZING SILTATION

Many effective means of preventing storage loss in United States reservoirs focus on the upstream environment and the transport of sediment entering the low-velocity area where particles settle out; however, minimizing settling inside reservoirs also serves an important purpose in regions where flood events carry the majority of sediment, and reservoirs serve only as water supply. The main management methods associated with this particular strategy are construction of sediment bypass structures, sediment pass-through (or sluicing), and venting of the density current.

Sediment Bypass Sediment bypass structures route high-sediment flows, generally resulting from floods, around the reservoir using canals, pressurized pipelines, or tunnels. Construction of canals is an expensive practice with its viability depending upon local topography, reservoir size and shape, and hydraulics of the river system. Pressurized pipelines for bypassing sediment are also rarely used and not often mentioned in literature due to the specific conditions necessary for its successful implementation and the high cost of construction (Batuca and Jordaan, 2000). Bypass tunnels are more common than canals or pressurized pipelines, but also suffer from high investment and management costs. A majority of these structures are operated in Switzerland and Japan where slopes are high (1% - 4%) due to mountainous topography and reservoirs are small (Sumi et al., 2004). The effectiveness of this management method is seen in the Nunobiki Dam in Japan whose tunnel has allowed the reservoir to maintain a constant storage volume since 1908 (Annandale, 2013).

Abrasion at the inlet due to high sediment concentrations is the main challenge with bypass tunnels. A design suggestion to combat the degradation of the inlet involves utilizing high strength concrete (30 N/mm^2 or more) and allowing for deep abrasion protection (10 – 35 mm); however, more research is necessary on the topic (Sumi et al., 2004).

From an ecological standpoint, sediment bypassing boasts a lesser impact on the downstream environment when compared to sluicing, flushing, or no management strategy at all. During flood events, sediment from the upper reaches of the river, which would naturally flow downstream without the existence of a reservoir, remains in suspension at approximately the same concentration (Auel and Boes, 2011). The suspended sediment concentration is neither higher from scouring of the reservoir bottom nor lower from releasing the clear water at the top of the reservoir.

The main overall advantage of sediment bypass structures, however, is that they do not interfere with regular reservoir operation, as no drawdown of the water level is needed. However, the method is difficult to apply, requires careful planning, and cannot be utilized in arid climates where the need for water is high (Tigrek and Aras, 2011). In addition, regions with flood control concerns will find that sediment bypassing undermines the original intent of the reservoir (Annandale, 2013).

Sluicing Sediment pass-through, also known as sluicing, is another way of abating sediment deposition in reservoirs. For this method, the reservoir level is drawn down during the flood season and allowed to flow through the sluice gates to maintain the incoming sediment in suspension (Tigrek and Aras, 2011). When particles enter the low-velocity area of a reservoir, they settle and form a delta consisting first of the heavier coarse sediments, then further on a more shallow layer of fine sediment. This phenomenon can be seen in the illustration in Figure 3. A depiction of the sluicing technique to reduce the development of this delta is shown in Figure 4. A 1996 study of the North Fork Feather River in Northern California determined that using sluicing as a sediment-management technique viably maintained the equilibrium of sediment between the reservoir and downstream environment over an extended operating period (Chang et al., 1996). The study also showed that sluicing would not result in adverse impacts on the fish habitat downstream as long as it followed the suggested operating rules.

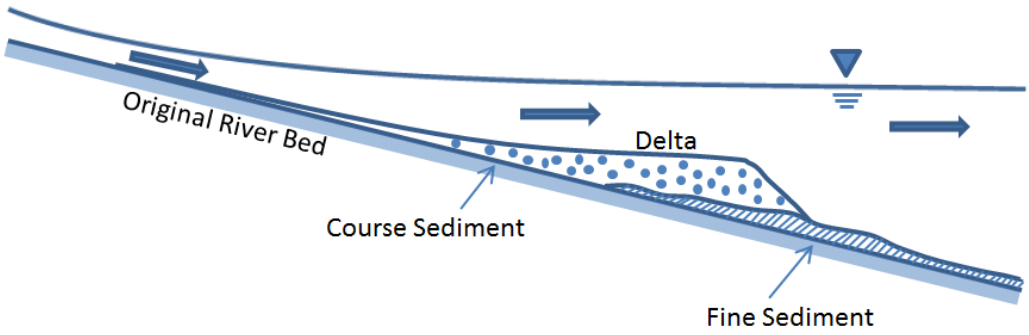

Figure 3. Longitudinal reservoir profile with delta formation.

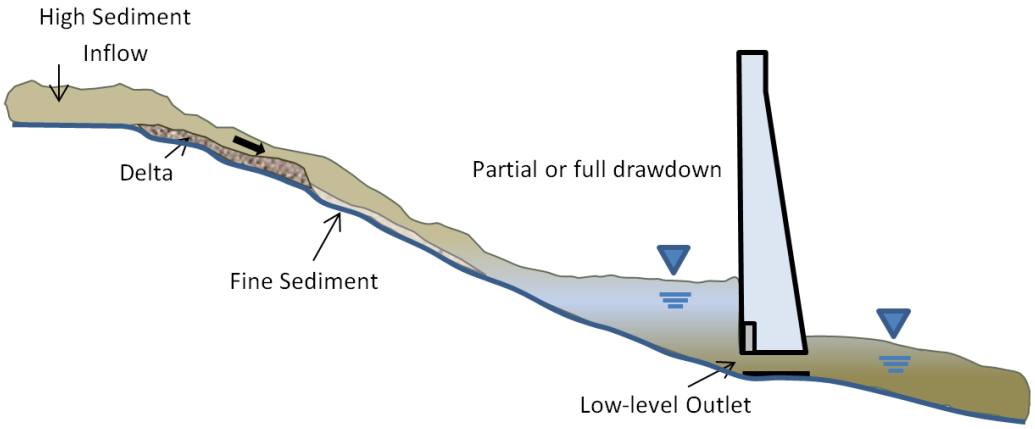

Figure 4. Longitudinal reservoir profile with sediment sluicing.

One restriction of sluicing is its dependence upon the existing structure of the dam, as sluice gates must be positioned appropriately along the bottom for the sediment to flow through efficiently. A 1988 assessment of several countries' sluicing techniques recommended that the sluice gates be at a height of 1.5 to 2.5 meters with an area determined from design curves presented in their paper (Paul and Dhillon, 1988). They also advised that only the width of the gate should be changed to increase effectiveness. In addition, Bogardi (1974) suggested that the sluicing technique is most effective when: 1) water depths are low and discharge is high; 2) sluice gates are wide and located near the bottom of the dam; 3) the original stream bed is steep and the reservoir has a short, straight bottom; 4) and the reservoir is in an advanced stage of siltation and the deposits consist of fine grained, recently settled material. With these specifications met, sluicing has been found effective in many instances, especially in China, where it is practiced routinely due to high sediment loads (Hotchkiss, 1990).

Density Current Venting Density current venting, a seldom-used technique, involves the discharge of turbid sediment-laden water from a low-level outlet (like a sluice gate) while the surface waters remain clear or unchanged. Turbidity currents develop when water with a high sediment load enters a reservoir and immediately plunges to the bottom, travelling through the original channel until settling near the dam in what is called a "muddy pool" (Morris and Fan, 1998). Management of these currents can drastically reduce sediment build-up at the base of a dam. However, density currents form only under certain conditions and can be difficult to detect. Under optimal conditions, approximately 50% of the total sediment can be vented, though the average is closer to 20% since early detection methods are lacking (Utah Division of Water Resources, 2010). One innovative way of managing density currents was developed in Japan at the Katagiri Dam where a curtain wall permitted only the sediment laden density current at the bottom of the reservoir to spill over the top of the dam (Annandale, 2013). A depiction of the standard density current venting method is shown in Figure 5.

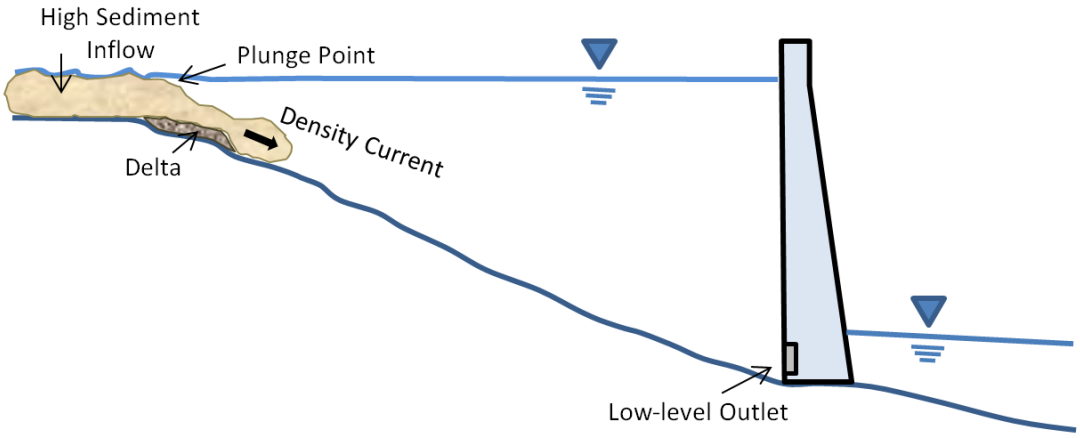

Figure 5. Density current along longitudinal reservoir profile.

A recent study of this method conducted on the Tsengwen Reservoir in Taiwan using 3D numerical models as well as measured and simulated typhoon flood events proposed the following formula for estimating the outflow concentration and venting efficiency of an outlet (Lee et al., 2014):

$$C_O = KC_L\left[\frac{(s-1)gh_L^{\ 5}}{Q_O}\right]^{1/5} \qquad \text{Eq. 1}$$

where C_o is the outflow concentration [ML^{-3}]; K is the venting coefficient calibrated based on the outlet structure [ML^{-3}]; C_L is the layer averaged concentration of the density current [ML^{-3}], s is the specific weight of the suspended solid [$ML^{-2}T^{-2}$], g is gravitational acceleration, h_L is the distance between the outlet center and the interface of clear water and dense layer [L], and Q_o is the outflow discharge [L^3T^{-1}].

REMOVING DEPOSITS

Removing sediment is quickly becoming an issue of great concern as reservoirs which were constructed decades ago without any consideration of sediment management have slowly built up enormous deposits of silt and sand and now are reaching levels which impede recreation and impact water supply. The main management methods associated with removing sediment from submerged reservoirs are flushing and dredging. Flushing can be further characterized as either drawdown or pressurized.

Drawdown Flushing Drawdown flushing is highly similar to sluicing; however, it is not executed during flood season. Rather, it is done when the river is at low-flow conditions so that drawing down the water level takes less effort and does not affect the water supply (Annandale, 2013). The operationally-favorable conditions for drawdown flushing generally occur before the flood season or at the end of the dry season (Batuca and Jordaan, 2000). A depiction of drawdown flushing is shown in Figure 6.

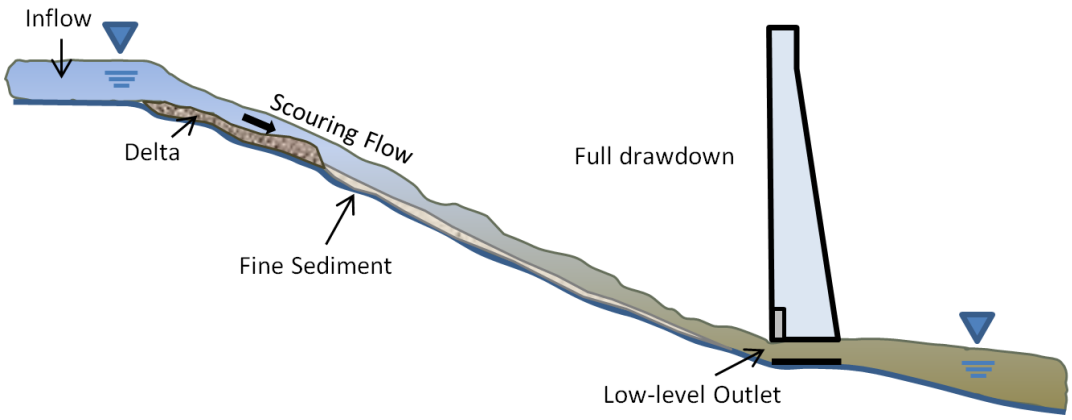

Figure 6. Longitudinal reservoir profile with sediment flushing.

A study of the Tapu reservoir in Taiwan used optimization of operational-rule curves to increase flushing efficiency, with a final recommendation that the particular reservoir be flushed every two to four years in the months of May or June (Chang et al., 2003). A more recent study on the Kali Gandaki hydropower reservoir used a three-dimensional numerical modelling program called Sediment Simulation in Intakes with Multiblock Option (SSIIM) to prove that this could be a practical alternative to the difficult task of planning and optimizing the flushing process for complex reservoir geometries (Haun and Olsen, 2012). The study also identified limitations of physical modeling of reservoir flushing, stating that the magnitude of bed forms is challenging to properly scale in a physical model.

Drawdown flushing is generally most effective in narrow, gorge-shaped reservoirs like the Gebidem reservoir in Switzerland, and water must be allowed to be fully drawn down, making it near impossible to implement in hydropower dams (Tigrek and Aras, 2011). This technique is also impossible to implement in reservoirs without low-level outlets, such as sluice gates.

Pressurized Flushing Pressurized flushing removes only a fraction of the amount of sediment when compared to drawdown flushing. This method is rarely used and its main purpose is to clear the area immediately surrounding the bottom outlets (Annandale, 2013). As the sediment is flushed out, the area around the outlet forms a funnel-shaped crater, known as a "flushing cone" (Emamgholizadeh et al., 2006). Meshkati et al. (2009) addressed the development of the flushing cone and identified a set of non-dimensional relationships which could be used to estimate the development of the cone and, therefore, increase efficiency and sediment output. Despite this progress, keeping the bottom outlets clear of sediment will likely continue to be the only valuable use of pressurized flushing.

The impact on the ecosystem downstream of the reservoir is an important consideration with either drawdown or pressurized flushing as a sediment-management method. A study of the Valgrosina reservoir in northern Italy where free-flow flushing was utilized to maintain reservoir capacity found that fish densities decreased up to 73 percent while biomass decreased up to 66 percent after a flushing event (Crosa et al., 2010). To avoid spikes in suspended solid concentration and to manage scouring effects, they recommended that a yearly flushing occur in that particular reservoir. An earlier study of regulated rivers in California suggested that flushing could help clean fine sediment deposits from downstream gravel to encourage fish spawning

(Kondolf and Matthews, 1991). However, it also observed that flushing could be counterproductive as potential high flow velocities might end up carrying some of this ecologically important bed load away with the fine sediment.

In addition to the effect on the downstream ecosystem, the associated high sediment concentrations also affect downstream infrastructure. Sediment can clog irrigation canals and heat exchangers for industrial cooling systems, wear down hydropower turbines, and cause issues at water purification plants with low capacities for suspended solids (Morris and Fan, 1998).

Dredging An expensive but effective solution to extreme storage loss in reservoirs, dredging is perhaps the most often used sediment-management technique. Dredging removes deposited sediment from the bottom of reservoirs using pumps, hydraulic suction, or clamshell buckets (Utah Division of Water Resources, 2010). A photograph of sediment-laden water being pumped as part of a dredging operation at Lake Panorama in central Iowa is shown in Figure 7. In 2010, the average cost of dredging reservoirs was estimated to be \$8.70/m^3, a serious investment for any small city operating on a budget (Smith et al., 2013). According to a 2008 study of Kansas reservoirs, dredging one of the larger reservoirs in the state could cost more than 100 times the original amount invested in constructing the reservoir (Baker, et. al, 2008).

Figure 7. Sediment-laden water pumped as part of a dredging operation at Lake Panorama in central Iowa (Photo by Lynn Betts; Photo courtesy of USDA Natural Resources Conservation Service; Photo by USDA NRCS).

One main issue with dredging is the environmental impact of disturbing several years of settled sediment. Closed buckets are recommended for areas with contaminated silts since they minimize the seepage of polluted water into the environment (Utah Division of Water Resources,

2010). However, it has also been proven that dredging can reduce eutrophication in shallow lakes and reservoirs. The 2009 report on the dredging of Lake Yuehu in central Wuhan, China, showed that internal nutrient loads were reduced and the zooplankton community had progressed toward a less eutrophic balance post-dredging (Zhang et al., 2009).

Dredging is often chosen over employing conventional best management practices (BMPs) concerning croplands. This can be attributed to the limited effect of these BMPs in comparison to the cost of implementation. It was determined in a 2013 economic study that BMP enactment should be carefully planned to optimize cost-effectiveness, and even the most effective practices may not preclude the need for future dredging (Smith et al., 2013).

SUMMARY

Sediment management in reservoirs is a complex and expensive undertaking no matter which technique is used. A perfectly sustainable solution for every situation does not exist, but efforts can be optimized for the particulars of each reservoir. Methods concerned with preventing the deposition of sediment such as sediment bypass structures, sluicing, and density current venting can be most effective in regions where high sediment loads occur often and in a predictable manner. Methods concerned with removing sediment deposits such as flushing or dredging are often used as a result of non-sustainable reservoir design in an effort to reclaim lost storage. With the aging of America's infrastructure, more attention must be focused on the upkeep of the nation's reservoirs before sedimentation renders them useless.

Abstract: The use of acoustic and other parameters as surrogates for suspended-sediment concentrations (SSC) in rivers has been successful in multiple applications across the Nation. Critical to advancing the operational use of surrogates are tools to process and evaluate the data along with the subsequent development of regression models from which real-time sediment concentrations can be made available to the public. Recent developments in both areas are having an immediate impact on surrogate research, and on surrogate monitoring sites currently in operation.

The Surrogate Analysis and Index Developer (SAID) standalone tool, under development by the U.S. Geological Survey (USGS), assists in the creation of regression models that relate response and explanatory variables by providing visual and quantitative diagnostics to the user. SAID also processes acoustic parameters to be used as explanatory variables for suspended-sediment concentrations. The sediment acoustic method utilizes acoustic parameters from fixed-mount stationary equipment. The background theory and method used by the tool have been described in recent publications, and the tool also serves to support sediment-acoustic-index methods being drafted by the multi-agency Sediment Acoustic Leadership Team (SALT), and other surrogate guidelines like USGS Techniques and Methods 3-C4 for turbidity and SSC.

The regression models in SAID can be used in utilities that have been developed to work with the USGS National Water Information System (NWIS) and for the USGS National Real-Time Water Quality (NRTWQ) Web site. The real-time dissemination of predicted SSC and prediction intervals for each time step has substantial potential to improve understanding of sediment-related water-quality and associated engineering and ecological management decisions.

INTRODUCTION

Streamflow, sediment, and water-quality data are needed to establish baseline information for water-resource managers to evaluate historical and current conditions and plan management alternatives. Real-time, continuous SSC data can be useful for monitoring river response downstream of areas affected by recent wildfires, construction or remediation activities, levee failures, or changing land uses. Additionally, real-time data can provide an early warning for operators of municipal water supply and hydroelectric facilities concerned with avoiding damage to infrastructure from sediment. Surrogates are becoming widely used to better understand physical and chemical processes in natural systems (Rasmussen and others, 2009). Acoustic technology is becoming increasingly used for velocity measurements and is also being used as a surrogate for sediment concentrations.

The Surrogate Analysis and Index Developer (SAID) tool is a standalone tool to assist in the development of ordinary least squares (OLS) regression models that relate response and predictor variables (Helsel and Hirsch, 2002) by providing visual and quantitative diagnostics to the user (figure 1). The tool is written in the Matlab® programming language. There is no limit on the number of explanatory variables to be used in the linear model and no requirement of which explanatory variables to use. SAID is under beta development and is not yet formally released as a USGS software product.

SAID has applications for relating surrogate-technology parameters such as turbidity, acoustics, and others. SAID can be used for processing acoustic parameters to be used as predictor variables for suspended-sediment concentrations (SSC).The sediment-acoustic method, which assumes a constant spatial suspended-sediment concentration and grain size distribution with respect to range along the acoustic axis of the beam, utilizes acoustic data from fixed-mount stationary acoustic Doppler velocity meters (ADVM). Some of the earliest USGS applications and research were done by Topping and others (2004, 2006, 2007), Wright and others (2010), Landers

(2012), and Wood and Teasdale (2013). The sediment-acoustic method, as described in these references, is used in SAID to compute the sediment attenuation coefficient and sediment corrected backscatter from ADVM acoustic parameters. SAID allows for quick adjustment of complex ADVM data-processing options, changes in the variables used in the regression, and evaluation of the created model. The tool also enables the user to transform loaded variables, build linear regression models, view linear model diagnostic statistics and plots, export the model information, and generate a predicted time series.

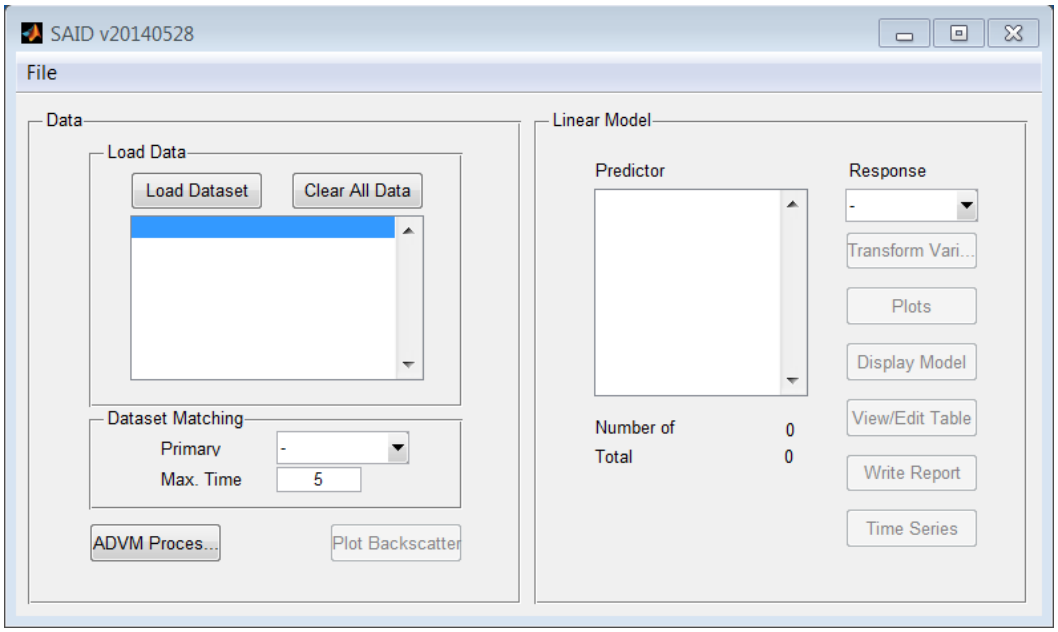

Figure 1 Main SAID window for beta version 20140528

This paper provides an overview on processing and loading data into SAID for developing regression models among surrogate data and measured constituents. In addition, this paper discusses the ADVM configuration parameters that are used in the calculation of acoustic surrogate parameters. Lastly, the paper gives an overview of how the regression models developed in SAID can be used in utilities that have been developed to disseminate predicted SSC in real-time.

SURROGATE ANALYSIS AND INDEX DEVELOPMENT

In the development of linear regression models, explanatory and response variables must be selected. These variables are contained in time series dataset files stored on disk. Because surrogate observations are continuous, and constituent observations occur at irregular time intervals, it is typical to store surrogate and constituent time series in separate dataset files. In order to choose observation sets of variables to develop a linear regression model, observations from the surrogate and constituent time series must be matched. Once a linear regression model is created from a set of matched observations, it must be evaluated for validity and appropriateness. SAID provides the ability to load and match datasets, select the response and predictor variables, and evaluate the created linear regression model. An overview of the dataset workflow is briefly described below and the following sections describe the process to develop regression models in more detail.

- ***Loading datasets***
  - Data that are stored on disk in ASCII files are loaded into memory by SAID.
- ***Choose primary datasets***
  - A dataset is selected that serves as the primary time series to synchronize observations. The selected dataset is known as the primary dataset and other loaded datasets become secondary datasets.
  - Adjusting the maximum time difference value (Max. Time) changes the upper limit of the time difference to which observations are synchronized.

- ***Choose linear model variables***
  - Available variables will be displayed in the Predictor Variables list box and the Response Variable drop-down list. SAID creates a linear model after a valid set of predictor and response variables are selected.
- ***Evaluate linear model***
  - SAID provides several diagnostic plots to determine if the created linear model created fits the assumptions of the OLS method.

Datasets: SAID is capable of loading two types of data. The term "loaded datasets" refers to datasets that have been loaded from disk. The data can be stored as tab delimited ASCII files or a collection of Argonaut ASCII files. Loaded datasets are not necessarily stored in separate files because of a constituent/surrogate relationship. Having dissimilar time steps is a typical reason for storing and loading datasets separately.

Variables with names that match the patterns CellXXAmpY and CellXXSNRY (where XX is the cell number, from 00 to 99, and Y the beam number, either 1 or 2) are dedicated variables for backscatter counts (Amp) and signal-to-noise ratio (SNR) and are used in the computation of the sediment attenuation coefficient and mean sediment corrected backscatter. These variables are not available for use in the creation of a linear model but are necessary in the computation of the ADVM acoustic surrogate metrics.

Variables named ADVMTemp and Vbeam also are dedicated variables used for the temperature and water depth. The temperature must be in units of degrees Celsius and is directly used in computing the ADVM parameters and is therefore necessary. The water depth is used to determine if the cell is out of water when the vertical orientation is selected in the ADVM Processing dialog box. A minimum Vbeam value also is set by the user in order to exclude samples taken when the water is below a certain depth.

During the time a dataset is being loaded, the program checks for variable names that are already loaded. If a variable that is in the dataset that is to be loaded exists in an already loaded dataset, then the selected dataset will not be loaded. Once the datasets are loaded, the data are then available for matching.

Matching Time-Series Observations: In order to build a linear model, it is necessary that a dataset with observations of predictor (surrogate) and response (water-quality) variables exist. Matching occurs in order to synchronize observations from the loaded datasets. The result of matching is the creation of a single dataset containing the matched data, which is then used to develop the linear model.

The primary dataset is the loaded dataset that contains the observations whose date and time of observation form the basis for matching in the secondary datasets. In a typical application for SAID, the primary dataset is the dataset that contains the constituent observations. The primary dataset is chosen by selecting it from the Primary Dataset drop-down list (figure 1). A linear model will not be created until a primary dataset is selected.

Secondary datasets are loaded datasets that contain observations that are matched to primary dataset observations. The term secondary dataset refers to all of the datasets that are not the primary dataset. Observations from the secondary datasets are only copied to the synchronized dataset if they have a date-time that matches a primary dataset observation within the user specified time interval allowance (Max. Time).

Selecting a primary dataset initiates the matching algorithm. For each observation in the primary dataset, SAID calculates the minimum absolute time difference between the observation date and time variables and the date and time variables of the secondary dataset being compared. If the minimum absolute time difference is less than or equal to the user specified value for the maximum time difference, the observations from the secondary dataset being compared are matched with the observations of the primary dataset and the values are copied to the matched dataset. If the minimum absolute time difference is greater than the user specified maximum time difference (Max. Time), then the corresponding variables in the observation in the matched dataset are set to an invalid value. In other words, the observation in the primary dataset will not be matched to an observation in the dataset being compared.

After a primary dataset is selected, the program will indicate that it is matching datasets and will remain unresponsive until the matching is complete. The time it takes for the program to create a matched dataset depends on the number of loaded datasets and the number of observations in each dataset. When the program has completed the matching algorithm, the variables available for use in the linear model are shown in the Predictor Variables and Response Variable lists.

Processing and Viewing Acoustic Backscatter Data (optional in SAID): The following ADVM-related parameters are required by SAID before the acoustic backscatter data are processed and acoustic surrogate parameters are computed:

- ADVM Configuration - Frequency, Effective Transducer Diameter, Slant Angle, Blanking Distance, Cell Size, Number of Cells
- ADVM Processing - Intensity Scale Factor (if Amp is selected for Backscatter Values), Minimum Mid-Point Cell Distance, Maximum Mid-Point Cell Distance, Minimum Vbeam

The configuration parameters are taken from a configuration record file that is saved by the ADVM with each ADVM data file. Once the required parameters in the ADVM Processing window have valid values, the ADVM parameters with at least one valid observation will be available in the Predictor Variables list. By clicking on the ADVM Processing button (figure 1), the ADVM configuration and processing options used in the calculation of the ADVM parameters can be changed (figure 2). ADVM configurations needed for input to SAID can be found in the setup parameters section of the ADVM software.

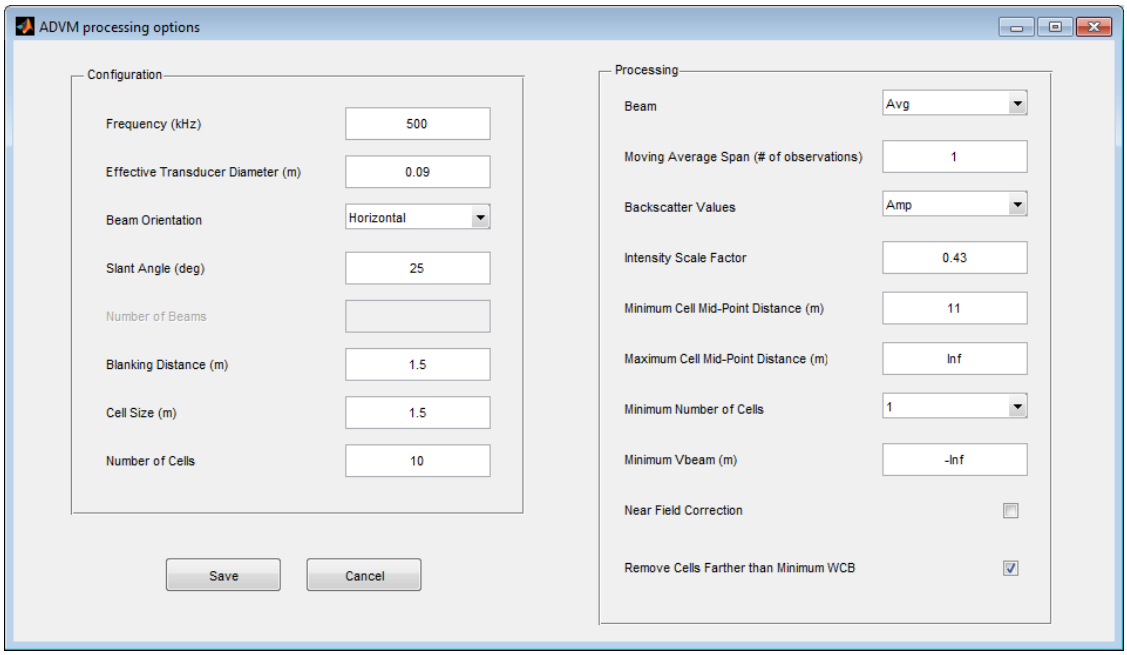

Figure 2 ADVM deployment configuration and acoustic parameter options window

Configuration Parameters: The following parameters indicate the ADVM type and setup and are necessary to compute the acoustic surrogate parameters (figure 2).

- ***Frequency*** – The frequency of the ADVM acoustic signal.
- ***Effective Transducer Diameter*** – The effective diameter in meters of the ADVM transducer. The effective transducer diameter is only used when the Near Field Correction option is selected in the Processing section.
- ***Beam Orientation*** – The orientation of the acoustic beams of the ADVM. If 'Vertical' is selected for this field, then the Vbeam for each observation is compared to the cell edges, and each cell that is out of water is marked as invalid.
- ***Slant Angle*** – The angle of the acoustic beam with respect to the vector that represents the cell distance from the instrument. This angle, along with the blanking distance, cell size, and number of cells, is used to find the mid-point distance of each cell along the acoustic beam.

- ***Number of Beams*** – The number of acoustic beams on the instrument. This value is not used. SAID assumes that the instrument has two beams.
- ***Blanking Distance*** – The distance in meters from the instrument to the beginning of the first cell. This value is used in the computation of the mid-point distance of each cell along the acoustic beam.
- ***Cell Size*** – The length of each cell in meters. This value is used in the computation of the mid-point distance along the acoustic beam of each cell.
- ***Number of Cells*** – The number of cells in the configuration of the ADVM under analysis. The number of cells directly affects the values displayed in the Minimum Number of Cells drop down list.

Processing Parameters: The following parameters control how ADVM backscatter data are screened and processed (figure 2).

- ***Beam*** – The beam number from which the backscatter values are taken. When 'Avg' is selected for this field, the average cell backscatter values are used.
- ***Moving Average Span*** – The span, in number of observations, used in a centered moving averaging of the backscatter time series. The span must be an odd positive integer.
- ***Backscatter Values*** – The backscatter values used in the computation of the ADVM parameters. When 'Amp' is selected, the backscatter values are multiplied by the value in the Intensity Scale Factor field. The Intensity Scale Factor field is made available only when 'Amp' is selected. (Caution: the model developed will be specifically for SNR or Amp units and cannot be switched without building a new model. All empirical testing for best model using SNR or Amp should be evaluated.)
- ***Intensity Scale Factor*** – The scaling factor to convert backscatter counts to decibels. This field is only available when 'Amp' is selected in the Backscatter Values drop-down list. The factor defaults to 0.43 (typical for SonTek® instruments); but should be taken from manufacturer literature for specific ADVMs.
- ***Minimum Cell Mid-Point Distance*** – The minimum distance in meters from the transducer that the mid-point of a cell has to be in order for it to be used in the computation of the ADVM parameters.
- ***Maximum Cell Mid-Point Distance*** – The maximum distance in meters from the transducer that the mid-point of a cell can be in order for it to be used in the computation of the ADVM parameters.
- ***Minimum Number of Cells*** – The required minimum number of valid cells that an ADVM sample has to have in order for its computed parameter to be included as an observation in the linear model.
- ***Minimum Vbeam*** – The minimum value for Vbeam that a sample must have in order for it to be used as an observation. Vbeam is the water height in meters that the ADVM reports.
- ***Near Field Correction*** – When the box is checked, a near field correction to the backscatter values is made (Downing and others, 1995). When the box is not checked, no near field correction is applied. In general, data from the near field should be avoided by setting the blanking distance and/or Minimum Cell Point distance greater than the near field for a given instrument.
- ***Water Corrected Backscatter (WCB) Profile Adjustment*** – When this box is checked, the range of cells that include and are beyond the cell with the minimum water corrected backscatter (minWCB) are not included in the calculation, unless the cell with the minWCB is the last or first cell in the range considered.
    - If the cell with the minWCB is the last cell, the value is retained and all cells are used to calculate the sediment corrected backscatter and attenuation coefficient.
    - If the cell with the minWCB is the first cell, all other cells are not considered, and the water corrected backscatter value in the first cell is used as the sediment corrected backscatter value for the observation, and no attenuation coefficient is calculated.

Viewing acoustic backscatter profiles: When a valid response variable is matched with valid predictor variables, the Plot Backscatter button will be made available. When this button is clicked, a window with three sets of axes is displayed. From the top, the axes show Sediment Corrected Backscatter (SCB), Water Corrected Backscatter (WCB), and Measured Backscatter (MB), all in decibels, versus the cell mid-point distance along the acoustic beam (figure 3). Also shown in the window is a list of observation numbers and times from the model. The observation times are taken from the primary dataset. Only the backscatter samples that correspond to observations in the linear model are shown. Selecting sample times in the list displays the plots of the backscatter values on the axes. Multiple observations can be selected and plotted.

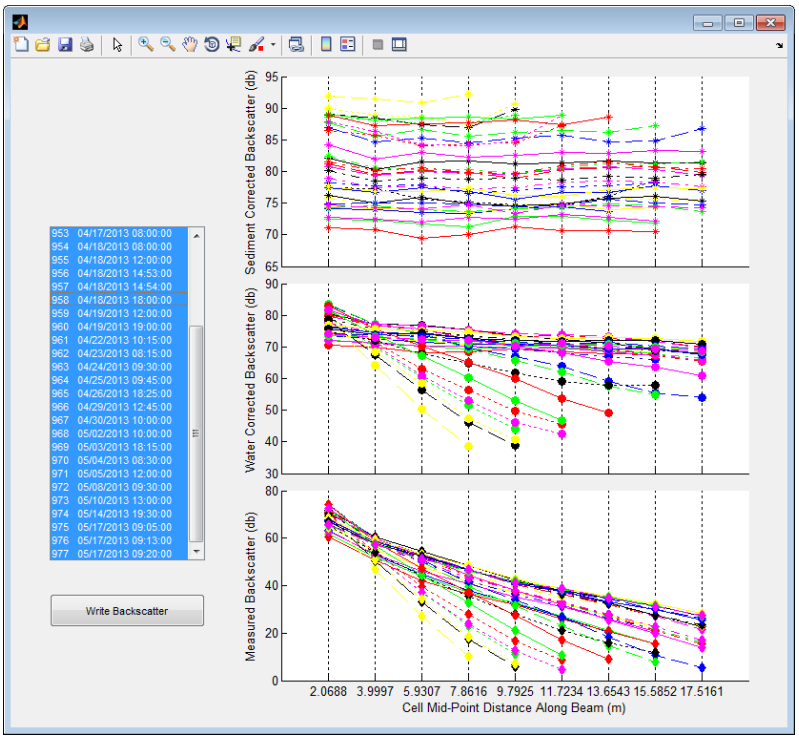

Figure 3 Backscatter profile plotting window

Development of Linear Regression Models: The available variables for use in the development of linear regression models in SAID appear in the Predictor Variable list and Response Variable in the Linear Model screen (Figure 4). There is no limit on the number of variables used in the creation of an Ordinary Least Squares (OLS) linear regression model, and there are no restrictions regarding which variables must be used. The Transform Variable button provides the option to transform a loaded variable using a transform function. When transformed, the variable will be available as a selection in the Predictor Variable list and the Response Variable drop down list.

As datasets are loaded, and if the Match Variable is a valid selection, the variables that are available for use in developing the linear model are shown in the Predictor Variables list and the Response Variable drop-down list. Selecting a variable in the Predictor Variables list, then one from the Response Variable drop-down list, will result in the generation of a model. Selecting the variable that is used for the Response Variable in the Predictor Variables list deselects the predictor variables and resets the response variable selection to the first in the list.

After a model is successfully created by selecting variables, a user can begin to evaluate the model results. This program includes tools to assist in model evaluation, available using the Plot Backscatter, View/Edit Table, Display Model, Write Report, Plots, and Time Series buttons. The number of observations used in the model is shown next to the Number of Observations label.

If a valid linear model exists within the program, the Number of Observations field will show the number of samples used in the development of the linear model. This corresponds to the number of valid observation values for the selected variables within the primary dataset. The Total Samples field shows the total number of samples in the loaded dataset. This number corresponds to the number of samples in the dataset that is selected in the Match Variable drop-down list.

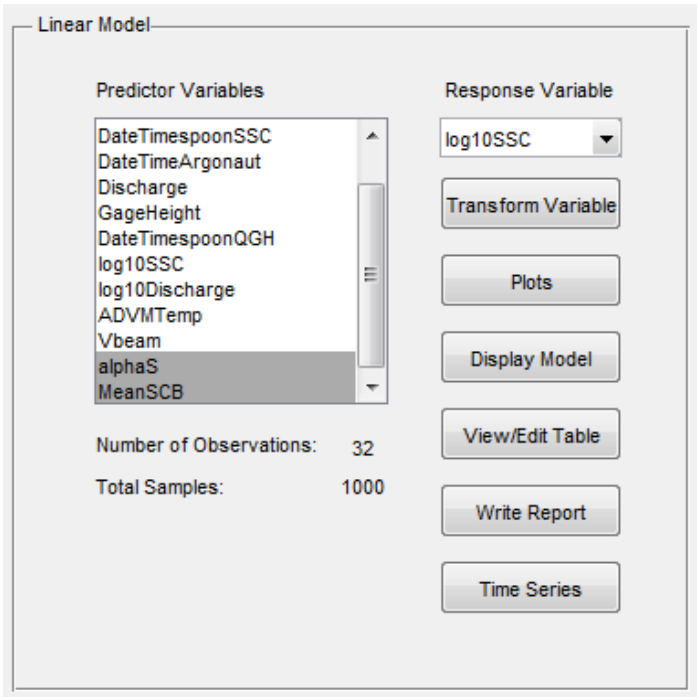

Figure 4 Linear Model options on the main SAID window

Evaluation of Regression Models: SAID provides several ways to graphically evaluate the linear model. Clicking on the Plots button within the main SAID window will display another window that provides several plotting options. In any plot figure, if Data Cursor Mode is enabled, any observation data point can be selected and the corresponding observation number will be shown along with the values plotted. The Model button will show different figures depending on if the linear model is a simple linear regression (SLR) or a multiple linear regression (MLR) or if the response variable is transformed. If the existing linear model is an SLR model, then a figure with the response observations plotted against the explanatory observed values will be shown (figure 5). When the existing model is an MLR, a partial residual plot for each variable in the model will be shown. If the response variable is transformed, then a linear-space plot will be shown with a smeared estimate fit line and confidence bounds.

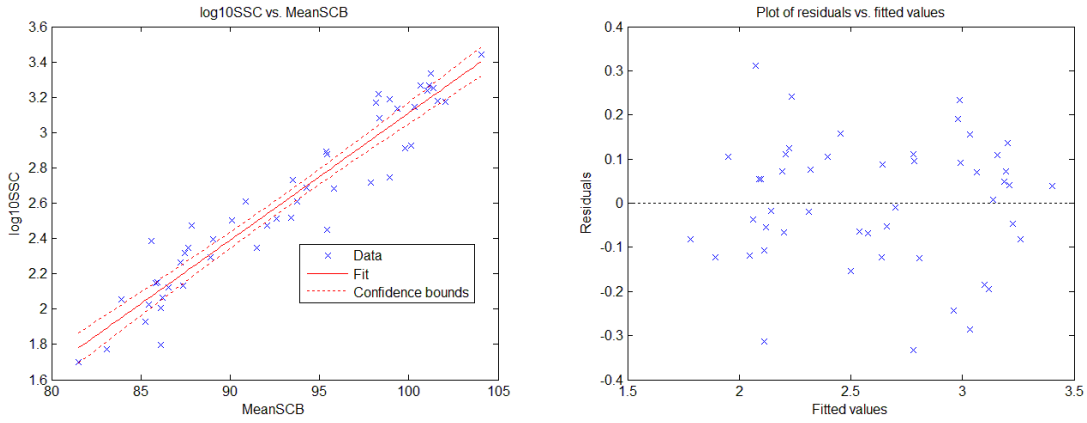

Figure 5 Linear model scatter plot and residual plot for a SLR model

Predicted versus observed plots can be selected to display the predicted response variable with the observed response variable. Also plotted is a one-to-one data line for comparison. If the response variable is transformed, then an additional figure will show the predicted versus observed values in linear space. Additionally the following residual plots can be selected:

- ***Raw Vs. Fitted***—Illustrates a plot of the raw residuals against the fitted response values.
- ***Probability***—Normal probability plot of raw residuals.
- ***Stan. Ser. Corr.***—Standard serial correlation plot of the residuals shown with a LOWESS fit line to detect autocorrelation. If the LOWESS fit line shows a trend that deviates far from 0, serial correlation may be present.
- ***Vs. Time***—Raw residuals plotted against time to see if a time dependent trend exists with the residuals.

The Display Model button will provide a window that displays the model results and statistics (figure 6). The information includes the linear equation, coefficient estimates, estimated confidence intervals, R^2 values for the model, and root mean squared error. This information also is written to a report with the Write Report button on the main SAID window.

Figure 6 Linear model regression model statistics window

Clicking on the View/Edit Table button will display a window that contains the observation information used in the model. The information shown is the observation number, the corresponding primary date and time variable, the response variable, and the predictor variables. Also shown are diagnostic statistics for each observation for outlier detection (Helsel and Hirsch, 2002). Calculated indicator values that exceed the corresponding critical values for the model are highlighted in red.

Observations can be removed by checking the boxes in the far left column and clicking the Remove Observation button. This action flags the date and time within the program and sets the variables that correspond to the date and time to an invalid value. Once a date and time is flagged as removed, any future variables that are used in the model will have the corresponding values set as invalid. This will continue until the Restore All Observations button is clicked, which clears the date and times flagged.

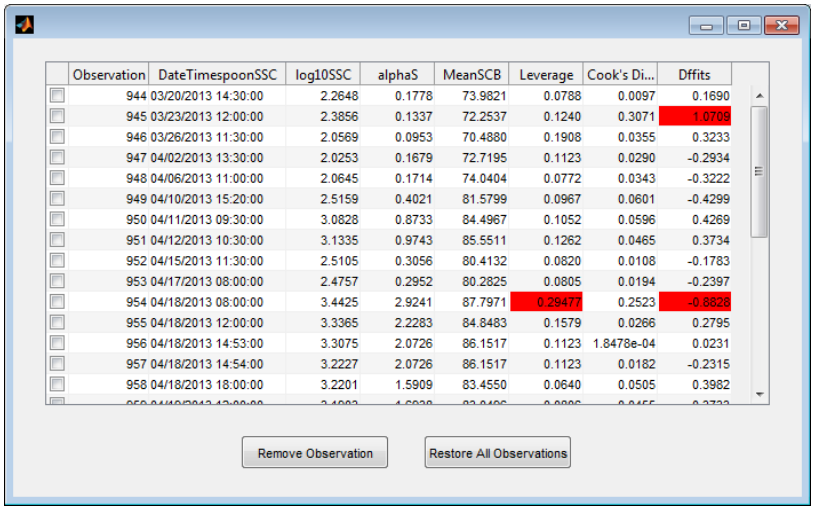

Figure 7 Observation table window used to view and remove observations from the model dataset

Generation of Report Output: To write a full summary report for the linear model, click on the Write Report button within the main SAID window. The user will be prompted for a location and name of a comma separated value file to write the report to. Selecting and entering a valid location and file name will write the report. The contents of the report include:

- ADVM configuration and processing options
- Dataset file names and locations
- Linear model summary and statistics
- Critical outlier indicator values
- The dataset observations that were used in the creation of the model along with Observation number, fitted response variable values, raw residuals, an estimate of the non-transformed variable with bias correction applied (if the response variable is transformed), and calculated outlier indicator values
- The observations that were removed from the model dataset

REAL-TIME DATA DISSEMINATION UTILITIES

After a surrogate regression model is developed and approved, the model can be used to generate continuous, real-time SSC estimates. The USGS has two utilities that make use of the computational algorithms in SAID to continuously estimate and display real-time sediment data:

- Real-time Acoustic Sediment Surrogate DAta Transfer (RASSDAT) program
- National Real-Time Water Quality (NRTWQ) program

RASSDAT is a Visual Basic Graphical User Interface (GUI) wrapped around a Python™ script that runs on a Windows® computer (figure 8), interfaces with the USGS National Water Information System (NWIS), and displays computed SSC on the NWIS Web Interface (http://waterdata.usgs.gov/nwis). NRTWQ is run from a centralized server and displays computed SSC on the NRTWQ Web site (http://nrtwq.usgs.gov/; figure 9). RASSDAT is under beta development and is not yet formally released as a USGS software product. Questions about RASSDAT development can be directed to the authors.

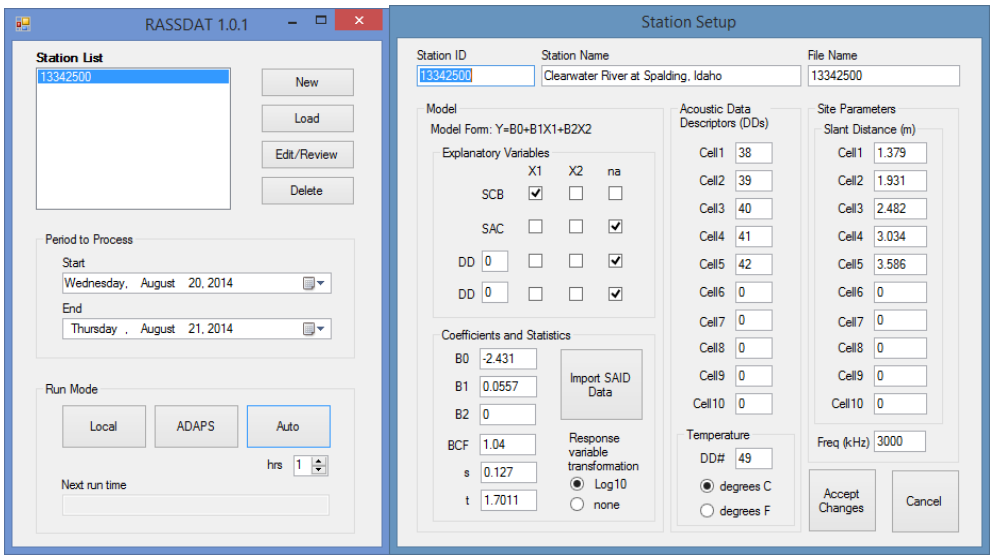

Figure 8 Screen captures of main processing (left) and station setup (right) windows from the USGS RASSDAT program, beta test version 1.0.1.

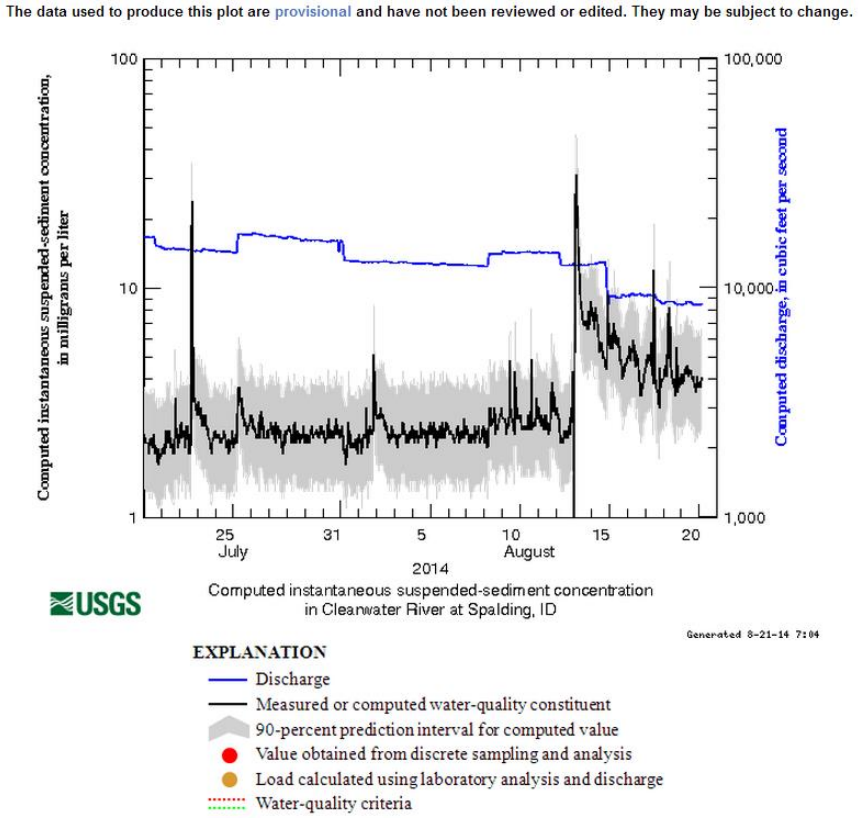

Figure 9 Screen capture from NRTWQ Web site showing example of SSC and SSC prediction intervals computed by using a sediment acoustic surrogate model developed for the Clearwater River at Spalding, Idaho (USGS Identification number 13342500).

SUMMARY

The use of continuous parameters as surrogates for water quality constituents has been successful in multiple applications across the Nation. Critical to advancing the operational use of surrogates are tools to process and evaluate the data along with the subsequent development of regression models from which real-time sediment concentrations can be made available to the public. Recent developments of these tools are having an immediate impact on surrogate research, and on surrogate technologies for monitoring, assessment, rapid decision making, and adaptive management. The Surrogate Analysis and Index Developer (SAID) standalone tool processes complex datasets and creates regression models that related surrogate to constituent data by providing visual and quantitative diagnostics to the user. SAID is currently under development and beta testing at the U.S. Geological Survey.

SAID can be used to create regression models between surrogate data and constituent measurements. Additionally, SAID is a standalone tool to assist in the development of ordinary least squares (OLS) regression models with any response and predictor variables by providing visual and quantitative diagnostics to the user. There is no limit on the number of variables that can be used in the linear model, and there are no restrictions regarding which variables must be used. The sediment acoustic method utilizes acoustic parameters from fixed-mount stationary equipment with the assumption that the sediment concentration along the acoustic beam path is constant for a given time period. Within SAID, the user can set ADVM configuration and processing options, transform a loaded variable, build linear regression models, view linear model diagnostic statistics and plots, export the model information, and generate a predicted time series.

After a surrogate regression model has been developed and approved, the model can be used to generate continuous, real-time SSC estimates. Results from SAID provide direct inputs to two USGS utilities: the Real-time Acoustic Sediment Surrogate DAta Transfer (RASSDAT) program and the National Real-Time Water Quality (NRTWQ) program. The output from these utilities are displayed on USGS Web sites as real-time continuously computed sediment data. RASSDAT, currently under development and in beta testing at USGS, is a Visual Basic Graphical User Interface (GUI) wrapped around a Python™ script that runs on a Windows® computer, interfaces with the USGS National Water Information System (NWIS), and displays computed SSC on the NWIS Web Interface (http://waterdata.usgs.gov/nwis). NRTWQ is run from a centralized server and displays computed SSC on the NRTWQ Web site. The real-time dissemination of predicted SSC and prediction intervals for each time step has substantial potential to improve understanding of sediment-related water-quality and associated engineering and ecological management decisions.

ACKNOWLEDGEMENTS

The USGS Midwest Region and the Federal Interagency Sediment Project supported the development of these utilities. The Midwest Region support was through the River Sediment and Nutrient Investigations Initiative. We thank the many beta testers for their thorough testing and comments. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Geological Survey.

THE INFLUENCE OF SAMPLING TECHNIQUE ON BEDLOAD PREDICTION

Darren D. Hinton, P.E., Ph.D., Northwest Hydraulic Consultants, 835 S. 192nd Street, Bldg C, Ste 1300, Seatac, WA 98148 | Phone: (206) 241-6000 | Email: DHinton@nhcweb.com

Abstract: The difficult task of predicting the quantity and timing of bedload motion in gravel bed streams is complicated by limitations in sampling technique. This work illustrates a specific example where two common direct sampling techniques (Helley-Smith and net trap sampler) failed during flood flows and describes a new low cost technique that was able to successfully collect bedload samples at high discharges.

Early in the spring of 2013 net trap samplers were set up at three sites along Hobble Creek, a coarse-bed stream that flows through Springville City, Utah into Utah Lake. Then exceptionally unusual weather patterns produced a series of flood events that exceeded bankfull discharge by as much as four times. The net traps were no longer accessible and the back-up method, hand-held Helley-Smith samplers, were unusable. Attaching net trap samplers to the end of a pole and securing the pole against the flow with a tether to both banks, bedload samples were able to be collected during the highest flows of the season. This new technique was referred to as a Stanley sampler, or pole-mounted net trap.

Forty-one samples were collected on a Central Utah stream using this new technique and are used to illustrate the influence of sampling technique on bedload transport rate prediction. Four bedload formulae are compared to the data to show how predictive success of any given formula is related to the sampling technique used to collect the data from which it was derived. In other words, a formula derived from Helley-Smith data will perform better predicting against other Helley-Smith data than a formula derived from net trap data, and vice-versa. This work also provides evidence that the Helley-Smith and net trap samplers collect two very different sampling populations that must be considered when selecting a predictive formula.

Abstract: The Rangeland Hydrology and Erosion Model (RHEM) is a newly conceptualized model that was adapted from relevant portions of the Water Erosion Prediction Project (WEPP) Model and modified specifically to address rangelands conditions. RHEM is an event-based model that estimates runoff, erosion, and sediment delivery rates and volumes at the spatial scale of the hillslope and the temporal scale of a single rainfall event. It represents erosion processes under normal and fire-impacted rangeland conditions. Moreover, it adopts a new splash erosion and thin sheet-flow transport equation developed from rangeland data, and it links the model's hydrologic and erosion parameters with rangeland plant community by providing a new system of parameter estimation equations based on diverse rangeland datasets for predicting runoff and erosion responses on rangeland sites distributed across 15 western U. S. states. A dynamic partial differential sediment continuity equation is used to route sediment along the hillslope, with sediment source terms to represent the detachment rate of concentrated flow and rain splash and sheet flow. Recent work on the model is focused on representing intra-storm dynamics, using stream-power as the driver for detachment by flow, and deriving parameters for after fire conditions. Additional work to the model is continuing on the RHEM system: a new component has been developed to estimate erosion in probabilistic terms for risk-based management decisions; it will be improved to allow for orographic effects on precipitation by incorporating existing technology based on PRISM and CLIGEN; the model will be improved for application to both undisturbed and disturbed conditions across the western US. The purpose of this paper is to present the Web-based RHEM system and demonstrate the tool for assessing annual runoff and erosion changes for each community phase of the Limy Upland 12-16" p.z. Ecological Site (ES) within Major Land Resource Area 41 (MLRA 41), southeastern Arizona, USA.

INTRODUCTION

Rangelands are estimated to cover approximately 31% of the United States (Havstad *et al.*, 2009), and developing tools for assessment of those lands is a critical resource management need. Predicting soil erosion is common practice in rangeland management for assessing the effects of management practices and control techniques on soil productivity, sediment delivery and offset water quality. Effective decision-making requires the integration of knowledge, data, simulation models and expert judgment to solve practical problems, and to provide a scientific basis for decision-making at the hillslope or watershed scale (National Research Council, 1999). Over the last 50 years the federal government has spent millions of dollars on the creation of spatial datasets and model development. While these simulation models are used extensively in research settings, they are infrequently incorporated into the decision-making process. One aspect of erosion modeling is the continued use of simpler, empirically-based erosion models (e.g. USLE, MUSLE, and RUSLE) instead of more complex, physically-based models (e.g. WEPP, DWEPP, EUROSEM). Reasons for the exclusion include: data requirements are usually only attained in research settings; deriving model input parameters is extremely time consuming and difficult; and the models are difficult to use with the current interfaces.

This problem can be addressed with improvement to model interfaces, lookup tables for model parameters, and internal file management. However, as erosion models continue to become more complex and integrate with other technologies, users will be required to have experience in GIS, computer operating systems, remote sensing, Internet

search engines for data gathering, and graphics, as well as good foundation of erosion processes knowledge. One solution to this problem is the development of Internet-based applications (Kingston *et al.*, 2000; Elliot, 2004; Flanagan *et al.*, 2004).

A Web-based interface for the Rangeland Hydrology and Erosion Model has been developed by the USDA-Agricultural Research Service, Southwest Watershed Research Center in Tucson, Arizona to assist different professional or stakeholder groups to develop, understand and evaluate alternative soil conservation strategies. It was built with the following goals in mind: 1) simplify the use of RHEM; 2) manage users sessions; 3) centralize scenario results (model runs); 4) compare scenario results; and 5) provide tabular and graphical results.

This paper describes the current status of the RHEM Web-based interface, and provides an example application of the software.

MODEL DESCRIPTION

Rangeland Hydrology and Erosion Model Concepts: RHEM computes soil loss along a slope and sediment yield at the end of a hillslope (Nearing *et al.*, 2011). Splash and sheet erosion is described as a process of soil detachment by raindrop impact and surface water flow, transport by shallow sheet flow and small rills, and sediment delivery to larger concentrated flow areas such as arroyos. Sediment delivery rate from hillslopes is computed by using an improved equation developed by Wei *et al.* (2009) using rangeland runoff and erosion data from rainfall simulation experiments. Concentrated flow erosion is conceptualized as a function of the flow's ability to detach sediment, sediment transport capacity, and the existing sediment load in the flow. The appropriate scale of application is for hillslope profiles. Details of the model have been published (Nearing *et al.*, 2011; Al-Hamdan *et al.*, 2012a, 2012b, 2013, 2014).

RHEM has been applied successfully to illustrate the influence of plant and soil characteristics on soil erosion and hydrologic function in MLRA 41 located in the Southeastern Basin and Range region of the southern U. S. (Hernandez *et al.*, 2013); assess non-federal western rangeland soil loss rates at the national scale for determining areas of vulnerability for accelerated soil loss using USDA Natural Resources Conservation Services (NRCS) National Resources Inventory (NRI) data (Weltz *et al.*, 2014); predict runoff and erosion rates for refinement and development of Ecological Site Descriptions (Williams *et al.*, 2014).

Model Parameter Estimation: The RHEM model requires 13 input parameters grouped in three categories: rainfall, soils, and slope profile. An important aspect of the model relative to rangeland application by rangeland managers is that RHEM is parameterized based on four plant lifeform classification groups (annual grass and forbs, bunchgrass, shrubs, and sodgrass) (Nearing *et al.*, 2011). RHEM is continuing to evolve and improve, in RHEM V [2.2], a new set of parameter estimation equations were developed based on the regression equations of Rawls *et al.* (1982), as a function of soil texture, litter percent cover and basal percent cover to estimate effective hydraulic conductivity for the Smith-Parlange infiltration equation. The link http://apps.tucson.ars.ag.gov/rhem/ provides further details about the equations to estimate effective hydraulic conductivity for the Smith-Parlange infiltration equation.

WEB-BASED RHEM INTERFACE

In this section, we describe the Web-based interface for RHEM and its components for assessing runoff and erosion changes under several land management alternatives. It was designed as a shared application to assist in the decision-making processes and to offset the software and data requirement typically required in a desktop application.

Software Architecture: The RHEM Web-based tool has been developed based on the Model-View-Controller* (MVC) software architectural pattern which promotes the separation between the application logic and the presentation or user interface. This software architecture style allows for future application modifications and updates to be more flexible, encouraging code modularity, code reuse, and data integrity. CodeIgniter* was the web application framework selected to implement MVC in the RHEM Web Tool. CodeIgniter* is a lightweight and high-performance web application framework written in PHP with a rich set of libraries that facilitate the

implementation of user authentication, web page caching, data persistence, session management, and application security. These features added agility to the development of the RHEM Web Tool.

Hardware Architecture: The RHEM Web Tool has been created based on a well-established three-tier architecture which is a client-server architecture in which the application presentation, processing, and data management functionalities are physically separated. The three tiers are: 1) the presentation tier, 2) the application logic tier, and 3) the data tier. For the RHEM Web Tool, the presentation tier is the user or client's PC whereas the application logic tier is powered by a Dell Xeon* 3GHz Windows* 2008 Server running IIS7. The data tier is powered by a Dell Xeon 3GHz Windows 2008 Server machine running MySQL* 5.1

*Trade names and company names, included for the reader's benefit, do not imply endorsement or preferential treatment of the product listed by the USDA or The University of Arizona.

Overview of the Web-based system: Figure 1 illustrates the operations performed within the system and the numbers on the inside of the circle show the sequence in which they are performed. First the user accesses the application through an Internet browser interface, and must register to use the application and to be notified of any major updates, and to allow the user to save and edit scenarios that they create. The following steps describe the sequence of actions to run the model: 1) create a new scenario, 2) select a climate weather station, 3) select a soil texture class, 4) provide a description of slope and topography characteristics, 5) provide estimates of foliar canopy cover and ground cover characteristics, 6) run new scenario, and 7) perform comparison of scenarios.

Once the user has logged in, they can create a new scenario within the Define Scenario Panel (1 in Figure 1) by typing a name that identifies the new scenario and providing a short description of the project on the Name and Description dialog boxes, respectively. A scenario is defined as a unique set of input parameters needed to run RHEM. It can be saved to view results, compared with other scenarios, or modified to create a new scenario. The user can select the units to be used for the current scenario's input and output values.

The second step involves entering the climate data to parameterize the simulation model. In the Climate Station Panel (2 in Figure 1) two dialog boxes are available, in the State dialog box select the state of the project location and in the Name dialog box select the name of the climate station that is close to the location being analyzed or a station with similar elevation to the study area. Climate data is obtained via the CLIGEN climate generator [Zhang and Garbrecht, 2003]. RHEM uses the CLIGEN model to generate daily rainfall statistics for a 300-year weather sequence that is representative of a time-stationary climate and used by the rainfall disaggregation component of RHEM. The disaggregation component uses rainfall amount, duration, ratio of time of peak intensity to duration, and the ratio of peak intensity to average intensity to compute a time-intensity distribution of a rainfall event. The CLIGEN database consists of 2600 weather stations across the continental US.

In the Soil Texture Panel (3 in Figure 1), the user defines the soil texture of the upper 4 cm (1.57 in.) of the soil profile. It is input as a class name from the USDA soil textural triangle. The RHEM database contains a list of soil hydraulic properties to parameterize the Smith-Parlange infiltration equation and look-up tables with percent of sand, silt and clay to estimate the Darcy-Weisbach friction factor (Al-Hamdan *et al*., 2013), and the maximum initial concentrated flow erodibility coefficient (Al-Hamdan *et al*., 2014).

To characterize the topography of the hillslope profile, the Hillslope Profile Panel (4 in Figure 1) presents three dialog boxes to enter the slope length, slope shape, and slope steepness. In regard with the estimation of the slope length in RHEM, we define slope length as the length of the path that water flows down a slope as sheet and rill flow until it reaches an area where flow begins to concentrate in a channel, or to the point where the slope flattens out causing deposition of the sediment load. Slope length up to 120 m (394 ft.) are supported. A distance greater than 120 m (394 ft.) is considered to be a very long slope length. In addition, RHEM provides four hillslope shapes for different topographic scenarios as follows: uniform, convex, concave, and S-shaped. In order to assess sediment delivery from a hillslope to a channel, the user must designate the shape of the hillslope either as a concave or S-shaped. These are the slope shapes that will experience toe-slope deposition. The slope steepness is the slope of the hillslope area rather than the average land slope.

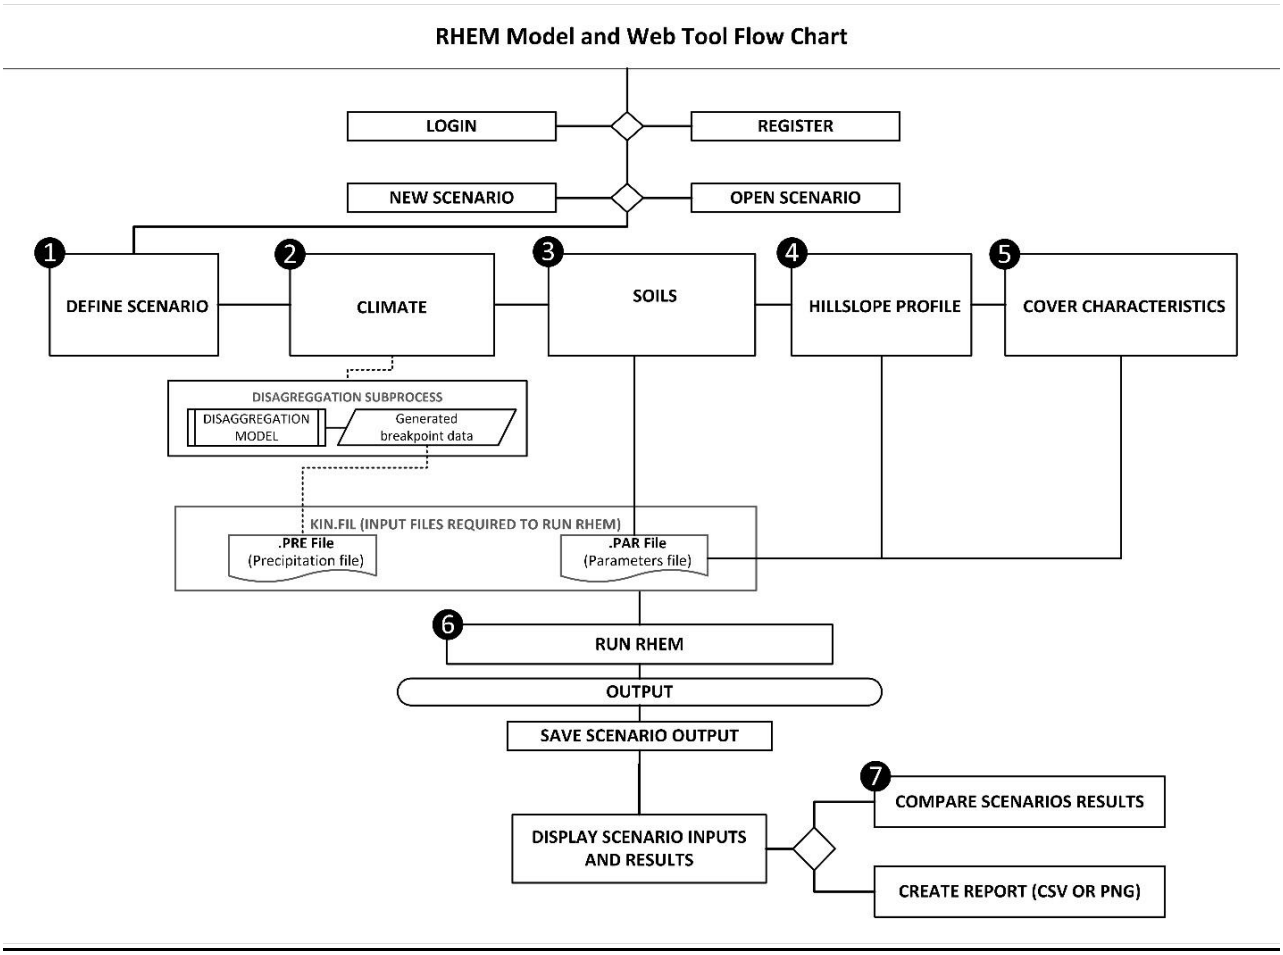

Figure 1. RHEM Web-based system schematic.

The Cover Characteristics Panel (5 in Figure 1) presents nine Dialog Boxes to enter information on vegetative foliar canopy cover and surface ground cover. RHEM's system of parameter estimation equations and procedure reflects the concept that hydrology and erosion processes are affected by plant growth forms and surface ground cover. Thus, the user can enter percent foliar canopy for four rangeland plant communities: bunchgrass, shrub, sodgrass, and annual grass and forbs. In regard with surface ground cover input parameters, RHEM was designed to require minimal inputs that are readily available for most rangeland ecological sites. Percent ground cover by component are defined as follows: rocks, plant litter, plant basal area, and biological soil crust.

The Run Panel (6 in Figure 1) is used to generate output from: a new scenario, an edited scenario, and re-named scenario. The web-based interface generates a summary report, input parameter file, and the storm file.

The Comparison Panel (7 in Figure 1) allows the user to compare up to five existing scenarios.

MODEL APPLICATION

The reminder of this paper will be comprised of an example application of the RHEM Web-based interface, and examining how it can be used to evaluate the hydrologic response of plant communities to management and disturbances as conceptualized within a State-Transition Model (STM) of an Ecological Site Description (ESD).

Experimental Site: We illustrate the use of the RHEM Web-based interface at the Kendall Grassland site ($109^{O}56'28"W$, $31^{O}44'10"N$), 1526 m asl), located in the Walnut Gulch Experimental Watershed (WGEW), *ca*. 11 km east of Tombstone, AZ. The mapping unit consisting of a complex of Loamy Upland and Limy Slopes covers much of the northeastern portion of the watershed, including the grass-dominated study area known as Kendall.

According to Skirvin et al. (2008), the Kendall Grassland is a desert grassland, historically dominated by black grama (*Bouteloua eripoda*), side-oats (*B. curtipendula*), hairy grama (*B. hirsute*), tangle-head (*Heteropogon contortus*), curly mesquite (*Hilaria berlangeri*), and the exotic South African bunchgrass, Lehmann lovegrass (*Eragrostis lehmanniana*). Soils at the Kendall site are in the Elgin-Stronghold complex and are dominated by Stronghold series, which are gravelly fine sandy loams, classified as coarse-loamy, mixed, superactive thermic Ustic Haplocalcids (Breckenfeld *et al.*, 1995). The climate of the area is semiarid with annual precipitation of 345 mm and a highly spatially and temporally varying precipitation pattern dominated by the North American Monsoon. Monsoon storms are typically characterized as short-duration, high intensity, localized rainfall events. Mean annual temperature is 17.7^{O}C.

Potential problems with Limy Slopes include invasion by Lehman lovegrass (*Eragrostis lehmanniana*) or the shrub species dominant on Limy Upland. With long-term erosion, Limy Slopes can lose their mollic cap and degrade to a Limy Upland site with calcic material at the surface (Robinett, 1992). Loamy Upland, found on 1 to 15 % slopes, is very prone to invasion by Lehmann lovegrass, as well as mesquite (*Prosopis sp*). Both Limy Slopes and Loamy Upland have a much greater natural potential to produce grass than Limy Upland, with up to 85% of the annual production on undisturbed sites coming from grass and grasslike species (Robinett, 1992).

A STM for the Limy Slopes ecological site is shown in Figure 2. The model for this site includes 4 states. The ecological states are outlined by bold black rectangles. Plant community phases are shown by light gray rectangles. Within the Historic Climax Plant Community (HCPC) state, fire and drought could cause temporary shifts between the two plant communities shown. The Eroded state is considered so degraded by soil erosion that it has crossed a threshold and now has a different, less productive, potential plant community.

By 2006, seed sources for the both shrub and Lehmann lovegrass (Transition 1a) had appeared in the upland areas around Kendall study area (Heilman *et al.*, 2010). The vegetation was beginning to transition from the HCPC state toward the Lehmann state as small shrub trees were getting established. Prolonged drought resulted in high perennial grass mortality prior to the 2006 summer monsoon (Robinett, 1992), and 2006 saw a significant shift toward the Exotic grass and the Shrub invaded states, which impacted the hydrological and sediment response of the system for a period of time (Polyakov *et al.*, 2010).

If the principal management objective is to minimize runoff and erosion, one might favor the Lehmann state, as this exotic grass can produce up to a third more biomass than native grasses, once established (Robinett, 1992).

Hydrology and Erosion Model: The RHEM model was applied to estimate annual runoff and erosion for each plant community phase of the Limy Slopes 12-16" p.z. ES. We applied the methodology developed by Williams *et al*. (2014) for integrating eco-hydrologic information into the ESD, therefore, key information was extracted from the approved NRCS ESD for the Limy Slopes 12-16" p.z. ES (USDA-NRCS 2014) and from the rainfall simulator study conducted by Hamerlynck *et al*. (2012) at the Kendall site. The study by Hamerlynck *et al*. (2012) was carried out on four 2 x 6 m plots that took place from 21 June to 24 July 2008 at the Kendall Grassland site, they recorded and classified canopy cover as grass, shrub, or forb. The relative dominance (% of plant canopy) of the invasive Lehmann lovegrass, all native bunch grasses, and broad-leaved forbs was estimated by dividing the sum of hits for each plant by the total number of plants hits for each plot. Ground cover was recorded as rock + gravel (> 2mm), litter, basal, and bare soil and was measured both under and between canopy cover. They defined litter as dead plant material in contact with the soil surface. Total vegetative canopy cover was 20-26% in low-cover plots and 43-56% in high-cover plots, however, with the former dominated by the invasive South African bunchgrass, Lehmann's lovegrass. Ground cover was similar in terms of litter and basal area.

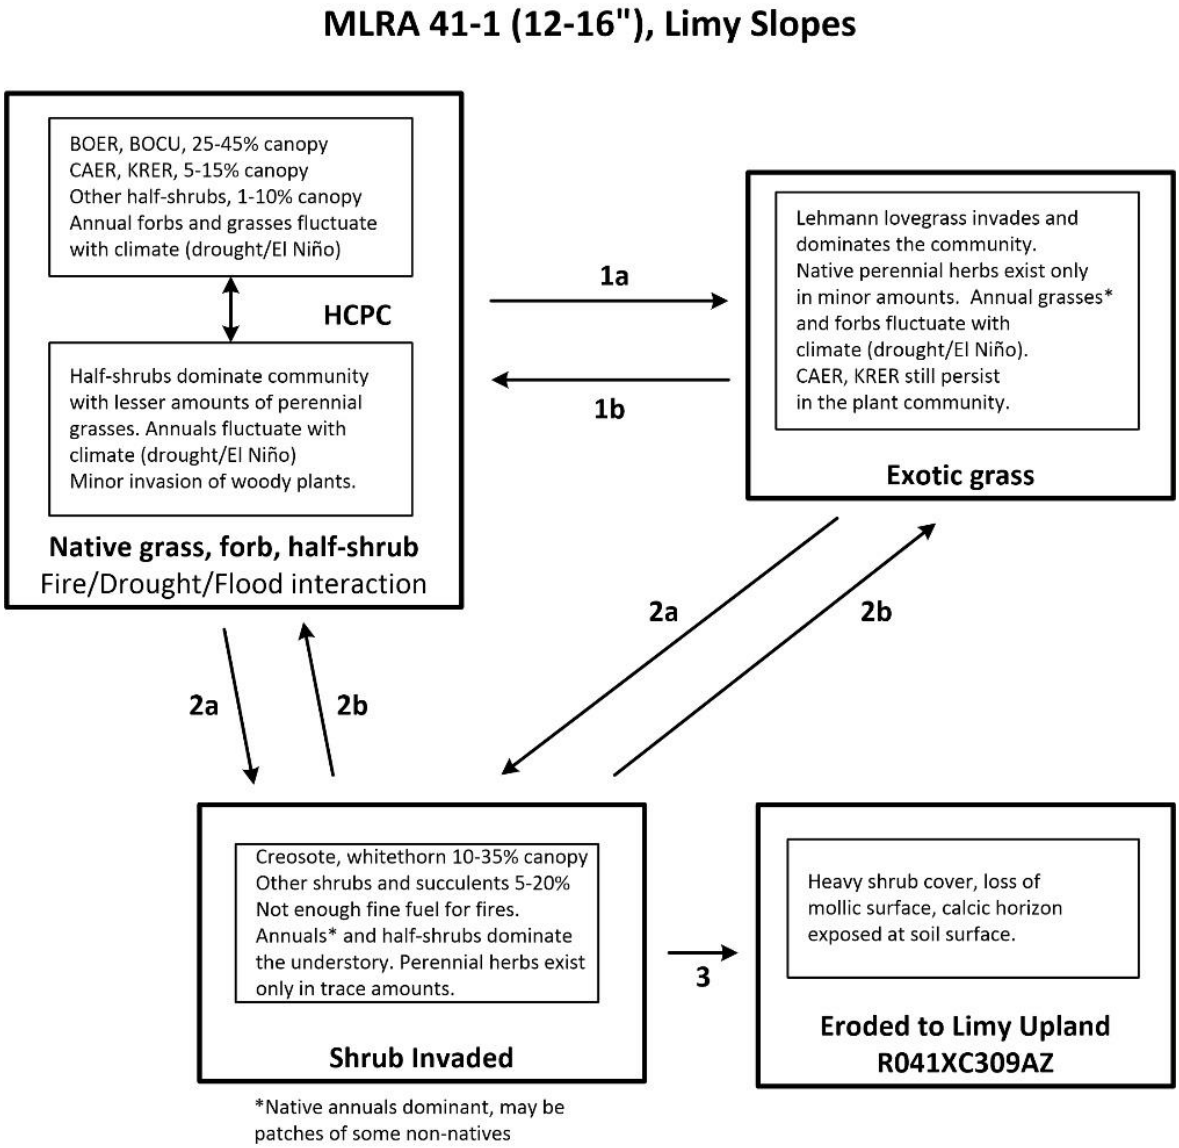

Figure 2. The State and Transition Model for the Limy Slopes 12-16" p.z. ES.

A baseline RHEM model scenario was configured to represent community phases using a CLIGEN station for rainfall inputs (Tombstone, AZ; Station ID: 0222, 1396 m elevation, 335 mm annual precipitation), sandy loam surface soil texture (46% sand, 39% silt, 15% clay), 50-m hillslope length, S-shape slope topography, and 12.5% slope gradient representative of the climate, soil, and topography attributes for the study site. In addition, the ESD provided a basis for foliar canopy and ground cover parameter estimation of the HCPC baseline scenario. Our baseline RHEM model scenario was applied to each plant community phase by adjusting cover characteristics (retaining the baseline climate, soil, and topography data) to reflect changes in the community composition. Foliar canopy cover information on the transition from native grass to Lehmann lovegrass in the STM was obtained from the 2 low-cover plots described in Hamerlynck *et al*. (2012), they pointed out that these plots were dominated by Lehmann lovegrass. Furthermore, foliar canopy cover for the shrub-invaded state was obtained from data presented in the STM. In addition, ground cover information was obtained from rainfall simulator studies on shrub-dominated plots at WGEW (Stone, unpublished data). Based on the description of the Eroded state in the STM (Figure 2), the site potential changes to something resembling to Limy Upland 12-16" p.z. ES, which includes the shrub-dominated Lucky Hills watersheds in the WGEW. Hence, canopy cover data was obtained from shrub-dominated rainfall simulator plots at this site. Ground cover remained similar in terms of rock cover across all states. Table 1 presents a summary of the input parameters of the Kendall Grassland site.

Runoff and erosion rates predicted by RHEM were consistent with published literature on the "Limy Slopes 12-16 p.z." (Nearing *et al.*, 2007; Polyakov *et al.*, 2010). Simulation results for each scenario are shown in Table 2. In the study by Polyakov *et al.* (2010), they analyzed 58 successfully sampled sediment events during 19 years of observation. Annual sediment yield for different periods varied from 1.64 t ha^{-1} to 0.01 t ha^{-1}. Hernandez *et al.* (2013) applied the RHEM tool on 134 of the National Resource Inventory (NRI) rangeland field locations with data collected between 2003 and 2006 in MLRA 41. The average annual soil erosion rates varied from 0.20 t ha^{-1} to 0.5 t ha^{-1} on the "Limy Slopes 12-16" p.z. Nearing *et al.* (2007) estimated average annual sediment yield for the Kendall watershed in WGEW (0.07 t ha^{-1}).

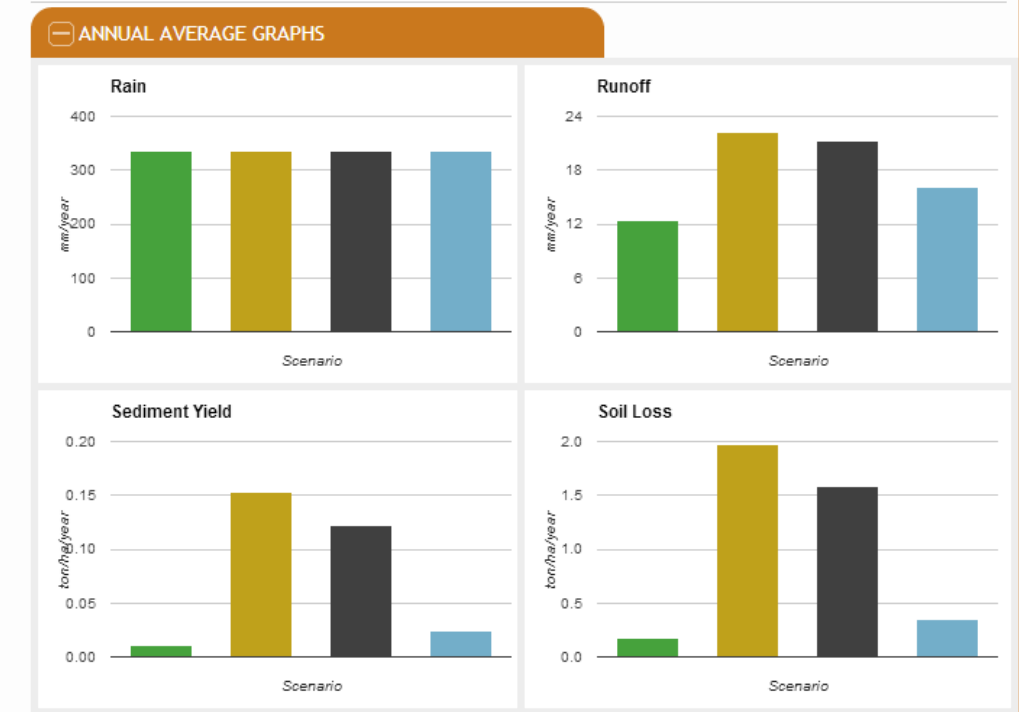
Table 2. Summary of predicted annual average runoff, sediment yield, and soil loss on the Kendall Grassland site "Limy Slopes 12-16 p.z." ES



ANNUAL AVERAGES

	HCPC	ERODED	SHRUB_INVADED	EXOTIC_GRASS
Avg. Precipitation (mm/year)	335.330	335.330	335.330	335.330
Avg. Runoff (mm/year)	12.417	22.223	21.201	16.187
Avg. Sediment Yield (ton/ha/year)	0.011	0.153	0.122	0.025
Avg. Soil Loss (ton/ha/year)	0.171	1.969	1.584	0.347

Analysis of the RHEM simulation runs on the "Limy Slopes 12-16 p.z." ES provides a basis for interpreting the impacts of vegetative canopy cover, surface ground cover, and topography on dominant processes in controlling infiltration and runoff as well as sediment detachment, transport and deposition in overland flow at each state. Our results suggest that RHEM can predict runoff and erosion according with vegetation structure and behavior of different plant community phases. That is, an explanation for the difference in runoff and erosion in the HCPC and Lehmann states can be related to the increased water storage on the native bunchgrasses due to the formation of litter dams. The grass cover and litter on the baseline state cause water to pond behind small litter and debris dams as it moves downslope, which has the effect of backing up water and allowing more time for infiltration (Mitchel and Humphreys, 1987; Nearing *et al.*, 2007). According to Polyakov *et al*. (2010), before the Lehmann lovegrass invasion, the microtopgraphy characteristic for the Kendall site where small terraces formed upslope of large clumps of vegetation. With die-out of native grasses and greater spread of Lehmann lovegrass, there were fewer obstructions, which allowed water to move down the slope more rapidly, increasing runoff and sediment yield. The erosion rate in both Shrub-dominated and Eroded scenarios is only slightly different as shown in Table 2.

FUTURE WORK

Additional work is continuing on the RHEM Web-based interface system, which is currently fully functional for estimating erosion rates on relatively non-disturbed (e.g., fire impacted) scenarios, and a fully functional product including risk assessment and fire impact is expected to be completed by the end of 2015.

RHEM will be improved for application to both undisturbed and disturbed conditions across the western US. This work is intended to allow it to represent disturbed conditions, develop parameter estimation procedures for disturbed conditions. Initial analysis of data from fire-disturbed rangeland sites illustrate the importance of intra-storm dynamics on soil erodibility and the dominance of detachment by small concentrated flow channels as opposed to broad sheet flow. A new component has been developed to estimate erosion, in probabilistic terms, for potential varying management scenarios. Based on a 300-year CLIGEN run, RHEM produces average annual soil loss rates with a probability of occurrence for each RHEM management scenario. In addition, because of the strong orographic effects that dominate spatial precipitation patterns in the western U.S, the model will be improved to allow for orographic effects on precipitation by incorporating existing technology based on PRISM and CLIGEN into the RHEM model system. This capability will also allow for assessing climate change scenarios with the model, building on previous work by the investigators on soil erosion and climate change (Zhang *et al.*, 2012; Nearing *et al.*, 2004).

CONCLUSIONS

RHEM, as applied in this study with input values reported in the literature, can be a valuable tool for predicting relative measures of runoff and erosion within the ESD framework. However, we caution against interpretation of RHEM results as absolute measures of runoff and erosion given the potential variability in soil loss across widely variable conditions within an individual ecological state or community phase and with increasing spatial scale. It is not possible to parameterize the model for all possible vegetation conditions of a given state or community phase. Rather, we suggest applying the model for average vegetation conditions and utilizing the results to interpret relative hydrologic and erosion function.

The framework of the RHEM tool facilitates the inclusion of new capabilities. Current research includes the integration of new equations for the application of RHEM in disturbed rangelands such as fire to predict surface erosion from postfire hillslopes, and to evaluate the potential effectiveness of various erosion mitigation practices. The RHEM probabilistic approach will be meaningful for land managers when they want to apply RHEM to risk-based management decisions.

Altinakar, Director and Research Professor, The University of Mississippi, Oxford, MS, altinakar@ncche.olemiss.edu; Reza Marsooli, Post-doc Research Associate, The University of Mississippi, Oxford, Mississippi, reza@ncche.olemiss.edu; Zhaosong Qu, President, SINFOTEK, Haidan District, Beijing, China, qsl188@126.com

Abstract: Developed at the National Center for Computational Hydroscience and Engineering, CCHE1D is a one dimensional numerical model for simulating unsteady flow hydrodynamics and sediment transport in natural dendritic channel systems, such as the drainage network of a watershed. CCHE1D has an Arc-GIS based user interface and can be run in coupled mode with AnnAGNPS and SWAT watershed models. The unsteady flow hydrodynamics uses a hybrid approach that solves full dynamic Saint-Venant equations when the flow is subcritical and reverts to a diffusive wave equation when the flow locally becomes transcritical or supercritical. The sediment transport and fluvial morphodynamics module calculates unsteady fractional sediment transport using a non-equilibrium sediment transport approach. The channel bed is modeled in three layers with the topmost layer being the mixing layer. The CCHE1D model calculates bed area change for each size class and tracks the percentage of each size class of sediment in the water column and in the upper two layers of the bed.

The CCHE1D model was used to model two laboratory experiments of sediment transport under unsteady flow conditions, which were carried out at the Hydraulic Research Laboratory of the Federal Institute of Technology in Lausanne, Switzerland. The experiments were performed in a 17.8m-long and 0.60m-wide tilting laboratory flume using symmetric triangular hydrographs with the same nominal base and peak discharge, but varying base widths. The mobile bed was made of gravel in the size range of 3−8mm, with a d_{50} of 5.8mm. During the experiments, the discharge in the supply pipe, the water-surface elevation at eight stations, and the velocity profiles at three stations were measured. In addition, the submerged weight of the sediment particles falling into a sediment trap located near the downstream end of the flume was also continuously measured and recorded. To track the length of travel of sediment particles, the bed upstream of the sediment trap was prepared by laying eight strips of sediments with different colors. Each strip had a length of 0.7m and the total length of the reach with colored sediments was 5.6m. The colored sediments were used as tracers to track the movement during the passage of the triangular hydrograph. After an experiment with a triangular hydrograph, each colored sediment strip was divided into four strips of equal length. The sediment particles in each 0.175m-long strip were separated by hand into color groups and the groups were weighed. Similarly, the sediments collected in the sediment trap were also separated into color groups and weighed. The experimental results show that the length of travel is related to the width of the base of the hydrograph.

To be able to track the travel distances and locations of sediments of different color and size class in numerical simulations a total of 27 size classes were defined. This corresponds to nine colors, including the natural uncolored sediments, and the same three size classes for each color. The paper presents the results of two experiments, CM01 and CM02, and the corresponding numerical models. The computed results are compared with experimental measurements.

DESCRIPTION OF THE EXPERIMENTAL STUDY

The unsteady flow experiments over a movable bed were performed in a 17.75 m long tilting flume. The channel has a rectangular section which is 0.60m wide and 0.80m high. The side walls are made of transparent glass. The flume can be tilted to any slope from -1% to +9%. All the experiments described in the paper, were performed with the same bed slope of $S_o = 0.3\%$.

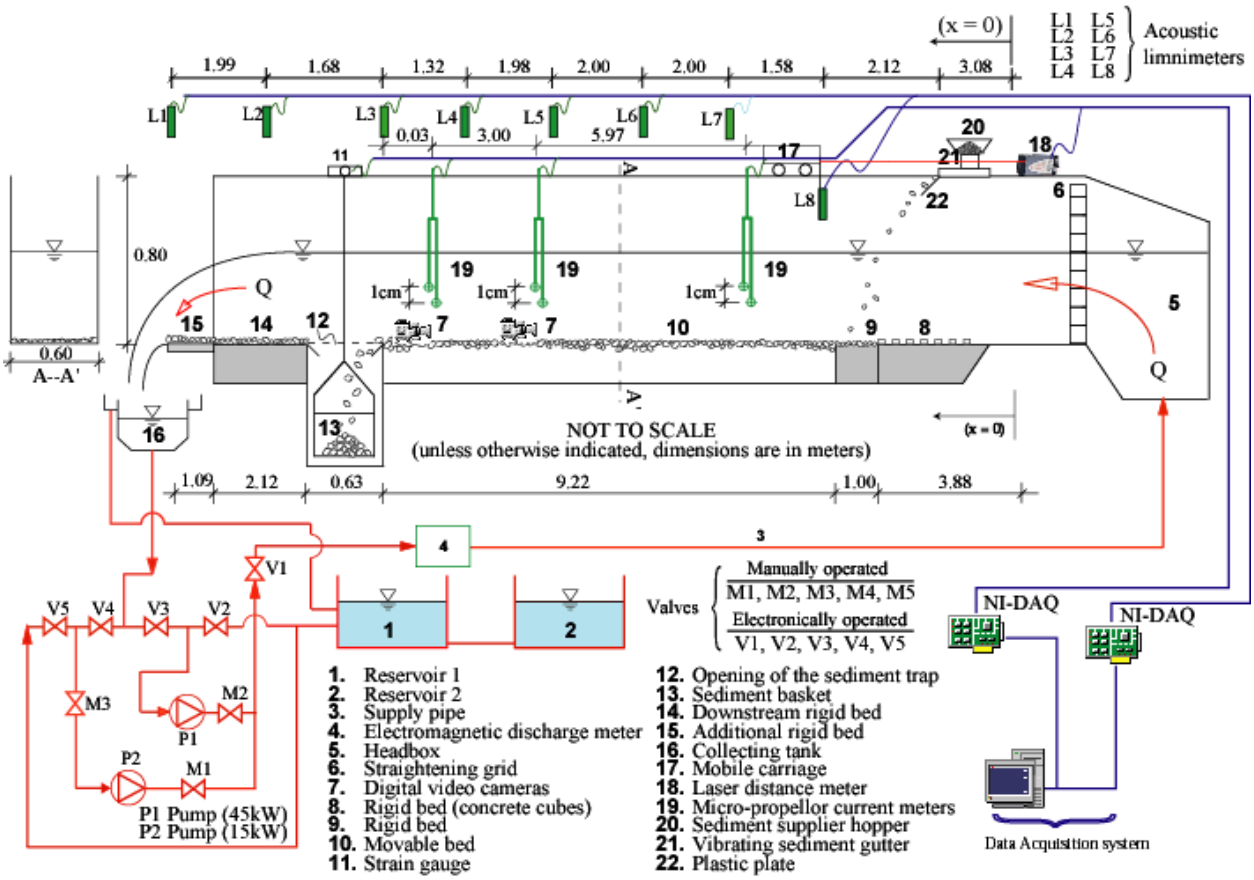

Figure 1 General view of the experimental installation and the measuring equipment.

Figure 1 shows the general view of the experimental installation and the locations of the measuring instruments. The flume was operated in a closed circuit mode. A pump controlled by a computer pumps the water stored in tanks 1 and 2 into the head tank of the flume according to a prescribed triangular hydrograph. The pumped discharge is measured continuously by the electromagnetic current meter mounted on the supply pipe. Water entering the flume through a flow straightener flows over a 4.88m-long fixed-bed reach roughened by gluing artificial elements to the first 3.88m and fine gravel particles to the remaining 1.00m. Downstream of the fixed-bed section, there is a 9.22m-long and 10cm-deep movable-bed section filled with compacted fine gravel. A sediment trap is located at the downstream end of the movable-bed section. The perforated basket inside the sediment trap hangs from a force transducer, which continuously measures and records the cumulative weight of the sediment particles falling into the basket in order to determine the sediment discharge. The section of the flume downstream of the sediment trap has a fixed bed on

which the fine gravel particles are glued. At the downstream end of the flume, the flow freely falls into a collector and returns to storage tanks 1 and 2 to complete the circuit.

The movable bed is filled with fine gravel having a specific density of 2.65. Figure 2 shows the grain-size distribution curve obtained continuously using a video imaging technique. A few representative sizes are listed on the same figure. Considering that $d_{95}/d_5 = 2.54 < 4$ and $\sigma_g = \sqrt{d_{84.1}/d_{15.9}} = 1.33 < 1.35$, the bed material can be considered as uniform (Raudkivi 1988). Before each experiment the bed was raked, leveled, and compacted. Attention was paid to keep the grain-size distribution of the sediment the same for all experiments. The bed elevation along the flume centerline was measured and recorded before and after each experiment using an ultrasonic limnimeter mounted on a carriage (L8 in Figure 1). There was no sediment feed at the upstream of the movable bed. The bed-load transport rate during the experiment was low and the maximum bed level change at the end of experiments was found to be about d_{50}.

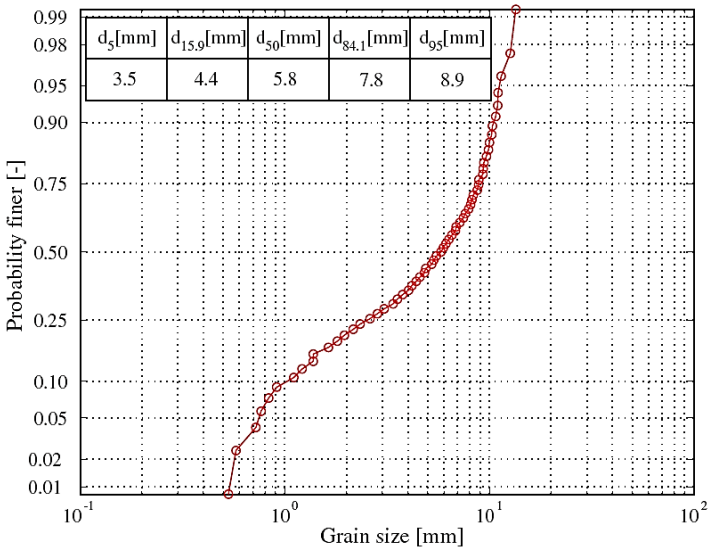

Figure 2 Grain size distribution curve of the fine gravel.

Figure 3 shows the longitudinal profile of the flume with the locations of the measuring stations and the layout of colored sediments used for bed-load tracking. The following variables were measured and recorded as a function of time:

- Discharge in the supply pipe was measured using an electromagnetic discharge meter.
- The flow depth were measured at eight locations along the flume length using ultrasonic limnimeters (L1 to L8 in Figure 3).
- Velocity profiles were measured at three locations along the flume (1, 2 and 3 in Figure 3) using six propeller current meters. At each measuring station two propeller current meters were positioned at prescribed elevations from the bed to measure the time varying local velocity. The same experiment was repeated 8 to 12 times by changing position of the propeller current meters. Time varying velocity profile over the entire flow depth was reconstituted from these point measurements. The velocity profiles were also then used to evaluate the time variation of shear stress, discharge and other useful flow parameters.

- The cumulative weight of the sediment particles falling into the basket in the sediment trap was recorded during the experiment. The bed-load transport rate at the end of the movable bed section was obtained from the cumulative weight curve. Given that the same experiment was repeated 8 to 12 times to obtain the complete velocity profile, it was possible to obtain a highly accurate measurement of time-varying bed-load rate by calculating the ensemble average.

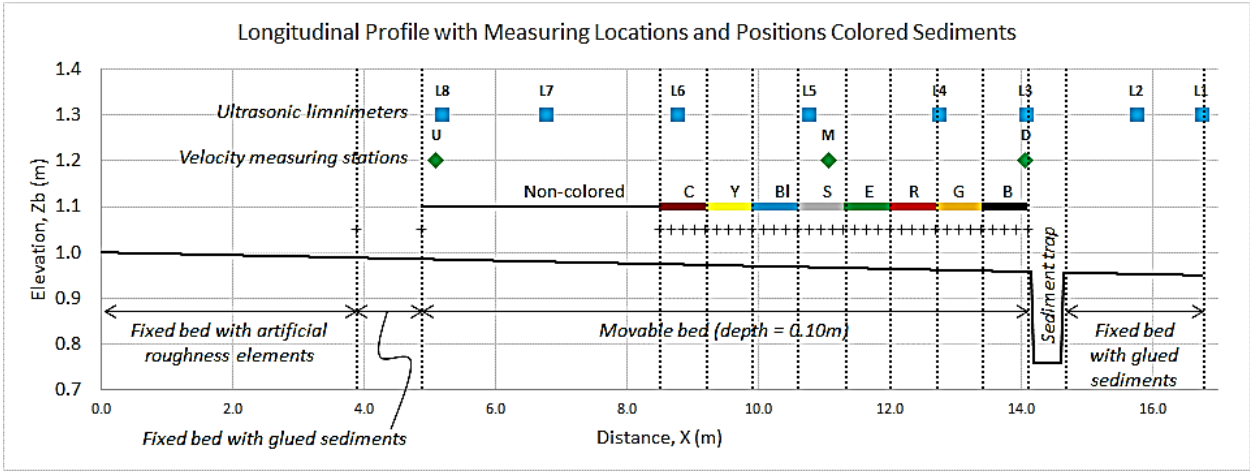

Figure 3 Longitudinal profile of the flume showing locations of the measuring instruments and the layout of colored sediments used for tracking bed-load movement.

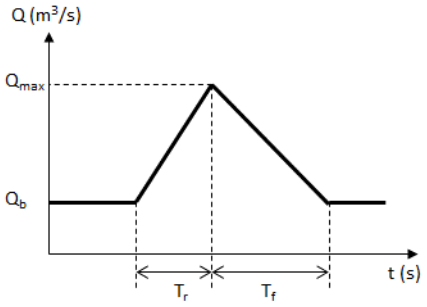

Colored-Gravel Exp.	Corresponding TM series Experiment	T_r (s)	T_f (s)	Q_b (m³/s)	Q_m (m³/s)	Ω (-)
CM01	TM01	150	150	0.050	0.140	0.41
CM02	TM03	50	50	0.040	0.160	1.64
CM03	TM06	10	10	0.040	0.140	7.45
	TM09	10	10	0.040	0.140	6.50
	TM10	10	10	0.040	0.140	6.80

Figure 4 Definition sketch for the triangular hydrographs and the list of experiments.

Figure 4 shows the definition sketch for the triangular hydrograph and provides a list of the experiments considered in this paper. As it can be seen the experiments were performed with three different symmetric hydrographs ($T_r = T_f$) with different base times: 300s (TM01), 100s (TM03), and 20s (TM06, TM09 and TM10). The base and the maximum discharges for the hydrographs are nominally same to each other. The unsteadiness parameter, $\Omega = (h/{u_*}^2)\,(\Delta Q/\Delta t)$, for the experiments is also listed on the last column of the table in Figure 4. After the experiments with three hydrographs were completed, one additional experiment was performed with each hydrograph using colored sediments for tracking the bed load. These experiments are listed in Figure 4 as CM01 (300s), CM02 (100s), and CM03 (20s).

The colored sediments were produced by painting the fine gravel used as bed material and have the grain-size distribution shown in Figure 2. The gravel was immersed in paint and then dried on plastic sheets. Attention was paid to keep the paint thin in order not to change the characteristics of the particles. Eight different colors were used Black (B), Golden (G), Red (R), Green (E), Argent (A), Blue (U), Yellow (Y), and Copper (C). Natural, uncolored sediments are denoted by "N". Before each bed-load tracking experiment, the colored sediments were carefully laid on top of the natural colored sediments in 0.70m-long stripes along the 5.6m reach immediately upstream of the sediment trap as shown in Figure 3. The thickness of the bed layer was about 3 cm (~5×d_{50}).

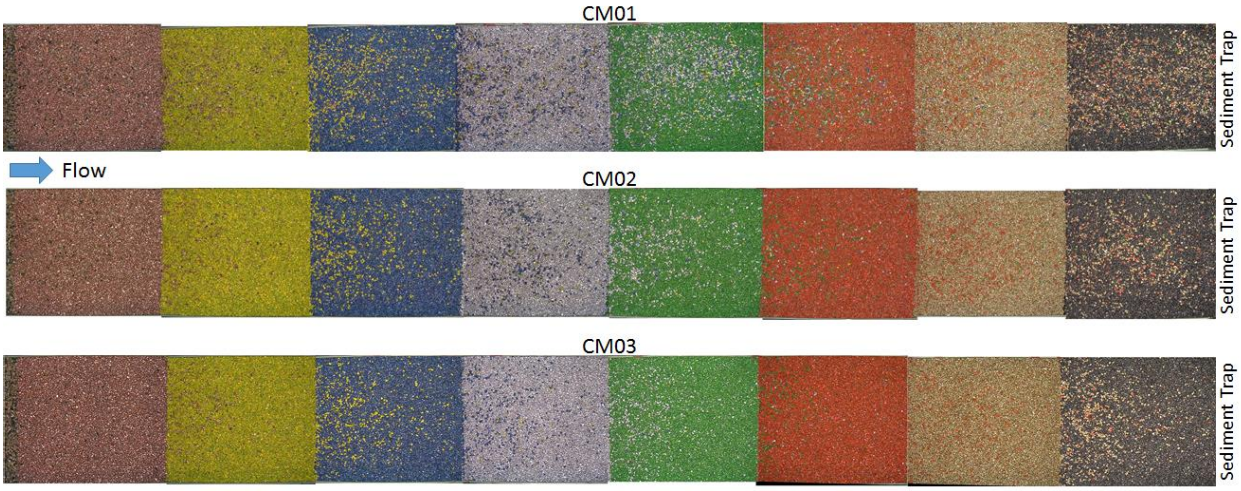

Figure 5 Appearance of the bed with colored sediments at the end of the experiments.

There is no sediment transport during the base flow. As the discharge increases, the bed shear increases above the critical shear stress to initiate the movement. The sediments are transported downstream as bed-load. The general appearances of the bed at the end of experiments CM01, CM02 and CM03 are shown in Figure 5. In order to determine how far the sediments traveled during the passage of the hydrograph, each color reach was divided into four equal length stripes of 17.5cm. The sediment particles in the 3cm-deep surface layer were collected carefully. The sediments collected from each stripe were then manually separated into different colors, including the natural sediments that were transported from upstream. Dry weight of sediments in each color were then measured and recorded.

The unsteady flow experiments discussed in this paper are part of an extensive experimental study performed at the Laboratory of Environmental Hydraulics of the Federal Institute of Technology, Lausanne, Switzerland. Detailed information on the complete set of experiments can be found in Qu (2002). A short presentation of the experimental study can be found in Qu et al. (2004). A preliminary analysis of the experiment with colored sediments is presented in Altinakar et al. (2014).

BRIEF DESCRIPTION OF THE CCHE1D NUMERICAL MODEL

The experiments CM01 and CM02 with colored sediments were simulated using the CCHE1D software, which was developed at the National Center for Computational Hydroscience and

Engineering, The University of Mississippi. CCHE1D is a software package to simulate one-dimensional unsteady free-surface hydrodynamics with unsteady non-equilibrium transport of non-uniform sediments and the resulting morphodynamic changes in dendritic channel networks. Modules are also available for modeling of contaminant transport and fate, and water quality, which includes nitrogen, phosphorous, and phytoplankton cycles. The CCHE1D can be run in coupled mode with AnnAGNPS and SWAT watershed models.

CCHE1D computes unsteady flows by solving the Saint-Venant equations given as:

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} = q \tag{1}$$

$$\frac{\partial}{\partial t}\left(\frac{Q}{A}\right) + \frac{\partial}{\partial x}\left(\frac{\beta Q^2}{2A^2}\right) + g\frac{\partial h}{\partial x} + g\left(S_f - S_o\right) = 0 \tag{2}$$

where *x* and *t* are the spatial and temporal axes; *A* is the flow area; *Q* is the flow discharge; *h* is the flow depth; S_0 is the bed slope; β is a correction coefficient for the momentum due to the non-uniformity of velocity distribution at the cross section; *g* is the gravitational acceleration; and *q* is the side discharge per unit channel length. S_f is the friction slope, defined as:

$$S_f = Q|Q|/K^2 \quad \text{with} \quad K = \sum_{l=1}^{3} \frac{1}{n_l} A_l {R_l}^{2/3} = \sum_{l=1}^{3} \frac{1}{n_l} {A_l}^{5/3} {P_l}^{-2/3} \tag{3}$$

where A_l is the flow area of subsection *l*; R_l is the hydraulic radius; P_l is the wetted perimeter; and n_l is the Manning's roughness coefficient. *l* is the index for subsections 1, 2 and 3 (left flood plain, main channel and right flood plain, respectively). CCHE1D employs an improved version of the implicit four-point finite difference scheme proposed by Preissmann (1961) to discretize the Saint-Venant equations. The solution scheme uses the increments in water depth Δh and flow discharge ΔQ as dependent variables. The resulting system of equations form a pentadiagonal matrix, whose solution is obtained with the help of the Thomas Algorithm, also called the Double-Sweep Method. CCHE1D adopts a hybrid dynamic/diffusive wave model. The dynamic wave model is solved when the Froude number is less than 0.9. For higher Froude numbers, CCHE1D solves the diffusive wave model.

The governing equations for the 1D non-equilibrium transport of non-uniform sediment and the resulting bed area change are given by the following expressions, respectively

$$\frac{\partial (AC_{tk})}{\partial t} + \frac{\partial Q_{tk}}{\partial x} + \frac{1}{L_b}(Q_{tk} - Q_{t^*k}) = q_{lk} \tag{4}$$

$$(1 - p')\,\frac{\partial A_{bk}}{\partial t} = \frac{1}{L_b}(Q_{tk} - Q_{t^*k}) \tag{5}$$

where C_{tk} is the section-averaged sediment concentration of size class k; Q_{tk} is the actual sediment transport rate of size class k; Q_{t^*k} is the sediment transport capacity of size class k; L_b is the

adaptation length of non-equilibrium sediment transport; and q_{lk} is the side inflow or outflow sediment discharge from bank boundaries or tributary streams per unit channel length, p' is the porosity of the bed material, and $\partial A_{bk}/\partial t$ represents the rate of change of bed area for the size class k. The first term on the left-hand side of Eq. (4) accounts for sediment storage, while the last term on the left-hand side represents the exchanges between the moving sediment and the bed material. The transport capacity for size class k can be expressed as:

$$Q_{t^*k} = p_{bk}\, Q^*_{tk} \tag{6}$$

where p_{bk} is the percentage of sediments of size class k in the bed material. The potential equilibrium transport rate for sediments of size, Q^*_{tk}, can be determined using a suitable empirical sediment transport formula. To take into account the variation of the vertical gradation of sediment size due to erosion and deposition processes, the bed is represented in three layers. The topmost layer is the mixing layer. All sediment particles in the mixing layer are subject to exchange with the water column. The second layer is the subsurface layer. The subsurface layer exchanges sediments only with the mixing layer. There is no sediment exchange between the subsurface layer and the bottommost third layer. The temporal variation of the bed-material gradation in the mixing and subsurface layers is determined using the following relationships, respectively:

$$\frac{\partial(A_m p_{bk})}{\partial t} = \frac{\partial A_{bk}}{\partial t} + p^*_{bk}\left(\frac{\partial A_m}{\partial t} - \frac{\partial A_b}{\partial t}\right) \tag{7}$$

$$\frac{\partial(A_s p_{sbk})}{\partial t} = -p^*_{bk}\left(\frac{\partial A_m}{\partial t} - \frac{\partial A_b}{\partial t}\right) \tag{8}$$

where A_m and A_s are the bed areas for the mixing and subsurface layers, respectively, A_b is the total bed area. The total bed deformation rate is the sum of bed deformation rates of all size classes, i.e. $\partial A_b/\partial t = \sum_{k=1}^{N} \partial A_{bk}/\partial t$ in which N is the number of size classes used. When $(\partial A_m/\partial t - \partial A_b/\partial t) \leq 0$ one has $p^*_{bk} = p_{bk}$, otherwise $p^*_{bk} = p_{sbk}$. This system of equations is closed by introducing semi-empirical expressions for various parameters, such as non-equilibrium adaptation length, L_b, thickness of mixing layer, sediment porosity, settling velocity of grains, etc. The system of equations is also discretized and solved using Preissmann's (1961) method.

SIMULATION OF EXPERIMENTS USING CCHE1D AND RESULTS

CCHE1D was used to simulate the experimental test cases CM01 and CM02 by dividing the grain size distribution curve shown in Figure 2 into three size classes: 1) coarse and very coarse sand (0.5mm<d<2mm); 2) fine and very fine gravel (2mm<d<8mm); and 3) medium gravel (8mm<d<16mm) where d is the sediment diameter. Furthermore, in order to be able to track the sediments with different colors during the simulation, the same size distributions were repeated for each of the eight colors as well as the natural sediments. This resulted in 27 size classes as shown in Table 1. All size classes have a dry specific density of 2.65.

The computational mesh comprises 336 grid nodes with a fixed grid spacing equal to 5 cm. The Manning roughness is calibrated as 0.016 $m^{-1/3}s$ and the time step is 0.5 second. The thickness of mixing layer is assumed to be twice the mean grain size. Wu et al. (2000) formula is used to

compute the transport capacity. The characteristics of the triangular hydrograph imposed at the upstream end of the model for CM01 and CM02 simulations are summarized in Figure 4.

Table 1 Sediment size classes used for tagging the sediments of different color. All sediments have a dry specific density of 2.65.

d_{rep}= representative diameter of a size class; d_{LL}= lower limit of a size class; d_{UL}= upper limit of a size class.

In Figure 6 and Figure 7, the water surface elevations computed at the locations of the eight acoustic limnimeters (L1 to L8 in Figure 3) are compared with the measurements for experiments CM01 and CM02, respectively. The agreement is relatively good although the computed hydrographs have systematically higher peaks. Since the travel distance of the wave over the length of the flume is short, the attenuation is not important and the wave keeps its shape. In Figure 8 and Figure 9, the discharge, velocity and flow depth computed at the three measuring stations, "D" (x=14.07m), "M" (x=11.07m), and "U" (x=5.10m), are compared with the measurements for experiments CM01, and CM02, respectively. For the experiment CM01 with slower rising and falling hydrograph, the computed discharge and depth shown in Figure 8 agree well with the measurements at all three stations. The computed velocity, however, is larger than the measured one for the stations "D" and "M". In Figure 9, similar plots are provided for the experiment CM02 with a faster rising and falling hydrograph. The measurements at the station "U" were not recorded due to a faulty cable. Although the computed flow depths agree well with the measurements at stations "D" and "M", the computed discharge and velocity are under predicted. This may be due to the secondary effects introduced by the faster hydrograph that are not well modeled with the Saint-Venant equations.

The CCHE1D continuously tracks the percentage of each size class in the bed. Since the ID numbers of three size classes representing each color, including the natural color, are known, it was possible to calculate the weight of each color as a function of the distance. This in turn gives the information about the travel distance of each size class during the passage of the triangular hydrograph.

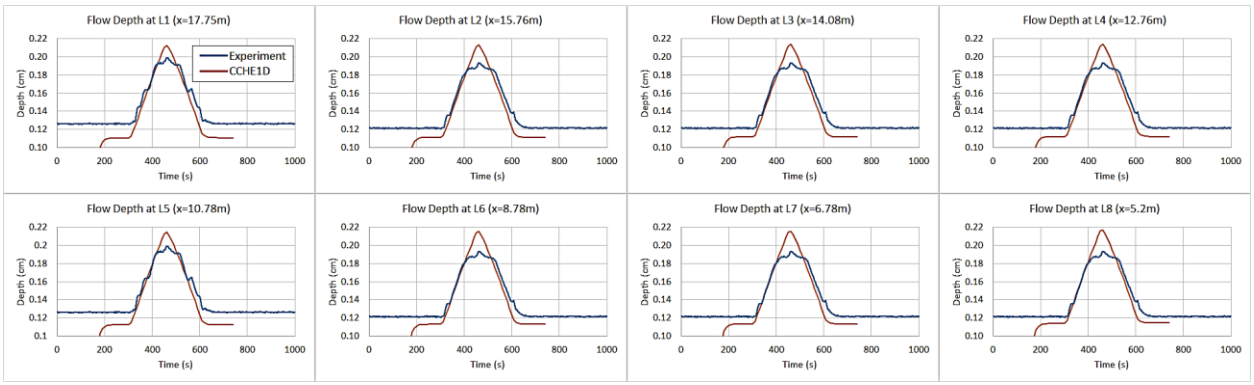

Figure 6 Comparison of measured and computed water depths for the experiment CM01.

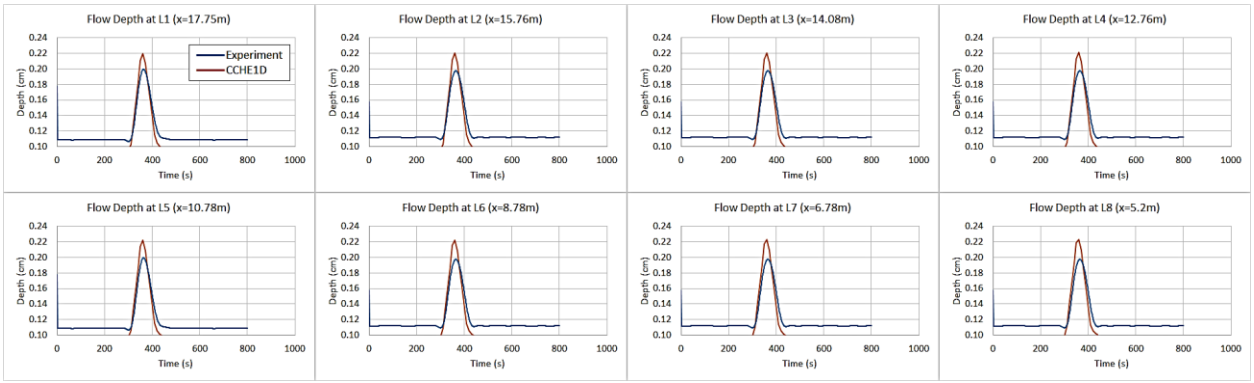

Figure 7 Comparison of measured and computed water depths for the experiment CM02.

The computed mass of the sediments of different colors composing the bed after the passage of the triangular hydrographs in CM01 and CM02 are plotted in Figure 10 and Figure 11, respectively. The experimental data are superposed on the computed weights. Since the black sediments are falling immediately into the basket of the sediment trap, the rightmost plot at the bottom row shows a histogram of the mass of the sediment of different colors accumulated in the basket. The agreement between the computed and measured sediment weights as a function of the distance is satisfactory despite some differences that are probably well within the uncertainty to be expected in comparison with a single sediment transport experiment. For the experiment CM01, the computed mass of the sediment accumulated in the basket is 1,609gr. A series of 12 experiments repeated with the same hydrograph as in CM01 yielded the average mass of the sediments as 1190.63gr±216.60gr. The computed value is about 200gr higher than the upper limit of experiments. Similarly, the computed mass of sediments falling into the basket is 698.65gr, whereas the experimental results a series of 12 experiments with the same hydrograph as in CM02 yields and average mass of 832.31gr±216.87gr. The computed value is well within the experimental range. Based on these results it can be concluded that the simulations of experiments with CCHE1D produce results that are comparable to those measured in the experiments.

CONCLUSIONS

The CCHE1D model developed at the national Center for Computational Hydroscience and Engineering was used to simulate two out of three experiments carried out at the Laboratory of Environmental Hydraulics of the Federal Institute of Technology, Lausanne, Switzerland, for tracking the movement of colored sediments during the passage of a triangular hydrograph. The hydrograph for CM01 rises from 50 m^3/s to 140 m^3/s in 150s and falls back to same base discharge in 150s. The hydrograph for CM02 rises from 40 m^3/s to 160 m^3/s in 50s and falls back to same base discharge in 50s. CM02 has a faster rising and falling hydrograph than CM01 for the same nominal base and peak discharges. The unsteadiness parameter, $\Omega = (h/{u_*}^2)(\Delta Q/\Delta t)$, where u_* is the shear velocity and $\Delta Q = Q_m - Q_b$, is 0.41 for CM01 and 1.64 for CM02. Comparison of computed results with the experimental results show that the computed water surface elevations, discharges and velocities agree well with the measurements. For the experiment CM02, the velocities are under predicted although discharge and flow depth show better agreement. This may be due to secondary effects that are not well represented by the Saint-Venant equations. The computed distances traveled by each color agree well with the experimental results. The computed mass of the sediments accumulated in the basket of the sediment trap located at the downstream end of the movable bed section also agree well with the experimental data. Additional simulations by varying various parameters such as the adaptation length and the mixing length thickness, are currently under way. Moreover, the simulations are also being carried out for the third colored experiment, which rises from 40 m^3/s to 140 m^3/s in only 10s and falls back to same base discharge again in 10s. This experiment has the fastest hydrograph and the unsteadiness parameter is about 6.9, which is significantly higher than those for CM01 and CM02. The results of the ongoing simulations will be reported during the conference.

Abstract Relations of bedload transport (Q_B) and flow competence ($D_{max,QB}$) with water discharge Q are difficult to measure or to accurately estimate in steep mountain streams. To further the understanding of how gravel transport and flow competence curves differ among streams, this empirical study relates exponents and coefficients of power functions fitted to gravel transport ($Q_B = aQ^b$) and flow competence curves ($D_{max,QB} = fQ^g$) to watershed, channel, and bed material parameters. Exponents b and g are found to systematically increase with basin area, the bankfull width/depth ratio and stream width, and to decrease with the bankfull unit runoff yield per basin area as well as the percentage of subsurface fines. The exponents are non-monotonically (convexly) related to stream gradient, unit stream power, relative bankfull depth, and roughness. A tight linear relation between the b- and g-exponents reveals that steep Q_B curves result when increasing flows find increasingly larger particles to transport, a feature best expressed in steep plane-bed streams. Coefficients a and f are inversely related to the b and g exponents, respectively, hence scaling relations positive for exponents are negative for coefficients and vice versa. Overall, r^2-values of scaling relations are within 0.3 to 0.6 and significant, sufficient to determine the range of expected exponents and coefficients, but not tight enough to predict them with certainty. Scaling relations are tightened, and their practical applicability for predicting Q_B and $D_{max,QB}$ curves enhanced, when stream types are segregated based stream gradient and basin area.

INTRODUCTION

Particle entrainment and subsequent bedload transport is difficult to predict in steep mountain streams because entrainment and transport are caused by complex interactions between flow hydraulics and sediment transport dynamics. Flow hydraulics, including turbulence, scour jets, wake eddies, and secondary circulation, exert fluctuating and variable forces on coarse channel beds. Coarse beds are typically comprised of not only a wide mix of particle sizes ranging from sand to boulders, but also contain a variety of structural characteristics that develop in response to the interactions between flow hydraulics and sediment supply (Church et al., 1998). Particles may be exposed on top of the bed, embedded firmly in the bed, integrated in steps, particle clusters or stone structures, or anchored to other particles, tree roots, or bedrock. Hence, bed particle entrainability ranges from highly mobile to very stable (e.g., Bunte et al., 2013). The variability of flow hydraulics, sediment supply, and channel bed characteristics between streams controls the rate at which the quantity and size of gravel in motion increases as discharge increases. As a result, each stream has a specific bedload transport and flow competence relation. The variability of transport and flow competence curves is evident in studies that bring together observations from numerous streams (Barry et al., 2004; Bunte et al., 2008, 2013, 2014; Bathurst, 2013; Schneider et al., 2014). Case studies also show that bedload transport and flow competence curves can vary for a given stream in response to changes in sediment supply which alter bed material conditions and particle transportability within or between events (e.g., Beschta, 1987; Lenzi, et al., Mao et al., 2012; Yu et al., 2009; Hassan et al., 2014). The complexities of flow hydraulics, sediment supply, and bed structure—all of which are difficult to quantify—cannot be accounted for in bedload transport equations typically used for estimating transport rates or incipient motion. To be simple enough for practical application, transport equations must be limited to a few parameters (typically flow depth, stream gradient, and the median size of bed surface particles). Those bedload equations therefore cannot capture the processes that determine how gravel transport rates and flow competence relate to flow in a specific stream, and computed transport rates can deviate from measured gravel transport rates by several orders of magnitude (e.g., Bathurst, 2007; Barry et al., 2008; Schneider et al., 2015).

Numerous applications in fluvial geomorphology and channel management would benefit from a method to quickly and accurately estimate the steepness (exponent) and *y*-axis intercept (coefficient) of gravel transport and flow competence relations from simple field-measured parameters, or more conveniently from parameters quantified from maps and areal photographs. This study uses an empirical approach similar to that used for quantifying suspended sediment transport relations (e.g., Asselmann, 1999, 2000; Syvitski et al., 2000; Dodov and Foufoula-Georgiou, 2005; Yang et al., 2006) and provides a comparison and prediction of exponents and coefficients of bedload transport and flow competence curves. Earlier studies that empirically predicted exponents and coefficients of bedload transport curves from watershed, flow, channel, and bed material parameters were based on a narrow range of *b*-exponents (Barry and Buffington, 2002; Barry et al., 2004), an artifact of the Helley-Smith samplers used (Bunte et al., 2004, 2008), or the empirical studies lacked robustness due to data paucity (Bunte and Swingle, 2003; Bunte and Abt, 2003; Bunte et al., 2006). For this study, we gathered a large dataset from a wide range of coarse-bedded mountain streams where gravel transport was measured with samplers suitable for gravel bedload to 1) show how watershed, flow, channel, and bed material parameters affect exponents and coefficients of bedload transport and flow competence curves; 2) to assess which parameters best capture the characteristics of the flow- and bed material interactions; and 3) to explore the potential for improving the prediction of bedload transport. While simple watershed, flow, channel morphometry, and bed material parameters are obviously not the direct factors entraining or restraining bed particles, this study proposes that those parameters have either provided conditions for actual channel processes or been influenced by them and hence serve as easily quantifiable proxies for actual gravel transport processes, especially when streams are segregated according to gradient and size.

METHODS

Compilation of datasets Of the 45 datasets of gravel bedload transport relations (Q_B curves) from wadeable, steep gravel- and cobble-bed streams worldwide compiled in this study, 29 datasets also include flow competence relations ($D_{max,QB}$ curves). Forty percent of the datasets are derived from gravel transport and flow competence measured mainly in the Rocky Mountain streams with snowmelt regimes. (Bunte et al., 2004, 2008, 2010a; Potyondy et al., 2010). The other datasets include streams in alpine and arctic pro-glacial environments, densely forested watersheds, and high desert environments. Sediment supply ranges from very high to very low with bankfull unit transport rates that extend over ten orders of magnitude from 1E-4 to 1E6 g/m·s. Study sites span a wide range of basin areas (1-260 km^2), bankfull stream widths (1-20 m), stream gradients (0.007-0.136 m/m), and bed surface sizes (D_{50} of 20 - 200 mm, D_{84} of 33-360 mm). Gravel transported in the study streams was collected either with bedload traps, vortex, net-frame, basket, and pit samplers (see references in Ryan et al. (2005a) and Bunte et al. (2013) for those samplers), as well as with hanging baskets, including those that deploy automatically (Rickenmann et al., 2012), or was quantified from continuous, automated surveys of an accumulating debris pile volume (Lenzi et al., (1999, 2004, 2006). Bedload data from pressure difference samplers were not included in this compilation because they yield Q_B and $D_{max,QB}$ curves that are significantly flatter that those from bedload traps (Bunte et al., 2004, 2008, 2010b) and are not thought to accurately represent the transport-discharge relation. Also not included are steep streams in which wedges of fine-grained sediment build up low-gradient sections between log steps (Green et al., 2014). Most of the gravel bedload datasets used in this study are described in Bunte et al. (2014), and many of the flow competence data are summarized in Bunte et al. (2013).

Fitted bedload transport and flow competence curves The increase of transport rates Q_B with water discharge Q (Q_B curves) is typically (and admittedly somewhat simplistically) described by power functions in the form $Q_B = a Q^b$, where a and b are empirically determined (e.g., Barry et al., 2004; Bunte et al., 2008, 2014). Exponents b, which refer to flow quantified by Q in this study, are lower than exponents of bedload transport curves obtained when water flow is quantified by flow depth d (or shear stress). Exponents b are independent of the units used to quantify Q_B and Q, while a-coefficients are unit-dependent. All the a-coefficients in this study are based on Q_B units of g/s and discharge in units of m^3/s. Flow competence relations ($D_{max,QB}$ curves) are also described by power functions as $D_{max,QB} = f Q^g$ (e.g., Mao, 2012; Bunte et al., 2013), where $D_{max,QB}$ is the largest bedload particle size collected in a sample, and f and g are empirically determined; Q is quantified in units of m^3/s, while $D_{max,QB}$ (often measured in 0.5 phi increments) is expressed in units of mm. For some of the study streams, sediment supply changed between the rising and falling limbs of flow during a highflow season, or between individually sampled years. When this caused notable differences, two separate Q_B and/or $D_{max,QB}$ curves were fitted. Mathematically complex function types may describe gravel transport or flow competence relations more accurately (e.g., Gaeuman et al., 2014), but simple power functions described all of the authors' Q_B and $D_{max,QB}$ curves. Power functions are

commonly reported for Q_B and $D_{max,QB}$ curves in other studies, and the empirically quantified exponents and coefficients are fully adequate to describe the scaling relations developed in this study.

Stream parameters Four stream parameters were quantified for the study datasets:

- basin area (A),
- bankfull unit runoff yield (q_{bf}/A) where bankfull flow Q_{bf} was field-determined or based on the 1.5-year recurrence interval flood (Castro and Jackson 2001), and bankfull unit flow is $q_{bf} = Q_{bf}/w_{bf}$,
- stream gradient (S), and
- the percentage of subsurface sediment < 8 mm ($\%D_{sub<8}$) (not available for all the bedload dataset in this study).

Study stream grouping The progression from step-pool to plane-bed morphology in mountain streams is generally concomitant with an increase in basin area. However, the lower gradient plane-bed streams with occasional riffle-pool sequences occur in small drainages <10 km^2 as well as in large drainages of 60 - 260 km^2. Similarly, some step-pool streams in this study have small basin areas of only a few km^2, while others have areas up to 27 km^2. To reflect the different sizes of streams with similar gradients, study reaches were first categorized into three stream gradient classes to denote the basic channel morphology (Montgomery and Buffington, 1997):

- step-pool,
- steep plane-bed with low, narrow steps but no pools, and
- low gradient plane-bed with occasional pool-riffle sequences, especially forced around sharp channel bends.

The three channel types were then segregated into those with small and large basin areas along a cutoff value of 15 km^2 (Table 1) which is slightly less than the dataset's geometric mean drainage size. Those group thresholds are somewhat arbitrary and are reflective of conditions encountered among the study streams and could shift if more data sets become available for this line of analyses.

Table 1 Stream type grouping based on basin area size and stream gradient.

Stream type	Drainage area (km^2)	Gradient range (mm)	Secondary morphological features	Abbreviation
Small step-pool	< 15	0.040 – 0.136	rare, short plane-bed reaches	small s-p
Large step-pool	> 15			large s-p
Small steep plane-bed [1)]	< 15	0.016 – 0.038	some low, narrow steps, no plunge pools	small steep p-b
Large steep plane-bed	> 15			large steep p-b
Small plane-bed	< 15	0.007 – 0.014	forced or occasional pool-riffle sequences	small p-b w/p-r
Large plane-bed	> 15			large p-b w/p-r

[1)] not encountered among the study streams

Regression analyses Exponents b and g as well as coefficients a and f from all datasets and for the stream groups delineated in Table 1 were regressed against the various watershed, channel, and bed material parameters. Power functions in the form of $b = \alpha_1 \cdot X^{\gamma 1}$, $a = \alpha_2 \cdot X^{\gamma 2}$, $g = \alpha_3 \cdot X^{\gamma 3}$, and $f = \alpha_4 \cdot X^{\gamma 4}$ generally obtained the best fit, where X denotes a watershed or streambed parameter; α and γ are empirically determined.

RESULTS AND DISCUSSION

Scaling relations of exponents from Q_B and $D_{max,QB}$ curves with watershed, channel, flow, and bed material parameters The steepness of the Q_B and $D_{max,QB}$ curves compiled in this study differed widely between streams. Exponents b covered a seven-fold range from 2.6 to 18.2, while exponents g spanned a 20-fold range from 0.27 to 5.5. These exponents vary systematically with watershed, flow, channel, and bed material parameters. Exponents b and g are both positively, moderately, but nevertheless significantly related to basin area size A with r^2-values of 0.32 and 0.40 (Figure 1a). Exponents b and g decrease with unit bankfull runoff yield (q_{bf}/A) (Figure 1b), a parameter that indicates the flow per drainage area available to supply and transport bedload. Scaling relations are likewise negative with $\%D_{sub<8}$ (Figure 1c). An abundance of subsurface fine gravel and a well-developed armor in coarse bedded streams typically suggest that a large supply of fine gravel is transported. The negative scaling relations (Figure 1b and c) are moderately well-defined (r^2 of 0.20 to 0.43) and likewise significant, and they confirm that Q_B (and $D_{max,QB}$) curves are flatter in streams with higher sediment supply and more bed mobility (Dietrich et al., 1989; Laronne and Reid, 1993; Lisle, 1995; Reid and Laronne, 1995; Laronne et al., 2001; Hayes et al., 2002; Lisle and

Church, 2002; Barry et al., 2004; Ryan et al., 2005b; Bunte et al., 2006; Gran et al., 2006; Hassan et al., 2008; Diplas and Shaheen, 2008).

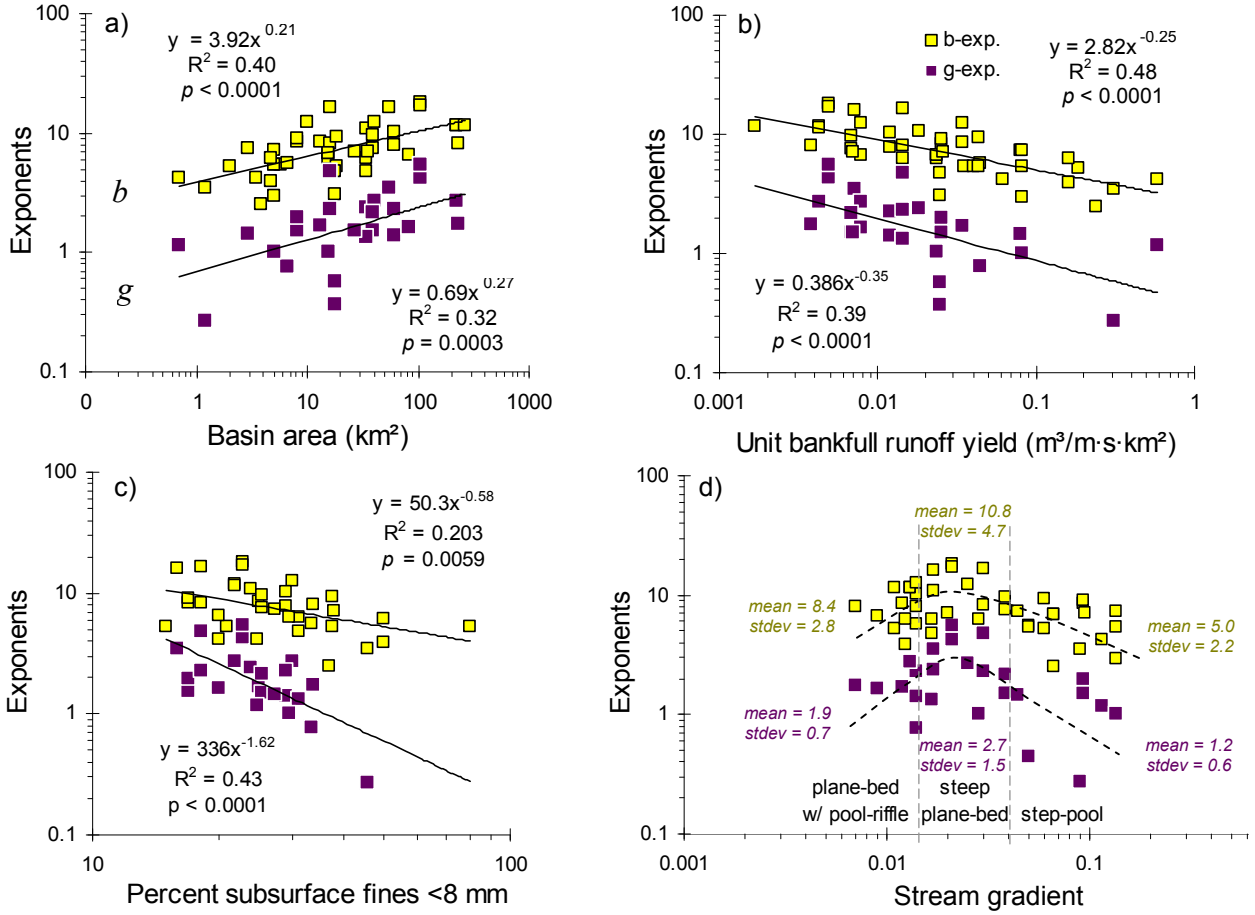

Figure 1 Scaling relation of *b*- and *g*-exponents with the four stream parameters from the 44 datasets show a positive trend with A (a), negative trends with q_{bf}/A and $\%D_{sub<8}$ (b, c), and a non-monotonic, convex trend with S (d). Yellow symbols denote *b*-exponents of Q_B curves and purple symbols denote *g*-exponents of $D_{max,QB}$ curves. All relations are significant.

Exponents non-monotonically related to stream type Among the study streams, the highest exponents coincide with streams that are moderately steep (S of 0.016 to 0.039 m/m), moderately rough (D_{84}/d_{bf} of 0.03 to 0.04), moderately deep (d_{bf}/D_{50} 6 to 8) and moderately powerful (ω_{bf} of 7 to 11 kg/m·s) (Figure 1d). Those reaches have steep plane-bed channels with occasional low, narrow steps, but no plunge pools. Exponents are lower in the lower gradient study reaches where $S \leq 0.014$ m/m, $D_{84}/d_{bf} < 0.03$, $d_{bf}/D_{50} > 8$, and stream power <7 kg/m·s. Those conditions are typical of the lower gradient plane-beds with occasional or forced riffle-pool sequences. The trend of rating curve flattening for lower gradient streams is attributed to higher sediment supply with less transport capacity and competence (see above). This study identifies a second, opposing trend: Compared to the steep plane-bed reaches, exponents are about half as large in the steepest streams where $S > 0.04$ m/m. These channels are coarse, rough, and shallow; they have high stream power, and exhibit step-pool morphology. As a result of two opposing trends, exponents *b* and *g* have non-monotonic (convex) relations with S (Figure 1d).

Occurrence of the steepest Q_B curves in steep plane-bed streams is attributed to the combination of two bed material conditions: The inundated bed surface harbors minimal fine gravels, and their scarcity keeps transport very low early in the highflow season. Transport is still relatively low at moderate flows, but at flows above bankfull, coarse gravel and cobbles on the upper surface of bar deposits—inaccessible at moderate flows—become available for transport. The large difference between very low transport rates of small gravels early in a highflow season and cobble transport at above bankfull flow may span 7-8 orders of magnitude and causes steeply increasing Q_B and $D_{max,QB}$ curves

in steep plane-bed streams. By contrast, flat Q_B curves result in step-pool streams where small gravel pockets provide ample bedload supply early in the highflow season, but flows above bankfull do not produce cobble transport because bar deposits are scarce and bed particles are restrained by structural bed stability. Low gradient plane-bed streams take an intermediate position. The low flow sediment supply is moderate, and an increase in Q_B and $D_{max,QB}$ at the highest flows may be slowed if moderate flows have already transported all but the very largest bed particles.

Scatter around the scaling relations Scaling relations in Figure 1 provide suitable estimates of the range of exponents to be expected for Q_B and $D_{max,QB}$ curves for a given parameter value. However, even for the best-developed scaling relations, measured *b*- and *g*-exponents vary by a factor of about ±2 around the predicted value. Much of this variability is attributed to natural inter-annual variability in Q_B and $D_{max,QB}$ curves that is not related to or not yet reflected in watershed, channel, runoff, or bed material parameters. Variability in exponents also arises from less than optimally measured Q_B and $D_{max,QB}$ relations due to sampling errors which may include a low number of field samples, a narrow range of measured flows, poor quantification of the lowest or highest Q_B, unfortunate timing of samples within the high-flow season, or a poor fit of measured data to a power function. The remainder of the variability reflects the suitability of a watershed, channel, flow or bed material parameter to serve as a proxy for processes that cause gravel transport, and the parameter's ability to provide or respond to the specific conditions that supply, entrain, or restrain particles and determine gravel transport.

Scaling relations for exponents segregated by stream type and stream size Prediction of *b*- and *g*-exponents is improved when scaling relations in Figure 1 are segregated by stream type. The discussion here is limited to *b*-exponents because the effects of stream-type segregation are very similar for *b*- and *g*-exponents, but *b*-exponents have richer datasets.

For scaling relations of *b* with *A* (Figure 2a), step-pool and steep plane-bed streams follow the same positive trend, irrespective of stream gradient. However, a secondary stratification by *S* occurs in the low-gradient plane-bed

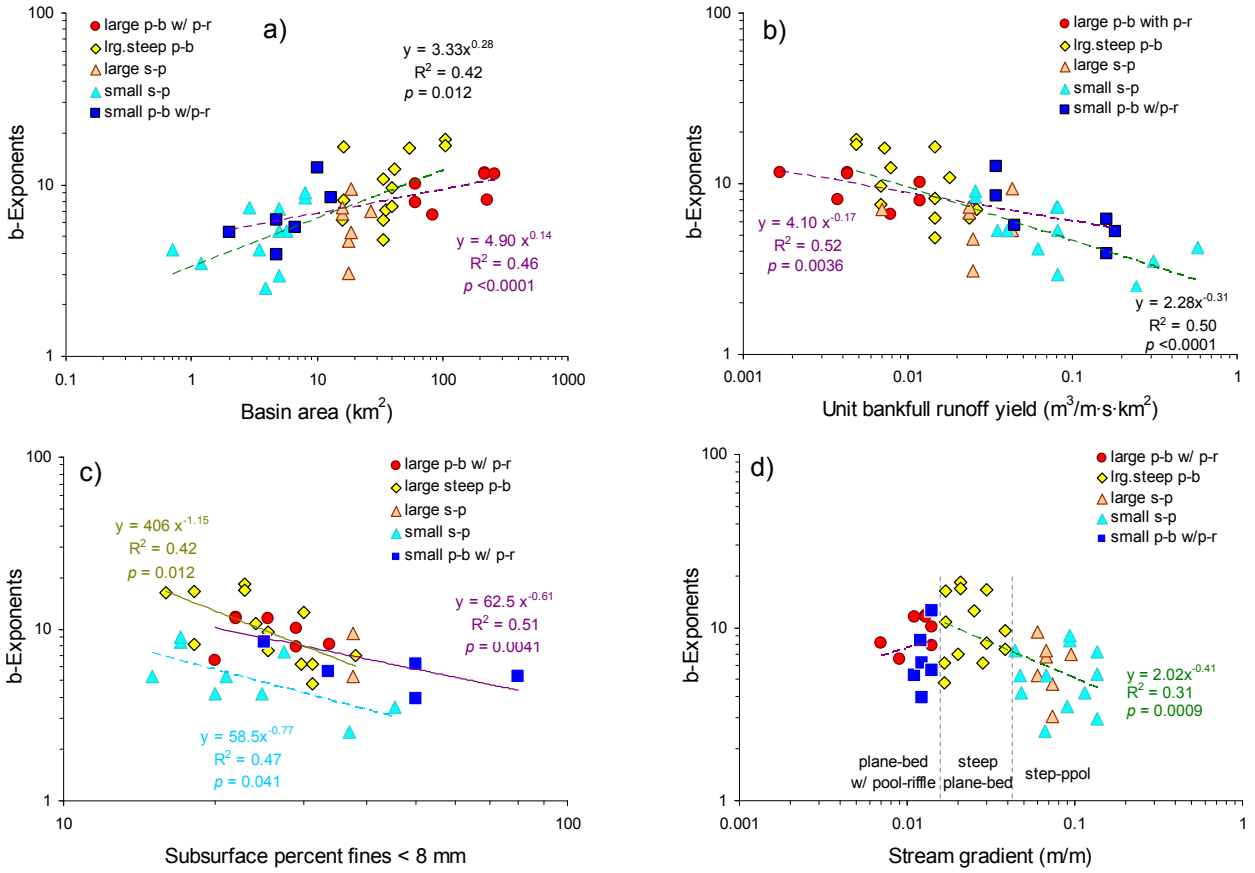

Figure 2 Scaling relations for *b*-exponents shown in Figure 1 segregated by stream type.

streams and describes a scaling relation with a flatter trend. The same segregation patterns hold true for scaling relations of b with q_{bf}/A (Figure 2b), which are better defined than for A and make q_{bf}/A a better predictor of b. The non-monotonic trend of b-exponents vs. S (Figure 2d) is not further segregated by basin area. However, gradient and basin area act together and define three distinct scaling relations for b with the $\%D_{sub<8}$ (Figure 2c). The b-exponents for step-pool and steep plane-bed streams are clearly differentiated by stream size, such that large, steep plane-bed and step-pool stream define a scaling relation of b with subsurface fines that is notably higher than that for small step-pool streams. The low-gradient plane-bed streams follow a flatter scaling relation, but again with higher exponents for larger, and slightly lower exponents for smaller streams. Segregation by stream type is especially effective for the parameter $\%D_{sub<8}$ as it narrows the range of b-exponents to a factor of about 2 for a given $\%D_{sub<8}$ and stream type, rendering $\%D_{sub<8}$ a parameter suitable for the prediction of b.

Interrelatedness of steepness and coefficients of Q_B and $D_{max,QB}$ curves

Exponents with exponents and coefficients with coefficients The a-coefficients and b-exponents of Q_B curves as well as the f-coefficients and g-exponents of $D_{max,QB}$ curves are strongly related. Exponents b and g increase in direct proportion with a well defined linear relation ($r^2 = 0.91$) as shown in Figure 3a. This proportionality explains the almost parallel trend of the scaling relations for b- and g-exponents shown in Figure 1 and lets g be computed from b and vice versa. The tight, positive relation between b- and g-exponents is not segregated by stream types and clearly shows that the steepness of Q_B curves depends on whether increasing flows find increasingly larger particles to entrain and transport. If that is the case, $D_{max,QB}$ and Q_B curves steepen.

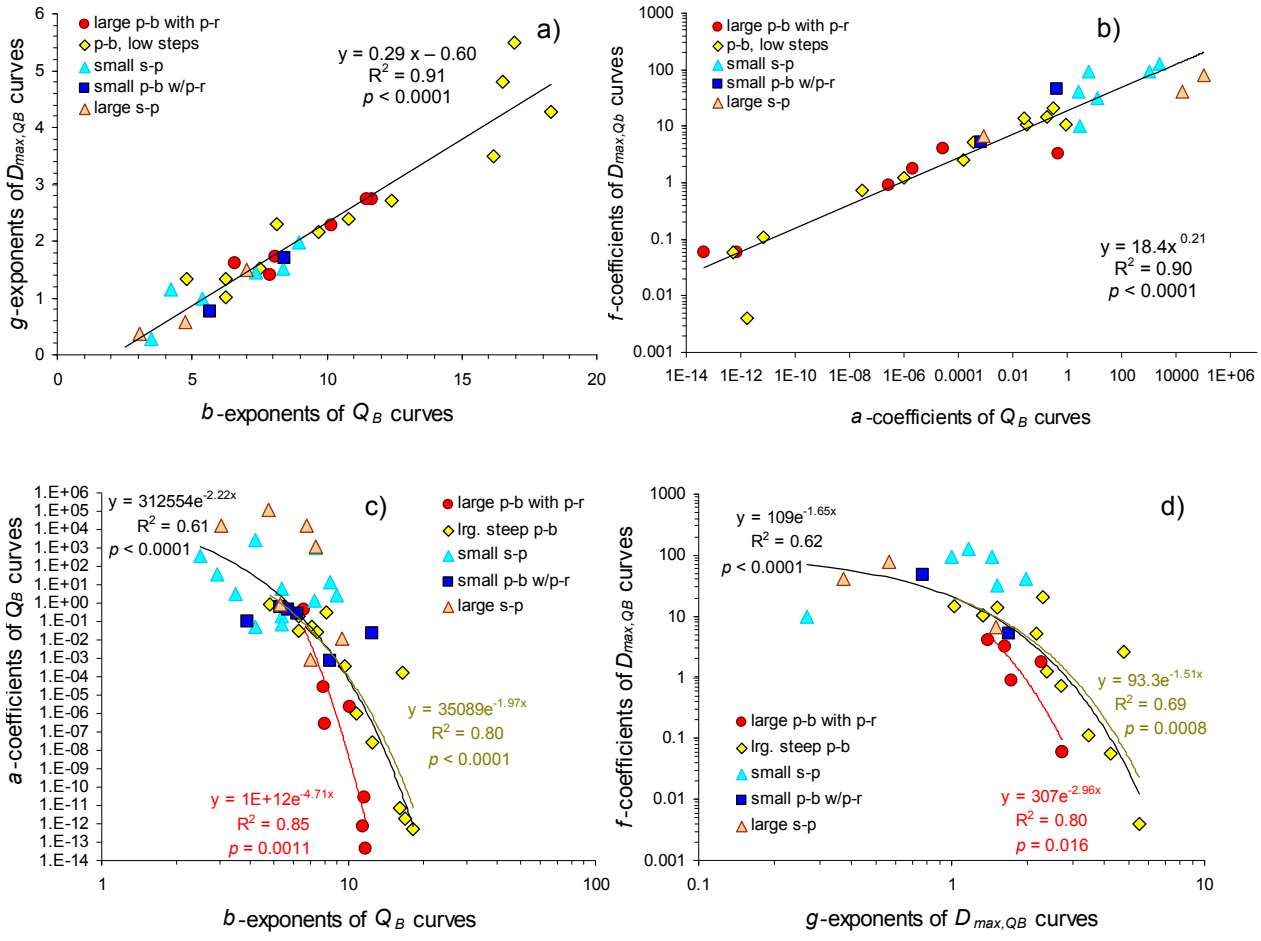

Figure 3 Interrelatedness of Q_B and $D_{max,QB}$ curves: among the two exponents (a), among the two coefficients (b), and among coefficients and exponents (c and d).

Inherent inverse relations between exponents and coefficients Power function coefficients represent not only the *y*-axis intercept for $x = 1$ but are also inversely related to the function's steepness. Negative relations between exponents and coefficients are a general feature of power functions. Consequently, all positive scaling relations for exponents (Figure 1) become negative for coefficients and vice versa. For the study stream Q_B curves, an increase of *b*-exponents by 1 is met by a 1 to 2 order of magnitude decrease in *a*-coefficients (Figure 3c); *f*-coefficients of $D_{max,QB}$ curves decrease less, by about half an order of magnitude as *g*-exponents increase by 1 (Figure 3d). Coefficients are also directly controlled by the magnitude of bedload transport rates. For example, a doubling in transport rates for all Q doubles the coefficient. The two-fold control of coefficients (by exponent steepness and by transport rates) complicates a comparison of coefficients among streams: A Q_B curve with a coefficient 10 times larger than that of another Q_B curve at a specified parameter *x*-value does not mean that transport rates of the two curves differ by a factor of 10.

Values of *a*- and *f*-coefficients from fitted Q_B and $D_{max,QB}$ curves extend over about 10 and over 4 orders of magnitude, respectively. Nevertheless, the negative relation between *a*-coefficients and *b*-exponents is fairly well and significantly described by an exponential function (r^2 of 0.61) (Figure 3c), as observed for suspended sediment (Syvitski et al. 2000; Yang et al. 2007). The relation between *a*-coefficients and *b*-exponents is clearly affected by stream type. Segregation by stream gradient raises the correlation for large, steep, plane-bed streams to an r^2 of 0.80 and to an r^2 of 0.85 for large, low-gradient plane-bed streams with occasional riffles and pools (Figure 3c). Hence for the large study streams, segregation by *S* narrows the range of *a*-coefficients for a given *b*-exponent from 10 to about 6 orders of magnitude. Stream size segregates the *a*-*b* relation for step-pool streams; large step-pool streams have a steep relation, while small step-pool streams have a flatter one. Stream gradient segregates the *a*-*b* relation between small streams with higher *a*-coefficient for small step-pool streams than for small, more gently sloped plane-bed streams.

For $D_{max,QB}$ curves, the trend between *f*-coefficients with *g*-exponents is likewise fairly well and significantly described by a negative exponential function (r^2 of 0.62) (Figure 3d). Segregation by stream gradient improves r^2 from 0.62 for all data to 0.69 for large steep plane-beds, and to 0.80 for large low-gradient plane-bed streams with occasional riffles and pools. However, a further segregation of step-pool streams by size or small streams by gradient is not evident.

Scaling relations of Q_B and $D_{max,QB}$ curve coefficients with watershed, channel, flow, and bed material parameters Coefficients of the Q_B and $D_{max,QB}$ curves are negatively related to basin area A (Figure 4a). A negative relation of *a* with A was also reported by Barry et al. (2004) for streams in Idaho. Following the inherent inverse relation between exponents and coefficients, coefficients are positively related to q_{bf}/A (Figure 4b). A positive scaling relation had also been expected for the bed material parameters $\%D_{sub<8}$ (Figure 4c) but is not revealed by the data. Similarly, the convex non-monotonic scaling relations observed for exponents with stream gradient does not turn into concave a non-monotonic relation for coefficients. Instead, coefficients display poorly to moderately well-developed positive trends with S (Figure 4d).

Predictability of coefficients Scaling relations for coefficients with the parameters A and q_{bf}/A (Figure 4a, b) are significant and tend to yield higher r^2-values than scaling relations for exponents (Figure 1a-b), but that does not render coefficients more predictable. Scatter around the fitted regression function is large, about ± 1 order of magnitude for coefficients of the $D_{max,QB}$ curves and ± 4 to 5 orders of magnitude for Q_B curves, which might preclude a meaningful prediction of Q_B coefficients from watershed and channel parameters.

Fitting Q_B and $D_{max,QB}$ curves with unit discharge $q = Q/w$ instead of total Q does not narrow the scatter in the scaling relations for coefficients. Compared to *a*, the range of a_q-coefficients obtained from Q_B curves with q instead of Q extend over a range about one order of magnitude wider than *a*, and neither the general trends of scaling relations (Figure 4), nor the patterns observed for individual stream groups change in a significant way between *a* and a_q.

Coefficients *a* of Q_B and *f* of $D_{max,QB}$ curves, like exponents, show a strong positive correlation ($r^2 = 0.90$) (Figure 3b), corroborating that gravel transport and flow competence increase in unison. The relation of *f*- vs. *a*-coefficients is not differentiated by stream type.

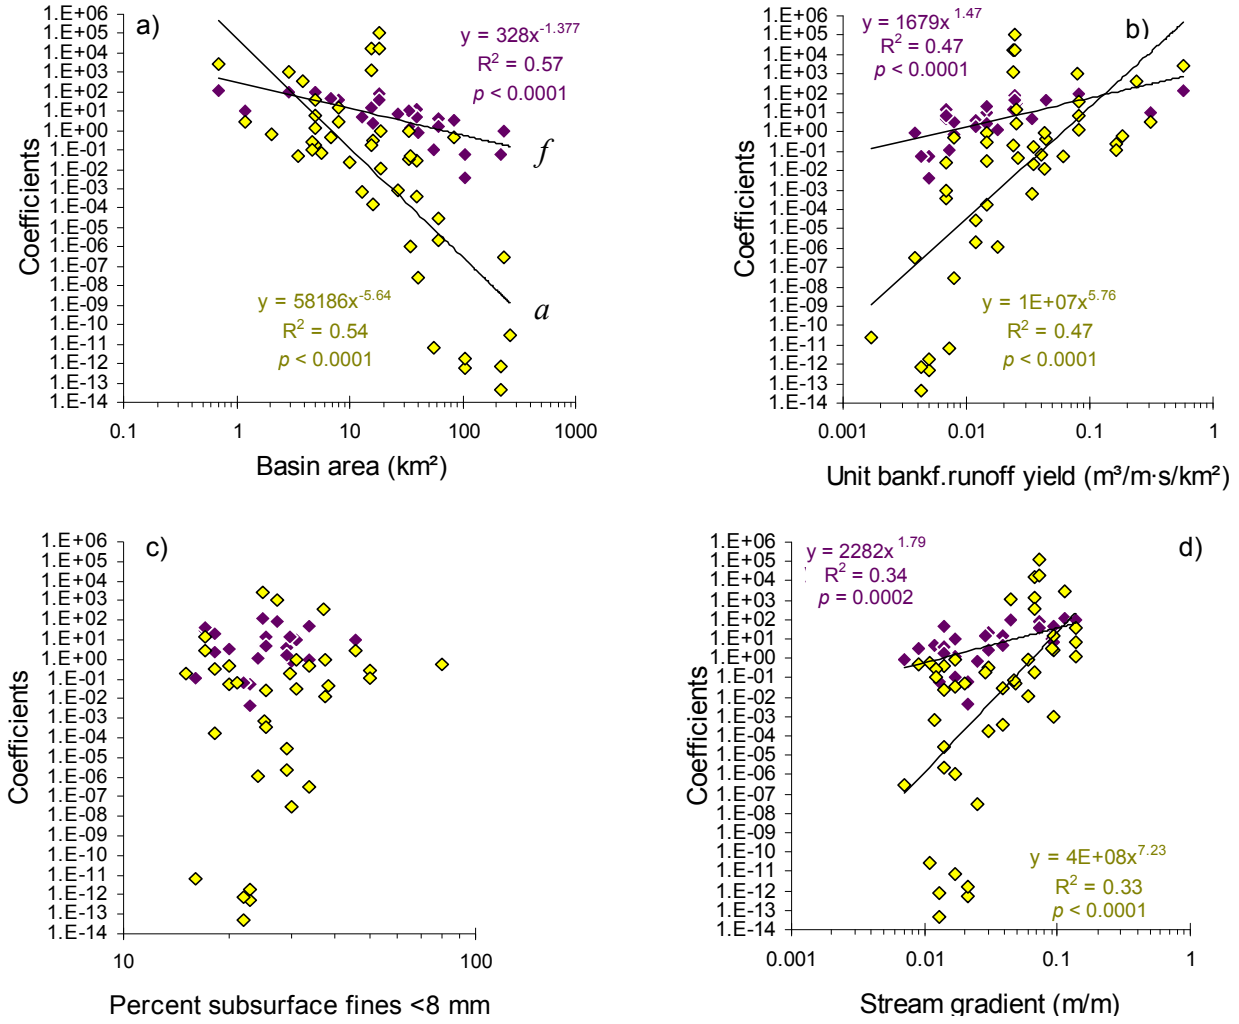

Figure 4 Scaling relations for *a*- and *f*-coefficients with the four stream parameters showing a negative trend with A (a), a positive trend with q_{bf}/A (b), a poorly defined positive trend with $\%D_{sub<8}$ (c) and a non-monotonic trend with S (d). Yellow symbols denote *a*-coefficients and purple symbols *f*-coefficients of $D_{max,QB}$ curves.

Differentiation of coefficients by stream type and stream size

The prediction of *a*- and *f*-coefficients from basin area, runoff yield, stream gradient, and the percentage of subsurface fines < 8 mm is improved when scaling relations are segregated by stream type; the discussion here is limited to *a*-coefficients for which datasets are richer than for *f*-coefficients. Segregation of the data scatter is primarily by stream size and indicates steep scaling relations for *a*-coefficients with all parameters for large streams, and flatter scaling for small streams. The resulting intersection of the two scaling relations for *a*-coefficients with A (Figure 5a) reflects two opposing segregation effects by stream gradient; among small streams, *a*-coefficients are clearly lower for plane-bed streams than for step-pool streams. The effect of gradient is reversed among large plane-bed streams; those with low-gradients have higher coefficients than those that are steeper. These segregation trends are not evident for all parameters. Trends for scaling relations of *a*-coefficients with A are reversed for the parameter q_{bf}/A (Figure 5b) except for the differentiation among gentle and steep-gradient plan-bed streams. Secondary stratification by stream gradient is consistent only among small streams and for all four parameters (Figure 5 a-d), with higher coefficients for the steeper streams. Being stratified by stream type in multiple ways makes A a better suited parameter for predicting *a*-coefficients.

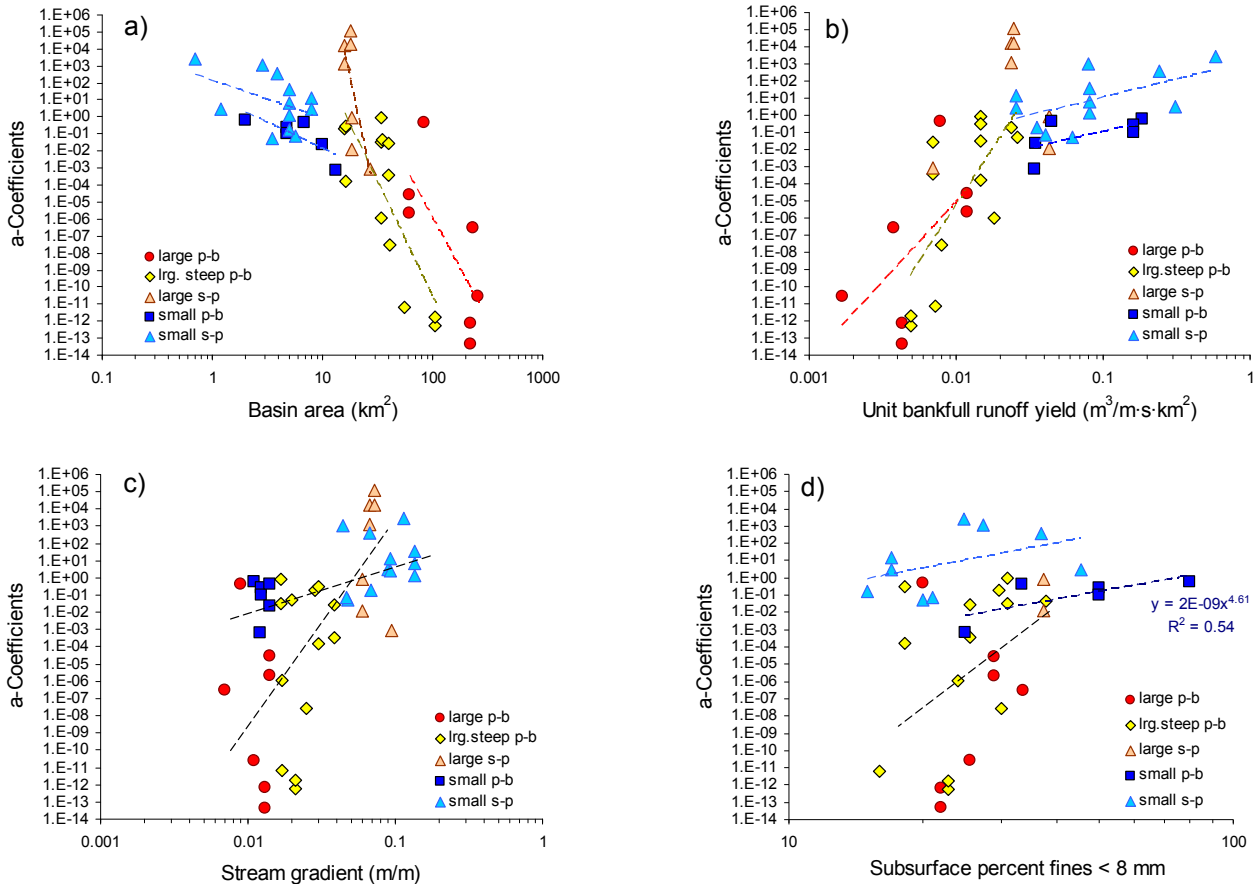

Figure 5 Scaling relations for *a*-coefficients shown in Figure 4 segregated by stream type. Dotted lines indicate possible trends.

SUMMARY AND CONCLUSION

- Study results demonstrate that exponents and coefficients of Q_B and $D_{max,QB}$ curves are systematically and significantly related to four parameters: basin area, runoff yield, stream gradient, and the percentage of subsurface fines < 8 mm. This finding is not reflected in current bedload transport equations and may serve to improve their application to gravel-bed rivers in mountain areas.
- Even though the data scatter is wide and the r^2-values are only moderate, the fairly large sample size of the study ensures significance and robustness of the scaling relations.
- The scaling relations of exponents with basin area, unit runoff yield, stream gradient, and percent subsurface fines scatter widely; hence a user can confidently determine the range of expected exponents but not accurately predict its value. Scaling relations of coefficients with those four parameters are slightly better correlated and likewise significant, but the wide scatter that extends over several orders of magnitude (especially for Q_B curves) appears to preclude any practical prediction of coefficients.
- Scatter can be narrowed when scaling relations for exponents and coefficients are differentiated by stream types.
- The specific effects of segregation by stream type on scaling relations differ among stream parameters as well as between exponents and coefficients, but segregation is primarily by basin area, and secondarily by stream gradient.
- At this stage of research, an iterative approach is suggested to estimate exponents and coefficients from scaling relations; the estimate is initially based on a parameter's *x*-value, and then narrowed based on stream type group. After repeating the process for all parameters, estimates are either averaged or weighted based on the parameter considered most relevant or reliable.

- Segregation by stream type can improve the r^2 of a scaling relation but decreases its significance. However, the lower sample size in data sets segregated by stream type lets an individual data point have influence on a scaling relation, hence a larger data base to increase certainty would be desirable.

Acknowledgment We thank all researchers who shared their hard-won bedload data with us: Gustavo Merten (Univ. of Minnesota, Duluth, USA) for data from Arvorezinha Creek, Francesco Comiti (Free University of Bolzano/Bozen, Italy) for Saldurbach data, and Luca Mao (Pontificia Universidad Catolica de Chile, Santiago, Chile) for Estero Morales data; Johannes Schneider and Jens Turowski (Swiss Federal Research Institute, WSL, Birmensdorf, Switzerland; Jens also at Helmholtz Centre Potsdam, GFZ, Potsdam, Germany) for data from the Riedbach and the Erlenbach. The National Stream and Aquatic Ecology Center (formerly Stream Systems Technology Center) of the USDA Forest Service, Fort Collins, Colorado, USA funded this study and the many years of field data collection that provided the basis for the analyses. We are indebted to John Potyondy (retired, Forest Service) for his vision and long-term support of our data collection efforts without which this study could not have been done.

ABSTRACT

Sediment is an important pollutant contributing to aquatic-habitat degradation in many waterways of the United States. This paper discusses the application of sediment budgets in conjunction with sediment fingerprinting as tools to determine the sources of sediment in impaired waterways. These approaches complement monitoring, assessment, and modeling of sediment erosion, transport, and storage in watersheds. Combining the sediment fingerprinting and sediment budget approaches can help determine specific adaptive management plans and techniques applied to targeting hot spots or areas of high erosion.

INTRODUCTION

In 2014, both sediment and turbidity were the second leading cause, after pathogens, of impairment of U.S. waterways (EPA, 2014). Typically, the sediment size class of concern is fine-grained silts and clays, which can degrade habitat, affect water supply intakes and reservoirs, and often carry pollutants of concern (Larsen et al., 2010).

When a stream is identified as impaired by sediment, the Clean Water Act requires states to develop numeric targets that describe the maximum amount of pollutants that a water body can receive over time, known as the "total maximum daily load" (TMDL). As part of the sediment TMDL protocol, the EPA requires that the sources of the sediment be determined (EPA, 1999). Many of the approaches used by states to identify sediment sources involve the use of models (EPA, 2008) or assessment tools such as the Watershed Assessment of River Stability and Sediment Supply (WARSSS) (Rosgen, 2006) and the Generalized Watershed Loading Functions (GWLF) (Haith et al., 1992). The TMDL Technical Advisory Group (TAG) was formed, consisting of scientists from universities, Federal and State agencies, and non-governmental organizations, to provide guidance.

In a 2002 review of sediment TMDLs in Georgia (EPA Region IV) 2 by the TAG (Keyes and Radcliffe, 2002), the following recommendations were made:

- A carefully crafted inventory of the potential sediment sources and pathways by which sediment enters the water body should be developed.
- To the greatest extent possible, problem identification should be based on currently available information, including water-quality monitoring data, watershed analyses, information from the public, and any existing watershed studies.

- It is also critical to have a thorough understanding of the relative contribution from various sediment sources. It is highly recommended that thorough onsite watershed surveys be conducted.
- Follow-up monitoring is a key component of the TMDL process and should be emphasized in the Phase 1 TMDLs.

Sediment is considered a nonpoint source pollutant when it originates from diffuse sources such as construction sites, crop and forest lands, and eroding streambanks (EPA, 2012). In a review of TMDL implementation, which included sediment, the U.S. Government Accountability Office (USGAO, 2013) reported that long-established TMDLs were not helpful for attaining reductions in nonpoint source pollution. In Pennsylvania, of the nearly 1,000 parts of water bodies identified as impaired by sediment, only two have been restored (USGAO, 2013).

These reviews clearly indicate a need for effective sediment-source identification in the TMDL process. In this paper, we describe combining sediment budgets and sediment fingerprinting, and present findings from a case study to demonstrate the effectiveness of sediment-source identification. The approaches we discuss are field efforts that may accompany modeling efforts to identify sediment sources supporting the TMDL process. These methods are part of a larger protocol for identifying sediment sources that is under development by the authors for EPA Regions III and V.

SEDIMENT-SOURCE INVENTORY

Sediment sources in any given watershed vary with location and time. In general, sediment sources can be divided into two broad categories: (1) upland sediment sources, and (2) channel sediment sources. Upland sediment sources include various land-use and land-cover types: forest, cropland, pasture, construction sites, roads, etc. Channel sediment sources can include the streambanks, beds, flood plain, and gullies. It is important to apportion sediment derived from uplands versus channels because sediment reduction strategies differ by source and require different management approaches. For example, reducing sediment loads from agricultural sources might require soil conservation and tilling practices, whereas channel sources might require streambank stabilization.

Erosion on upland surfaces can occur though sheetwash, rilling, gullying, and mass movements. Periods of heavy rain that lead to saturation excess overland flow or infiltration excess overland flow can mobilize and erode upland sediment. Streambanks erode during high flows, from mass wasting, and as a result of freeze and thaw activity in cold climates. The channel bed can be a source of sediment in incising channels. However, fine-grained sediment from channel beds has not traditionally been considered a sediment source, since in the absence of significant channel incision, sediment mobilized from the channel bed is typically thought to represent temporary storage of sediment originating from upstream sources (Gellis et al., 2009).

SEDIMENT BUDGET

The sediment budget approach quantifies the erosion, deposition, and storage of upland and channel elements in a watershed. A sediment budget can be presented as an equation:

$$I + \Delta S = O \quad (1)$$

Where I is the sediment input, ΔS is the change in sediment storage, and O is the sediment output.

The steps to generate a sediment budget for a given watershed are:

1. Choose the watershed scale of interest for the sediment budget.
2. Distinguish a time period of interest for the sediment budget.
3. Determine the geomorphic elements contributing to (I) or storing sediment (ΔS).
4. Ascertain what size sediment class is to be budgeted.
5. Determine approaches to quantify steps 1 through 4 (Table 1)
6. Define the watershed output (O) point and approaches to quantify sediment transported out of the watershed (Table 1).
7. Estimate or measure I, ΔS, and O over desired time period.
8. Extrapolate measurements of I and ΔS to the entire watershed to obtain a volume.
9. Using the density of soil or sediment representative of each geomorphic element, convert volume measurements from step 8 to a mass per unit time.
10. Sum mass per unit time values from step 9 for each geomorphic element and compare the results to the output (O).
11. Communicate results and provide error analysis.

In the first two steps of sediment budgeting, initial decisions on spatial and temporal scales of interest are made that will influence the design of the sediment budget. These scales will be determined by the management questions of interest. The watershed scale for the sediment budget can range from hillslopes (m^2) to major river basins (>100,000's km^2) (i.e. the Mississippi River). For this paper, it is assumed that small to medium watershed scales of up to hundreds of kilometers are of interest.

Time periods for which the sediment budget is developed can also vary, from single storm events to thousands of years (Reid and Trustrum, 2002). In regions that have had widespread land clearing from agriculture or clearcut logging, long-term time scales are of interest in order to compare
pre- and post-disturbance differences (Knox, 2001; Fitzpatrick and Knox, 2000). Budgets that include flood-plain sedimentation are useful for time scales of decades to centuries (Knox, 2001; Trimble, 1999; Fitzpatrick et al., 2009). For modern sediment budgets that cover a few years, sediment loads are typically measured at the watershed outlet (Gellis and Walling, 2011).

In step 3 of the sediment budget approach, potential sources of sediment can be identified in a watershed using a geographic information system (GIS) analysis, reconnaissance of the entire basin, "riverwalks" or reconnaissance along channels, field experiments, monitoring, and photogrammetric analysis using aerial photographs. Sources of sediment are then defined as a combination of geomorphic elements and human uses (i.e. streambanks, upland cropland, pastured gullies, and forests). Next, the outlet of the watershed is defined and appropriate techniques are used to quantify the sediment transported out of the watershed over a specified period of time (Mg/yr) (Table 1). The sediment size of interest is also decided initially (step 4) and can include all sediment sizes or individual size classes. If both fine and coarse sediment are of interest, watershed outlet measurements need to consider both suspended- sediment load and bedload (Edwards and Glysson, 1999).

Table 1 Examples of approaches and methods used in sediment budgets

Sediment budget element (I = input, S= storage, O=output)	Method	Method is used to quantify	Measurement dimension	Time scale of measurements
Channels (I,S)	Aerial photography airborne light detection and ranging (Lidar)	Channel morphologic changes in channel width, sinuosity, bar formation, and channel patterns (Thoma et al., 2005; Kessler et al., 2013)	m	Years, decades
Channels (I,S)	Surveys	Changes in channel width, depth, and slope (Gellis et al., 2012)	m	Per storm (days) to years
Channels (I,S)	Bank pins; Terrestrial LiDAR	Bank erosion and deposition (Hupp et al., 2009; O'Neal and Pizzuto, 2011; Schenk et al., 2012)	cm, m	Per storm (days) to years
Channels	Rapid geomorphic assessments	Qualitative condition of the erosional/depositional characteristic of the streambanks (Simon and Downs, 1995)	NA	NA
Channels (S)	Stratigraphy	Identification of time horizons (anthropogenic, geologic, radionuclides) to estimate changes in deposition rates (Allmendinger et al., 2007; Trimble, 1983)	cm	Years, decades, millennia
Channels (I,S)	Scour chains	Quantify change on the channel bed (Leopold et al., 1966)	cm	Days to years
Flood-plain Deposition (S)	Feldspar Pads	Flood-plain deposition rates (Hupp et al., 2008)	mm	Per storm (days) to years
Uplands (I,S,O)	Lake/Pond surveys using ^{137}Cs	Sediment loads and sediment yields, and changes in sedimentation over time (Gellis et al., 2006)	kg/m^2	Years, decades
Uplands (I,S)	^{137}Cs	Upland erosion and deposition rates (Gellis et al., 2009; Walling and He, 1999)	tons/hectare	Decades (50 yrs)
Uplands (I)	Sediment traps	Sediment yield (Gellis et al., 2012)	kg/m^2	Per storm (days) to years
Uplands (I,S)	Pins (nails)	Land-surface erosion (Gellis et al., 2012)	cm	Per storm (days) to years
Uplands (I)	Nets, silt fences	Erosion and sediment yield (Robichaud and Brown, 2002)	kg/m^2	Days to years
Uplands (I)	Aerial photographs	Qualitative description of areas that may contribute sediment (agriculture, mining, landslides, roads, etc.) (Reid and Dunne, 1996)	NA	NA
Uplands (I,S)	Dendro-chronology	Coring trees and counting rings to determine deposition and erosion rates (Hupp and Bazemore, 1993; Allmendinger et al., 2007)	cm	Decades
Uplands (I)	Eolian traps	Quantify eolian deposition (Gellis et al., 2012)	g	Years
Uplands (I) and Channels (I)	Multiple geochemical fingerprints	Quantify the contribution of sediment from source areas (Walling et al., 2008; Gellis and Walling, 2011)	%	Days to years
Sediment transport (O)	Collection of suspended sediment and bedload	Sediment loads (Gellis et al., 2006, 2012)	kg	Per storm (days), years to decades

The erosion and storage of sediment is determined for each geomorphic element (step 7) over the measurement period using the approaches outlined in Table 1. Most of the measurements in Table 1 produce linear (cm) or cross sectional area (cm^2) rates of change that are extrapolated

for each geomorphic element (step 8) over the entire watershed to obtain a volume (m^3) which is then converted to mass (kg) using the density (g/cm^3) of eroded/deposited sediment. Extrapolation can be performed using different independent variables, including, but not limited to, stream order, stream type, landscape feature, geomorphic landform, and geologic areas (Fitzpatrick and Knox, 2000; Fitzpatrick et al., 2009; Gellis et al., 2012). For example, bank pins might be used to measure erosion or deposition in centimeters. Erosion and deposition are then averaged for a bank face (cm) to obtain an area of bank change (cm^2). This value is extrapolated to a channel length (m) representative of that bank (i.e. stream order) to obtain a volume of bank change (m^3). Finally, mass (kg) is obtained by multiplying the density of the bank sediment (g/cm^3) by the volumetric change (m^3). Density can be measured by inserting core samplers of known volumes into the streambank.

For 30- to 50-m high valley bluff failures along tributaries to Lake Superior, aerial photograph analyses of bluff retreat rates, along with field measurements of bluff retreat, length, height, and stratigraphy, were used to determine that the bluffs were a major source of the eroded sediment that was causing burial and scouring of spawning gravels downstream (Fitzpatrick and Knox, 2000; Fitzpatrick et al., 2014). Flood-plain cores and interpreted sedimentation rates were extrapolated over appropriate areas based on geomorphic landform and cultural features such as bridges, railroads, and levees that influence the distribution of sediment deposition during floods (Fitzpatrick et al., 2009).

The erosion and deposition of each geomorphic element is summed and values are compared to the sediment measured at the outlet (step 10). Theoretically, all sediment inputs and storage terms should balance to the output (Eq. 1), however, this rarely happens (Kondolf and Matthews, 1991). Kondolf and Matthews (1991) reported imbalances > 100% of the total sediment output. The error represents the cumulative uncertainty of measurements and estimates over the range of both spatial and temporal scales. Error analysis can be performed by displaying the range of sediment budget results on each geomorphic element as confidence intervals around the mean (i.e. 10^{th} and 90^{th} percentiles).

Results from a sediment budget analysis can be presented as maps, diagrams, and tables (Fitzpatrick et al., 2009). Areas of high erosion, defined using the sediment-budget approach, can be portrayed in these ways to improve communication of the results and, subsequently, inform targeted management actions.

SEDIMENT FINGERPRINTING

Sediment fingerprinting identifies the source contribution of sediment delivered to a point in the watershed. The approach entails the identification of specific sources of sediment through the establishment of a minimal set of physical and/or chemical properties, i.e. fingerprints or tracers that uniquely define each source in the watershed. Tracers that have successfully been used as fingerprints include mineralogy (Motha et al., 2003), radionuclides (Walling and Woodward, 1992; Collins et al., 1997), trace elements (Devereux et al., 2010), magnetic properties (Slattery et al., 2000), and stable isotope ratios ($^{13}C/^{12}C$ and $^{15}N/^{14}N$) (Papanicolaou et al., 2003).

By comparing the tracers of the target sediment to the tracers of the source samples, and using a statistical "unmixing" model, the sources of the target sediment can be apportioned (Gellis and Walling, 2011). Target sediment can be deposited (bed sediment or flood-plain sediment) or transported (suspended sediment). Because tracer activity is largely found on fine sediment,

sediment fingerprinting is typically conducted on sediment less than 63 microns in diameter (Gellis and Walling, 2011).

Sediment sources in sediment fingerprinting are typically the same sources accessed in the sediment budget. In sediment fingerprinting, sediment samples from upland areas (i.e. agriculture, forests, and construction sites) are collected from the top 1.0 cm of the soil surface with a plastic hand shovel. A plastic shovel is used to protect the sample from metal contamination. To account for variability in tracer properties, sediment is collected across transects and composited. A representative sample of the streambank is collected 1 cm into the vertical bank and along the entire bank. Three to five transects spaced 10 m apart along the stream reach are sampled and composited into one sample.

Several statistical procedures are used to identify the optimum set of properties that will be used in the final composite fingerprint to distinguish the potential sources and establish their relative contribution to the sediment flux at the watershed outlet (Figure 1). The goal is to determine those properties that clearly identify the potential sources and to select a small subset that optimizes the discrimination provided by the composite fingerprint. The statistical steps outlined in Figure 1 were run using the free software statistical package R (R Core Team, 2013) from a Microsoft Access database platform*. Field data are entered into the database and the program guides the user through the necessary statistical procedures to produce relative source contribution results and an error analysis.

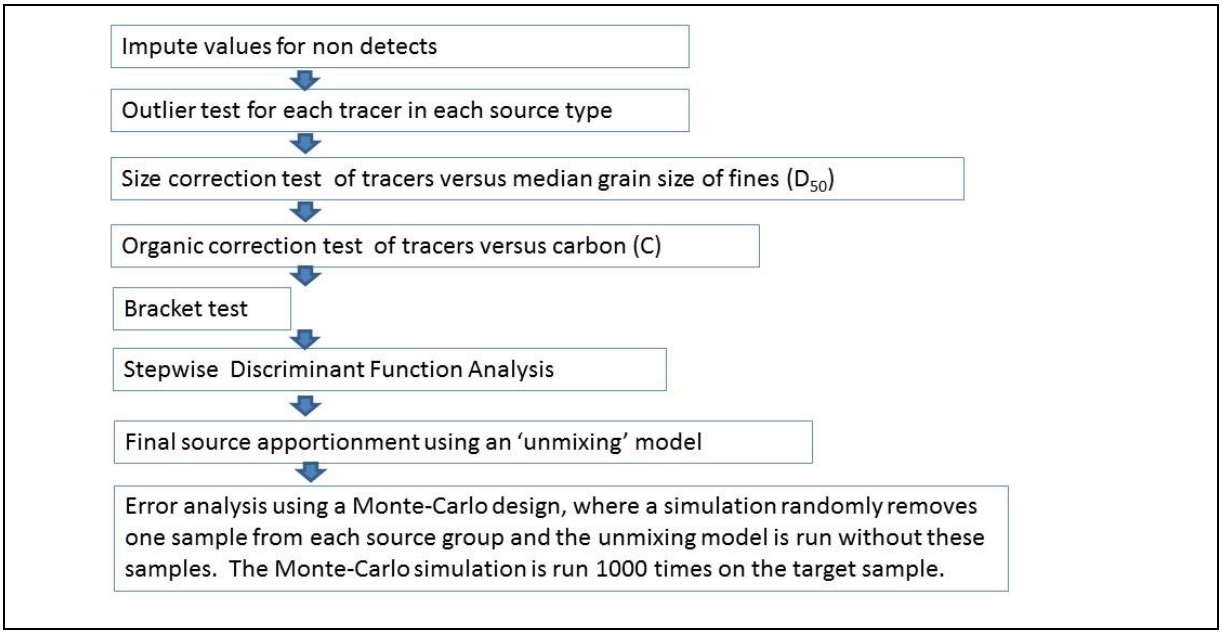

Figure 1 Statistical steps used to apportion sediment in the sediment-fingerprinting approach (From Gellis and Noe, 2013).

* Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

The sediment-fingerprinting approach provides an apportionment of the sources of sediment but it does not provide quantification of the rate of erosion, overall mass of delivered sediment, or target "hotspots" of erosion. For example, sediment fingerprinting may indicate that the streambanks are a major source of sediment in a watershed, but areas with the highest rates of bank erosion cannot be identified using the sediment fingerprinting approach. The sediment budget approach, however, can help target prominent sources of erosion. Erosion and deposition results from the sediment budget can be combined with the sediment fingerprinting results and provide information on sediment delivery ratios (SDRs; the amount of delivered sediment to the amount of eroded sediment) (Gellis and Walling, 2011).

CASE STUDY – Linganore Creek, Maryland

Linganore Creek, Maryland is an example of a source-identification study where both the sediment budget and sediment fingerprinting approaches were used to determine the significant sources of fine-grained sediment between 2008 and 2010 (Figure 2) (Gellis and Noe, 2013; Gellis et al., 2014). Linganore Creek drains 147 km^2 of agricultural (62%) and forested (27%) land in the Piedmont Physiographic Province of the Chesapeake Bay watershed. Sediment budget results indicated that the greatest mass of sediment was eroded from agricultural lands, followed by streambanks and forests. Sediment storage areas included flood plains and farm ponds. The final sediment budget for Linganore Creek expressed as equation 1 is shown in Table 2.

During the period of study, 194 suspended-sediment samples were collected over 36 storm events and were used to determine their sources using the sediment fingerprinting approach. Samples were collected from 40 streambanks, 24 agricultural areas (cropland and pasture), and 19 forested sites. According to the sediment fingerprinting results, agricultural lands contributed 45% of the total fine-grained sediment transported out of the watershed, streambanks contributed 52% and forests contributed 3%. Combining the sediment fingerprinting results with the sediment budget approach indicated that 96% of the eroded agricultural sediment went into storage resulting in a SDR of 4%; 56% of the eroded streambanks went into storage with a SDR of 44% ; and 92 percent of eroded forest sediment went into storage with a SDR of 8 percent. Important storage sites of sediment included ponds, which stored 15 percent and flood plains, which stored 8 percent of all eroded sediment (6.33 x 10^7 kg/yr).

Management Implications

The sediment fingerprinting results indicated that the two main sources of fine-grained sediment delivered out of the Linganore Creek watershed were streambanks (52 %) and agricultural land (45 %). With a higher SDR for streambanks (44 %) compared to agricultural land (4 %), management actions implemented to reduce fine-grained sediment export out of the Linganore Creek watershed may be more effective if they are directed at stabilizing eroding streambanks. In addition, it would be informative to determine the geomorphic agent responsible for the erosion, such as increased runoff. These additional geomorphic insights can help to guide specific treatments for bank erosion within a broader adaptive management plan.

Table 2 Final annual fine-grained (<0.063 mm) sediment budget for Linganore Creek, Maryland, 2008-10. [Negative values in the sediment budget indicate erosion and positive numbers indicate deposition. The output of sediment was determined from the average annual suspended-sediment load computed for Linganore Creek near Libertytown, Maryland, 2008-2010 (USGS Station ID 01642438).]

	***I* (Mg)**	**ΔS (Mg)**	***O* (Mg)**
Agriculture (pasture + cropland)	-54,800		
Forest	-2,030		
Streambanks	-6,440	1,040	
Channel Bed	80	780	
Flood Plains		5,180	
Farm Ponds		9,320	
Unaccounted for sediment in budget		41,600	
Suspended sediment export at sediment station			-5,450

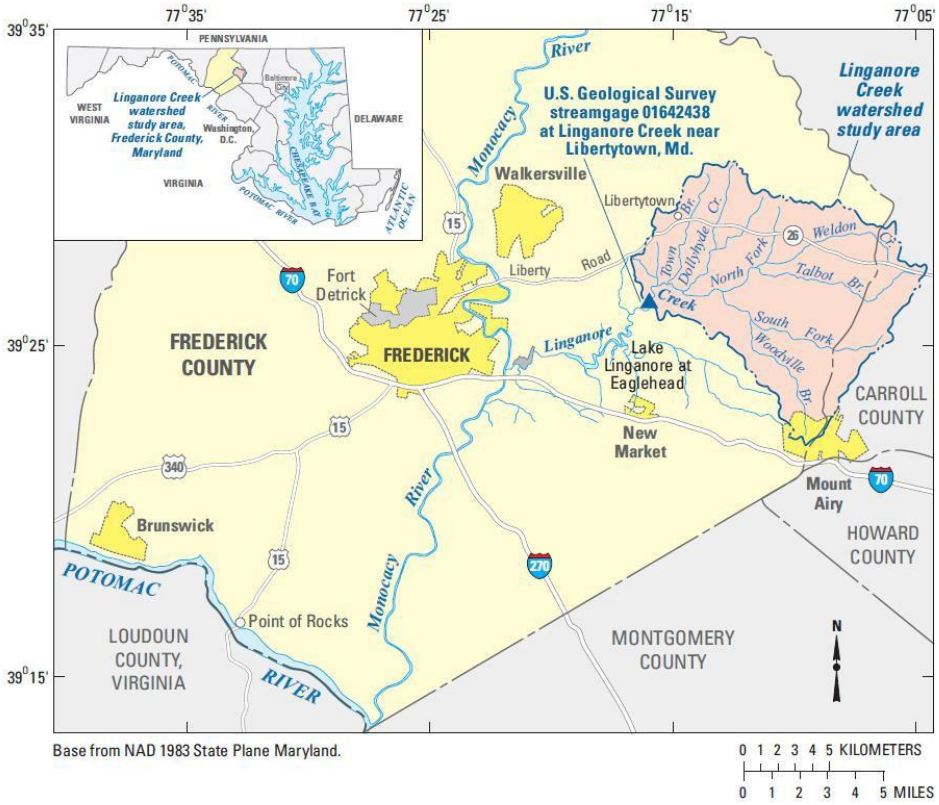

Figure 2 Location of Linganore Creek study area, Maryland.

Understanding sediment storage can be just as important as knowing where the erosion is occurring because sediment deposition influences the delivery and transport of fine-grained sediment to the measured outlet. Impoundments and flood plains were important sites of sediment storage in Linganore Creek. The ponds were estimated to store 9,320 Mg/yr of fine-grained sediment, which was 15 percent of the total eroded sediment. The estimated amount of sediment deposited on flood plains was 5,180 Mg/yr, or 8 percent of the total eroded sediment.

SUMMARY

Sediment is one of the leading causes of surface-water impairment in the United States. Two complementary approaches, sediment fingerprinting and sediment budgets, can be integrated to identify significant sources and sinks of fine-grained sediment in the sediment TMDL assessment process. These approaches can be used in addition to monitoring and assessment, as well as modeling of sediment erosion, transport, and storage in watersheds. Sediment fingerprinting determines the relative source contributions of fine-grained suspended sediment delivered out of a watershed, whereas the sediment budget approach utilizes measurements and estimates to quantify the erosion and deposition of sediment on various geomorphic elements throughout the watershed (streambanks, flood plains, channel beds, specific tributaries or land uses, and upland areas). In combination, these two approaches can help develop adaptive management plans and techniques that target specified hot spots.

PROGRESS ON DAM REMOVAL ANALYSIS GUIDELINES FOR SEDIMENT

Timothy J. Randle, Supervisory Hydraulic Engineer, Bureau of Reclamation, Denver, Colorado, trandle@usbr.gov and Jennifer A. Bountry, Hydraulic Engineer, Bureau of Reclamation, Denver, Colorado, jbountry@usbr.gov

INTRODUCTION

The Subcommittee on Sedimentation (SOS) recognizes that dam removal has become somewhat common in the United States as dams age and environmental values increase. American Rivers estimates that nearly 1,150 dams that have been removed in the United States between 1912 and 2013 (http://www.americanrivers.org/initiatives/dams/faqs/), with most dam removals occurring after 1980. Sediment management can be an important component of some dam removals, but there are no commonly accepted methods to assess the level of risk to river-related resources associated with the sediment stored behind dams. Therefore, SOS began sponsoring an effort in 2008 to develop the Dam Removal Analysis Guidelines for Sediment. This project only provides technical guidance and makes no endorsement on the merits of dam removal.

The process began by convening two technical workshops of invited experts from Federal agencies, universities, consultants and non-governmental organizations: October 14–16, 2008 in Portland, Oregon and October 27–29, 2009 in State College, Pennsylvania. The second workshop tested the guidelines on actual case studies. Preliminary results from this effort were presented at the 9th Federal Interagency Sedimentation Conference (Randle et al., 2010). At the time of this preliminary work, available literature was sparse and nearly all of the removed dams were small with just three notable exceptions:

- The 12-foot high Stronach Dam on the Pine River in Michigan, USA was removed between 1997 and 2003 and the reservoir contained 1 million yd^3 of sediment (Burroughs et al., 2009).
- The 50-foot high Marmot Dam on the Sandy River in Oregon, USA was removed in 2007 and the reservoir contained 0.95 million yd^3 of sediment (Major et al., 2012).
- The 28-foot high Milltown Dam on the Clark Fork River in western Montana, USA was removed in 2008 and the reservoir contained 6.6 million yd^3 of sediment (Wilcox et al., 2008).

Since 2010, two other large dam removal projects were completed:

- The Elwha River Restoration Project on the Elwha River, Washington, USA included the concurrent removal of the 105-foot high Elwha Dam and 210-foot high Glines Canyon Dam between September 2011 and August 2014 (Bountry et al., 2015). The combined reservoir sediment volume of 27-million yd^3 was the largest ever associated with a dam removal project.
- The 125-foot high Condit Dam on the White Salmon River, Washington, USA, was suddenly breached on 26 October 2011 and the reservoir contained 2.4 million yd^3 of sediment (Wilcox et al., 2014).

A great deal more was learned from these large projects and associated recent literature about phased dam removal, cases where there is still a significant reservoir pool, timing of dam

removal relative to seasonal hydrology, channel evolution in the reservoir sediments, and downstream transport (Wildman and MacBroom, 2005; Cannatelli and Curran, 2012; Sawaske and Freyberg 2012; Ferrer-Boix, 2014; East et al., 2015; Gelfenbaum et al., 2015; Magirl et al., 2015; Randle et al., 2015; Warrick et al., 2015). For example, phased dam removal can have significant control on the rate and extent of reservoir sediment erosion downstream sediment release. The actual hydrology, during and after dam removal, can affect the amount, rate, and timing of reservoir sediment erosion. The Dam Removal Analysis Guidelines for Sediment will now be completed using this new and important information.

GUIDELINE APPLICATION

The primary theme of the guideline is to link the amount of recommended pre-project data collection, analysis, and modeling to the risk associated with potential impacts from the reservoir sedimentation. The risk is defined as the product of the probability of impact and the consequence of impact. The greater the risk, the greater the recommended level of data collection, analysis, and modeling. The risk is intended to be a qualitative analysis in collaboration with technical experts, stakeholders and resource managers. The risk may be evaluated within the reservoir landscape or along the river channel upstream and downstream from the reservoir. For the purposes of this guideline, the reservoir sediment volume, relative to the annual sediment load or transport capacity of the river, is used as a surrogate for the probability of impact from releasing sediment as a result of dam removal. If the reservoir sediment contains contaminants above background levels, then the consequence of the potential release of contaminants to the environment will likely determine the level of risk for the project and if reservoir sediment can be released downstream.

In the guideline, the probability of reservoir sediment release is classified as negligible, small, medium, or large depending on the ratio of the reservoir sediment mass (γV_{res}) to the mean annual load or capacity of the river (Q_s):

Negligible Probability $$\frac{\gamma(V_{res})}{Q_s} < 0.1 \quad (1)$$

Small Probability $$0.1 \leq \frac{\gamma(V_{res})}{Q_s} < 1 \quad (2)$$

Medium Probability $$1 \leq \frac{\gamma(V_{res})}{Q_s} < 10 \quad (3)$$

Large Probability $$10 \leq \frac{\gamma(V_{res})}{Q_s} \quad (4)$$

Where the reservoir sediment mass is the product of the unit weight of sediment (γ) and the reservoir sediment volume (V_{res}). The ratios can be computed separately for coarse and fine sediment. For cases of little or no reservoir sediment, the probability and risk are assumed to be negligible and very little data collection and analysis are recommended.

Risk could be calculated by complex numerical analysis, but a more qualitative approach is presented in this guideline where the consequence and risk are categorized as small, medium, or

large. A qualitative risk calculator is presented in Table 1. If the consequence to any of the resources of concern is considered high, then the risk will be either medium or high, depending on the relative reservoir sediment volume.

Table 1 Qualitative risk estimate based on the combination of probability and consequence.

	Consequence of resource impact		
Probability (Fine or Coarse sediment)	**Low**	**Medium**	**High**
Small	Low	Low	Medium
Medium	Low	Medium	High
Large	Medium	High	High +

For the qualitative analysis, a list of potential management concerns and associated sediment-related consequences is generated for the project. Each potential consequence is linked to whether consequence would occur from released coarse reservoir sediment, fine reservoir sediment, or both. For example, the release of an excessive amount of coarse sediment could aggrade the river bed resulting in burial of habitat features, increased flood stage and the potential for stream bank erosion. The release of fine sediment could affect water quality for the aquatic environment and downstream water users, or affect habitat by filling interstitial spaces in downstream riverbed gravels.

Examples of low consequence are where there is no infrastructure or property that could be impacted by the release of reservoir sediment, such as in a canyon reach of river. In addition, there are no threatened or endangered aquatic species that are sensitive to sediment and present at the time and location of impacts. Other examples of low consequence might include natural resources that would benefit from the release of reservoir sediment, such as spawning gravels, recovery of habitat beneath the reservoir, reconnection of the channel with adjacent wetlands and floodplains, or coastal beach restoration.

Medium consequence might include cases where sediment-related impacts would be localized or temporary and such impacts may require mitigation. A medium consequence might also include cases where the consequence is not necessarily low or high.

Examples of high consequences would include streambed aggradation, leading to flooding or erosion of property or infrastructure. High sediment concentrations that would make it very difficult or impossible for water users to obtain water for beneficial uses. Threatened or endangered species that would be irreversibly harmed.

The consequences of an impact depend on the potential effects, regulations, and the perception of stakeholders to resources of concern. The potential concerns of stakeholders needs to be identified to help determine the level of consequences from the release of reservoir sediment upon dam removal. A qualitative judgment may have to be used to estimate the level of

consequence. Public and regulatory perception of the types and magnitude of potential sediment impacts may be greater than the actual impacts. Public education and outreach on hydraulic and sediment processes may be a useful way to help the public understand what the actual sediment effects may be and a collaborative way of determining the level of potential consequences to resources and stakeholders. For example, a medium relative reservoir sediment volume (and medium probability) would have a high level of risk if the consequence(s) were high. Conversely, a medium relative reservoir sediment volume would have a low level of risk if the consequence(s) were low.

For a given dam removal project, there may be a wide range of potential consequences of concern that could range from low to high. For determining the level of data collection, analysis, and modeling, it is recommended to take the highest risk associated with coarse and fine sediment separately. However, it is important to limit the potential consequences to what may actually occur based on the available reservoir volume and particle size gradation (fine versus coarse percentages). For example, Savage Rapids Reservoir near Grants Pass, Oregon had 98% coarse sediment stored in the reservoir with only 2% fine sediment (Bountry et al., 2013). Initially, there was concern about the potential for water quality impacts and release of contaminants. However, for this example, the sediment analysis emphasis was focused on coarse sediment because no contaminants were found above background levels and the fine sediment volume was too small to cause any significant water quality impacts. The types of data collection, analysis, and modeling needed for a high level of risk from coarse reservoir sediment would be different than from fine sediment.

GUIDELINE PROCUDURES

Application of the sediment analysis guidelines is described in the following nine steps:

Reservoir Data Gathering Steps

1. Reconnaissance
2. Characterize reservoir sediment
3. Contaminant assessment

Significance of Reservoir Sediment Volume

4. Determine the relative reservoir sediment volume

Sediment and Dam Removal Alternatives

5. Selection of dam removal and sediment management plan alternatives

Sediment Analysis and Modeling

6. Reservoir and downstream effects analysis

Uncertainty, Monitoring, and Adaptive Management

7. Assess prediction confidence
8. Discussion on sediment effects
9. Develop monitoring and adaptive management plan

An overview of the general guideline steps are presented in Figure 1.

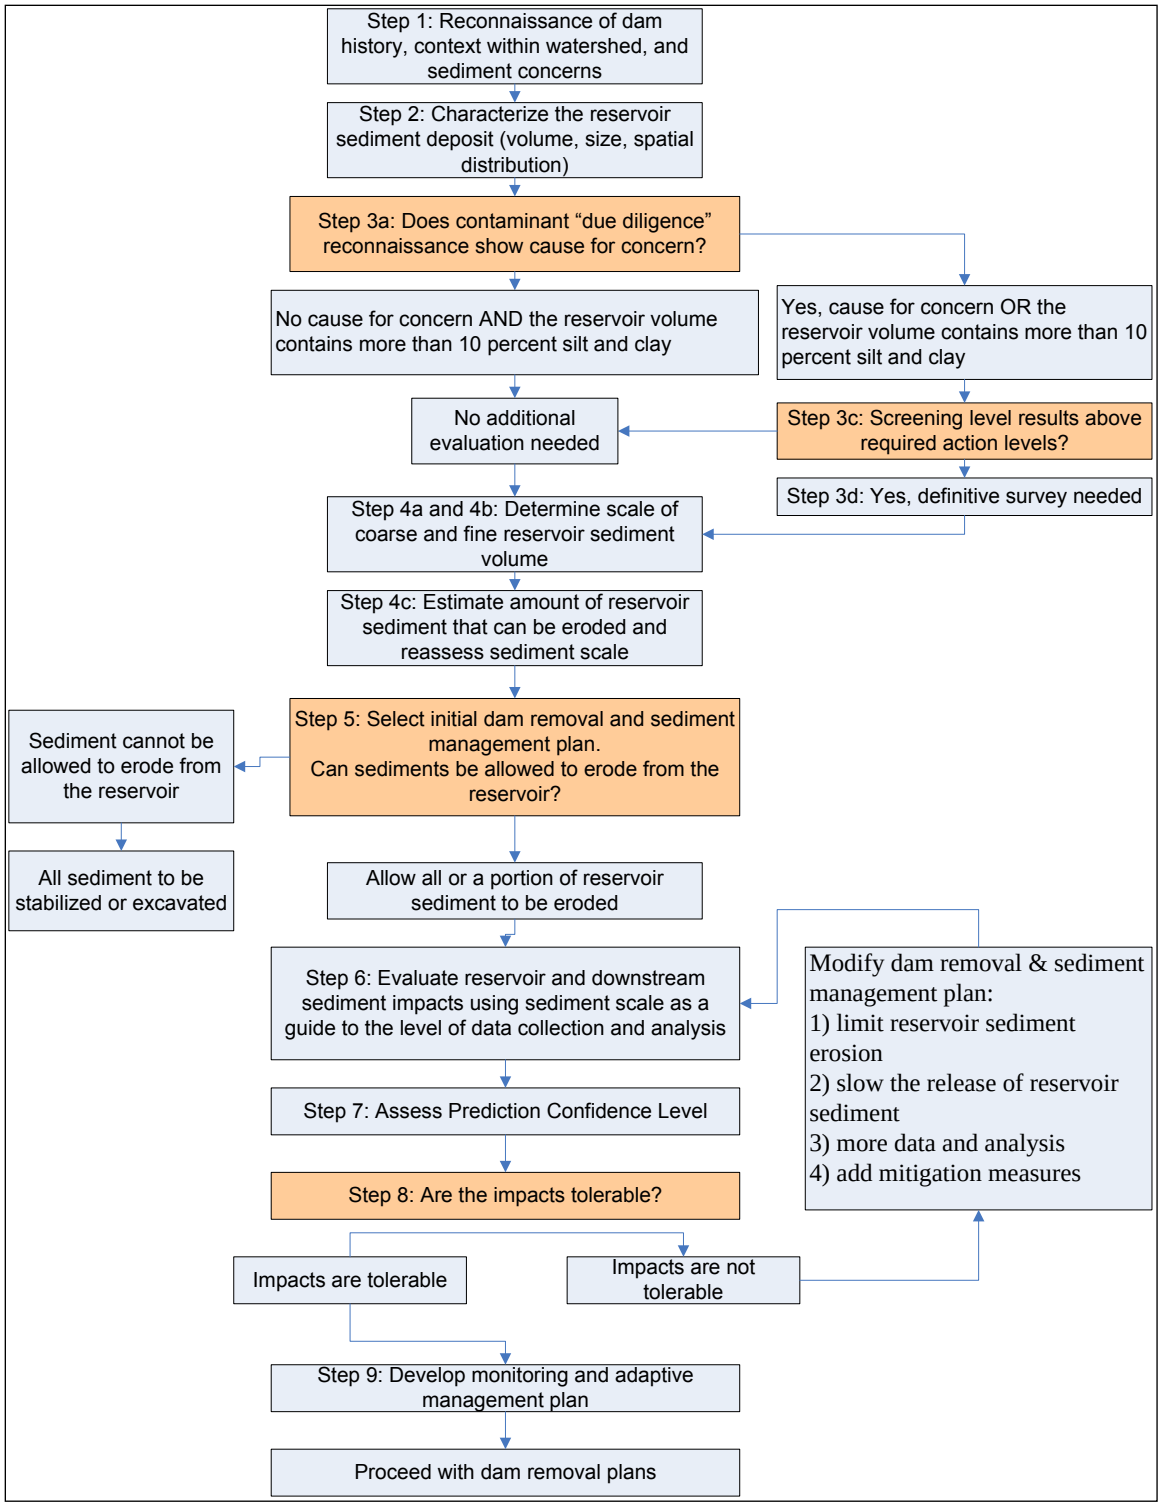

Figure 1 General sediment analysis steps are outlined in a flowchart.

TESTING OF ANALYSIS GUIDELINES

The dam removal sediment analysis guidelines will be tested with data from at least 20 actual dam removals case studies. These case studies will include dams from the eastern, Midwestern, and western United States and include reservoirs with negligible to very large relative sediment volumes.

CONCLUSIONS

The sediment-related impacts of dam removal fundamentally depend on the reservoir sediment characteristics (mass, size gradation, quality, and spatial distribution) and on the extent and rate of reservoir sediment erosion. The level of investigation for sediment impact predictions should be a function of the sediment risk, which is related to the relative reservoir sediment volume or mass.

The next steps to complete the guidelines are listed below:

- Include information from dam removals with large reservoir sediment volumes
- Synthesize results from tested case studies
- Obtain independent peer review
- Obtain approval from Subcommittee on Sedimentation
- Obtain approval from Federal Advisory Committee on Water Information
- Publish guidelines

INTRODUCTION

Adaptive management is a structured, iterative process of robust decision making in the face of uncertainty, with an aim of reducing uncertainty over time via system monitoring (Williams and Brown, 2012). Adaptive management involves developing conceptual models, based on specific assumptions about the resource system, and identifying actions that might be used to resolve the problem. Testing of underlying model assumptions against monitoring data provides a foundation for learning and improvement of management actions based on what is learned. The Elwha River Restoration Project involved the largest and unprecedented sediment release associated with a phased dam removal. This three-year project provided an excellent opportunity for learning more about the benefits and challenges of adaptive management in a real-time environment.

The Elwha River flows north from the Olympic Mountains for about 70 km and enters the Strait of Juan de Fuca at Angeles Point, about 10 km west of Port Angeles, WA. In 1913, Elwha Dam was built 7.9 km upstream from the river mouth, and then removed between September 2011 and April 2012. This 32-m- high concrete gravity dam had 30 m of head and formed Lake Aldwell, which had a storage capacity of 10 million m^3 at the time of removal. Glines Canyon Dam was completed in 1927, 21 km upstream from the river mouth, and was removed between September 2011 and October 2014. This 64-m-high concrete arch dam had 59 m of head and formed Lake Mills, which had a storage capacity of 32 million m^3 at the time of removal (Bountry et al., 2011). Both dams were constructed to produce hydroelectric power. The dams virtually eliminated bed-material sediment supply to the river reaches downstream, forming large deltas at the upstream end of each reservoir. The deltas were composed of clay to cobble-sized sediment, while the lakebeds were composed of mostly silt with about 15 percent clay. The reservoir sediment also contained all sizes of wood and litterfall. In 1992, the United States (U.S.) Congress passed the Elwha River Ecosystem and Fisheries Restoration Act, which authorized the U.S. Department of the Interior to purchase and remove the privately constructed Elwha and Glines Canyon dams to restore fish passage. Rather than sediment excavation, a river erosion plan was selected for dam removal that utilized the natural stream power of the Elwha River to erode and redistribute reservoir sediment during phased dam removal and reservoir drawdowns (ONP, 1996). At the time of removal, Lake Aldwell contained 4.9 million m^3 of sediment and Lake Mills contained 16.1 million m^3 (Randle et al., 2015a).

Sediment Plan: The sediment management objective was to use phased reservoir drawdowns to erode as much of the sediment as possible during dam removal and to redistribute a portion of the eroded sediment along the valley margins to form a series of varying height sediment terraces (Randle et al., 2012). Based on a field drawdown experiment in 1994 (Childers et al., 2000), numerical modeling (Randle et al., 1996), and a physical model study of dam removal rates (Bromley, 2007), drawdown increments of 4.6 m were selected with 14-day hold periods in between (Randle and Bountry, 2010). The rate of dam removal was designed to be fast enough that sediment impacts would affect only a few brood years of fish, but slow enough that the rate of reservoir sediment erosion and redistribution kept pace with the rate of dam removal. Three additional reservoir hold periods (1½ to 2 months per period) were incorporated into the final dam removal plan to limit the release of reservoir sediments into the downstream river during critical fish usage periods referred to as fish windows. Modeling indicated elevated downstream sediment concentration loads would continue to occur for a few years post-removal, but reduce over time with the occurrence of large floods. The river erosion alternative required the construction of mitigation measures, prior to dam removal, to ensure adequate water supply and treatment for downstream users during the period of increased suspended sediment concentration and turbidity. Mitigation was also required to address potential impacts to downstream flood stages from the deposition of coarse sediment on the river bed (aggradation). The plan allowed for reservoir hold periods to be lengthened if monitoring data indicated the pace of reservoir sediment erosion was not keeping pace with the rate of dam removal, or there was risk of exceeding mitigation measures.

Vegetation Plan: An active plan to re-vegetate the reservoirs was designed to preempt invasive species colonization and to plant native forest species to initiate forest succession (Chenoweth et al., 2010). However, vegetation establishment on deep layers of inorganic sediment after dam removal was not well understood in 2011. Although over 1,000 dams had been removed in the United States before 2011, very little research had gone into documenting vegetation colonization of dewatered reservoirs (Heinz Center for Science, Economics and the Environment, 2002). It was clear that natural recolonization of the reservoirs would be dependent on distance from seed sources (Halpern and Harmon, 1983). One of the few surveys of vegetation development after the removal of several small dams in Wisconsin revealed a rapid colonization of the former reservoirs by invasive species such as reed canarygrass (Orr and Stanley, 2006). The Elwha reservoirs are large and inundated more than just the floodplain; upland terraces and valley walls were also inundated. The Elwha reservoirs were also unique in how sediment had accumulated over the last 80-100 years along with all sizes of wood and litterfall. Estimates prior to dam removal suggested the valley walls would be covered in 0.3-1.5 meters of fine sediment (silt and clay) and the valley bottom would be covered in 3-18 meters of sediment (upper 3-6 meters would be coarse sands and gravels) by the end of dam removal. Such deep layers of sediment were expected to be water stressed after the reservoirs were drained. It was also anticipated that sediment texture would influence successional trajectories. Several studies have demonstrated a relationship between substrate texture and plant species performance (Harper et al., 1965; Grubb 1986; Keddy and Constabel 1986; Smith et al., 1995; Leps et al., 2000; Walker and del Moral 2003; Naiman et al., 2005; Michel and Helfield, 2011). Leps et al. (2000) found that fine textured substrates favor colonization by graminoids over forbs or woody species. If the fine-textured sediments favor grasses and coarse sediments are substantially water stressed, rates of succession to forests and the return of ecosystem processes to pre-dam levels may be delayed due to the slow colonization of woody species into the basin. With so much uncertainty, the revegetation plan called for deliberate and gradual planting, combined with intensive monitoring over a 7-year period, to respond to vegetation growth and mortality and to respond to reservoir sediment erosion.

METHODS

Real-time monitoring of reservoir sediment erosion and export was accomplished through repeat topographic surveys that could be compared to pre-dam estimates of the valley bottom, and the pre-removal surveys completed in 2010. Surveys of channel slope and active channel width were accomplished using a real-time kinematic global position system (RTK GPS) during early dam removal, and later with more comprehensive methods such as LiDAR and photogrammetry. Changes in reservoir topography were tracked in a geographical information system relative to the 2010 surface (Bountry et al., 2011), which was represented by polygons of unique size gradation, aerial extent, and thickness (Gilbert and Link, 1995). Volumetric changes in fine (silt and clay) and coarse (sand, gravel, and cobble) sediment were computed between measurements. A sediment budget model, relying on empirical relationships of slope and channel width related to discharge, was used to predict future sediment erosion volumes and downstream concentrations throughout dam removal (Randle et al., 2015b). The empirical relationships were frequently updated using real-time monitoring information. Time-lapse cameras throughout the reservoirs provided documentation on the occurrence of daily channel change that could be correlated with discharge measurements made at the United States Geological Survey (USGS) McDonald Bridge gaging station. The USGS also measured turbidity and suspended sediment concentrations (SSC) upstream of (background) and downstream of the dam sites (Magirl et al., 2014). Downstream river aggradation as a result of released reservoir sediment was measured using photogrammetry for above water areas and RTK GPS and sonar for below water areas. Staff gages were also installed at about 20 river cross-sections to track discharge-stage rating curves that were used as a surrogate to infer periods of aggradation (East et al., 2014).

Monitoring of how fish populations responded to dam removal was accomplished using a variety of methods. Adult salmon abundance and distribution during dam removal was monitored through a combination of sonar observations (LEKT and Denton, 2014), spawning ground surveys (McMillan and Moses, 2013; McMillan et al., 2014), and an adult capture weir (Anderson, et al., in preparation). Juvenile abundance and distribution was evaluated through a combination of smolt traps (McHenry et al., 2014), snorkel surveys, and electrofishing.

The slow drawdown of the dams provided a unique opportunity to adaptively manage the vegetation development as the reservoirs receded. In the first two years of drawdown, experimental plantings were installed to determine native species performance in the deep layers of fine and coarse sediments covering the original forest soils. Permanent plots were established in both planted and unplanted areas to determine the effectiveness of treatments compared to natural patterns of recovery. Since random plot distribution does not always provide a complete picture of the

evolving patterns of natural vegetation development, the restoration ecologist frequently visited the newly exposed surfaces throughout each of the first three growing seasons. Areas within 50 meters of seed sources were left to naturally regenerate. To monitor the performance of planted native species, 860 plants representing 6 species were tagged in the first year and 675 plants representing 5 species were tagged in the second year. Water availability was monitored throughout the year in the sediments of the former Lake Mills reservoir using a tensiometer.

RESULTS

Reservoir Drawdown and Sediment Release: Elwha Dam was removed in the dry by periodically diverting the river, using cofferdams, through a spillway channel excavated in the left abutment. Lake Aldwell had one early drawdown in June 2011 followed by a 16 week hold period, and five additional drawdowns starting in September 2011 and ending in April 2012 when dam removal was completed. The hold periods after reservoir drawdown ranged from 2 to 8 weeks. During each reservoir drawdown, erosion of the reservoir delta occurred as a result of base-level lowering. The eroded sediment was re-deposited in the remaining lake, building new deltas that progressed downstream toward the dam site as the lake reduced in aerial extent and capacity. Downstream sediment releases were minor while sufficient trap efficiency remained in the lake, with a few minor peaks of sediment release during winter storms in November and December 2011 (Figure 1). By mid-March 2012, only 5% of the lake capacity was left and in April 2012 the sediment delta reached the dam site and bedload was released into the downstream channel. Suspended sediment levels in the downstream channel increased from mid-March to early July 2012, and then reduced to low levels as flows receded during late summer and fall. About 90 percent of the fine was transported to the sea, but some fine sediment deposited as thin coatings of mud along low-relief gravel bars and floodplain surfaces that were inundated during the spring 2012 snowmelt season (East et al., 2014). Sand and fine gravel released as bed-material load from Lake Aldwell resulted deposited in the larger downstream pools and eddies, but no aggradation of hydraulic controls (riffles and rapids) occurred.

The contractor completed the dam removal 4 months ahead of the government's estimated schedule (Figure 1). No large floods occurred during this initial dam removal period, and monitoring data indicated no problems with water quality. As expected, delta progradation kept pace with the rate of dam removal and reservoir. Therefore, no adaptive management changes were made to the dam removal schedule. There were issues with cofferdam breaches during winter high flows, but dam removal proceeded. A large portion of the pre-removal Lake Aldwell delta remained in place throughout dam removal. The river quickly incised along the far right side of the delta into cohesive sediment layers during the first two drawdowns; no large floods occurred during reservoir drawdowns that were capable of laterally eroding across the entire wide delta. Adaptive management actions were considered on the Lake Aldwell delta such as a reservoir drawdown one year prior to dam removal that would include a winter flood season. A center pilot channel was also considered during fall 2011 to encourage additional erosion of the Lake Aldwell delta during the dam removal period. Resource managers determined an early drawdown was not procedurally possible before June 2011, and no pilot channel was implemented because the amount of sediment remaining in the Lake Aldwell delta was small enough that impacts would be tolerable if erosion occurred after dam removal. Additionally, the Lake Mills sediment release was expected to be much larger and of greater focus for the adaptive management efforts. Monitoring data showed that small amounts of lateral erosion and channel incision did continue in Lake Aldwell during the two years following dam removal. The most extensive lateral erosion of the remaining delta occurred during a 3-year winter flood in December 2014.

On Lake Mills, a physical model (Bromley, 2007) predicted that excavation of a center pilot channel on the delta was necessary to prevent the river from incising on the valley margin and leaving tens of meters of delta sediment in place. Because of the larger delta size relative to Lake Aldwell, the first adaptive management action in September 2010 was to excavate a center pilot channel along the upstream portion of the delta, block off the main channel along the edge of the delta with a constructed log jam, and remove an existing log jam at the head of the delta to divert river flow into the pilot channel. A large flood followed in December 2010 that widened and deepened the pilot channel and refilled the reservoir. However, the pilot channel was successful in becoming the primary delta channel with a center alignment.

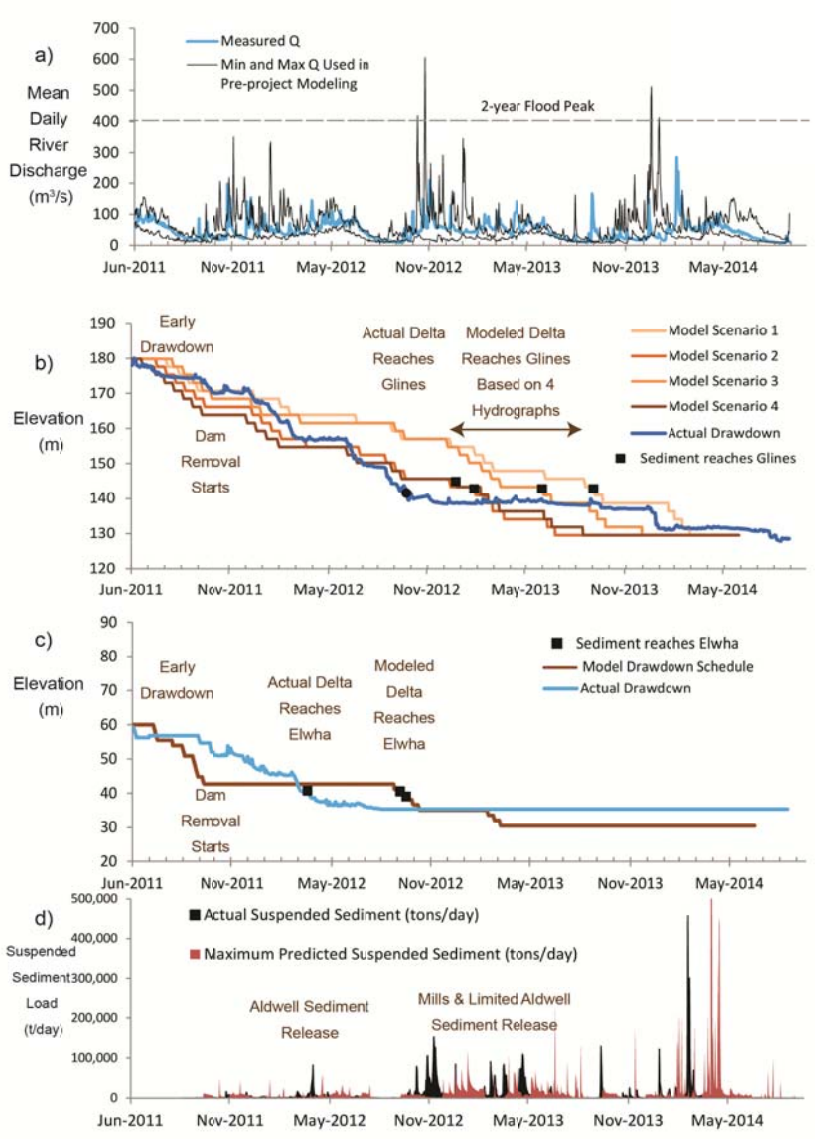

Figure 1 Monitoring results during June 2011 to September 2014 versus pre-project model assumptions for equivalent time periods using four different hydrograph assumptions: a) actual measured river discharge during dam removal compared with range of discharges assumed in model scenarios, b) Lake Mills actual drawdown compared with four model scenarios (differing rate dependent on hydrology), c) Lake Aldwell drawdown compared with model scenarios (same rate regardless of hydrograph), and d) actual suspended sediment load compared with maximum of four model scenario predictions.

An early reservoir drawdown of Lake Mills occurred during July 2011 followed by a 10 week hold period. Starting in September 2011 through April 2012, the first 21 m of Glines Canyon Dam was removed using a hoe ram sitting on a barge while flow was diverted through the gated spillway or through notches cut into the dam crest. The remaining 37 m of Glines Canyon Dam was removed using drill and blast techniques to cut notches on alternating left and right sides of the arch dam. Nine reservoir drawdown increments occurred following dam removal notches between October 2011 through October 2012 when the sediment delta reached the dam. The first hold period of 10 weeks occurred in November and December 2011. Although the first November-December fish window was not required, the hoe ram broke and dam removal had to be temporarily halted until new equipment could be brought to the site. After dam removal resumed in January 2012, hold periods ranged from 2 to 3 ½ weeks, except for the May-June fish window, which resulted in a 10-week hold period. The pace of Glines Canyon Dam removal began to

exceed original predictions in July 2012 because the blasting method was more efficient than the original plan to use a diamond-wire saw. Additionally, less than 10% of the reservoir capacity remained so the sediment was about to reach the dam site. A new round of predictions was made using the sediment budget model to evaluate varying rates of continued dam removal. The contractor was allowed to continue at a faster pace through October 2012, but adaptive management was used to reduce the total possible dam removal rate by one-third. The coarse sediment delta reached the dam after the last allowed blast in October 2012 (Figure 1). At that point, adaptive management was used to halt additional dam removal while new predictions and monitoring occurred to evaluate the first major sediment impacts to downstream water quality and river stage. Rates of sediment release were high until late December 2012 when flows reduced, but then increased with each set of subsequent high winter and spring snowmelt flows. Sediment released into the downstream river not only filled pools, but also aggraded the entire river bed causing the stage-discharge relationships to increase by up to 1 m as the sediment wave passed through. Although peak concentrations of fine sediment did not exceed predictions, the surface water intake designed prior to dam removal became overwhelmed in winter 2012 due to long duration and high volumes of silt, clay, sand, gravel, and organic material entering the plant. Dam removal had to be halted for one year until solutions could be implemented that reduced the amount of sediment entering the water treatment plant.

During the one year hold period, vertical incision up to 9 m and tens of meters of lateral erosion continued in Lake Mills despite the lack of additional base-level lowering at Glines Canyon Dam. The continued reservoir sediment erosion resulted in several years of average annual sediment load being released past the dam site during the one year hold period. Dam removal blasting resumed during fall 2013 with reservoir drawdowns during October 2013, January 2014, February 2014, and the final blast in August 2014. Adaptive management did not have to be used in the final year of dam removal because improvements to the water diversion and treatment plant were successful and river-bed aggradation had reduced. Channel aggradation did result in minor flooding of low relief campgrounds along with bank erosion in many locations along the river. Similar to Elwha Dam, large boulders were also present in the narrow canyon downstream of Glines Canyon Dam, possibly originating from construction activities in the late 1920s. These boulders created a new hydraulic control that increased river water surface upstream from the dam site after removal. Adaptive management was implemented to blast some of the boulders, but others continue to constrict the canyon and increase upstream water stage, possibly impacting fish passage.

At the end of the three year dam removal period, monitoring data indicated about half of the available 21 m^3 of Lake Aldwell and Lake Mills sediment had been eroded and released downstream. Actual river flows during the three year dam removal period never exceeded the 2-year flood for the Elwha River. The annual background suspended sediment load (fine sand, silt, and clay) was only 2 to 6% of the suspended sediment load released from the reservoirs. The largest background suspended sediment load occurred during a March 2014 storm, but was still only 3% of sediment load eroded from the reservoirs. Sediment erosion and release above background levels continued in the year following dam removal, particularly during the 3-year flood in December 2014.

Fisheries: The Elwha Project fisheries restoration plan assumed that mainstem water quality conditions below Glines Canyon Dam would be detrimental to natural fish production, particularly as there is very limited clean water refugium below Elwha Dam (Ward et al., 2008). Salmonids are sensitive to suspended sediment loading, and have been found to exhibit behavioral changes at concentrations as low as 100 ppm, while mortality directly related to turbidity has been seen at concentrations of 1000 ppm (Cook-Tabor, 1995). These effects are exacerbated by the duration of the exposure. Due to concerns regarding elevated turbidity loads during dam removal, the fish restoration plan relied on two fish hatcheries for protection of fish stocks during the sediment-impact period and to help initiate re-colonization following dam removal.

The intent of the fish windows were to provide extended periods of clean water (≤100 FNU) when salmonids (both hatchery and natural origin) could migrate into the river as adults or emigrate from the river as juveniles (Ward et al., 2008). The May-June fish window was specifically designed to accommodate emigration juveniles of all species, as well as the upstream migration of adult native steelhead. The August-September fish window was designed to accommodate the upstream migration of adult Chinook salmon and pink salmon, while the November-December fish window was designed to coincide with the upstream migration of adult Coho salmon, chum salmon, and hatchery origin steelhead (a program which was ultimately discontinued prior to the beginning of dam removal). Adult hatchery origin salmon were expected to recruit naturally to their hatchery of origin, although plans were also made to capture and relocate adults from the river to the hatcheries as necessary. Natural origin adults were expected to either migrate upstream to the best available habitat, or stray into the hatcheries as they sought out cleaner water.

Actual turbidity during the fish windows differed substantially from the modeled conditions (Figure 2; Table 1), being significantly higher than anticipated during the winter and spring periods, or lower than anticipated during the summer periods. More importantly, releases of hatchery fish were not consistently timed with the fish windows, due to either their age of release (yearling Chinook released in April vs fingerling Chinook released in June) or more rapid maturation in the hatchery than originally anticipated (Coho releases in April rather than May).

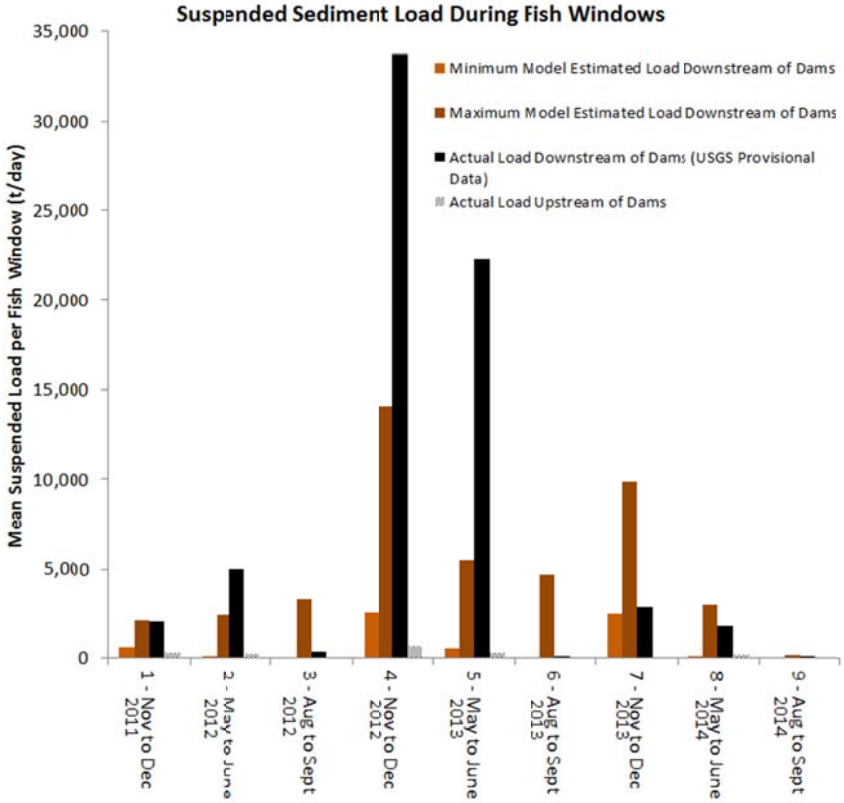

Figure 2 Predicted versus actual suspended sediment loads upstream of (background) and downstream of (actual SSC) the dam sites. Actual data is based on provisional USGS measurements (Magirl, 2014).

Table 1 Percent of time turbidity or discharge exceeded thresholds important to fish during fish windows.

	Mean of 4 model scenarios % Fish Window Exceeding			Actual Turbidity % Fish Window Exceeding			Actual Discharge Exceeded Mean Annual
Fish Window During 3 Year Dam Removal	>100 FNU	>500 FNU	>1000 FNU	>100 FNU	>500 FNU	>1000 FNU	
1 - Nov to Dec, 2011	45%	3%	1%	54%	2%	0%	28%
2 - May to June, 2012	22%	3%	3%	100%	2%	0%	100%
3 - Aug to Sept, 2012	74%	31%	19%	11%	0%	0%	2%
4 - Nov to Dec, 2012	66%	44%	30%	100%	97%	48%	87%
5 - May to June, 2013	7%	6%	3%	100%	77%	28%	90%
6 - Aug to Sept, 2013	11%	2%	1%	2%	0%	0%	0%
7 - Nov to Dec, 2013	17%	11%	5%	72%	36%	3%	7%
8 - May to June, 2014	6%	1%	1%	49%	3%	0%	92%
9 - Aug to Sept, 2014	0%	0%	0%	0%	0%	0%	0%

The largest mean-suspended sediment loading during any given fish window was nearly 35,000 tons/day, during the Nov-Dec window in 2012 (Figure 2). During this time, turbidity exceeded 100 FNU continuously and exceeded

1,000 FNU nearly 50% of the time (Table 1). The models had predicted that turbidity would exceed 100 FNU about 66% of the time and 1,000 FNU about 30% of the time. While turbidity and suspended sediment concentrations were substantially higher than projected, Coho and chum salmon moved into the river opportunistically, but tended to recruit primarily to the hatchery facilities. There was little indication that any Coho volitionally moved upstream of the Elwha Dam site (McMillan and Moses, 2013). Suspended sediment concentrations were also significantly higher than modeled during the May-June fish window of 2013. Although the mean concentrations were lower than those observed during the 2012 Nov-Dec window (~22,000 tons/day), turbidity greatly exceeded modeled conditions (Table 1). Turbidity exceed 100 FNU 100% of the time (modeled at 7%), exceeded 500 FNU 77% of the time (modeled at 6%), and 1,000 FNU 28% of the time (modeled at 3%).

While certain cohorts of hatchery fish were released during the spring fish windows (e.g. fingerling Chinook), other cohorts were released prior to the fish window (yearling Chinook, Coho). In April 2013, periods of high turbidity were associated with large scale observations of juvenile Chinook mortality following their release from the WDFW hatchery. Returns of Coho salmon in the fall of 2014 (originating from juveniles emigrating during the spring of 2013) were significantly lower than anticipated (PFMC, 2014). Conversely, turbidity and suspended sediment concentration during the summer fish windows was significantly lower than modeled; rarely exceeding 100 FNU and never exceeding 500 FNU (Table 1). This was conducive for Chinook and pink salmon upstream migration and spawning. Spawning ground surveys conducted in the mainstem channel and larger tributaries during the late summer of 2012, 2013, and 2014 observed 217, 765, and 1,310 redds respectively. Many of these redds were located in the mainstem channel above the Elwha Dam site (LEKT et al., In preparation). Unlike Coho salmon, very few Chinook recruited to either hatchery facility. The majority of adults needed for hatchery broodstock were collected from the river and transported to the WDFW hatchery.

Snapshot overview of vegetation establishment results on Mills and Aldwell: Phased dam removal and reservoir drawdown had a profound impact on the successful establishment of planted and natural vegetation; although sediment texture and distance from seed sources were important factors. The most likely explanation for the rapid colonization and high survival of planted species was the high water availability in the sediments due to the gradual reservoir drawdowns. The reservoirs left behind saturated sediments and a slowly-declining water table during the early phases of dam removal. In particular, the hold periods during the 2012 growing season (May, June, August, and early September) in the Lake Mills benefitted the establishing plants. High water availability proved critical to the germination and establishment of vegetation and to the performance of planted native species in both the fine textured surfaces and the coarse terraces.

However, over time, sediment texture has proven to impact vegetation. In general, vegetation establishment (tree species included) was rapid on fine-sediment surfaces and slow on coarse-textured terraces covering the valley bottom. The newly exposed valley slopes covered in fine sediments benefit from close proximity to seed sources. Natural regeneration was swift in most areas. Bare ground declined rapidly. In 2012, the first full growing season for most of the valley slopes; bare ground was 78%. Bare ground declined to 28% in 2013 and to 9% in 2014. The decline in bare ground is not exclusively the result of colonization by herbaceous species. Tree species were a significant component of the natural vegetation; with red alder (*Alnus rubra*) dominating many sites covered in fine sediments in both the former Lake Aldwell reservoir and the former Lake Mills reservoir. Woody species cover is increasing each year, from a low of 1% in 2012, 14% in 2013 to 57% in 2014. Planted sites also performed well on the valley slopes, with survival rates of 92% in 2012 and 96% in 2013 (Whisman, 2013; Calimpong, 2014).

Vegetation recovery on the coarse terraces has been slow. Most of the coarse terraces are not only water stressed, but are also far from seed sources. As a result, substantial natural regeneration has been limited. Bare ground on coarse terraces is declining slower than on fine sediment sites. In 2013, the first year of substantial exposure of coarse sediment in the former Lake Mills reservoir, bare ground was 90%. In 2014, bare ground declined to 77%, mostly as a result of planting and seeding efforts. Survival of planted species in the deep terraces of coarse sediment was high in 2012 and 2013 (88% and 90% respectively), most likely due to the water available during drawdown. In 2014, when the river had nearly dropped down to its pre-dam elevation, plant survival on the coarse sediments was extremely low, only 42%. This was due in part to unusually high summer temperatures (over 3 degrees Fahrenheit above average in July, August and September) and below average precipitation. However, some species performed surprisingly well. Black cottonwood and Nootka rose (*Rosa nutkana*) both had a 73% rate of survival on coarse terraces in 2014, demonstrating significant draught tolerance.

Natural vegetation colonization patterns were strongly influenced by the reservoir drawdown timing. The season of drawdown influenced the composition and rate of vegetation establishment. Drawdowns that occurred during the late fall and winter months were relatively slow to be colonized by vegetation. On fine sediment sites, red alder eventually colonized sites within 100 meters of mature trees. The most rapid and prolific establishment resulted from reservoir drawdowns that occurred during the seed dispersal of Salicaceae species. Willow (*Salix* species) and black cottonwood (*Populus balsamifera* ssp. *trichocarpa*) have very short-lived seed with very specific germination requirements tied directly to river discharge patterns in late spring (Naiman et al., 2005). Seeds are dispersed long distances by wind and water in May and June. Once seeds are saturated, they remain viable for only 2-3 days and must find appropriate sites to establish, usually newly exposed gravel bars in floodplains. Because reservoir drawdown was gradual over two years, there were two opportunities for substantial cottonwood and willow establishment during drawdown. The first opportunity was in 2011 when the first 4.5 to 5.5 meters of reservoir drawdown occurred in both reservoirs from June 2-11. The rate of drawdown created the perfect environment for seed germination and establishment. The wave action from the lake deposited saturated seed of cottonwoods and willows in perfect rows on the newly exposed shoreline (Figure 3a). In the former Lake Aldwell, mean sapling densities at these sites by the end of 2013 were 56,100 stems per acre and were over 2 meters tall. Most of the saplings were cottonwoods with a significant component of Sitka willow (*Salix sitchensis*). In 2012, a similar establishment event occurred in the former Lake Mills reservoir in both fine and coarse sediments. The most remarkable establishment was on a coarse-textured terrace that formed during drawdown in the former Lake Mills. Thousands of cottonwood seedlings successfully germinated and established on newly deposited sediments slowly drying during the summer of 2012. As dam removal progressed, the terraces became perched approximately 15 meters above the water table. Three years later the cottonwoods are thriving, having successfully established in xeric conditions (Figure 3b). The plants are small (less than 1 meter tall), but healthy and are one of the few woody species to naturally occur on the coarse terraces. On other coarse terraces not exposed during the late spring, cottonwood and willow establishment is limited to seasonal creeks meandering across the terraces.

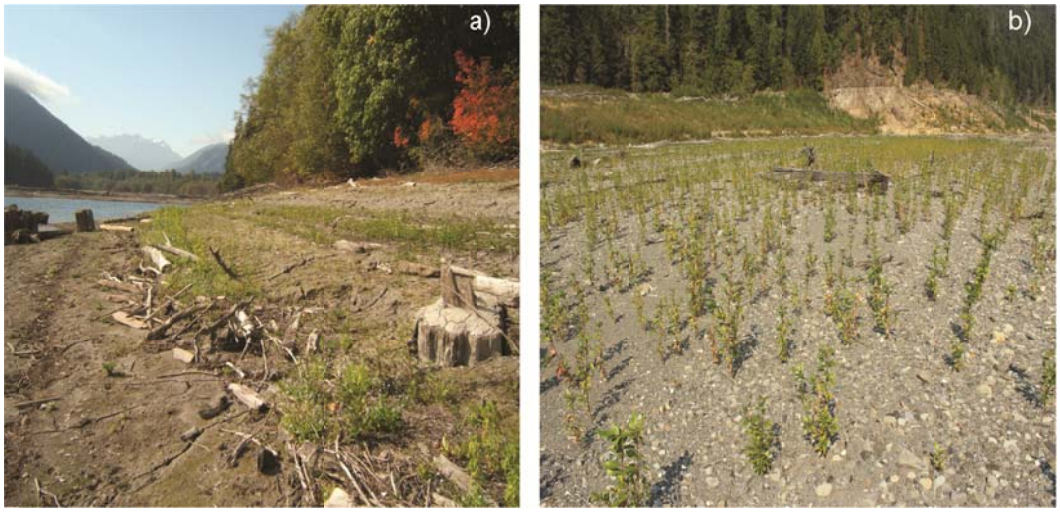

Figure 3 Vegetation growth in newly exposed reservoirs: a) Seedlings of cottonwoods and willows established during the June 2011 drawdown in the former Lake Aldwell reservoir - photograph taken September 12, 2011; b) three-year old cottonwood seedlings established in 2012 on a high terrace in the former Lake Mills reservoir - photograph taken September 16, 2014.

Many of the coarse textured terraces are not only water stressed, but are also far from seed sources. As a result, substantial natural regeneration has been limited and tends to be restricted to small seasonal creeks that are scattered across the landscape. The cover of bare ground at coarse sediment sites is much greater than on fine sediment sites. In 2013, the first year of substantial exposure of coarse sediment in the former Lake Mills reservoir, bare ground was 90% of the reservoir surface. In 2014, the bare ground declined to 77%, mostly as a result of planting and seeding efforts. Survival of planted species in the deep terraces of coarse sediment was high in 2012 and 2013 (88% and 90% respectively), clearly benefitting from the water still available during drawdown. In 2014, when the river was nearly down to its original elevation, plant survival on the coarse sediments was extremely low, only 42%. This was due in part to unusually high summer temperatures (over 3 degrees Fahrenheit above average in July, August

and September) and below average precipitation. However, some species performed surprisingly well. Black cottonwood and Nootka rose (*Rosa nutkana*) both had a 73% rate of survival in 2014, demonstrating significant draught tolerance.

DISCUSSION

Outcomes of phased dam removal were assessed for the Elwha River adaptive management program to evaluate how actual dam removal results compare to expectations from pre-project predictions. Differences in actual and expected results are investigated to identify which, if any, of the possible causes identified in adaptive management literature occurred: incorrect assumptions, poorly executed actions, changed environmental conditions, inadequate monitoring, or some combination of these causes (Williams and Brown, 2012).

Sediment Erosion during Early Drawdown and Dam Removal While a Lake Remained: Adaptive management is most successful when the ability to control the system with management decisions and actions is high. For the case of the Elwha Dam and Glines Canyon Dam removals, the greatest control on sediment release was both predicted and found through monitoring data to be prior to and during the phased-drawdown period while a lake still remained. Prior to dam removal, the early drawdowns on both lakes and pilot channel excavation on Lake Mills delta were effective at increasing the amount of sediment eroded and retained in the lake. This matched pre-project model assumptions of the benefit of early drawdown and starting delta channel along center alignment. However, we learned through monitoring that the effectiveness of early drawdown on sediment erosion rates and magnitude could have been increased by implementing the early drawdown prior to high flow periods, rather than at the after. Additionally, monitoring data indicated that reservoir sediment erosion tended to occurred when flows exceeded the mean-annual flow of 42 m^3/s and were not limited to occurrence of large floods (see Figure 1). Early drawdown was implemented after snowmelt recession. Dam removal started at both sites during the low flows of September 2011. Implementing the first drawdowns prior to the high flow period of the year (October through June) would have allowed more erosion to occur while the reservoirs still remained. This is consistent with other dam removal literature documenting that timing dam removal with hydrology of the river basin can be an effective tool (Cannatelli and Curran, 2012).

Sediment Impacts during Fish Windows after Lake Was Lost: More efficient construction methods at both dam sites resulted in a faster base level lowering and delta progradation to the dam sites than government estimates. For Lake Aldwell, the delta reached the dam just as the May-June snowmelt period and fish window was beginning. Discharge exceeded the mean-annual flow and was capable of eroding sediment 90-100% of the May-June fish windows, and a wider range of 7-87% during the November-December fish windows (see Table 1). The combination of faster reservoir drawdown and long duration flows effective at eroding and transporting sediment resulted in higher than anticipated sediment loads during the high flow fish windows and thus higher than expected impacts to fish. By adjusting the rate of dam removal, sediment impacts could have been shifted and potentially spread out to occur over the summer or following winter during high flows. The sediment delta reached Glines Canyon Dam just before the November-December fish window, 3 to 12 months ahead of the assumed schedule in pre-project model runs. The Lake Mills sediment volume released was large enough that the river needed several months during winter and snowmelt flows to transport the reservoir sediment through the downstream river channel. Given the large volume of reservoir sediment, it was not likely possible to minimize sediment impacts during the high-flow fish windows after the lake was lost in November-December or May-June. Monitoring data showed that despite the halting of dam removal after the lake was lost, higher than predicted sediment erosion volumes continued to occur and be released downstream even during a one-year long hold period. Channel incision was deeper, and knickpoint migration continued at a slower rate, than predicted during the year-long hold period. The incision was deeper because the reservoir-sediment grain size was finer with depth. The river in the middle of the reservoir incised as much as 9 m during the one-year hold period. The knickpoint migration tended to stall when river discharge was less than the mean-annual flow. Lateral erosion into the coarse and non-cohesive sediment terraces was much greater than predicted. A slower rate of dam removal would have reduced the sediment concentrations released downstream, but prolonged the duration of impact.

Vegetation Establishment versus Drawdown Timing: In general, vegetation establishment benefits tremendously from a gradual reservoir drawdown. Timing of drawdown also significantly impacts the rate of response and species composition and can lead to extensive establishment of Salicaceae species. The pattern of Salicaceae establishment,

related to the timing of drawdown, is not unique to the Elwha as it occurred during a 4-year drawdown of a large reservoir in Colorado (Auble et al., 2007). Black cottonwood is a particularly good species for early succession in a stressful environment because it is surprisingly draught tolerant, fast to grow, and is a critically important species for riparian restoration (Collins and Montgomery 2002). Residual moisture from the receding reservoirs may be the key to establishing woody species over graminoids on fine lacustrine sediments. Residual moisture also appears to create favorable conditions for planting on coarse sediments. For example, Douglas-fir (*Pseudotsuga menziesii*) had better rates of survival in coarse sediments in 2012 and 2013 (40% and 91% respectively) compared to after the sediments had dried out in 2014 (only 28%). The Douglas-firs established and tagged in 2012 and 2013 had very high survival in 2014 (100% and 89% respectively), showing the value of planting while moisture is high, allowing plants an opportunity to grow a root system capable of resisting future water stress. The moisture available to vegetation resulting from gradual reservoir drawdown creates a plant window, providing management a unique opportunity to establish desirable native species. This is particularly important for coarse-grained sediments that are slow to support natural vegetation.

Adaptive management of the vegetation during dam removal proved successful. The gradual planting plan in the first two years allowed the rapid pace of natural recolonization on most of the valley slopes to occur unhindered. The valley slope areas far from seed sources that were planted during drawdown had high rates of survival and continue to thrive after three years. Annually monitoring the changes to bare ground and species cover allows us to ensure our goal of accelerating forest development is being met. Our plots and the general observations from site visits have also showed us the need to focus management on coarse-sediment terraces and allow valley slopes to predominantly recover naturally. Tagging plants early in the project provided critical information that allowed us to shift our plant production to species best suited to plant into the coarse terraces.

Implementation Challenges of Adaptive Management for Dam Removal: A challenge of utilizing adaptive management during a real-time construction project was the need to incorporate new predictions with real-time monitoring data in a timely manner. The combined effect of implementing adaptive management that changed reservoir drawdown schedules with the lack of a large flood occurrence resulted in the need for more model iterations than planned to move forward with management decisions. Although the added model runs posed budget and time challenges, the adaptive management method of incorporating new knowledge from monitoring experience as the project moved forward was successfully utilized for each management decision on reservoir drawdown schedule. Another challenge was cross-coordination of multiple disciplines to help inform management decisions during dam removal. We formed an interdisciplinary team to discuss monitoring results and predictions so varying perspectives could be incorporated and used to get consensus on technical recommendations associated with dam removal. The most beneficial monitoring data that either confirmed or changed assumptions used for predictions was documentation of changing river width, elevation, and slope and corresponding river discharge hydrographs. Evolving monitoring methods from quarterly survey profiles and cross-sections to continuous and more frequent coverage with photogrammetry increased the accuracy of computations and better captured the non-uniform channel geometry. Time-lapse photography and collection of aerial photography was crucial to help with interpretations of complex and rapid changes in channel morphology that included super-imposed rounds of incision and lateral erosion from multiple drawdowns. Suspended sediment and bedload data (collected by partner agencies and Reclamation using research funds), along with staff gates and river profile surveys greatly improved monitoring information and our ability to analyze downstream sediment transport as part of the adaptive management program.

CONCLUSIONS

Through the use of key monitoring data and updated predictions, adaptive management was successfully implemented on the Elwha Dam removal project to control the rates of reservoir sediment erosion. Pre-project predictions were crucial to establishing mitigation measures, setting the initial pace of dam removal, and establishing the monitoring plan. We did not have to alter the type of real-time sediment monitoring data, but did benefit from improved methods that captured greater complexity at more frequent intervals than planned. The level of adaptive management control on downstream sediment release, and thus impacts to flooding, water quality, and fish, was highest while the reservoirs remained and eroded sediment was largely contained. Vegetation growth benefitted from the timing and rate of phased drawdown on both reservoirs, but was not planned to coincide with vegetation seed dispersal. While suspended sediment concentrations exceeded modeled expectations during a number of the fish windows, conditions during the May-June window of 2013 were of the greatest concern to hatchery and natural origin juveniles. This was exacerbated by the fact that releases of hatchery yearling Chinook,

hatchery Coho, and hatchery chum salmon occurred prior to the beginning of the fish window, as fish were smolting. Future adaptive management projects may benefit by analyzing what if implementation scenarios in pre-project planning that could result in increased or shifted timing of dam removal rates and associated sediment impacts, overlaid with vegetation growth seasons and fisheries considerations.

Randle, Supervisory Hydraulic Engineer, Bureau of Reclamation, Denver, Colorado, trandle@usbr.gov; Jennifer Bountry, Hydraulic Engineer, Bureau of Reclamation, Denver, Colorado, jbountry@usbr.gov; Kurt B. Wille, Supervisory Physical Scientist, Bureau of Reclamation, Denver, Colorado, kwille@usbr.gov

Abstract: An empirically based, sediment-budget model was developed in a geographic information system (GIS) framework to support an adaptive sediment management program for two dam removals on the Elwha River near Port Angeles, Washington State, USA. This numerical model had the advantages of being able to handle the complex three-dimensional topography of sediment layers in a reservoir, rapidly incorporate new monitoring data, and quickly simulate multiple future scenarios in response to changing conditions. Even though the model did not simulate the detailed hydraulics, it was able to simulate the most important aspects of channel evolution through reservoir sediments during dam removal.

Model simulations were used to aid the adaptive management program by predicting the channel evolution in the reservoir and forecast the coarse (sand and gravel) and fine (silt and clay) sediment release to the downstream river channel over time under various hydrologies and dam removal schedules. The simulated three-dimensional reservoir topography could easily be visualized in GIS. The model predictions helped to guide and focus the monitoring activities while the monitoring results helped to revise and calibrate the numerical model. This combined approach of hypotheses, incorporated into the numerical model, and monitoring results increased the rate of learning compared to singular approaches of only monitoring or modeling.

INTRODUCTION

This paper describes the development and application of an empirically based, sediment-budget model for the adaptive management program associated with a project to remove two large dams on the Elwha River near Port Angeles, Washington, USA. The model accounts for the primary geomorphic processes (e.g., channel incision, lateral erosion, aggradation, and new delta formation), but not the detailed hydraulics. The model was developed in a geographic information system (GIS) framework to account for the complex three-dimensional reservoir geometries and to facilitate the display of simulated reservoir topography.

The National Park Service, with technical support from the Bureau of Reclamation, removed Elwha and Glines Canyon Dams on the Elwha River to restore anadromous fish and the natural ecosystem (Figure 1). The Elwha River dams had blocked fish migration for a century. The two dams were the largest ever removed and together (before their removal) contained 27 million yd^3 of reservoir sediment (Randle et al., 2015). These dams were concurrently removed in controlled increments over a one and three-year period, which began in September 2011.

The 105-foot high Elwha Dam was completed in 1913 at river mile 5 and formed Lake Aldwell, which had an original storage capacity of 9,100 acre-feet (U.S. Department of the Interior and U.S. Department of Commerce, 1994). The 210-foot high Glines Canyon Dam was completed in 1927 at river mile 13 and formed Lake Mills, which had an original storage capacity of 40,500

acre-feet. Both dams were constructed to produce hydroelectric power and neither reservoir provided flood control or water supply storage.

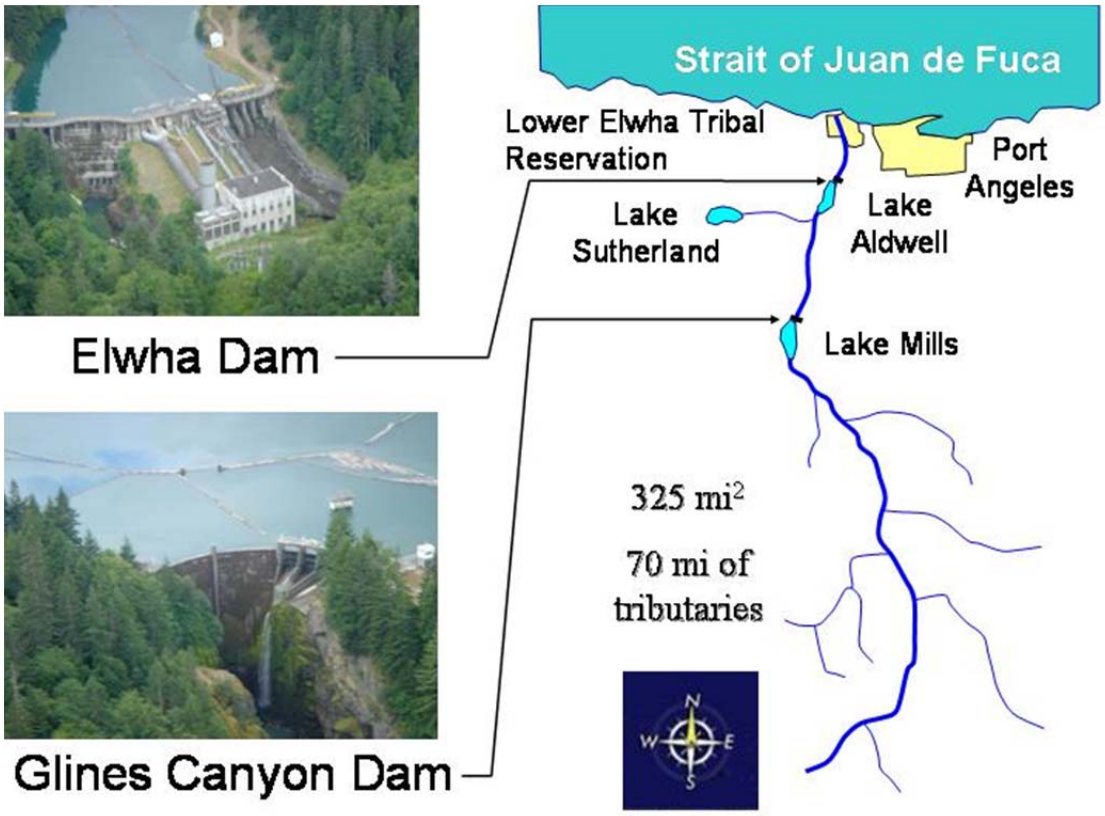

Figure 1. Elwha and Glines Canyon Dams are located on the Elwha River near Port Angeles, Washington, U.S.A.

In July 2010, reservoir sedimentation in both lakes was estimated to be 27 million yd^3 (Randle et al., 2015), which was 35 percent of the original storage capacity. Most of the coarse reservoir sediment (sand and gravel) had deposited as a large delta in Lake Mills (the upstream reservoir). The thickest delta deposit, measured from drill holes in 1999 and 1994, was 70.5 feet in Lake Mills and 42.6 feet in Lake Aldwell (Gilbert and Link, 1995).

In preparation for dam removal, new facilities were constructed for water quality and flood protection. The quantitative sediment effects of dam removal were initially predicted for an environmental impact statement (U.S. Department of the Interior, 1996) based on measured sediment erosion during the 1994 Lake Mills drawdown experiment (Childers et al., 2000), sediment and topographic surveys of the reservoir, a numerical sediment-budget model, and numerical modeling of the downstream river channel (Randle et al., 1996). Later, a laboratory model was utilized to evaluate the extent and rate of reservoir sediment erosion as a function of the dam removal rate (Bromley, 2007). Prior to the beginning of dam removal, the empirically-based sediment-budget model (initially developed by Randle et al., 1996) was updated and re-written in a GIS framework. The model described in this paper was used to provide up-to-date predictions based on dynamic reservoir sediment conditions, hydrology, and updated dam removal schedules. The model simulated the reservoir channel evolution, amount and timing of

coarse (sand and gravel) and fine (silt and clay) sediment erosion and release from both reservoirs and the volume and future topography of sediment remaining in the reservoirs.

An adaptive management program was designed to ensure that Elwha River Restoration Project management objectives were met and that sediment impacts were contained by mitigation facilities (Randle and Bountry, 2010 and Bountry, 2015 these proceedings). Key monitoring activities focused on the extent and rate of vertical and lateral erosion of the exposed reservoir sediment, downstream water quality impacts associated with release of fine sediment from the reservoirs, downstream aggradation from the release of coarse reservoir sediment, and forecasting the sediment release through the reservoirs with numerical modeling. Measured sediment effects were compared with predictions, so that adjustments in the dam removal schedule (or other corrective actions) could be taken when necessary.

The empirically-based, sediment-budget modeling approach was used, rather than a one- or two-dimensional (1D or 2D) sediment transport model. A 1D model could not simulate important lateral erosion and delta progradation processes. A 2D model would have required many days or weeks of computer time to simulate the necessary range of hydrologies and changing dam removal schedules and there would have been difficulty automatically adjusting the 2D model mesh with continued sediment terrace bank erosion. The sediment-budget model runs relatively fast and was able to track the complex three-dimensional topography of each reservoir over time.

DAM REMOVAL AND SEDIMENT MANAGEMENT PLAN

The dam removal and sediment management plan was to concurrently remove both dams in controlled increments and allow the Elwha River to incise and erode a portion of the reservoir sediments downstream to the Strait of Juan de Fuca (U.S. Department of the Interior, 1996). The model incorporated reservoir drawdown increments of 5 to 15 feet at a maximum allowable rate of 3 feet per 49 hours. After each reservoir drawdown increment, the remaining reservoir pool was held at relatively constant levels for two weeks to two months to induce lateral erosion of the exposed sediments. The longer reservoir hold periods were known as “fish windows” and corresponded to important fish migration periods: May 1 to June 30, Aug. 1 to Sep. 15, and Nov. 1 to Dec. 31.

Because of the anticipated large sediment release, several water quality and flood protection facilities were designed and constructed to mitigate impacts. Water treatment plants, new wells, and a new surface water intake were constructed to protect existing water users from high suspended sediment concentrations. Some new levees were constructed and the heights of existing levees were increased to protect property and infrastructure from possible increases in flood stage that could result from coarse sediment aggradation in the downstream river channel.

NUMERICAL MODEL OBJECTIVES AND OVERVIEW

The primary numerical model objectives are: (1) simulate the reservoir sediment erosion, re-deposition, and release of fine and coarse-sized sediment over time from both reservoirs; (2) predict the portion of sediment retained within the reservoir after dam removal; and (3) provide a framework to guide the collection and synthesis of monitoring data.

The empirical rules of the numerical sediment-budget model are based on geomorphic and sediment transport principals and field measurements. The model tracks fine sediment separately from coarse sediment. As the reservoir is drawn down, the river is assumed to erode a primary channel through the exposed reservoir sediments. The coarse sediment that is eroded during this process is assumed to redeposit in the receded reservoir so long as the reservoir exists. Fine sediment that is eroded during this process is assumed to become suspended in the receded reservoir. A portion of this fine suspended sediment is assumed to re-deposit on the lakebed while the remainder is assumed to transport past the dam. After the reservoir has been drained, eroding coarse and fine sediments are assumed to be transported past the dam.

The numerical sediment-budget model consists of three computer programs for each reservoir:

1. The pre-processing FORTRAN program determines the daily reservoir water and sediment inputs, the daily reservoir drawdown schedule, and the GIS model time steps. These GIS model time steps are variable, but typically range from one to two months and include a given reservoir drawdown increment and subsequent hold times, which may be extended due to high flows or fish windows.
2. The GIS model simulates the channel evolution through the complex topographic surfaces of the reservoir sediment terraces for each model time step.
3. The post-processing FORTRAN program computes the daily coarse and fine sediment loads and concentrations released past each dam based on the output from the GIS model.

MODEL BOUNDARY AND INITIAL CONDITIONS

The upstream model boundary conditions include hydrographs of water discharge and sediment load and the dam removal schedule. The initial conditions consist of the reservoir bathymetry and percentages of coarse and fine sediment for various sub-areas of the reservoir.

A range of historic discharge hydrographs (13-year periods) were used to simulate future conditions: (*i*) water years 1950 through 1963 (normal hydrology), (*ii*) water years 1969 through 1991(dry hydrology), (*iii*) water years 1971 through 1994 (normal hydrology), and (*iv*) water years 1999 through 2002 (wet hydrology). As dam removal progressed, each hydrology was updated with the measured discharge values. Discharge was measured at the McDonald Bridge stream gage (12045500), located between Glines Canyon Dam and Lake Aldwell. The fine and coarse sediment loads from the upstream watershed were computed from sediment-discharge rating curves (Randle et al., 1996).

The future reservoir drawdown schedules (a downstream boundary condition) were determined by the model based on the following information: (*i*) contractor's proposed construction schedule, (*ii*) reservoir inflow discharge, (*iii*) reservoir drawdown rate restrictions, (*iv*) reservoir drawdown increment limits, (*v*) overtopping flow work restrictions, and (*vi*) required reservoir hold periods, including fish windows.

Initial reservoir model conditions consisted of the reservoir bathymetry (measured in July 2010 by Bountry et al., 2011), coarse and fine sediment percentages, and initial alignment of river channels on the delta. A pilot channel was constructed on the Lake Mills delta during September

2010 and was incorporated into the initial topographic conditions. The predam reservoir topography was used by the model to represent the lower limit of reservoir sediment erosion. For Lake Mills, the predam topography was based on a 1921, 10-foot contour map. The Lake Aldwell predam topography had to be estimated from drill holes and thickness probes, and later by incorporating exposed pre-dam topography (Gilbert and Link, 1995; Randle et al, 2015). Percentages of coarse and fine sediment were specified for reservoir polygon areas defined by Gilbert and Link (1995). Single sediment layers were typically specified, but three vertical sediment layers were specified for the Lake Mills delta.

SIMULATION OF RESERVOIR CHANNEL EVOLUTION

For each model time step, the GIS spatial model computes a sediment balance between the upstream sediment-supply volume, the river-erosion volume of the exposed sediment, and the corresponding reservoir-deposition volume. The river-erosion volume is a function of the reservoir-drawdown increment, longitudinal erosion slope, peak discharge, and the river erosion width along the upstream portion of the delta and where the river meets the receded reservoir (Figure 2 and Figure 3). So long as a reservoir remains between the delta and the remaining dam, the coarse sediment fraction of the river erosion volume is assumed to re-deposit as a new delta in the receded reservoir on top of the fine lakebed sediment. The model is able to account for compaction of the underlying fine sediment. During each increment of reservoir drawdown, the delta front extends farther downstream into the receded reservoir causing some aggradation along the upstream erosion channel (Figure 2 profile view).

The fine sediment fraction of the river-erosion volume is assumed to enter the reservoir as suspended sediment. Using a sediment trap efficiency equation (Pemberton and Lara, 1971), the model calculates the portion of fine suspended sediment that will settle to the reservoir bottom and the portion that will be transported in suspension past the dam. Once the delta has prograded all the way downstream to the remaining dam, the reservoir pool no longer exists, and all eroded sediments are released past the dam.

For future simulations, the GIS spatial model uses the concepts illustrated in Figure 2 to simulate erosion and deposition of the complex topographic surfaces to ensure separate volume balances for coarse and fine sediments. The spatial model consists of a set of vector-based customizations and a series of raster-based analysis tools that are run at each time step according to the reservoir drawdown schedule. The vector-based customizations are used to determine potential erosion and deposition geometries. The vector geometries are fed into the raster-based analysis tools that update an input surface raster (10 ft × 10 ft) to reflect the sediment inflow, erosion, deposition, and downstream release.

The delta erosion, topset, and foreset slopes (S_T, S_T, and S_F) are specified by the model user while geometric dimensions of delta length, upstream channel width and channel width where it meets the lake (D_L, W_{min}, and W_L) are computed by the model. The volume calculations are linked where the river erosion channel meets the receded reservoir. At this location, the computed river erosion width equals the reservoir deposition width (W_{max}). Aggradation in the erosion channel is linked to the length of new delta deposition. Therefore, the model uses an iterative approach to achieve the volume balance for coarse sediment.

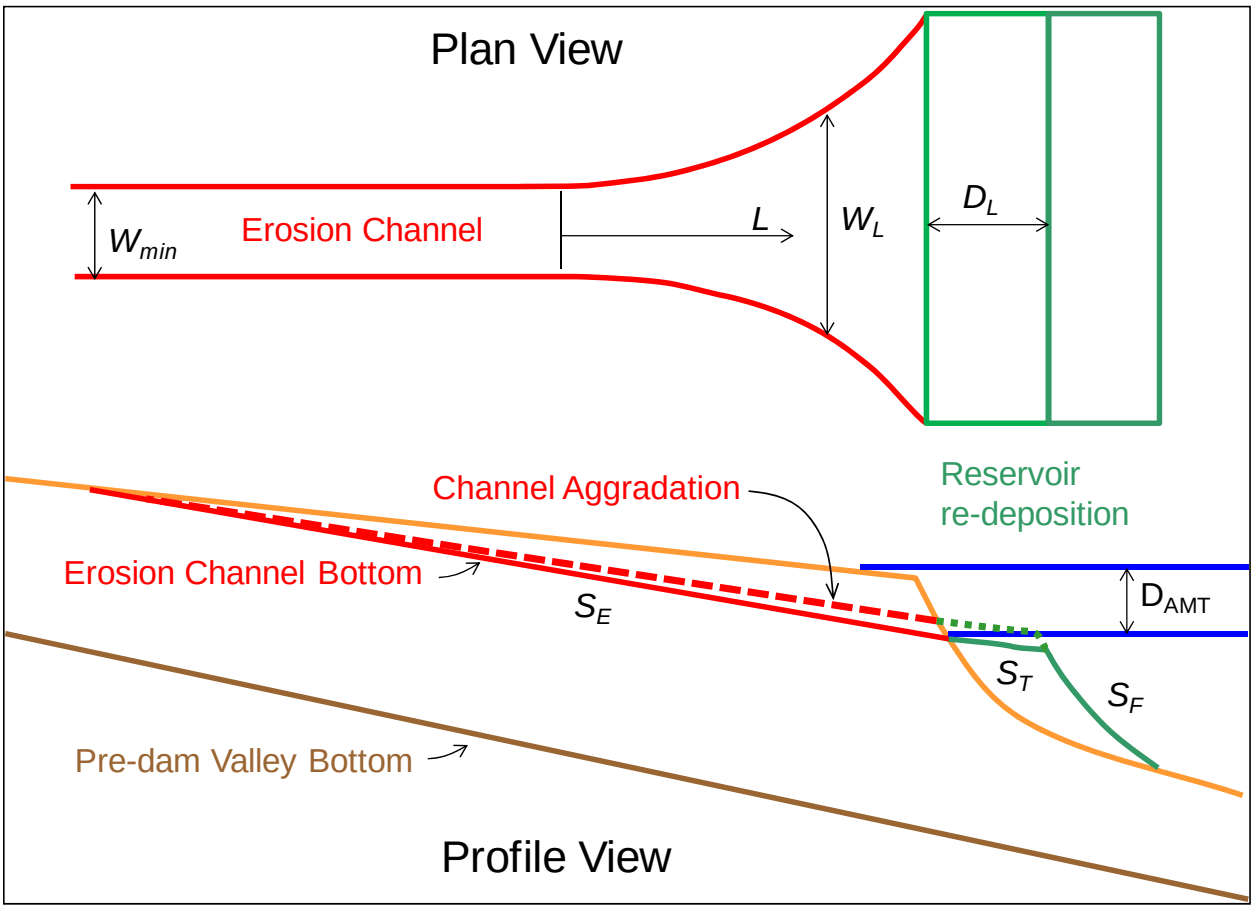

Figure 2. Plan and profile sketch of reservoir sediment erosion and re-deposition. The variables shown in the figure are described in the body of the paper.

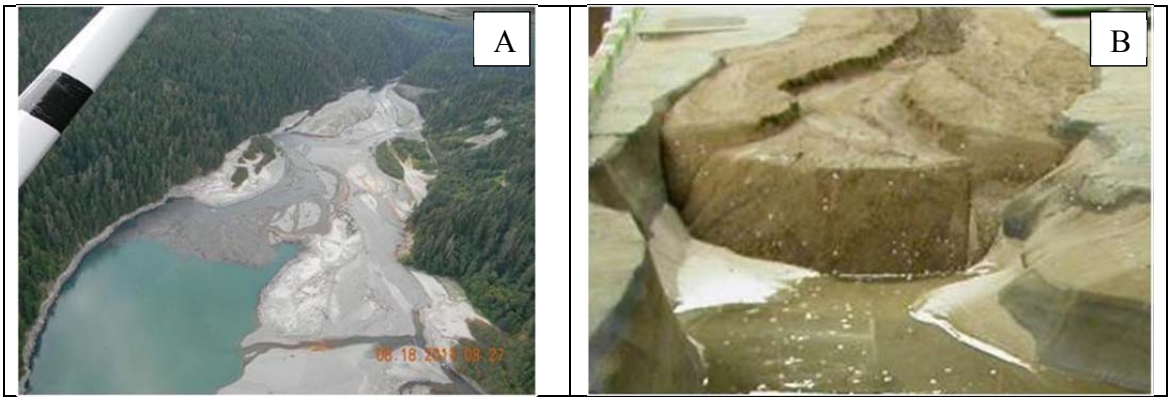

Figure 3. Photographs of sediment erosion and re-deposition at Lake Mills (A) as observed in August 2011 (16 feet of spillway drawdown prior to dam removal) and (B) in a laboratory model of Lake Mills conducted by Bromley (2007).

The model computes the sediment erosion volume using the topography at the beginning of the time step, the delta erosion slope (S_E) corrected for aggradation, and the channel erosion widths (Figure 2 plan view). The model computes the coarse, reservoir deposition volume using the delta topset slope (S_T) adjusted for aggradation, foreset slope (S_F), the deposition width across the receded reservoir (W_{max}), and the reservoir bathymetry at the beginning of the time step. After the Lake Mills delta prograded all the way to Glines Canyon Dam, there was a year-long hold period in order to reduce the rate of reservoir sediment erosion and downstream release. For this long hold period, the model exponentially decreased the channel erosion slope over time.

$$S_E(t_n) = S_E e^{(-7.57\text{E}-04\ T_Q)} \tag{1}$$

Where T_Q is the cumulative number of days since the delta reached the dam (10/23/2013) where the discharge was greater than a transport threshold (2,000 ft^3/s).

The reservoir drawdown increments in Lake Aldwell and Lake Mills nearly always eroded enough coarse sediment to deposit a new delta across the entire width of the receded reservoir. For this common case, the model computed the downstream length of the new delta topset (D_L). For the few cases where the erosion volume was not sufficient to deposit a new delta across the entire reservoir width, a default topset length wa9s specified and the model computed the delta deposition width (which is also equal to the maximum erosion width).

Sediment Erosion Volume Calculations For future simulations, the model computes the minimum erosion-channel width (W_{min}), for each time step, as a function of the peak discharge (Q_{max}) and a time-adjustment factor (T_A), which was developed from monitoring observations.

$$W_{min} = \left[aQ_{max}{}^{b}\right]T_A \tag{2}$$

The coefficient a is calibrated from measured erosion widths and the exponent b is chosen from literature (typically 0.5). The time-adjustment factor (T_A) is based on the number of days (N_D) (during the model time step) where the mean-daily discharge equals or exceeds the mean discharge (for the model time step) and is also above a user-specified threshold. An empirically determined coefficient (α) is also used in Eq. 3.

$$1 \le T_A = (\alpha N_D + 1) \qquad \alpha = \frac{2/3}{10} = 0.0667 \tag{3}$$

The minimum erosion width is assumed to increase as the river erosion channel approaches the receded reservoir where the channel laterally migrates to deposit sediments.

$$W_L = 2cL^2 + W_{min} \tag{4}$$

where W_L is the erosion width as the river approaches the receded reservoir, L is the longitudinal distance along the erosion channel centerline (Figure 2), and c is a coefficient computed by the model so that the erosion channel width equals the reservoir deposition width where the erosion channel meets the reservoir. The total length of channel (L_{max}) where the erosion width increases is specified by the model user as a function of the local reservoir width.

$$L_{max} = f\, W_{max} \tag{5}$$

Computation of the river-erosion volume begins with the reservoir drawdown increment. The downstream extent of the erosion channel is computed as the intersection of the erosion channel and the receded reservoir. Initially, the channel bottom elevation at the downstream end is assumed to equal the lowered reservoir-water surface elevation. From this elevation, the user specified longitudinal erosion slope is projected upstream to the intersection with the upstream sediment surface or the predam surface, whichever is encountered first. The aggradation volume in the sediment erosion channel is computed after the new delta length (D_L) is computed.

The erosion channel centerline is specified by the model user. The left and right banks of the river erosion channel are determined from the channel centerline and the computed erosion-channel widths. Alternatively, when measured bank-line data are available from the monitoring program, they can be used as an input feature in place of the computed erosion-channel widths in conjunction with the user-specified centerline. This was of particular value when the actual erosion width was non-uniform along substantial portions of the channel length.

Reservoir Sediment Trap Efficiency Calculations The reservoir sediment trap efficiency (P) is computed as a function of the sediment particle fall velocity (ω), inflow discharge (Q), and surface area of the remaining reservoir (A_s) (Pemberton and Lara, 1971). The sediment particle fall velocity (ω) is a function of the median fine sediment particle size (d, ft) and the water viscosity (ν, ft^2/s), which is a function of water temperature (T, ^{o}C).

$$P = \left(1 - \frac{1}{e^{\left(\frac{1.005\omega A_S}{Q}\right)}}\right) \tag{6}$$

$$\omega = \frac{\sqrt{36.064\, d^3 + (6\,\nu)^2} - 6\,\nu}{d} \tag{7}$$

$$\nu = \frac{0.00002}{(1.0334 + 0.03672\, T + 0.0002059\, T^2)} \tag{8}$$

Daily Reservoir Sediment Release Calculations The post-processing FORTRAN program uses the fine and coarse-sediment erosion volumes (computed by the GIS model for each simulation time period) to compute the daily fine and coarse sediment-release rates past each dam. A daily factor (D_F) is computed to distribute the sediment release volumes from the longer GIS model time step. Initially, each daily factor (D'_F) is computed as the weighted sum of the daily reservoir drawdown factor (R_F) and the daily discharge factor (Q_F) (Eq. 9). The daily factors within each GIS model time step are then adjusted to sum to 1 (Eq. 10). In the equations below, t_n indicates the value at day n and t_o indicates the value at the beginning of the time step. Model coefficients and exponents are described in Table 1, Table 2 and Table 3.

$$D'_F(t_n) = c_7 R_F + (1 - c_7) Q_F(t_n) \tag{9}$$

$$D_F(t_n) = \frac{D'_F(t_n)}{\sum_{n=1}^{m} D'_F(t_n)} \tag{10}$$

The computation of the daily reservoir drawdown factor (R_F) depends on whether the reservoir is drawing down, holding, or refilling. The daily reservoir drawdown increment (D_{INC}) (Eq. 11) and the cumulative drawdown increment since the beginning of the GIS model time step (D_{AMT}) (Eq. 12) are computed from the daily water surface elevations (WSE). The daily change in mean-daily discharge (ΔQ_w) (Eq. 13) is also computed to determine if the discharge is increasing.

$$D_{INC}(t_n) = WSE(t_n) - WSE(t_{n-1}) \tag{11}$$

$$D_{AMT}(t_n) = WSE(t_n) - WSE(t_o) \tag{12}$$

$$\Delta Q_w(t_n) = Q_w(t_n) - Q_w(t_{n-1}) \tag{13}$$

If the reservoir is drawing down, $D_{INC}(t_n) < c_3$, then

$$R_F(t_n) = 0.020\ c_1^{\left(\frac{-1\{D_{AMT}(t_n)\}}{1.5ft}\right)} \tag{14}$$

If the reservoir is holding, $D_{INC}(t_n) \geq c_3$, then

$$R_F(t_n) = c_2\ R_F(t_{n-1}); \tag{15}$$

If the reservoir inflow discharge is increasing, $\Delta Q_w(t_n) \geq 1{,}000$ ft^3/s, or the inflow is high, $Q_w(t_n) > 3{,}500$ ft^3/s, then

$$R_F(t_n) = 0.020\ c_1^{\left(\frac{Q_W(t_n)}{1{,}000ft^3/s}\right)} \tag{16}$$

Initially, the daily discharge factor (Q'_F) is computed as a function of the mean daily discharge (Eq. 17).

$$Q'_F(t_n) = (Q_w)^{c_4}(t_n) \tag{17}$$

$$Q_F(t_n) = \frac{Q'_F(t_n)}{\sum_{n=1}^{m} Q'_F(t_n)} \tag{19}$$

The model computes the concentration of fine sediment (ppm) being transported past the dam from the sediment trap efficiency (P), erosion volume (V_F), unit weight of sediment (γ), and the mean-daily river discharge (Q_w). A time lag is also applied to account for travel time through the reservoir.

$$Conc = \frac{(1-P)V_F\gamma}{Q_w}\left(\frac{2{,}000lbs/ton}{(62.4lbs/ft^3)(3{,}600s/hr)(24hrs/day)}\right)1{,}000{,}000 \tag{19}$$

Turbidity is computed from the concentration by use of a power equation, but the coefficient and exponent were found to vary over time under changing sediment conditions.

$$Turbidity = c_5\ (Conc)^{c_6} \tag{20}$$

MODEL CALIBRATION

Although there are many model calibration parameters, the coefficients and exponents appeared to be very reasonable. Compaction of fine reservoir sediment was considered, but not used. The median grain size for fine sediment was calibrated to a value of 0.01 mm, which represents fine silt. The delta channel erosion widths, lengths of delta erosion affected by deposition, and longitudinal erosion slopes were calibrated separately for Lake Mills and Lake Aldwell. The erosion channel centerline of the exposed delta is a user input. Measured past channel alignments were delineated in GIS. Future channel migration of the erosion channel alignment is based on past migration, geologic controls within the reservoir landscape, whether the channel was eroding into non-cohesive (coarse) or cohesive (fine) sediment, and professional judgment. Post processing model parameters were calibrated to match the pattern and magnitude of measured turbidity downstream from Elwha Dam. Summary lists of model input parameters are presented in Table 1 for river erosion, Table 2 for new delta deposition, and Table 3 for daily sediment release past the dam.

Table 1. Summary list of model input parameters for river erosion.

Variable	Description
a and b	Coefficient ($2.3 < a < 6$) and exponent (typically b = 0.5) used to compute the minimum erosion-channel width as a function of discharge (Eq. 2).
α	Coefficient used to compute the time-adjustment factor ($T_A = 0.0667$) (Eq. 3).
c	Coefficient used to compute the erosion-channel width near the receded reservoir. This coefficient is calculated by the model (Eq. 4).
f	Multiplier used to compute the maximum channel length (L_{max}) upstream from the receded reservoir where the erosion width is influenced by new delta deposition ($1 < f < 3$) (Eq. 5).
S_E	Longitudinal slope of the river erosion channel ($0.003 < S_E < 0.011$).

Table 2. Summary list of model input parameters for new delta deposition.

Variable	Description
D_L	Default topset length ($D_L = 200$ feet)
S_T	Topset slope ($S_T = 0.0009$ for Lake Aldwell and 0.0050 for Lake Mills)
S_F	Foreset slope ($S_F = 0.020$ for Lake Aldwell and 0.032 for Lake Mills)
Reservoir sediment trap efficiency parameters:	
d	Median particle size of fine sediment ($d = 0.010$ mm) (Eq. 7)
T	Water temperature ($T = 50$ degrees Fahrenheit) (Eq. 8)

Table 3. Summary list of model input parameters for daily sediment release.

Variable	Description
c_1	Sediment concentration time factor for continued reservoir drawdown ($c_1 = 1.10$) (Eq. 14 and 16)
c_2	Sediment concentration time factor for continued reservoir holding or refilling (if $t_n \leq 30$ days, then $c_2 = 0.97$; if $t_n > 30$ days, then $c_2 = 1$) (Eq. 15)
c_3	Threshold to distinguish between reservoir drawdown and holding or refilling ($c_3 = -0.50$ ft/day) (Eq. 14 and 15)
c_4	Exponent for weighting the discharge ($c_4 = 3.50$) (Eq. 17)
c_5	Coefficient to convert sediment concentration to turbidity ($c_5 = 0.992$) (Eq. 20)
c_6	Exponent to convert sediment concentration to turbidity ($c_6 = 1.0044$) (Eq. 20)
c_7	Weighting factor to compute the daily factor (D'_F) ($c_7 = 0.333$) (Eq. 9)

EXAMPLE MODEL RESULTS AND DISCUSSION

The reservoir sediment erosion model has been applied numerous times during concurrent dam removal to simulate a range of hydrologies and proposed dam removal schedules (Bountry et al., 2015 these proceedings). An example simulation, performed in April 2012, is provided using the historical flow records from water years 1950 through 1968, except that the actual flows were used for the period October 2010 through April 2012. Simulated hydro-graphs of reservoir water surface elevation, discharge, and turbidity are presented in Figure 4.

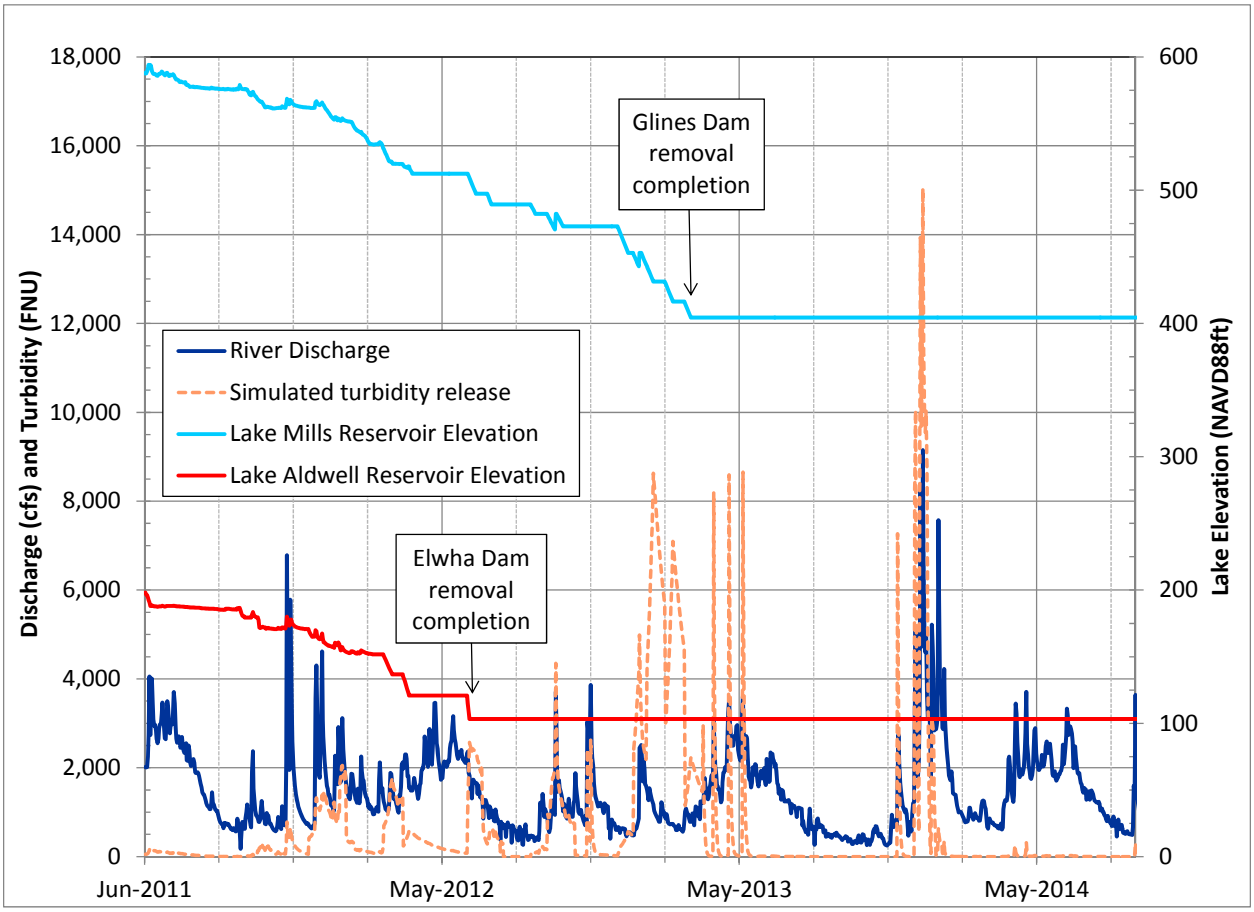

Figure 4. Example simulation of fine-sediment release from Lake Mills and Lake Aldwell.

The simulated reservoir sediment thickness before and after dam removal is presented in Figure 5 for Lake Mills and in Figure 6 for Lake Aldwell. Colored areas represent reservoir sediment terraces. The darker color red corresponds to the areas of thickest sediment while the gray areas represent areas where the sediments have been eroded down to the estimated predam surface.

For this example simulation, 50% of total reservoir sediment would be transported past the dam, 10 years after dam removal. About half of the sediment was measured to erode from the reservoirs by the end of 2014. The model correctly predicted the time when the eroding reservoir delta would reach the dam and the correct order of magnitude of downstream

turbidities. The model incorrectly assumed that the channel incision from a given reservoir drawdown increment would completely occur during a one- to two-month time step.

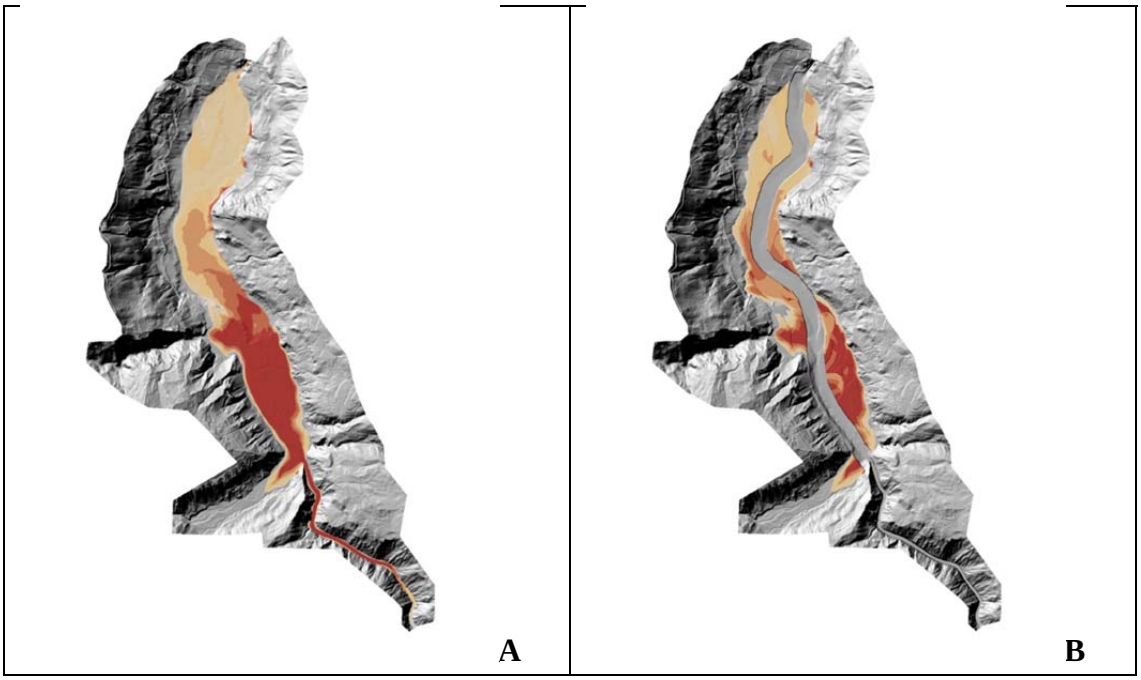

Figure 5. Example simulation of Lake Mills sediment thickness before (A) and after dam removal (B).

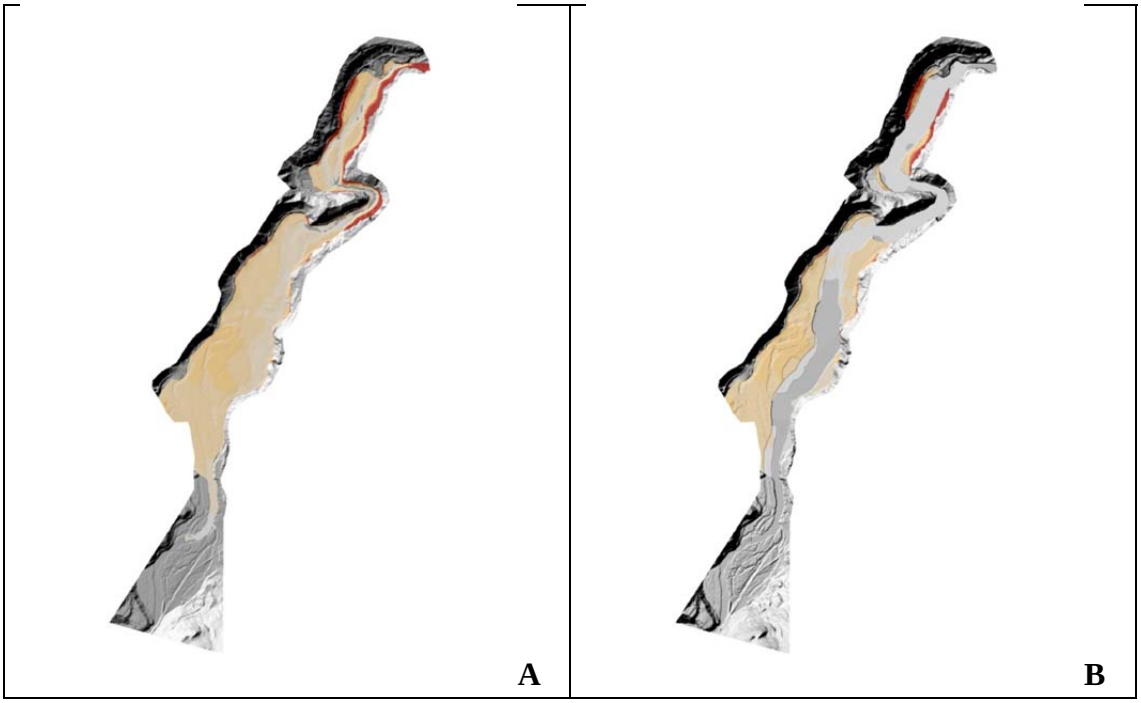

Figure 6. Example simulation of Lake Aldwell sediment thickness before (A) and after dam removal (B).

Actual knickpoint migration proved to be much slower, especially in Lake Mills. However, the actual reservoir erosion width, slope, and alignment could be updated as dam removal progressed, along with the hydrology and dam removal schedule, so that simulations of future scenarios were increasingly more accurate. The simulated volume of sediment erosion was most influenced by erosion channel width and slope. The daily patterns of sediment concentration and turbidity released downstream were most influenced by the coefficients c_1, c_2, c_3, c_4, and c_7.

Future model simulations were used in the decision to hold Glines Canyon Dam removal activities for the second year of project implementation. Actual river discharges were a bit different than the four historic hydrologies. Actual peak discharges were less than the 2-year flood peak during the first three years of project implementation, but mean discharge was above average. The dam removal contractor could work faster, and during higher river discharge, than assumed in the initial model simulations.

CONCLUSIONS

The reservoir sediment erosion model is able to simulate the channel incision, lateral erosion, and redeposition of sediment during phased dam removal. Model application requires the user to specify numerous parameters. All the physically-based model input variables are based on direct field measurements or calibrated using field measurements. Coefficients c_1 through c_7 (Table 3) are based on professional judgment, but are generally close to 1. The model was able to simulate the most important channel evolution processes and was able to simulate a large number of future scenarios of concurrent dam removal during project implementation.

In addition to the predictive capabilities, the numerical model represented a set of linked hypotheses that could be tested and updated based on monitoring data. The testing of these hypotheses with monitoring results increased the rate of learning compared to singular approaches of modeling or monitoring alone. The required model inputs and the outputs help focus and organize the monitoring data that were crucial for testing the hypotheses. The model was updated throughout the project as new information became available on dam removal schedules and monitoring on the rate and extent of sediment erosion.

NEGOTIATING HYDROLOGIC UNCERTAINTY IN LONG TERM RESERVOIR SEDIMENT MODELS: SIMULATING ARGHANDAB RESERVOIR DEPOSITION WITH HEC-RAS

Gibson, S. PhD, Senior Hydraulic Engineer, Hydrologic Engineering Center, U.S. Army Corps of Engineers, Davis, CA. stanford.gibson@usace.army.mil
Pridal, D. PE, Senior Hydraulic Engineer, U.S. Army Corps of Engineers

Abstract: Water stored in the Arghandab Reservoir, in northeastern Afghanistan, supports subsistence agriculture in the Arghandab valley. The reservoir's contributing watershed is mountainous and mostly unvegetated, contributing unusually high sediment concentrations. Since its 1952 closure, sediment has filled about 45% of the reservoir volume. Lost reservoir capacity makes meeting downstream demand during low flow years difficult. The HEC-RAS sediment model was constructed and calibrated with a systematic, three step calibration process, targeting: 1) total volume, 2) longitudinal distribution and 3) gradation of sediment deposits. The calibrated model predicted reservoir stage-volume curves for four scenarios, including current conditions and three spillway raises. However, hydrologic uncertainty complicated prediction.

Gage flow records in this region are discontinuous, making hydrologic modeling challenging. Truncated time-series introduce uncertainty in sediment delivery and deposition simulations over standard, 50-year "project" time scales, longer simulations predicting reservoir lifespan. Therefore, stochastic scenarios of future hydrology included unobserved, low probability (1% to 0.1%) synthetic time series to quantify the uncertainty on long term (200 year) reservoir lifespan analyses associated with a brief measured flow record. This paper describes a systematic, three-stage method to calibrate 1D reservoir models, and an approach to hydrologic uncertainty in long-term sediment studies with short flow records.

Keywords: Sediment Modeling, Reservoir sedimentation, hydrologic uncertainty, sediment calibration, HEC-RAS

INTRODUCTION

The Arghandab River, and the irrigation systems built around it, made agriculture possible in arid southern Afghanistan, and are responsible for most of the region's economy (CID, 2008). The river supports subsistence agriculture in the Arghandab valley with water from mountain snow. Snow-melt hydrology is episodic, so converting it into reliable irrigation requires storage. The Arghandab reservoir, impounded by Dala -am, the second largest in Afghanistan, storing the episodic snow-melt regime and releasing predictable flows required for agriculture and irrigation. However, the mountainous, unvegetated watershed delivers unusually high sediment loads, filling 45% of the reservoir's capacity since the dam closure in 1952. As reservoirs fill with sediment, water storage is reduced and they lose the capacity to buffer communities against either floods or droughts. Storage lost to sediment increases the risk that water demand in dry years will not be met, which could have devastating social impacts on downstream agricultural communities.

The U.S. Army Corps of Engineers Omaha District and Hydrologic Engineering Center built hydrologic, hydraulic, and sediment models of this system to estimate the reservoir lifecycle and predict sedimentation effects on future drought vulnerability. The models also evaluated three spillway raise proposals and the influence these would have on reservoir life and future drought

risk on these estimates. The sediment modeling encountered two obstacles common in reservoir sediment transport modeling, equifinality and hydrologic uncertainty. The study documented approaches to:

1. Negotiate equifinality with a three-stage process of sediment calibration.
2. Quantify hydrologic uncertainty with stochastic analysis featuring hybrid time series including historical and synthetic hydrology.

These approaches to these common problems could inform and improve similar future work.

THREE-STAGE SEDIMENT CALIBRATION PROCESS

"Equifinality" - multiple parameter combinations can produce the same calibration results -is a challenge for any multi-parameter modeling problem (Beven, 1993; Pappenberger et al., 2005). Calibrating models with multiple, sensitive, uncertain parameters introduces non-unique solutions. Multiple parameter combinations can produce the same model result, reducing the confidence in the calibration and increasing the uncertainty of predictive results. Ordering free parameters by sensitivity and confidence can isolate the most important parameters (Ruark, 2011; USACE, 2014), those that are both sensitive and uncertain, but sediment models still often require multi-parameter calibration. Because sediment data are usually rare, sediment load magnitude and gradation are usually mostly uncertain. This is true in Western systems, but especially in regions of conflict like Afghanistan.

Evaluating a model against multiple, independent, calibration time windows (i.e. calibration-validation, though the terminology and methodology are controversial) is the classical approach to mitigate equifinality (e.g. Shelley and Gibson, 2015). However, in the absence of multiple calibration time-series, comparing results to several different prototype measurements over a single calibration window can help modelers negotiate non-unique calibration problems, converging on more robust models.

In an analogy of the n-equation solution to n-variable problems of more elegant mathematical systems, numerical calibration can mitigate equifinality with a multi-stage calibration approach, evaluating a multi- parameter calibration against multiple prototype measurements. In this case, two sensitive and uncertain parameters were estimated in a three-step calibration process.

Sediment calibration should always follow hydraulic calibration (HEC, 1993; Thomas and Cheng, 2007; e.g. Shelley and Gibson, 2014). Sediment models depend on good hydraulic calibration, as sediment results are highly sensitive to hydraulic parameters like bed roughness. Hydraulic calibration could be considered an additional stage to calibrate a third uncertain parameter (n-value). When possible the hydraulic calibration should be followed by a robustness analysis to test numerical stability, (HEC, 1993; Thomas and Cheng, 2007) though fundamentally non-equilibrium problems, like reservoir deposition, make the robustness concept difficult to apply.

After hydraulic calibration, the sediment calibration Arghandab Reservoir for the progressed through three stages, calibrating two free parameters by comparing model results to three

prototype measurements over a single calibration window (Table 1).

Table 1 Uncertain/sensitive model parameters and the prototype measurements used to estimate them.

Estimated Parameters	Evaluation Measurements
1. Load Magnitude	1. Total sediment volume
2. Load Gradation	2. Longitudinal sediment distribution
	3. Longitudinal bed gradation trend

1. Total Sediment Volume: Calibrating Load Magnitude

Most reservoir sediment models specify boundary sediment loads with flow-load rating curves. Even when the data to develop flow-load curves are available, scatter around a selected curve often span one- to-two orders of magnitude, making the flow load relationship a common calibration variable.

Mort et al. (1973) measured transects of the reservoir along historical, as-built cross sections, in 1971. A few years later data series end because of regional conflicts. These measurements created a 19-year calibration window that aligned with continuous upstream flow and reservoir stage data.

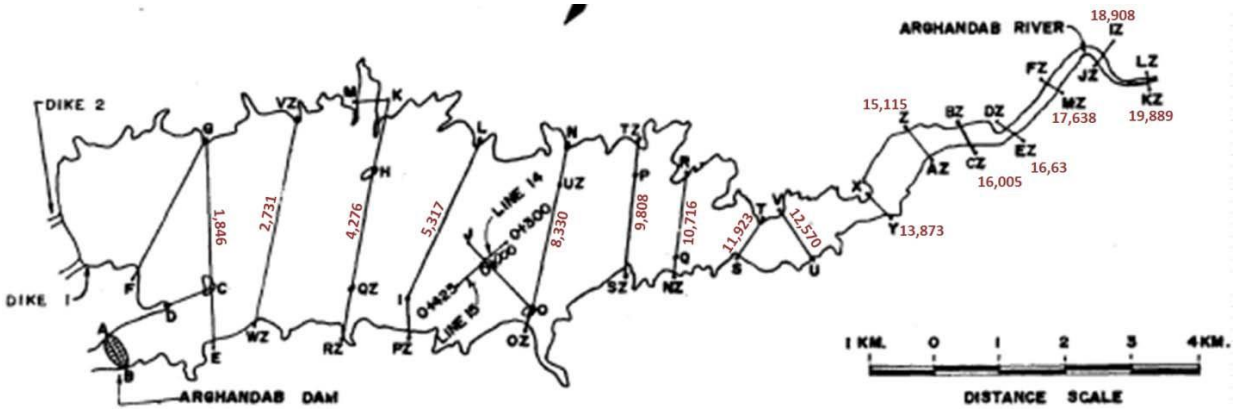

Figure 1 HEC-RAS cross section stations (red numbers) associated with the corresponding Mort et al. (1973) transects.

An as-built HEC-RAS model was constructed with the 1952 cross sections and run over the calibration period. Sediment volume change results were compared to the 89 million m3 deposition computed from the Mort et al. (1973) transects. The flow-load curve was adjusted until the model reproduced the total observed deposition volume. Results were compared to a few available load measurements and other regional flow-load curves.

2. Longitudinal Sediment Distribution: Calibrating Load Gradation

Most sediment transport models require sediment boundary conditions by grain class. Therefore, two uncertain parameters are wrapped up in the sediment load boundary: magnitude and

gradation. While load magnitude data are rare and noisy, load gradation data are usually even more uncertain, based on fewer and more erratic measurements.

In depositional environments however, load gradation can be calibrated to the longitudinal distribution of the deposits. Reservoirs sort sediment longitudinally by gradation and models use fall velocity to simulate that sorting relatively precisely (relative to the uncertainty in other transport algorithms). Therefore, once the total load is established with the flow-load curve, the gradational distribution of the inflowing loads can be adjusted to fit the longitudinal trend.

In the Arghandab model, load gradations were adjusted until the Arghandab HEC-RAS model re-created volume change at each location (Figure 2). This step sometimes requires feedback with the total volume analysis (Section 3.1), because moving mass to finer grain classes (e.g. clay or very fine silt) to induce deep pool deposition with trap efficiencies <100%, can reduce the total sediment mass deposited, requiring adjustments to the magnitude of inflowing loads. However the modeled trap efficiency and sediment releases through the dam should be checked against actual reservoir release concentrations, to verify that the estimated fine components are justified.

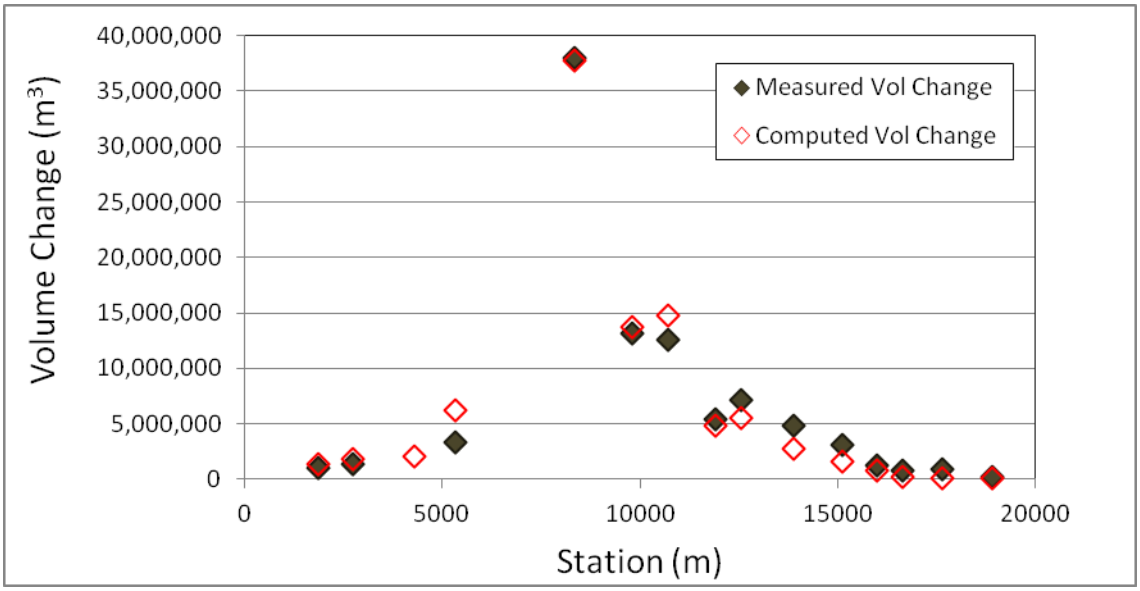

Figure 2 Computed and measured longitudinal volume change. Bed change at each cross section in the Arghandab reservoir between 1952 and 1971. The gradation of the upstream load boundary was adjusted to fit the computed result to the measurements.

3. Gradational Trend: Check and Update Load Gradations

Finally, the calibration was checked against bed gradations and updated accordingly. This could be considered a single-time-series analogy "verification," but verification terminology is controversial (Oreskes et al., 1994; Rykiel, 1996; Gibson, 2013), and production level models do not simply "fail" verification, but use the new data to update parameterization to produce the best final model possible.

Gradations were extracted from HEC-RAS calibration results and compared to a handful of 1973

bed gradations (Figure 3). Both the model and prototype gradation data must be interpreted carefully in this comparison. Computing gradational evolution results from active layer sediment models (like HEC- RAS) can be challenging. Cover layer gradations in HEC-RAS are a function of layer thickness, which are sometimes confounded by non-linear mixing dynamics. Especially detailed, multi-layer Lagrangian mixing methods like the Thomas and Copland methods (Exner 5 and 7 respectively in version 4.1) in HEC-RAS (which are required to develop and maintain the armor layers in the upper reach of the model), often reset cover gradations, making the surficial gradations at any time step stochastic, evolving non- monotonically.

Therefore, "computed gradations" were extracted from "total mass change" results, which develop more consistently. Because reservoir deposition is mainly monotonic, gradations can be computed from the depositional mass. This approach integrates vertical gradations in the deposit, extracting finer model gradations than the surficial prototype samples. As a reservoir delta progrades, finer material deposits deep in the reservoir, at the toe of the delta. Later, coarser deltaic deposits cover these deep, fine, materials. Reservoir sediment samples tend to collect the coarser, surface materials. The Arghandab model produced this result as the measured total-deposit gradations were coarser than the computed deposits (Figure 3).

Despite these complexities in comparing computed gradations of the active layer against surficial measurements, the comparison provided an independent evaluation of the model to mitigate equifinality uncertainty. Calibrating the model against three observations increased confidence and mitigated uncertainty in predictive results.

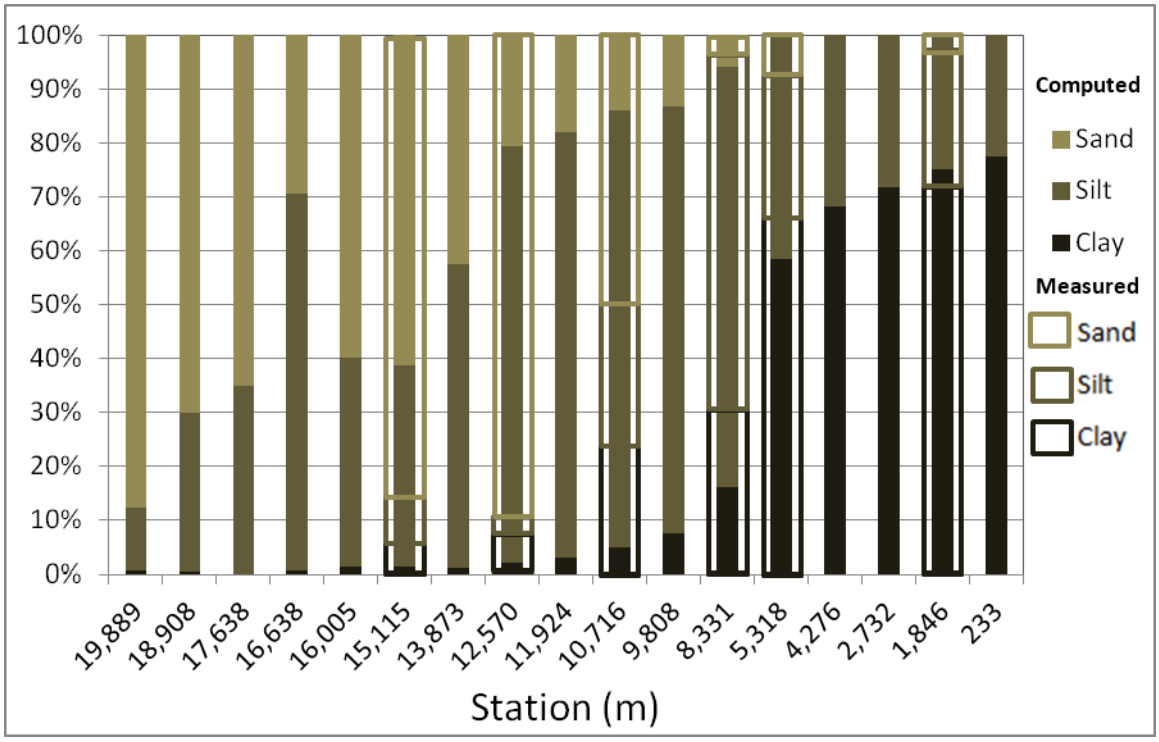

Figure 3 Computed and measured bed gradations for the 1952-1971 calibration of Arghandab reservoir deposition. Computed, vertically integrated, deposits are finer than the surficial measurements, as expected, but the trend "validates" load gradation calibration.

QUANTIFYING PREDICTIVE HYDROLOGIC UNCERTAINTY FOR SEDIMENT MODELS

Most reservoirs operate based on upstream and downstream flow gages, which provide good historic flow data for sediment models. Therefore sediment parameter uncertainty, confounded by limited data and scatter when data are available, usually overshadows historic flow uncertainty. However, when sediment analyses move from historic to predictive simulations, hydrologic uncertainty can dominate in a well-calibrated reservoir sediment model. Sediment transport is a non-linear function of flow, making projected deposition, reservoir life cycle, and future drought or flood protection heavily dependent on the flows in the following decades, particularly the frequency and timing of large events.

Historically, predictive sediment models have either ignored hydrologic uncertainty, by simply repeating historical records, or collapsed historical records into "representative years," sometimes augmented with probabilistic flows, that are repeated for every year of the simulation.

These approaches have limitations, however. Reservoir life cycles depend largely on the unknown time- series of future hydrology, so a repeated time-series will only predict the future (or even simulate a probable future) if it does not over or under predict flood frequency. Repeating the historical record can be particularly problematic in a system like Arghandab, where the regional history left a hydrologic record of only 28 years, and anecdotal evidence suggests that the ungaged records include much larger flows than those included in the measured time-series (Needham, 2006). Additionally, bed response to large events depends on their timing, sequence, and temporal relation to other events. A 1% event, five years into a simulation, may affect the system very differently than the same event in year 45.

Synthetic hydrographs of future conditions were developed to quantify hydrologic uncertainty in the Arghandab study. These stochastic hydrologic time-series were developed from a combination of 1) historical annual flow series and 2) synthetic flow years.

The HEC Statistical Software Package (HEC-SSP) (Brunner and Fleming, 2010) ordered the historic annual time-series and associated each with an exceedance probability based on peak seven-day flow volumes with a Log-Pearson III distribution (Figure 4). Each historical annual flow record was assigned a range of probabilities surrounding its plotting position. The ordered peaks had an "S-shaped" alignment, however, so the right half of the data (larger than average flows) had a prominent negative skew. Negative skew makes the log normal distribution (i.e. LPIII with zero skew) over predict high flows, so historical flow series were scaled to align with the flow at the corresponding position on the flow-frequency curve. For example, the 1954 flow record was assigned probabilities between 0.33 and 0.365 (based on where it plotted on the flow-frequency curve) and high flows were multiplied by a scaling factor of 0.94 to bring the seven-day volume in line with the log normal distribution.

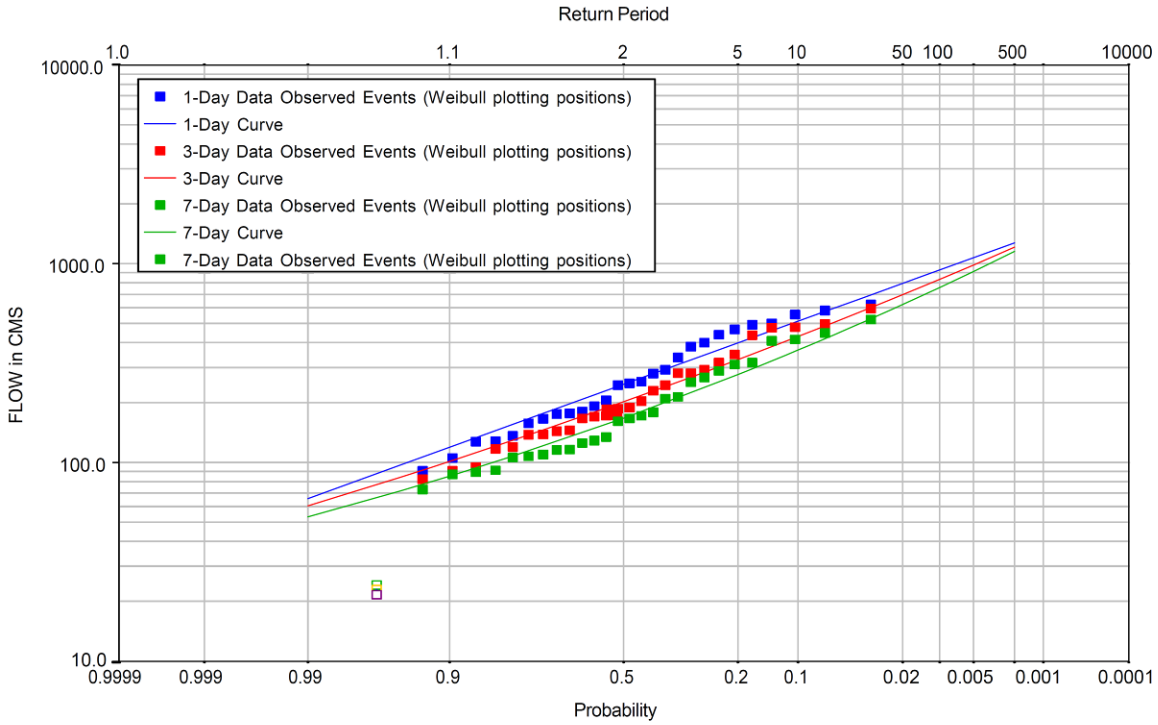

Figure 4 Volume frequency analysis for the gage upstream of Arghandab Reservoir (September 1951 to Mar 1979).

When using plotting positions, a 6% exceedance probability is assigned to the largest historical flow. Rarer events (5%, 2%, 1%, 0.5%, and 0.1%), were constructed by scaling a regularly shaped, single peak, historic "model" hydrograph (Water Year 1965) into synthetic, low-frequency flood events. The flood season flows of the model hydrograph were scaled by the ratio of the peak flow (computed in a separate HEC- SSP analysis) to the 1965 peak (Figure 5). Twenty, 50-year, synthetic flow series (1,000 total flow years) sampled these historic and synthetic annual time-series (Figure 6) with a random number generator, including nine 1% events, two 0.5% (200 year) events, and one 0.1% (1,000 year) event.

The HEC-RAS sediment model (with estimated contemporary bathymetry) simulated 50-year futures including a no-action alternative and three proposed spillway raises, by repeating the historic time-series and each of the twenty stochastic time-series for each of the four alternatives. Final bed elevation profiles for the three alternatives and no-action condition with the repeated historic record are plotted in Figure 7. However, the stochastic hydrologic analysis made it possible to compute and communicate the potential range of results hydrologic variability could produce. In Figure 8, the 50-year reservoir storage volume computed from the analyses in Figure 7 are plotted with results from the stochastic simulations, placing the repeated historic time-series results in the context of its hydrologic uncertainty.

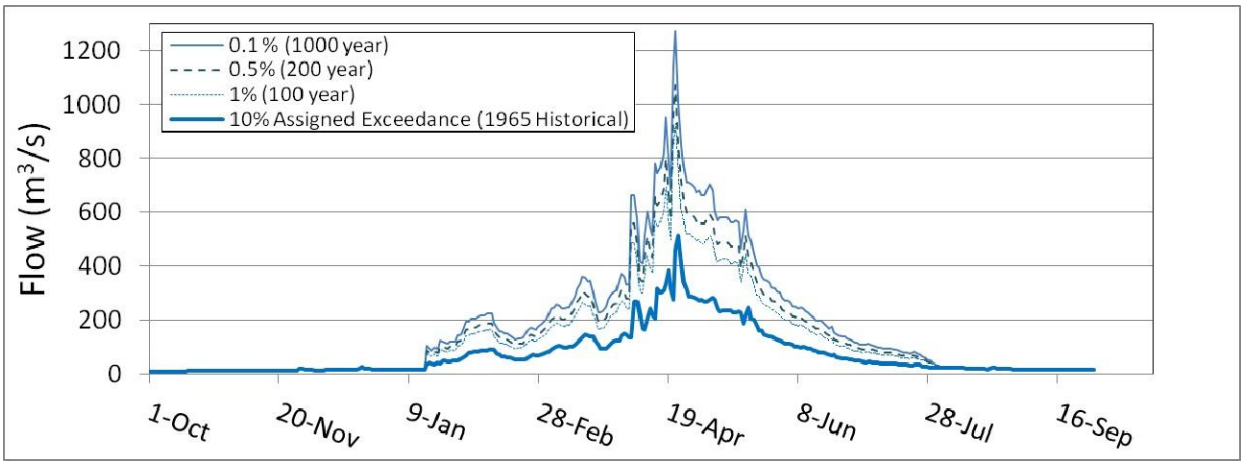

Figure 5 Synthetic annual flow series, low probability flows, larger than those observed during the 32 year flow record, constructed by scaling the 1965 event to the 7-day probabilistic volumes computed by HEC-SSP.

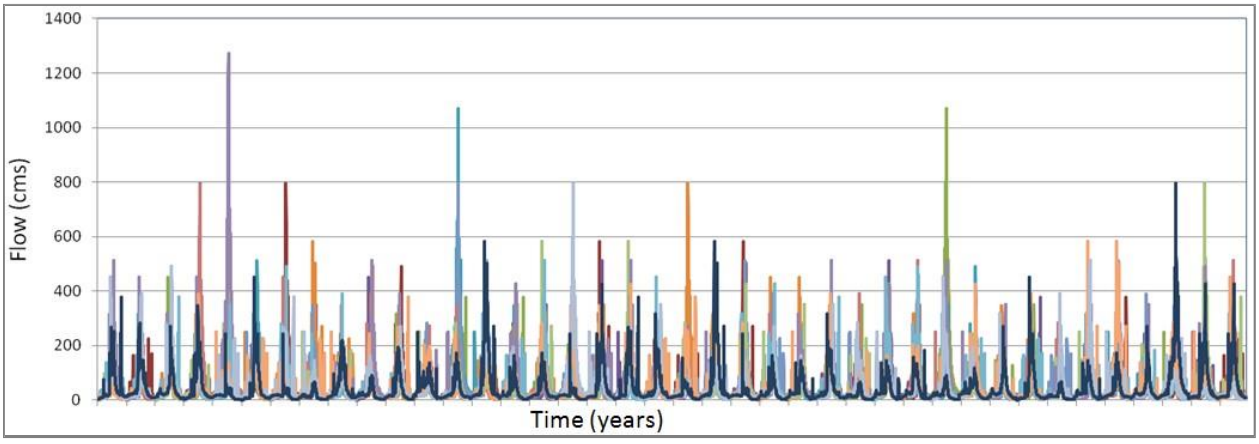

Figure 6 Twenty synthetic flow series used to quantify hydrologic uncertainty.

RECENT DEVELOPMENTS

Customized code generated stochastic hydrologic time-series in this study. Since then, HEC has developed unsteady sediment transport capabilities in HEC-RAS (Gibson and Boyd, 2014; Shelley et al., 2015) and automated time-series sampling in the HEC-WAT (Dunn and Baker, 2010). Combining these capabilities automate sediment model hydrologic uncertainty analyses, like the one described above.

HEC-WAT creates time-series from historic and synthetic annual time-series like those depicted in Figures 5 and 6, and automatically launches HEC-RAS sediment simulations with each realization automatically. These developments will simplify hydrologic uncertainty for sediment models.

CONCLUSIONS

The uncertainty surrounding sediment models can reduce their utility and is sometimes cited as a reason to forgo modeling that could add value by reducing uncertainty. Good calibration against multiple time-series, or in their absence, against multiple measurements, can reduce model uncertainty to acceptable levels. However, the uncertainty associated with sediment transport model results is a fundamental characteristic of the analysis. Providing results with explicit uncertainty analyses puts results in the context of the project risk portfolio and provides the range of probable outcomes.

SEDIMENT MONITORING DURING SHORT-TERM DRAWDOWNS OF FALL CREEK LAKE, UPPER WILLAMETTE BASIN, OREGON

Liam Schenk, Hydrologist, USGS Oregon Water Science Center, Klamath Falls field office, lschenk@usgs.gov; Heather Bragg, Hydrologic Technician, USGS Oregon Water Science Center, hmbragg@usgs.gov;

INTRODUCTION

In December 2012 and December 2013, the U.S. Army Corps of Engineers (USACE) conducted operational drawdowns of Fall Creek Lake, Oregon, to enhance downstream passage of Endangered Species Act-listed juvenile spring Chinook salmon in response to requirements in the 2008 Biological Opinion on continued operations of the Willamette Valley Project (National Marine Fisheries Services, 2008). During these drawdowns the lake elevation was lowered from the normal winter low-pool elevation of 728 feet to approximately 690 feet, allowing inflowing water to pass freely through the regulating outlets of the Fall Creek Dam. The U.S. Geological Survey (USGS) monitored the resulting suspended sediment release and has estimated sediment loads transported during these events. Data generated from the monitoring efforts provides the USACE with important information regarding the amount of sediment transported during these operational drawdowns.

DATA COLLECTION

The USGS monitored turbidity and suspended sediment over a range of hydrologic and sediment transport conditions before, during, and after drawdown operations at Fall Creek Lake. Monitoring occurred from November 2012 through February 2013 during water year (WY) 2013 and November 2013 through March 2014 (during WY 2014). In WY 2013, six monitoring stations were established for the lake and at strategic locations downstream, including the two main inflows to Fall Creek Lake, Fall Creek below Fall Creek Dam (Fall Creek Outflow in Figure 1), Little Fall Creek (a tributary to Fall Creek), and two sites on the Middle Fork Willamette River (Dexter and Jasper, Figure 1). During WY 2014, only the station at Fall Creek Outflow was monitored. Turbidity sensors measuring in Formazin Nephelometric Units (FNUs) were deployed and Equal-Width-Increment (EWI) suspended-sediment concentration (SSC) samples were collected at all sites. Automatic pump samplers were installed at several sites to provide additional SSC data. Correction coefficients were calculated to adjust the pump sample concentrations to cross section EWI samples. All samples were analyzed for SSC (in milligrams per liter [mg/L]) and percent finer than 63 microns (percent fines) at the USGS Cascades Volcano Observatory sediment lab. Each discrete SSC sample was assigned an associated turbidity and streamflow (in cubic feet per second [cfs]) value from the continuously monitored instream data.

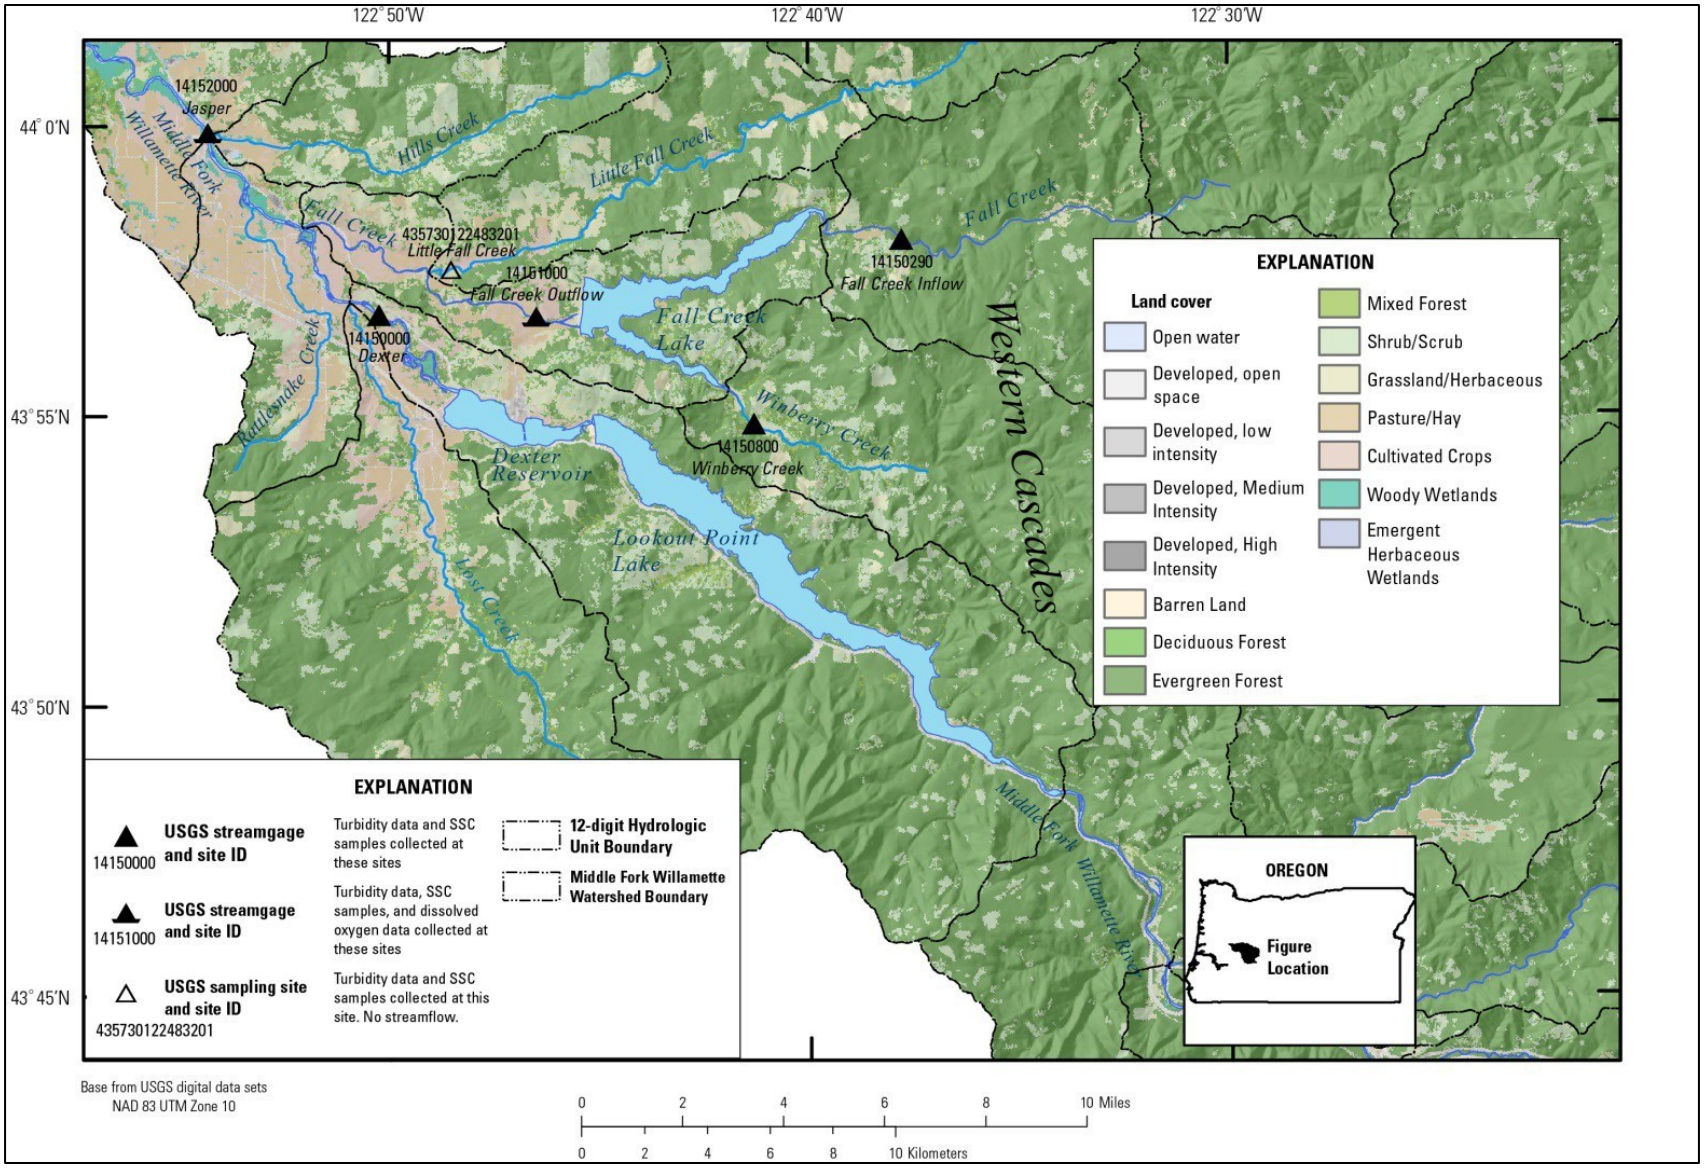

Figure 1 Location of study area and monitoring stations, Middle Fork Willamette Basin, Oregon (from Schenk and Bragg, 2014)

DATA ANALYSIS

Site-specific regression models were developed from discrete turbidity, streamflow, and SSC data. Sample data for sites downstream of the dam were divided into pre-drawdown, drawdown, and post-drawdown analysis periods. Log10-transformed and untransformed turbidity and streamflow data were used to create both simple and multiple linear regression models which were evaluated on residual plots and summary statistics. Model development followed USGS guidelines outlined in Rassumussen and others (2009). The preferred models were used to compute continuous SSC records for each of the sites. Continuous suspended-sediment loads were computed from the SSC and streamflow records. For WY 2013, suspended-sediment loads were computed for all six stations. For WY 2014, suspended-sediment loads were only computed for the single station (Fall Creek Outflow) before, during, and after the drawdown for comparison to the suspended sediment loads calculated in WY 2013.

RESULTS

The FY 2013 drawdown occurred for six days in December 2012 (Figure 2) and resulted in the net transport of approximately 50,300 tons of sediment from the lake, accounting for approximately 83% of the total suspended-sediment load delivered from Fall Creek Lake during the study period. The drawdown also resulted in approximately 16,300 tons of sediment deposited in the river reaches between Fall Creek Lake and a site on the Middle Fork Willamette River (Jasper), which was ten miles downstream of the lake (Schenk and Bragg, 2014).

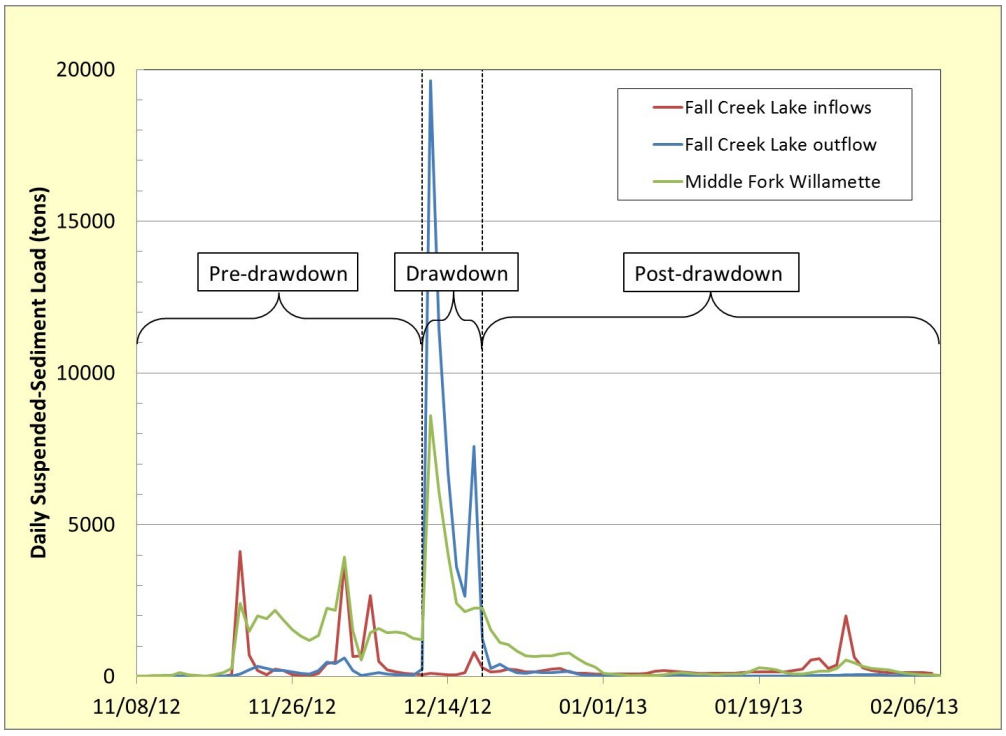

Figure 2 Water year 2013 daily suspended-sediment loads for Fall Creek Lake inflows, Fall Creek Lake outflow, and the monitoring site ten river miles downstream of Fall Creek Lake (Jasper) on the Middle Fork Willamette River.

Due to unseasonably cold weather, the suspended-sediment load during the WY 2014 drawdown was particularly low. The area received 8–10 inches of snow followed by air temperatures consistently below freezing for most of the drawdown period. The sediment exposed in the lakebed was frozen and unavailable for transport. During the first 5½ days of the ten-day drawdown in December 2013, only 3,300 tons of sediment was transported from the lake (Figure 3). Turbidity data were lost for the last 4½ days of the drawdown due to sensor fouling, and sediment loads were computed using daily mean values of SSC and streamflow, resulting in a total sediment load of approximately 5,220 tons during the ten-day drawdown period. This accounted for approximately 19% of the total sediment load during the study period and was 90% less than the previous drawdown in WY 2013.

Most of the sediment transport in WY 2014 occurred in February 2014, when the lake elevation dropped to approximately 700 feet, which was concurrent with extremely high streamflows (>3,500 cfs, peak streamflow of the WY). Monitoring was not conducted at the inflows to the lake in WY 2014, so how much of the suspended- sediment load came from upstream inflows compared to bank erosion or sediment re-suspension within the lake is unknown. However, given the limited contribution from the inflows in WY 2013 (approximately 2.5% of total sediment load) it is likely their contribution was similarly small in WY 2014. A preliminary analysis for the WY 2015 drawdown conducted in November 2014 suggests that approximately 20,000 to 35,000 tons of sediment was transported during a seven-day period, further highlighting the inter-annual variability in sediment transport during the operational drawdowns.

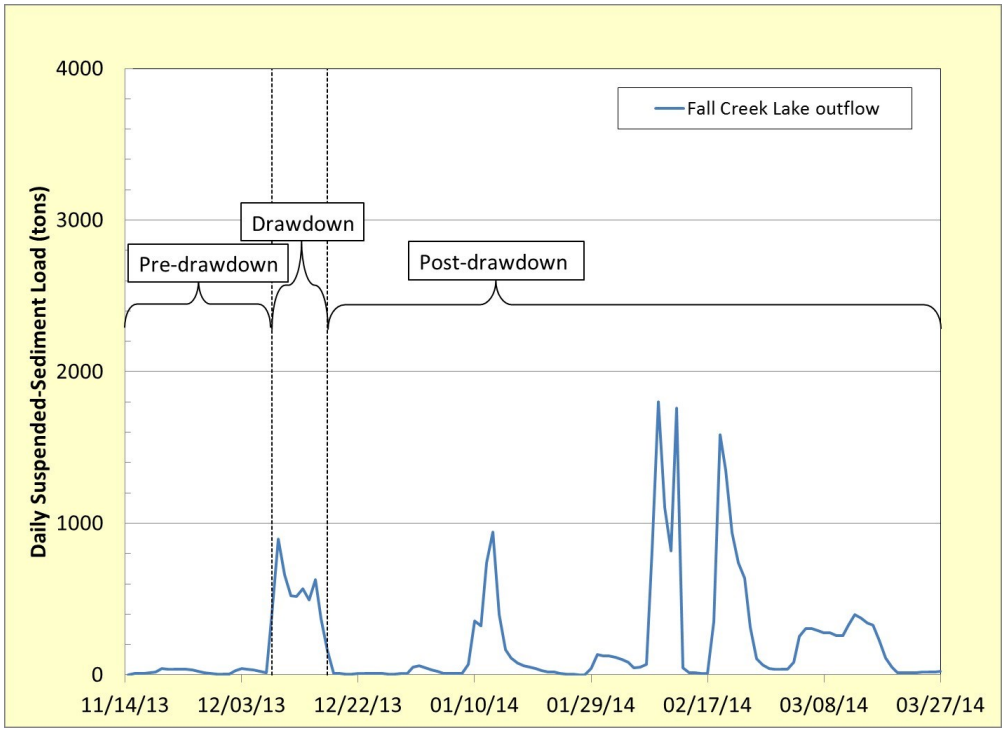

Figure 3 Water year 2014 daily suspended-sediment loads for Fall Creek Lake outflow.

SUMMARY

Results from suspended-sediment monitoring at Fall Creek Lake during two operational drawdowns suggest that variability in hydrologic and climatic conditions and lake elevation play an important role in sediment transport and supply. This is highlighted by the difference in sediment load estimates from the December 2012 and 2013 drawdown operations. Monitoring results suggest a 90% reduction in sediment loads from the 2012 to 2013 drawdown operations, but this decrease in loads was likely forced by weather conditions rather than a reduction in sediment supply after the previous drawdown. Ongoing monitoring and data collection efforts will continue to investigate inter-annual variability in sediment transport during these operational drawdowns, and provide useful information about changes in reservoir storage capacity that is beneficial for future flood control efforts.

TIME SERIES AND GEOSPATIAL DATA INTEGRATION FOR RESERVOIR SEDIMENTATION STUDY THAT INCORPORATES MULTIPLE SEDIMENTATION MODELS AND RATES FOR CONVERGENT VALIDATION

Nathaniel Todea, USDA Natural Resources Conservation Service Hydraulic Engineer, 125 South State Street, Room 4010, Salt Lake City, Utah 84106, 801.524.4573
Nathaniel.Todea@ut.usda.gov

Abstract: As part of the Tibble Fork Dam Rehabilitation Environmental Assessment, a sedimentation study was undertaken to determine the current and future storage needed to provide at least 50 to 100 years of dam life. Tibble Fork Reservoir, located in American Fork Canyon in Utah County, Utah, is a small, 259 acre-foot reservoir fed by a 35 square-mile watershed, with an average elevation of 8,600 feet above mean sea level. Multiple analyses were used to determine erosion rates from the Van Dugway landslide and watershed sediment yields that directly contribute sediment into Tibble Fork Reservoir. Tibble Fork Reservoir was constructed with assistance from the U.S. Department of Agriculture, Soil Conservation Service, now the Natural Resources Conservation Service (NRCS), in 1966. Construction of the dam was accomplished through the authority of the Watershed Protection and Flood Protection Act, Public Law 566 (PL-566). NRCS is developing a dam rehabilitation plan for the dam that includes an auxiliary spillway analysis, sedimentation volume calculations, and seismic/geotechnical analyses to meet current dam safety criteria.

In 2012, Todea and Hasenyager made a sedimentation study of the Tibble Fork (Todea and Hasenyager, 2012). The results of that study were compared to new calculations as part of the dam rehabilitation environmental assessment study. Bedload measurements were taken during the 2011 spring runoff and were modeled using the U.S. Army Corps of Engineers (USACE) Hydrologic Engineering Centers River Analysis System (HEC-RAS) sediment transport model to estimate the sediment contribution (USACE, 2010). The RiverMorph and FlowSed/PowerSed (RIVERMorph, 2008) models were used to determine annual average bedload and suspended sediment loads from the 2011 spring runoff event. The Automated Geospatial Watershed Assessment (AGWA) (Burns et al., 2007) software, and the Soil and Water Assessment Tool (SWAT) (Arnold et al., 1994) were evaluated to estimate the watershed sedimentation rates that contribute to the reservoir. As part of the 2012 study, the Bridges 1973 sedimentation map was reviewed and correlated to the above studies. The following models resources were also considered:

1) The "*Managing Sediment in Utah's Reservoirs*" Utah State Water Plan produced by the Utah Division of Water Resources (UDWR) in 2010. Four reservoir sedimentation rates were filtered and compared due to the elevation and location of the reservoirs.
2) The Rangeland Hydrology Erosion Model (RHEM) (Nearing et al., 2011) is a slope-based program, not applicable for high alpine watershed erosion scenarios, but the model was used as part of this study.
3) Slaymaker (1977) reported on eleven relevant basins in the report "*Estimation of sediment yield in temperate alpine environments*."

Trap efficiency of the reservoir was considered and calculated using the USDA SCS (1975, revised) procedure titled "*Procedure-Sediment Storage Requirements for Reservoirs – Technical Release No. 12*" (TR 12).Finally, all methods were compared to bathymetric surveys that were conducted in 2010 and 2014.

The results of the 2012 study by Todea and Hasenyager estimated that an average 2.02 acre-

feet per year of material is deposited in Tibble Fork Reservoir. The compilation of sediment rates from the nine evaluations in the 2012 study ranged from 0.02 to 0.76 acre-feet per square mile, with most values ranging near or below 0.10 acre-feet per square mile. The 2014 bathymetric survey estimated an average annual sedimentation rate of 2.92 acre-feet (or 0.08 acre-feet/square mile) in the pool. This assumes that the original pool was accurately measured at 259 acre-feet of storage for the original design. The 1964 design sediment rate was calculated to be 3.32 acre-feet per year on average, this includes considering trap efficiency. Bridge's 1973 map is a good tool for providing initial estimates. Pairing of results from Rivermorph PowerSed/FlowSed with bedload and suspended sediment, HEC-RAS bedload with RiverMorph PowerSed/FlowSed suspended sediment, and AGWA SWAT with HEC-RAS bedload provided useful results. The RHEM is not optimally suited for these environmental conditions, but provides supporting documentation. Trap efficiencies in TR 12 (USDA SCS, 1975) are relevant.

INTRODUCTION

This study is a continuation of a sedimentation study performed by Todea and Hasenyager in 2012 for the Tibble Fork Reservoir. Todea and Hasenyager (2012) contains the following introduction: *"As part of a dam rehabilitation plan for a constructed Watershed Protection and Flood Prevention Public Law 566 (PL-566) dam, a sedimentation study was undertaken for Tibble Fork dam. Tibble Fork Reservoir, constructed in 1966, is located in American Fork Canyon in the Wasatch Mountains of Utah (Figure 1). To meet United States Department of Agriculture (USDA), Natural Resources Conservation Service (NRCS) Watershed Rehabilitation Program objectives, the dam rehabilitation outcome must have a design life of no less than 50 years* [and no more than 100 years]. *As part of the rehabilitation plan, alternatives that include decommissioning of the dam were analyzed. Sedimentation accrual within a dam and the effects on the design life must be considered when a dam is being rehabilitated. The original project in 1966 estimated a sediment storage capacity of 3.32 acre-feet/year (USDA SCS, 1964). The Van Dugway landslide located approximately 6,400 feet upstream has been actively contributing additional sediment to the reservoir since 1966. Multiple analyses were conducted to determine bedload gradation and suspended sediment material that is being deposited in Tibble Fork Reservoir*".

The components of the Todea and Hasenyager 2012 study were compared to a 2014 bathymetric survey. As part of this study the following were reviewed, modeled, or calculated:

- The Utah State Water Plan – "*Managing Sediment in Utah Reservoirs"* was reviewed and four dams that meet comparative requirements were reviewed.
- The Rangeland Hydrology Erosion Model (RHEM (Nearing et al., 2011) was calculated for a hillslope.
- Measured data from Slaymaker (1977), a sediment yield in temperate alpine environments study, were used.The Bridges 1973 sedimentation map was reviewed and sediment yield was determined for the Tibble Fork watershed study area.
- Trap efficiency (USDA SCS, 1975) was calculated and applied to the comparative sedimentation analysis.

The Todea and Hasenyager 2012 study used sedimentation techniques that include components from AGWA SWAT (Burn et al., 2007, and Arnold et al., 1994); bedload and sediment transport models from HEC-RAS; and Rivermorph FlowSed/PowerSed models

with bedload from the 2011 spring runoff measured upstream of the reservoir.

Figure 1 Tibble Fork Watershed Location Map (Todea and Hasenyager, 2012)

BACKGROUND

The Tibble Fork watershed is 35 square miles in area, at an elevation of 8,600 feet above mean sea level. The Van Dugway Landslide has contributed large amounts of sediment to the American Fork River for a reach length of 1,500 feet. The actively eroding portion of the landslide is located on the north, or right bank (looking downstream) of the American Fork River. The highest section of the landslide on the right bank of American Fork River is approximately 50 feet tall (Figure 2).

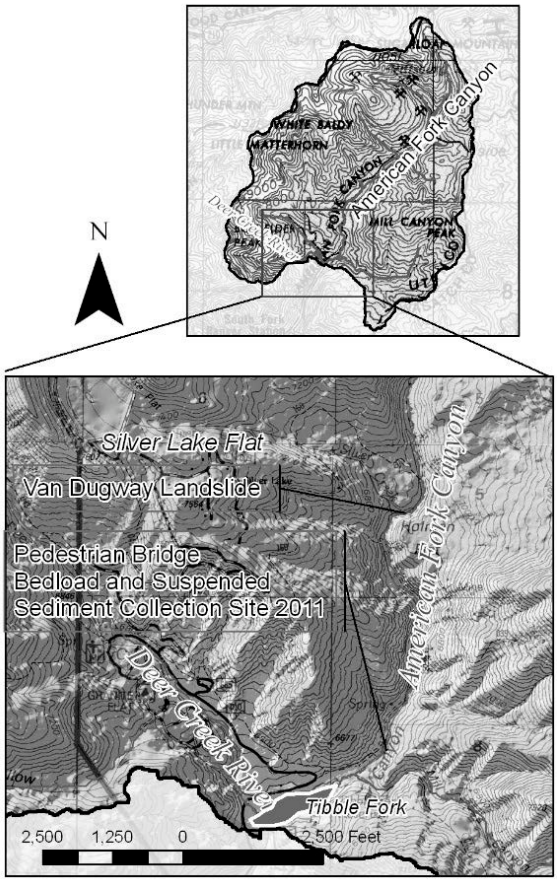

Figure 2 Tibble Fork Reference Map (Todea and Hasenyager, 2012)

The American Fork Canyon has a drainage area of approximately 26 square miles, and the adjacent Deer Creek has a 9.5-square-mile drainage area. They interconnect at the Tibble Fork Reservoir, providing a total watershed contribution area of 35.5 square miles (Figure 2). The American Fork Canyon drainage area contains the Van Dugway landslide. Below Van Dugway landslide, the American Fork River is characterized as a steep, confined valley with a Rosgen channel type B (Rosgen, 2006), that provides transport of large bedload material. Bedload samples were collected as part of Todea and Hasenyager (2012) study at a pedestrian bridge that crosses the river 2,700 feet upstream of Tibble Fork Reservoir, where the valley opens slightly and the channel is a Rosgen type C, which allows for transport of large cobbles at larger flows. Downstream from the pedestrian bridge to the Tibble Fork Reservoir the channel is a braided, Rosgen type D, where cobbles and gravels are deposited. The braided channel has distinct deposits of bed materials where the upper portion contains cobbles and the lower portion contains sand and fine gravels. Light Detection and Ranging (LiDAR) data were collected by Aero-Metric, Inc. (2010) as part of the Todea and Hasenyager (2012) study and was used for the hydraulic analysis.

Bathymetric data was collected by AMEC under contract with the NRCS in 2010 (AMEC, 2010). The bathymetric data and NRCS as-built drawings at ten-foot contours were analyzed by the Utah Division of Water Resources in 2011 to determine the volume of sediment contributed to the Tibble Fork Reservoir. It was determined that the sediment contributed to Tibble Fork Reservoir was between 84 and 142 acre-feet from 1966 to 2010 (UDWR, 2011), at an average rate of 1.91 to 3.23 acre-feet/year. This is approximately 1.41 to 0.09 acre-feet/year lower than the original estimate of 3.32 acre-feet/year. HDR Engineering, Inc. (2011) provided a study that resulted in a sedimentation rate of 2.21-2.82 acre-feet/year.

During the 2011 spring runoff, bedload and suspended sediment was measured. The Elwha bedload sampler was used to collect bedload material. A total of four samples was collected that included the rising and falling limb of the hydrograph of the spring runoff. Both the bedload and suspended- sediment samples were collected using guidance from USGS Field Measurements for Measurement of Fluvial Sediment (Edwards and Glysson, 1999). Suspended sediment was collected using a US DH-48 sampler. It is noted in the 2012 Todea and Haseyanger study *"Although the bedload is at a lower rate on the falling limb than the rising limb, the suspended sediment has the largest concentration of material captured on the falling limb of the hydrograph"*. This could have had an effect on the results that is artificially increasing the bedload and decreasing the suspended sediment, if only the rising limb values were used, resulting in higher bedload and lower suspended sediment values.

The purpose of the 2012 Todea and Hasenyager 2012 study was to obtain a more accurate estimate of sedimentation rates and provide information to determine the validity of mitigating the Van Dugway landslide. In 2011, NRCS conducted a bedload and suspended-sediment sampling program during the spring runoff on the American Fork River, below the Van Dugway landslide and above Tibble Fork Reservoir at the pedestrian bridge.

The Todea and Hasenyager study used multiple software programs and computations from collected bedload and suspended sediment approximations to narrow the range of estimates of sediment transported to Tibble Fork Reservoir. The Automated Geospatial Watershed Assessment (AGWA) (Burns et al., 2007) that uses Soil and Water Assessment Tool (SWAT) (Arnold et al, 1994) was evaluated to estimate watershed sediment yields. The RiverMorph (2008) FlowSed/PowerSed model was used with measured bedload to estimate the annual average bedload that passes through the sampling site. The AGWA SWAT model for the American Fork River (using 26 square miles of contributing area) calculated that 2,196 tons of material, on annual average, is transported into Tibble Fork Reservoir.

The Todea and Hasenyager study also used the HEC-RAS sediment transport model to estimate bedload contributions from the Van Dugway landslide and American Fork Canyon, and to determine the amount and gradation of bedload material being deposited into Tibble Fork Reservoir. The bedload data was collected during the one-percent recurrence interval from the spring runoff of 2011. The bedload material collected during the spring runoff was modeled by HEC-RAS as an estimate, until it mimicked observed and measured bed material from below the pedestrian bridge to Tibble Fork Reservoir. Four 100-pebble counts of the bed material were conducted from the pedestrian bridge to Tibble Fork Reservoir and used in the HEC-RAS model. The Yang (1972) transport function, Exner 5 (USACE, 2010) sorting method, and Rubey (1933) fall velocity method were used for sediment transport functions within HEC-RAS. USGS stream gage 10164500 15-minute discharge data was reduced by ten percent and used in the HEC-RAS model. Finally, United States Geological Survey (USGS) gage peak flow data (USGS, 2011), and flow frequency bedload curves were used to estimate bedload transport to the reservoir in Microsoft Excel, and to analyze the gradation of the material deposited as estimated from the HEC-RAS sediment transport model. The HEC-RAS sediment transport model calculated that of the 5,086 tons of material that passed below the pedestrian bridge in 2011, only 2,059 tons were actually deposited in the Tibble Fork Reservoir. The material that was deposited in Tibble Fork included fine gravel, very-fine gravel, and coarse sand.

Todea and Hasenyager (2012) used RiverMorph FlowSed/PowerSed to estimate annual

average bedload using a defined period within the stream gage records. Bedload measurements and estimated suspended sediment from the 2011 survey were used to calculate user-defined bedload and suspended sediment curves to be input into the RiverMorph model. Flow durations curves were generated in RiverMorph using records from the USGS stream gage 10164500 (USGS, 2011). RiverMorph FlowSed/PowerSed model and user-defined bedload and suspended sediment curves estimate an annual average bedload transport rate of 3,624 tons/year and a suspended sediment rate of 5,748 tons/year that passes under the pedestrian bridge at the collection site.

METHODS

The 2012 Todea and Hasenyager study (i.e. the 2010 bathymetry; bedload study from the Van Dugway landslide; HEC-RAS sediment transport model to Tibble Fork Reservoir; the RiverMorph FlowSed/PowerSed model calculations of material moving through the system annually) were compared to the 1973 USDA sedimentation maps, selected dams in the Utah Divisions of Water Resources (UDWR) sediment study for reservoirs, the study on sediment yield in temperate alpine environments (Slaymaker, 1977), and the Rangeland Hydrology Erosion Model (Nearing et al., 2011). USDA SCS Technical Release TR 12 "*Procedure--Sediment Storage Requirements for Reservoirs* was also evaluated and applied to all sediment rates to determine the range and applicability of sedimentation applications. Finally, 2014 bathymetry measurements were taken with a Z-Boat to determine current volumes or capacity of the reservoir.

The Bridges 1973 map entitled "*Estimated Sediment Yield Rates for the State of Utah*" has many referenced data sources as part of the map, including:

- Great Basin Upper Colorado and Lower Colorado Regions, Comprehensive Framework Study, Appendices VIII, Water Management, June 1971, Pacific Southwest Inter-Agency Committee/Water Resources Council,
- Utah State soils map and soil descriptions,
- Reservoir surveys by NRCS and USBR,
- Suspended load measurements by USGS, USGR and NRCS,
- Watershed studies by SCS/NRCS, and
- General knowledge of the state from regular NRCS program work.

Bridges notes "*Do not use these rates to determine sediment yields at specific sites. Large variations in sediment rates may occur within the delineated areas*".

The 2010 UDWR sediment study for the reservoir provides reference to 18 Utah dams, and includes tables provided by the nationwide REServoir SEDimentation Database (RESSED). As stated by UDWR, *"Sedimentation data exist for only 18 of Utah's major reservoirs; that is, those larger than 1,000 acre-feet. Much of these data comes from reservoir surveys conducted between 1930 and 1975 by the U.S. Soil Conservation Service (now the Natural Resources Conservation Service, NRCS) and the U.S. Bureau of Reclamation. The data were collected and published in a national summary of reservoir sediment deposition surveys (Dendy and Champion, 1978). This nationwide database was revised in 2009 and is now the REServoir SEDimentation Database (RESSED) available online at http://ida.water.usgs.gov/ressed/ and http://pubs.usgs.gov/ds/ds434/. The database is a cumulative historical archive that includes data from 1755 to 1993. The 1,823 reservoirs included in the database range in size from farm ponds to the largest U.S. reservoirs. Results from 6,617 bathymetric surveys are available in the database,*" (UDWR, 2010).

Table 1 illustrates data from four dams in the UDWR (2010) study used in the Tibble Fork project. The elevation of the reservoirs were also taken into consideration.

Table 1 Utah Department of Water Resources, reported sediment in selected reservoirs

Reservoir	Date Built	Storage Capacity Initial Survey (AF)	Drainage Area, square miles	Period Assessed	Sedimentation Rate (percent annual capacity loss)	Estimated Annual Sediment Volume (acre-	Average Annual Sediment Volume per mi^2 of DA	Estimated Capacity Loss as of

Iliff Anrus	1949	20	1.1	1949-1966	4.1	0.82	0.76	100

The 1977 Slaymaker study, "*Estimation of sediment yield in temperate alpine environments*" was reviewed to compare measured sediment yield at specific sites. The purpose of the Slaymaker paper was to compare sediment yield data and measurements of geomorphic process. Out of five locations and eight river basins, the Rio Nambe in the Sangre de Cristo Mountains was selected as the most applicable comparative site, based on available data, elevation, and watershed size.

As described by the RHEM developers (Nearing et al., 2011), "*RHEM is an event-based derivation of the WEPP model made by removing relationships developed specifically for croplands and incorporating new equations derived from rangeland data. RHEM estimates runoff, erosion, and sediment delivery rates and volumes at the spatial scale of the hillslope and the temporal scale of a single rainfall event*". SSURGO data was used to characterize the types of surface texture of the soils to be entered into RHEM. Precipitation data were pulled from the RHEM list of available stations that best matched the upper American Fork watershed. The hillslope was considered uniform and represented only a few slopes. Shane Green, a Range Conservationist with the NRCS, was consulted on the foliar cover percent averages for the study area.

In addition to the methods described above, USDA SCS Technical Release TR 12 (1975), "*Procedure – Sediment Storage Requirements for Reservoirs*" was evaluated and compared to the Todea and Hasenyager (2012) results. This was done to provide a reference calculation for sediment yield to material deposited into the Tibble Fork Reservoir. TN 12 provides trap efficiencies of reservoirs using the watershed size, reservoir capacity, and runoff, which are calculated into a Capacity – Inflow ratio. A curve for trap efficiency of reservoirs is also used based on the capacity-inflow ratio. TN 12 contains three sediment curves that include: 1) bedload or coarse material (highly flocculated and coarse-grained sediments); 2) colloids, dispersed clays, and fine silts and; 3) sediment consisting of a wide distribution of various grain sizes. The curve associated with colloids, dispersed clays, and fine silts was used for this study.

A Z-boat was provided by the Wyoming NRCS State office, and the survey was completed in July, 2014. The Z-boat is a remotely-operated survey boat that uses both Global Positioning Systems and echo sounders to receive location and associated depths (OceanScience, 2014). The Z-boat data were correlated to LiDAR data that had been was gathered for this project. The combined data were used to define a continuous terrain and to determine current

sediment volumes within the reservoir.

RESULTS

The range of values derived from the above methods is 0.02 – 0.76 acre-feet per square mile. When considering trap efficiencies, the range is 0.67 – 21.28 acre-feet per year. Table 2 illustrates annual sediment rates calculated in associated tons, including reservoir trap efficiencies for final deposition into Tibble Fork Reservoir. Also included are the 2012 Todea and Hasenyager values with reservoir trap efficiencies.

*Denotes method and how the data were initially captured.
**Denotes that watershed is normalized and interpolated to have consistent units.

The UDWR reservoir study has the largest differences among its dataset. However, the Duck Fork Reservoir does fall within an acceptable range. Of the four dams reported in this study, this dam has the highest elevation above mean seal level. The Iliff Anrus Reservoir location is currently unknown. The mean elevation of the Duck Fork Reservoir is 9,300 feet above

mean sea level. The mean elevation of the Tibble Fork watershed is 8,600 feet. The elevation difference between the Duck Fork and Tibble Fork watersheds is significant enough for the UDWR reservoir study to provide a cursory approximation or provide ranges when conducting sedimentation studies.

Bridges' sediment map provided the best results with the easiest amount of effort. At first glance, this method appears to be a good verification tool. However, as suggested by Bridges (1973), this method should not be used to determine specific yields at specific sites.

Of the Slaymaker (1977) sites, the Rio Nambe in the San de Cristo Mountains provided the best- suited environmental setting range. However, it did not correlate well. Nor did the AGWA SWAT interpolated results. This is due to user unfamiliarity and the variation of values that could be applied within the software. The Rivermorph FlowSed/PowerSed (bedload and suspended sediment) did correlate well.

The known transported bedload to Tibble Fork was computed by HEC-RAS. The number could be nearly half of the 3,624 tons of material that moved through the measured site using RiverMorph FlowSed/PowerSed opposed to what was modeled in HEC-RAS. That is, the HEC-RAS model provides results of 1,403.6 tons that was computed to reach the Tibble Fork pool.

The RHEM numbers did correlate well and estimated high, since only one hillslope face was estimated for the entire watershed. Due to the limited data fields of the program, it is reasonable to believe that with more hillslope entries, the sediment yield may be more accurate. Note that RHEM is not applicable due the tolerance of hillslope lengths being exceeded.

The Z-boat calculations produced an annual sediment deposition rate of 2.92 acre-feet per year. With the trap efficiency of 20 percent, the sediment yield is expected to be 3.63 acre-feet per year.

CONCLUSION

Having actual measurements provided confidence in the modeled results. As previously mentioned, the Bridges map narrowed down values to get a realistic picture of the potential for sediment deposition. The Utah dams could be further analyzed to determine sediment yields and trap efficiencies. The author does not fully endorse the use of AGWA SWAT due to his limited use and knowledge of the software. The potential of using the software to accurately provide sediment yields may be promising.

Although a bathymetric survey was supplied, additional familiarity with sedimentation methods is required to predict future conditions. Data acquisition using historic flows, the stream gages, and SSURGO data are precursors to understanding the sedimentation within the system. As mentioned before, the Todea and Hasenyager bedload study provided insight that data on the rising limb of the hydrograph are the most critical, however, both the falling and rising limbs were considered in the sediment-discharge curves, and this artificially raised the amount of bedload being transported to Tibble Fork. Ideally, all possible sediment would be accounted for. Understanding the process of sedimentation is crucial for dam design, as it has an impact on dam size and the longevity of the structure. The system of averages may be too general, but using many methods may be validated due to the consequences of under- or over-estimating the sediment that is either being delivered or moved through the reservoir.

ACCOUNTING FOR IMPERFECT RESERVOIR OPERATIONS IN THE TRUCKEE RIVER SYSTEM

Caleb Erkman, Project Engineer, Precision Water Resources Engineering, caleb@precisionwre.com; Shane Coors, Principal, Precision Water Resources Engineering, shane@precisionwre.com; Jeff Boyer, TROA Implementation Coordinator, TROA Planning Office, jtboyer@troa.net; Patrick E. Fritchel, P.E., Hydrologic Engineer, TROA Planning Office, pfritchel@uswatermaster.org

Abstract: The Truckee River System in California and Nevada contains seven reservoirs in its upper basin. Under the proposed Truckee River Operating Agreement (TROA), several parties are able to store and use their water supplies in new ways, consistent with their water rights. Prior to TROA and in TROA, all of the water that is impounded in the seven upper Truckee River basin reservoirs is allocated, and thus all storage and releases from reservoirs must be credited or charged to the appropriate account and owner. TROA provides new mechanisms for parties to establish credit waters, exchange water from one reservoir to another, and release water to meet their operational goals.

A RiverWare© model is used to determine the best operation of the reservoirs based on the TROA policy, the goals of the parties and the forecasted inflows to the system. Once operations are executed, the same RiverWare© model is then used to determine the final accounting of water in the system based on the measured release from each reservoir and the measured inflows. These measured outflows will differ from the intended or perfect operation of the system due to operational imperfections/imprecisions, inaccuracies in the forecast, and errors in gaging. It is necessary to account for these various imperfections so that the end-of-day accounting of the system correctly charges all of the water that was released to the appropriate accounts in the respective reservoirs.

An accounting method is under development that fully allocates the flow from each of the reservoirs, releases the desired amount of each party's water and closely matches the requests and availability to establish and exchange water throughout the system. Due to the complex and multi-objective nature of the releases a simple algorithm is not sufficient to provide an acceptable solution. Additional considerations must be taken when considering imperfections on reservoirs in series as opposed to reservoirs in parallel.

An overview of the RiverWare© model, the allocation process for imperfect operations, and an approach to testing the algorithm will be discussed in the following sections.

INTRODUCTION

Truckee River History: Water rights in the Truckee River Basin are well defined and fully appropriated. Original water rights from the Truckee River are mostly vested rights established by historic use for irrigation and power generation between 1861 and 1878. The vested rights were adjudicated between 1913 and 1926 and recorded in the Orr Ditch Decree (ODD), Orr Ditch Decree (1944).

Water management policy to satisfy ODD rights during the dry season and during more extended drought periods is established by the 1935 Truckee River Agreement (TRA), Truckee River Agreement (1935). The TRA provides for a simple-to-manage, supply driven system that specifies required rates of flow at the California/Nevada state line based on month of the year and the water surface level of Lake Tahoe. These specified flows are measured at the Farad Gage near the town of Floriston, California (see FaradGage in Figure 1) and are known as Floriston Rates (FR). The critical FR measurement point is down-stream from all Truckee Basin storage reservoirs. When the FR is met there is adequate water instream to satisfy all ODD water rights. During runoff season, water can be stored if the FR is met. FR storage is later released during the dry season to increase river flows up to the FR.

Water right markets (Nevada's water law that allows water right owners to apply to change manner and place of use) and a lengthy list of court rulings have accommodated the demand-shift for limited water resources from agricultural (Ag) to municipal and industrial (M&I) uses as well as for some newly recognized environmental purposes. However, the market transfers of ownership and use to date, have not been paired with suitable changes in reservoir operating policy. Specifically, M&I drought supplies have not been increased, because the FRs have not changed.

The proposed Truckee River Operating Agreement (TROA), Truckee River Operating Agreement (2008), system for river and reservoir management changes the operating system from one that is supply-driven and relatively simple to manage to one that is much more complex, but better meets separate, modern demands, Wilds (2010). TROA allows some water right owners to hold back a portion of their water right out of FR releases to establish Credit Waters to be released to directly meet their specific scheduled demands. The new TROA system is demand driven, adds many new Credit Water categories and sub-categories, responds to water right owners Scheduling requests and requires a very detailed, complex daily monitoring and accounting approach.

In October 2014, TROA was authorized, which will allow the parties to store and use their water more flexibly with much added complexity. A map of the Truckee River Basin is included in figure 1 for reference.

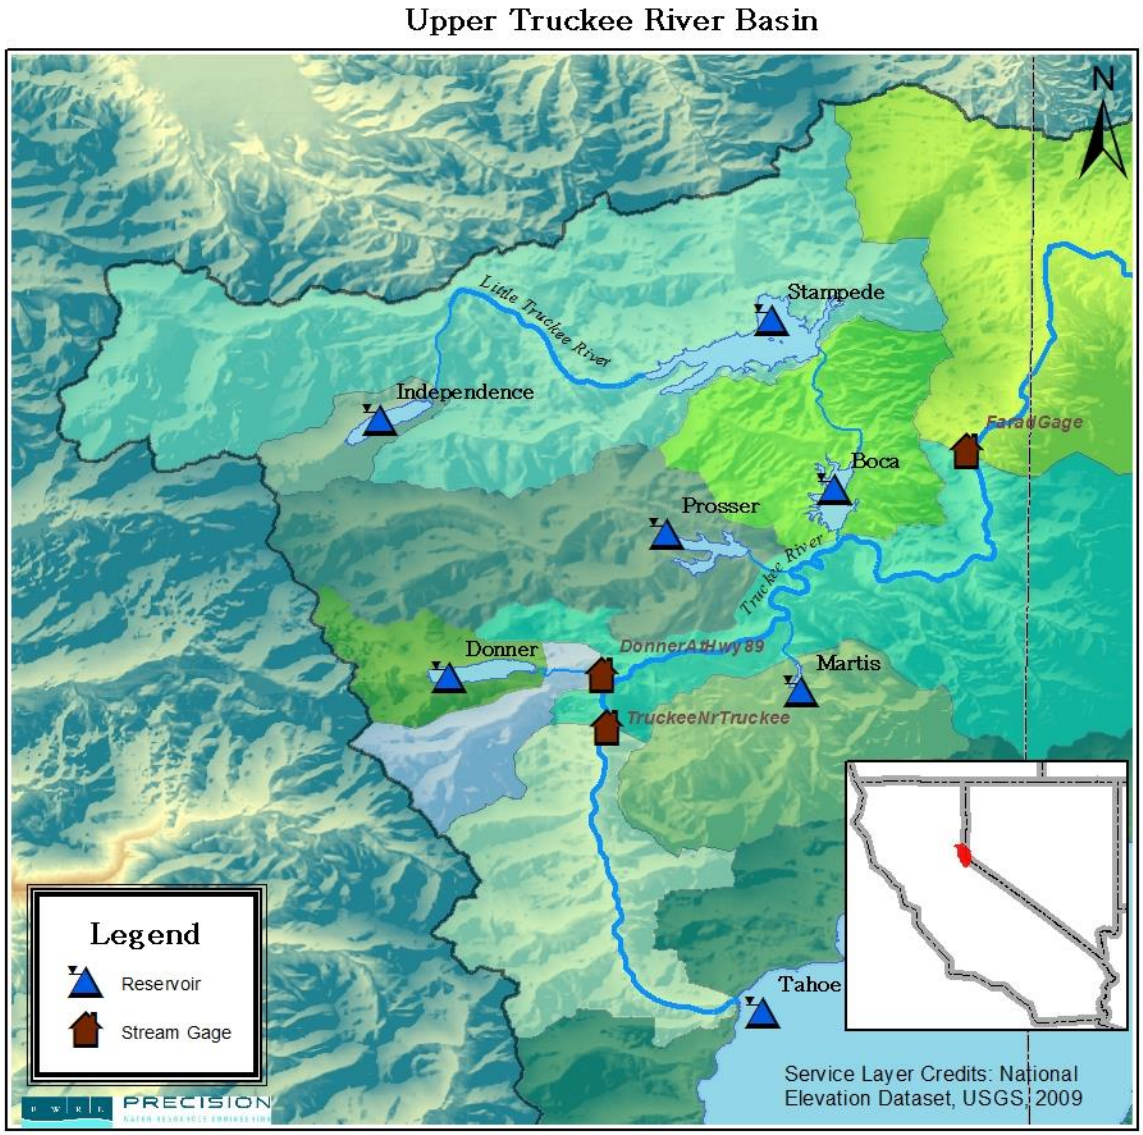

Figure 1 Map of the Truckee River Upper Basin Reservoirs

TROA Policy: TROA allows parties to establish credit water by holding back a portion of the FR release to establish credit water for later use at their scheduled request. A holdback can occur when FR water is being released from a reservoir to meet the Floriston Rate, as shown in the Pre-Holdback condition in Figure 2, the reservoir release is reduced and the amount that was held back is transferred from the FR account on the reservoir to the account of the party requesting the hold back on the reservoir. The net effect is that the outflow of the reservoir is reduced, the storage of a specific category of credit water in the reservoir is increased, credit water is established for Account B, and the storage of FR water in the reservoir is unaffected (i.e., FR Account is reduced by 150 cfs in both cases).

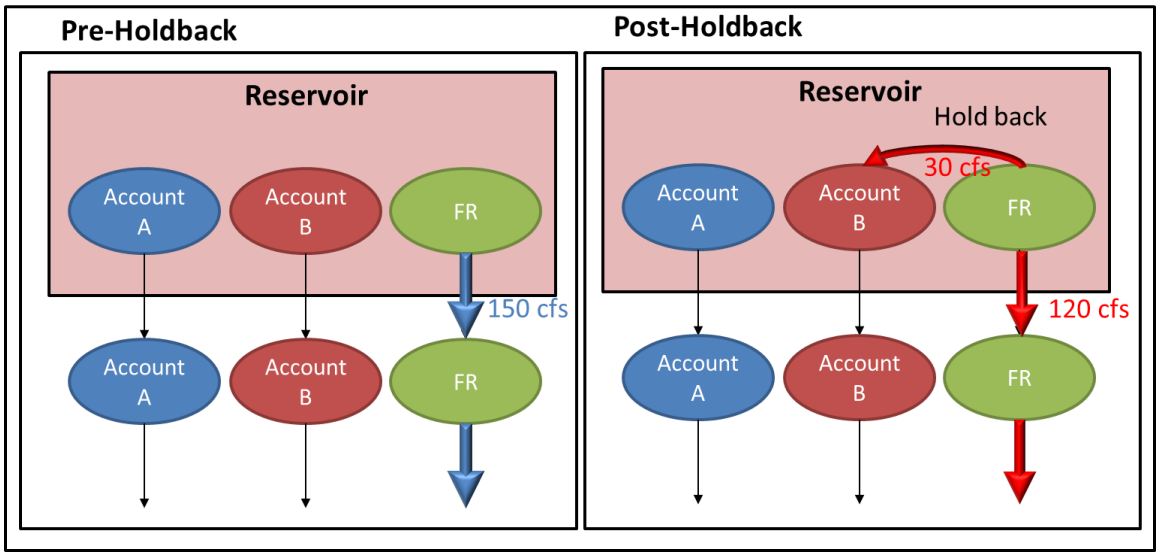

Figure 2 Typical Holdback of a FR Release on a Reservoir.

Once credit water is established TROA provides mechanisms for parties to move water between reservoirs, including trades and exchanges. For a trade, two parties with water in different reservoirs switch the location of an equal amount of water at the mutual consent of each party. If a party would like to move its credit water into a reservoir where a different party is releasing water then there is opportunity for an exchange. This process is best illustrated with the example shown in figure 3. The party that has a demand to release water, the FR Account, would be releasing 150 cfs of demanded water from Reservoir 2 as shown in the Pre-Exchange condition. The party that is moving its water, Account B, releases and transfers 30 cfs of its credit water from Reservoir 1 into the FR Account in the river. This is known as the Borrow as shown on Reservoir 1 in the Post-Exchange condition. Next the party releasing water for a demand (FR Account in Reservoir 2) reduces its release by 30 cfs and transfers 30 cfs of FR water into the account of the party that is moving water (Account B). This is known as the Payback as shown on Reservoir 2 in the Post-Exchange condition. Note that at the confluence below the two reservoirs, the river flow remains unchanged at 150 cfs. These processes give greater flexibility to the parties so that drought sources can be maintained in a secure location. Additionally, this same process can be used to increase streamflows in select reaches of the river to achieve other desirable goals set for recreation and the environment (e.g., rafting, fishing, and riparian habitat).

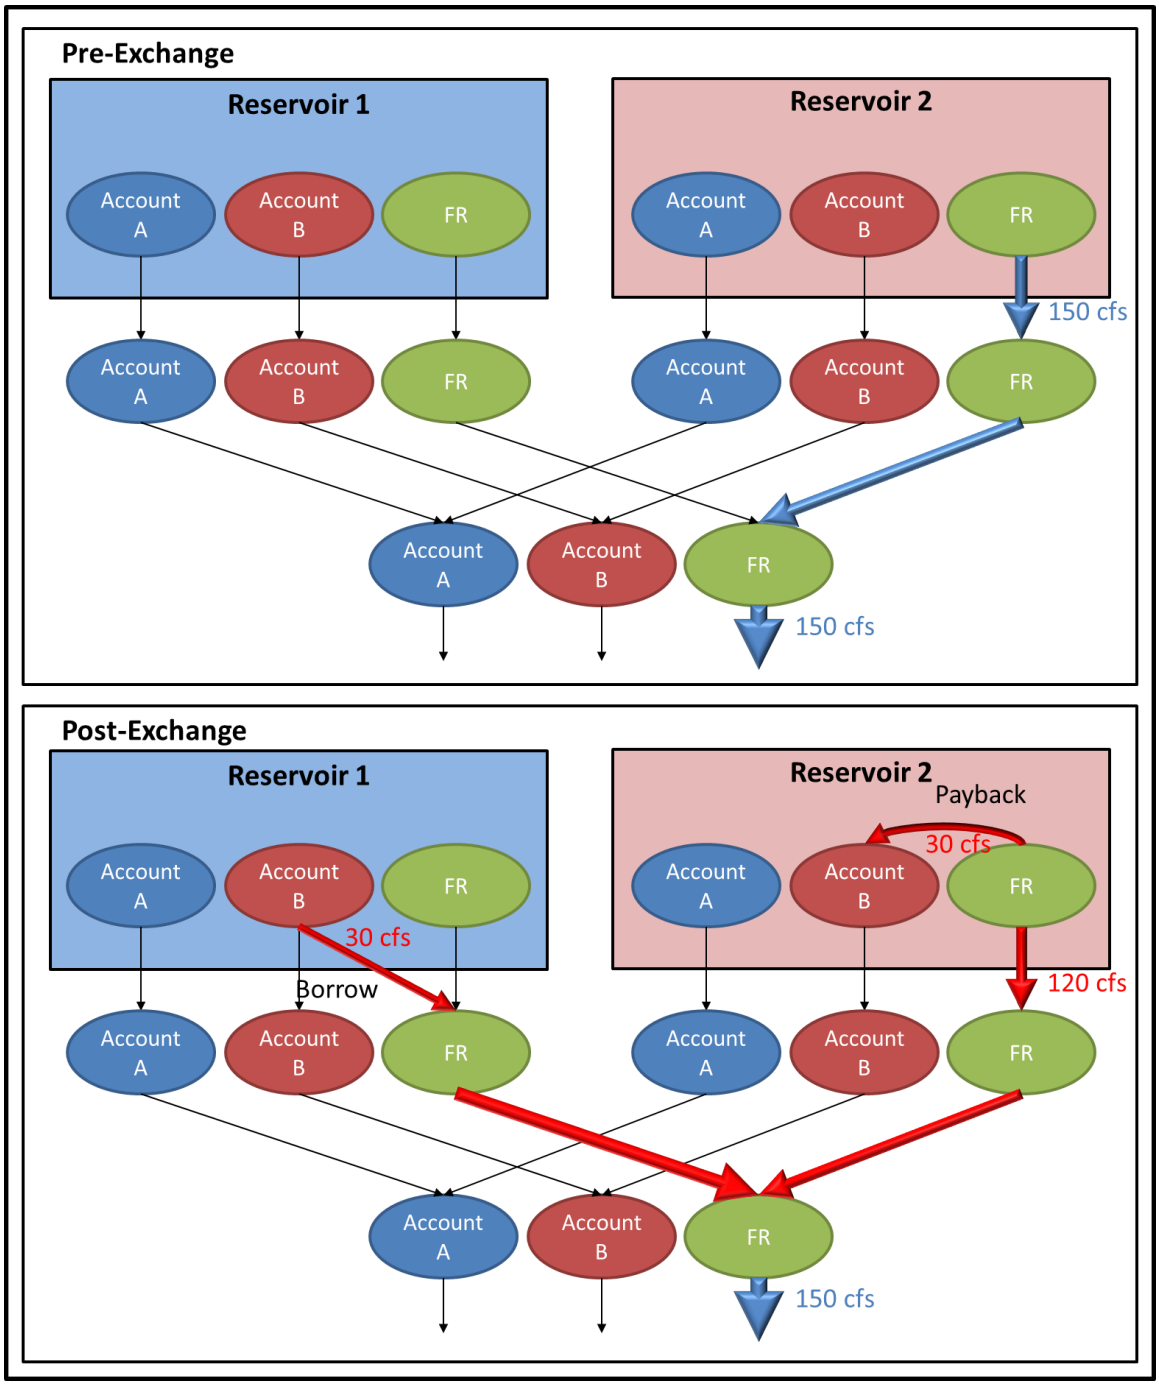

Figure 3 Typical FR exchange between two reservoirs showing the Pre-Exchange condition and the Post-Exchange condition.

Accounting Approach: A RiverWare© model is used to determine the best operation of the reservoirs based on the TROA policy, the goals of the parties and the forecasted inflows to the system. Once operations are executed the same RiverWare© model is then used to determine the final accounting of the system based on the actual release from each reservoir and the measured inflows. These measured outflows will differ from the intended or perfect operation of the system

for several reasons, including but not limited to: operational imperfections/imprecisions, inaccuracies in the forecast, and errors in gaging. It is necessary that the reservoir water accounting reflect these various imperfections so that the end-of-day accounting of the system charges all of the actually released water to the appropriate accounts in the respective reservoirs.

A method was developed to optimize allocations for the releases that fully allocates the flow from each of the reservoirs and releases the desired amount of flow from each party's storage account. Due to the complex and multi-objective nature of the releases, a simple algorithm is not sufficient to provide an acceptable solution. Additional considerations must be taken when considering imperfections on reservoirs in series as opposed to reservoirs in parallel. In the Truckee River system there are both reservoirs in series and reservoirs in parallel. To meet these objectives, a three step approach to reconciling imperfect accounting has been developed:

1. Determine Farad Process Allocation
2. Determine Main Truckee Reservoir Process Allocations
3. Determine Little Truckee Reservoir Process Allocations

Processes, as referred to in this paper, include the release, storage, establishment, or exchange of a specific category of water (e.g., M&I Credit Water Establishment). The three step approach is discussed in the following sections.

DETERMINE FARAD PROCESS ALLOCATION

In priority based systems such as the Truckee River Basin, it is desirable that the senior water rights be afforded higher protection than junior water rights. This is the practice when setting operations and it is desirable to approach accounting in a similar way such that the priority order is honored. With this approach we can use the imperfections as a way to perfect operations for the higher priority waters and their associated processes. Imperfections in the operations would be distributed to the lower priority waters. The advantage of a priority based system is that in most cases all processes achieve the desired allocation except for the lower priority process(es). A lower priority process, or floater, reconciles the imperfections to balance all or part of the system. By starting from the bottom of the system and working our way up we can use flexibility within the location of process releases to achieve the system goals. Setting a valid Farad allocation is the first step to ensure the success of the later steps in the imperfect operations accounting algorithm.

MAIN TRUCKEE ALLOCATION

Once the Farad allocation is set, the process allocation for the parallel reservoirs can be completed. These reservoirs include: Tahoe, Donner, Prosser, Martis, and the Little Truckee (LT) as shown in Figure 1. Because Boca is the outlet of the Little Truckee River and its release includes releases from Boca, Stampede and Independence, we will consider these three series reservoirs as a single reservoir, referred to as the LT, in this step.

This process has several goals:

1. Fully allocate the outflow of each reservoir.

2. The sum of the allocations on all main Truckee reservoirs for each process should match the Farad allocation for the respective process.
3. The allocation for each process on each reservoir should be as close as possible to the perfect operation.

The following loops outline the method that was found to give the best results in achieving the goals specified above, see Figure 4 for a flowchart that diagrams the steps below. These steps are meant to summarize the algorithm that has been developed and are therefore not comprehensive.

1. Loop over processes in order of increasing number of reservoirs involved (this is the loop in the upper left corner of Figure 4).
2. For each process, loop over the reservoirs that are releasing that process (this is the loop in the lower right corner of Figure 4). Each reservoir will fall into one of three categories (a-c) and will be allocated as specified below and in the respective part of Figure 4.
    a. If the current process is the floater process for the current reservoir, then set the reservoir process allocation to reconcile the reservoir while honoring the necessary limits and tolerances
    b. If the current reservoir is the last reservoir on the process list, reconcile the process while honoring the necessary limits and tolerances
    c. For all other cases allocate the theoretical perfect process allocation while honoring the necessary limits and tolerances.

The last allocation will reconcile the last process and the last reservoir at the same time, giving a reconciled system. This works because the sum of the Farad allocation for all processes is equal to the sum of the actual releases from the Main Truckee reservoirs.

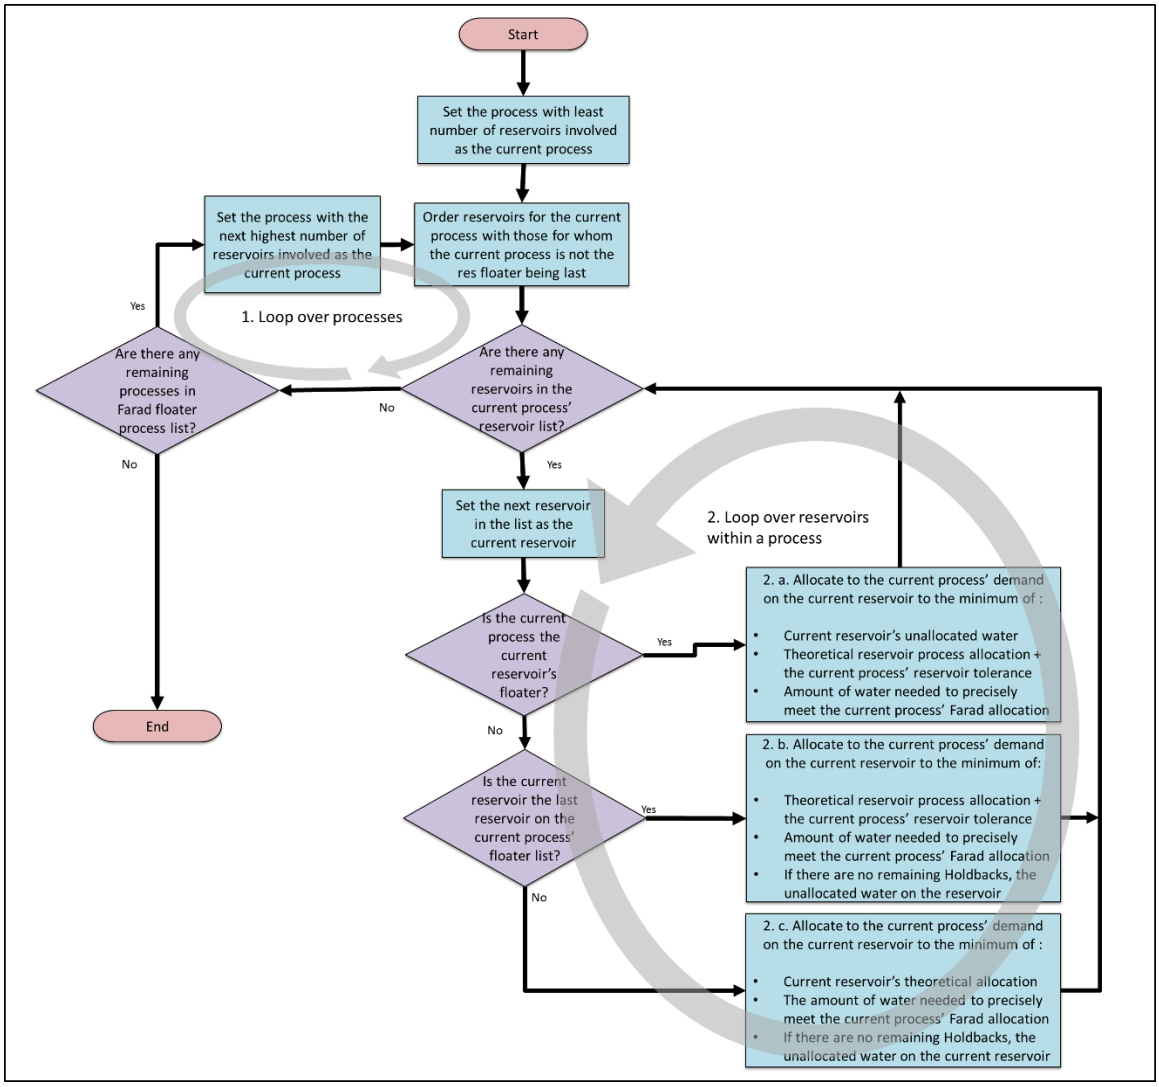

Figure 4 Flow chart for setting process allocations for the Main Truckee reservoirs**.**

LITTLE TRUCKEE ALLOCATION

Once the Main Truckee reservoirs are reconciled, the allocations for the LT aggregate reservoir can now be disaggregated into allocations for the three series reservoirs: Boca, Stampede and Independence.

Here, the remaining flow on a reservoir is difficult to determine until the flow from the upstream reservoir(s) are accounted for. Part of the release from a reservoir may be water being passed through from an upstream reservoir's release, and some of it may be a release from that reservoir. Another complication is that an upstream reservoir may release water with the intention of restoring it in a downstream reservoir. Considering these complications, it was determined that the best approach was to apportion releases to meet the LT allocation for each process letting the most downstream reservoir with each process float, if possible. Once this step is completed and the LT allocations set in the previous step are met, a check is made if the sum of the releases from

the reservoir and pass-through releases from upstream reservoir(s) is greater than the reservoir outflow. When this occurs it is necessary to re-label a process release on an upstream reservoir to a more downstream reservoir, if possible. If this is not a viable solution, an exchange can be created that moves credit water storage to a more upstream reservoir. The type of water moved is at the discretion of the TROA Administrator and may be used to meet standing requests of the parties. This allows reconciliation of the system even in dire scenarios. When the sum of the releases from storage for a reservoir and all pass-through releases from upstream reservoirs is less than the measured outflow from that reservoir, the remainder is labeled as a release to be restored in the next downstream reservoir. The account that is restored is prioritized based on the Administrator's discretion, and may meet a standing request of a party.

SYSTEM RELIABILITY AND TESTING

Because TROA has not been implemented, there is no measured data available to test the algorithm. Therefore, it is necessary to manufacture realistic synthetic data for testing purposes. Thorough testing of the algorithm discussed previously will provide for a smoother transition into administrating TROA when implementation begins.

In order to facilitate reasonable testing it is important that data be randomized to simulate the imperfections that will occur primarily from imprecise reservoir releases and imperfect knowledge of the system inflows. If data is randomized for too long of a period at once the perfect operation will diverge from the randomized operation due to changes in storage in the reservoirs. To avoid this and best simulate the day-to-day practice of setting releases and performing accounting of the measured flows the following day, it is important that the flows be randomized for each day and the operation for the next day be set based off of the storage from the accounting of the previous day's imperfect operations. This is done by coupling the RiverWare© operations and accounting model with a spreadsheet that randomizes the system flows and reservoir levels one day at a time. This process must be completed for each day in a water year which makes it a prime candidate for automation. To do this a RiverWare© batch mode script was written that simulates one day of reservoir operations based off of a forecast. The system operation is then sent to a spreadsheet via a RiverWare© Data Management Interface (DMI), where the reservoir outflows and system inflows are randomized. These randomized flows are then inputted to the RiverWare© model via another DMI as if they were measured in the field. The RiverWare© model is then run again and the newly randomized flows are accounted for using the accounting algorithm. The RiverWare© model then performs the best operation based off the supplied forecast and the process is repeated. This method allows for testing of a year of operations and accounting using the imperfect operations model by running a script overnight. In this way the RiverWare© accounting model can be tested for many hypothetical years with varying initialization and hydrological conditions. By analyzing the results of the hypothetical accounting years the accounting algorithm can be improved to address a wide variety of potentially difficult scenarios. This testing and development routine should provide a smoother transition once TROA is implemented.

PROVISIONS FOR NON-STANDARD OPERATIONS

Although it is desired to approach reservoir accounting in a systematic way it is understood that many obscure scenarios may occur where the systematic approach is insufficient to reconcile the

system. These scenarios may occur for a variety of reasons including maintenance, extreme natural phenomena, experimental reservoir operations, etc. Since many of these events are one time occurrence it is desired to have a method to complete the reservoir release accounting manually instead of developing special provisions in the RiverWare© accounting algorithm for these extra-ordinary scenarios. With this goal in mind, a method to review the daily results of the accounting algorithm was developed which provides the necessary information for the TROA Administrator to manually set the reservoir release allocation when deemed necessary.

SUMMARY

Considering the complexity that TROA introduces into Truckee River operations, it is necessary for the TROA Administrator to have a reliable and systematic method to perform the final reservoir accounting of the measured releases from the reservoirs. A three step priority based algorithm has been developed to perform the reservoir release accounting. These steps include:

1. Determine Farad Process Allocation,
2. Determine Main Truckee Reservoir Process Allocations, and
3. Determine Little Truckee Reservoir Process Allocations.

In order to provide a smooth transition into administering TROA, a method to generate realistic synthetic reservoir operations has been developed to test the reliability of the accounting algorithm.

Abstract: The Knife River is a tributary to Lake Superior in northern Minnesota draining 56,000 acres of mostly forested and wetland areas with minimal development. The river is home to the North Shore's only wild Steelhead population and is the only tributary with no barriers to upstream migration. Although development is minimal, the morphologically active and flashy nature of the watershed results in large sediment loads which impact the harbor downstream, aquatic invertebrate habitat, the trout fishery, and contribute large quantities of sediment to Lake Superior. Because of the morphologically active nature of the watershed, the river is sensitive to engineering modifications and large structural solutions may be ineffective. This places an emphasis for watershed management on understanding the sensitive hydrologic nature of the system and careful land use decisions. Our study took a multi-disciplinary approach focused on gaining an understanding of the watershed system by looking at causes, linkages, and relative contributions of different channel modifications and landuse changes within the watershed on sediment and hydrologic dynamics. We used a combination of desktop analyses, geomorphic assessments, modeling (river hydraulics, watershed modeling, and snowpack ripening), regional analyses, and sensitivity scenarios to understand relative importance of different drivers of the hydrologic system. As part of a sensitivity assessment, we examined the impacts of different forestry practices, beaver dam management, and conversion of wetlands. Our study identified areas within the watershed that that may be sensitive to land use conversion or logging. In addition, we provided a summary of how beaver dam activity and management might impact hydrology and aquatic habitats, how changes in landuse might change snowmelt characteristics, and how changes in climate patterns (snowpack dynamics and rainfall intensity) might change sediment loading patterns. With this multi-disciplinary approach, we were able to provide an overview framework for proactive watershed management in a complex and morphologically active system by understanding relative importance of many facets of the watershed hydrology.

INTRODUCTION

Watershed management for reduction of sediment loads often focuses on sediment loading from soil erosion; however, in watersheds with numerous natural and anthropogenic forces driving sediment loads, this approach may be inadequate. In systems that are geologically young and morphologically active, rivers are especially sensitive to engineering modifications and hard engineering solutions may fail. This places an emphasis for watershed management on a big-picture understanding of the sensitivity of morphologic drivers and relative contribution to

sediment load and erosion in order to make effective management and engineering decisions at the watershed scale.

The Knife River (Figure 1), a tributary to Lake Superior in northern Minnesota, is a prime example of a watershed with a very large sediment load causing impairments to aquatic life, yet land use change and development are minimal within the watershed. The watershed drains 56,000 acres of mostly forested and wetland areas (Figure 2). The river is home to the North Shore's only wild Steelhead (*Oncorhynchus mykiss*) population, and it is the only tributary with no barriers to upstream migration. Post-glacial rebound results in morphologically-active valleys in this region, and the naturally flashy nature of the watersheds creates large sediment loads which impact harbors and estuaries downstream, degrade aquatic invertebrate habitat and the trout fishery, and which contribute large quantities of sediment to Lake Superior (Riedel, et al, 2005).

Figure 1 Knife River under high flow conditions carrying large sediment load

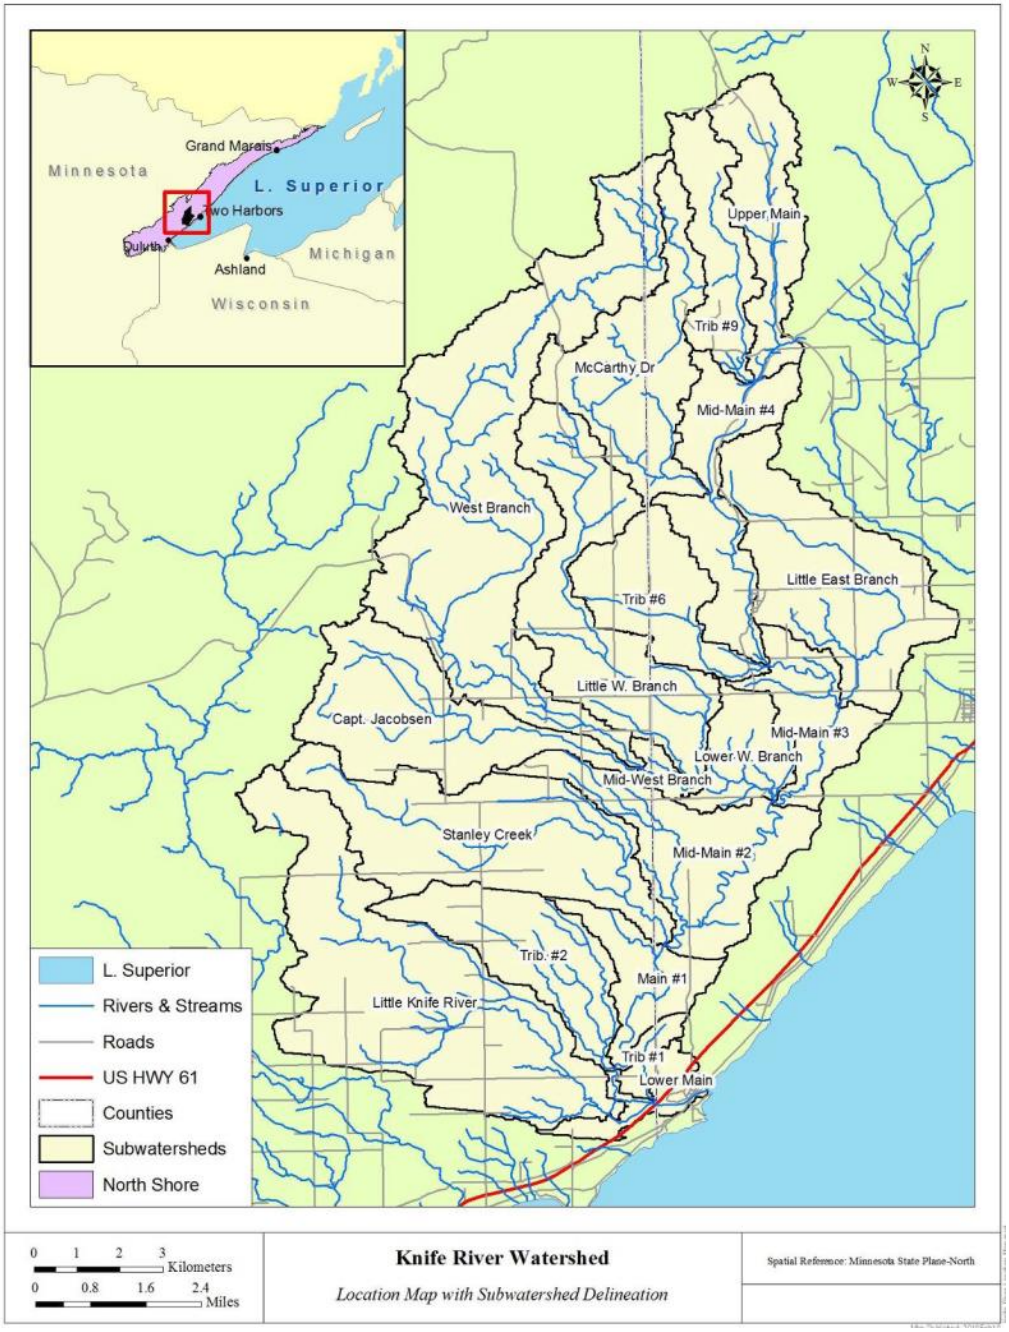

Figure 2 Knife River watershed location

While lacustrine clay and clay-dominated tills in the area under natural land cover are generally resistant to erosion (NRCS, 1998), activities within the watershed that expose soils or disturb banks can increase runoff resulting in fluvial erosion and destabilized channels (Riedel et al., 2005; Riedel et al., 2002). Our study took a multi-disciplinary approach focused on gaining an understanding of the Knife River watershed system by examining causes, linkages, and relative contributions of different channel modifications and land use changes within the watershed to hydrology and sediment loads. The knowledge gained from this multi-disciplinary approach can be used to support effective decision-making for watershed managers.

METHODOLOGY

We used a combination of desktop analyses, modeling, and sensitivity scenarios to determine the relative importance of different drivers of hydrology and sediment loading in the Knife River watershed. Four major factors driving sediment load in the watershed were examined by this study:

- Watershed physiography (climate, geology, soils, terrain, river network characteristics)
- Beaver *(Castor canadensis*) activity
- Watershed land use and disturbance
- Sediment loading relationship to hydrology

Literature and Data Review: The first step in the approach was to review available studies and data. This review included existing reports and studies as well as interviews with local and state resource managers. Data gathered for the study area included historic flow and sediment data as well as geospatial data to support desktop analyses and modeling (MPCA, 2009). Spatial data to support the study included elevation, landcover, soil, geology, canopy, and detailed wetland coverage. In addition, a comprehensive review of literature on beaver activity was conducted to understand how land use changes have resulted in dramatic changes in beaver habitat and resultant populations, density, and behavior (USDA, 2002).

Desktop analyses: The datasets collected during the literature and data review were used to complete desktop analyses to give further insight into the hydrology and morphology of the watershed. Elevation datasets were used to calculate fluvial power and pinpoint areas that may be susceptible to higher levels of erosion and mass wasting. These datasets were also used to develop longitudinal profiles of all streams within the watershed to identify potential areas of head-cut migration or river valley evolution associated with natural or anthropogenic causes.

Historic flow and sediment records from the USGS gage near the mouth of the river were reviewed to examine flow frequency, flashiness, seasonality, and historical changes in flow. Understanding the magnitude and frequency of both flood and low-flow events in the watershed from a historic perspective and existing conditions is key to understanding sediment loading patterns and the relative impact of land use changes on hydrology.

Modeling: A suite of hydrologic, hydraulic, and snowpack models were developed to understand existing conditions in the watershed and to support scenario analyses for different land management decisions. The modeling builds upon the analyses done in the literature and data review both for providing input data and context for what scenarios to assess for sensitivity analysis and management scenarios.

Beaver activity in the watershed has increased dramatically since pre-settlement conditions due to reductions in trapping (Butler and Malanson, 2005). Dam-building activity creates a step-pool structure in tributaries which disconnects riverine habitat for fish and changes thermal regime (Pollock et al., 2003), and may cause floods from cascading failures (Butler and Malanson, 2005). A 1-D HEC-RAS model of a representative reach in the watershed was developed to simulate the impacts of a variety of beaver-dam densities on the river. Pre-settlement dam density in this area was 3.0 dams/mile (Winchell and Upham, 1884), while current conditions are

much higher at 10.6 dams/mile (Verry, 2005). Results showed step-pool structures caused by high-density beaver activity with cascading dam failures under flood conditions (Figure 3).

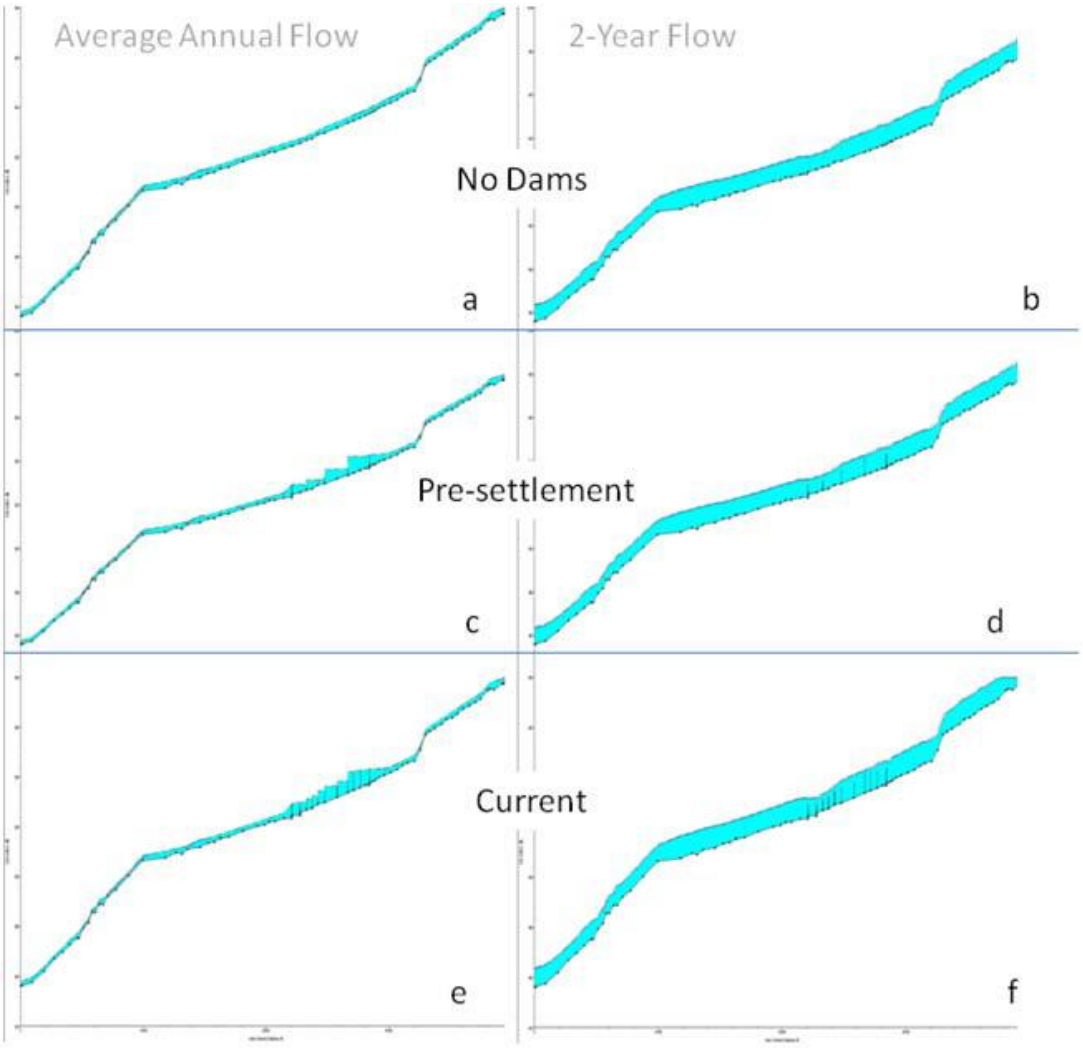

Figure 3 Beaver dam hydraulic modeling results. Beaver dams were represented under each scenario for typical spacing and density as reported in literature.

A watershed hydrology model was developed using HSPF (Hydrological Simulation Program – Fortran) to model existing conditions and simulate the hydrologic impact of potential land use changes. Several scenarios were simulated including pre-settlement conditions, various timber harvesting practices, forest restoration, and wetlands conversion. Results showed the watershed hydrology was most sensitive to conversion of wetlands relative to other land management scenarios. Wetlands play a key role in hydrologic response in the watershed, especially given the naturally low infiltration capacity of the clay soils in the watershed. Results of the existing conditions hydrology mode,l as well as the scenario applications, supported identification of areas susceptible to erosion under existing conditions as well as subwatersheds that may be sensitive to various land use changes in the future. An example of the sensitivity ranking results is shown in Figure 4.

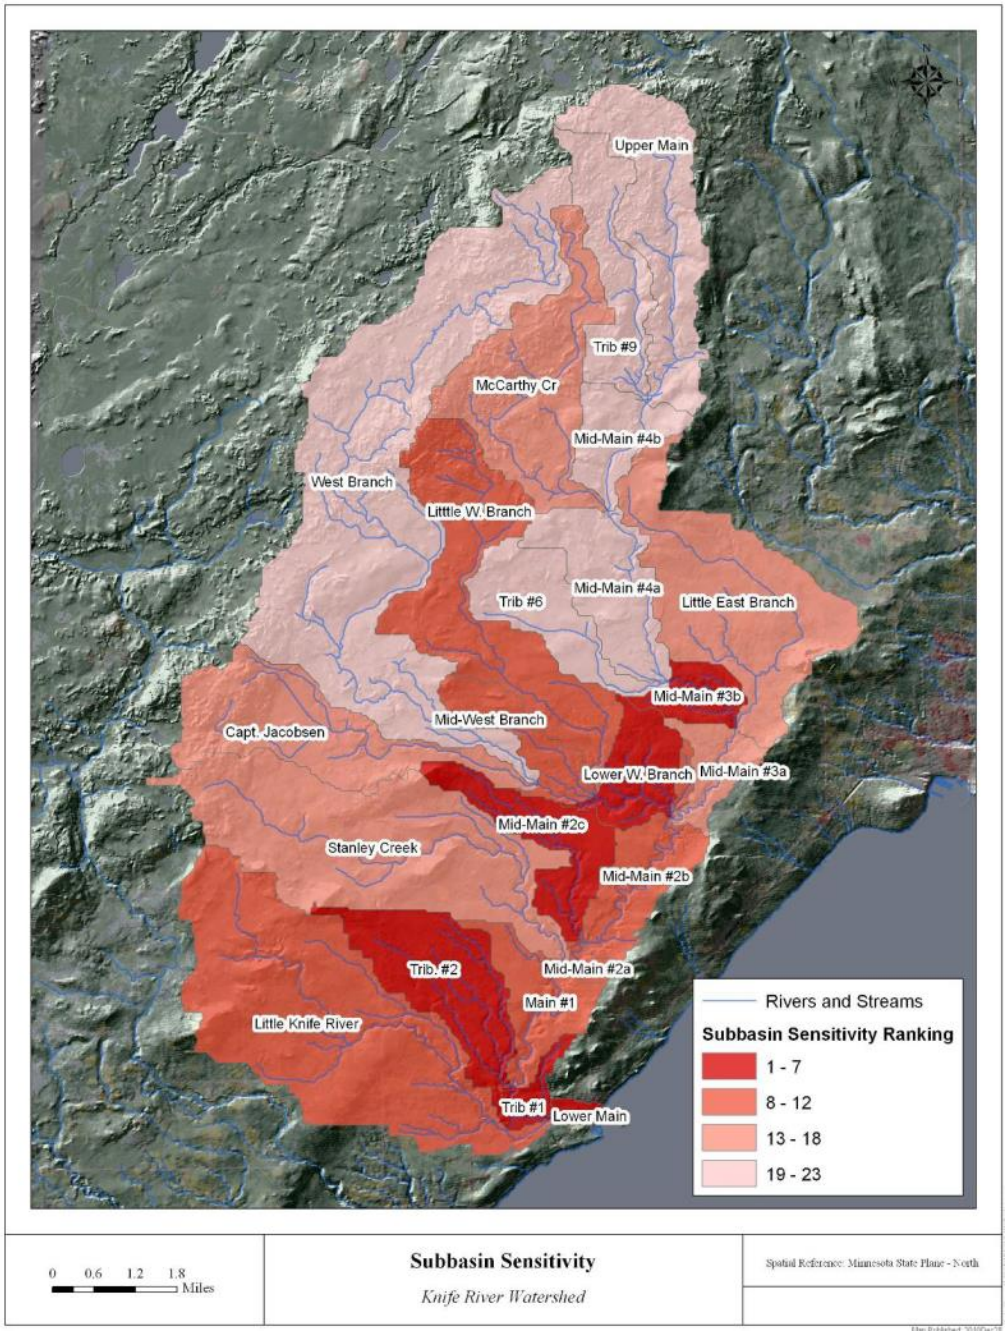

Figure 4 Example subbasin sensitive ranking

The snowmelt period plays a very important role in the hydrology of the watershed as 50 % of the runoff near the mouth occurs from mid-March through the end of May. Logging in the Midwest has been shown to have a potentially large impact on water yield and peak runoff during spring melt (Verry et al., 1983; Verry, 1986). Because of the relative importance of the melt runoff, a mechanistic snowpack model was developed to simulate the potential impacts of various land management practices on snowpack development and the corresponding melt. The HSPF model was also examined in detail during this period under several scenarios to compare results to the snowpack model.

Sediment budget analysis: Finally, a sediment budget analysis was conducted to develop a range of estimates for sediment yield for the watershed (Riedel et al., 2008). This included a variety of regional studies as well as detailed review of sediment data collected at the USGS gage. Estimates of sediment loads using a simple relationship between discharge and suspended sediment concentration fell within the expected range for yields for this region (Figure 5). The analyses indicated a strong positive relationship between discharge and sediment concentration. This observation is key in interpreting hydrologic and hydraulic analyses in relation to sediment load in the basin. Despite being predominantly forested and having extensive wetlands in its headwaters, the Knife River exhibited sediment yield results similar to watersheds with extensive agricultural land use conversion. This is because the geologic setting in this region is much more vulnerable to land disturbance and changes in climate compared to more geologically mature and evolved watersheds (Riedel et al., 2002).

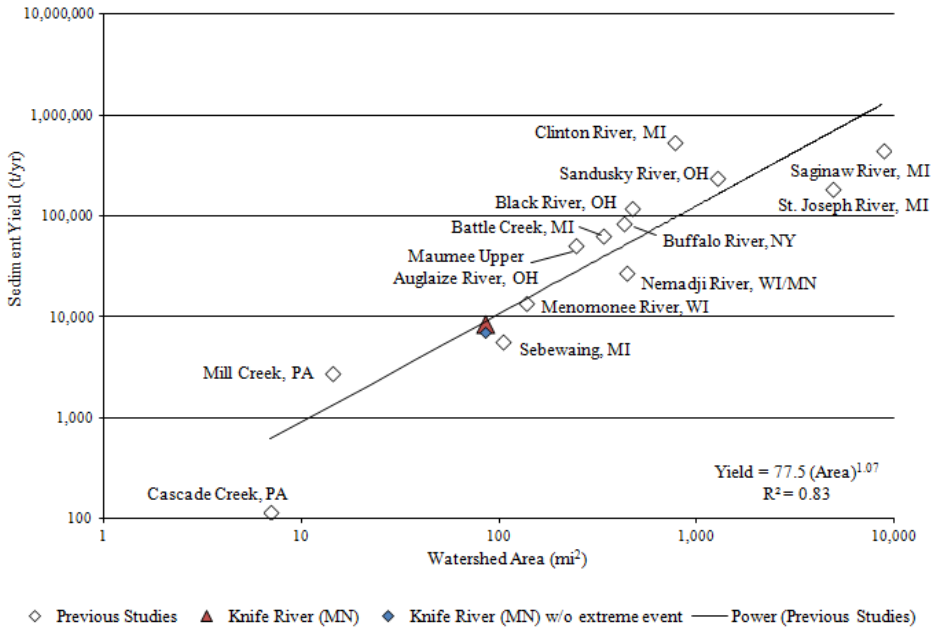

Figure 5 Regional sediment yields based on watershed area from other Great Lakes studies

Review of literature indicated that bank erosion and valley wall failure play a significant role in sediment loading in the watershed (Nieber et al., 2008). Using sediment data collected by the USGS in conjunction with local metrological data, multiple linear regression analysis was used to identify potential key weather drivers for large sediment loads. Results indicated that an interaction between rainfall intensity and cumulative rainfall (resulting in saturated soils) plays a significant role in watershed loading as well. Changes in rainfall patterns for the region may result in changes in sediment loads based on this analysis.

CONCLUSIONS

In a watershed where anthropogenic forces may not be the principal driver of sediment loads, understanding the existing conditions and sensitivity of the basin to different management practices is critical for watershed managers. Because of the morphologically active nature of the watershed and the river valleys due to post-glacial rebound, the sediment load is more sensitive

to changes in land use and changes in climate patterns than more mature watersheds. By taking a multi-disciplinary approach in the Knife River watershed, we were able to identify potentially sensitive regions within the watershed, assess the potential impact of various land management practices, provide a summary of the general impact of beaver dam activity and management, and examine how potential changes in climate patterns (snowpack and rainfall) might change sediment loading patterns. With this approach, we provide a framework for proactive watershed management in a complex and morphologically active system by understanding relative importance of many facets of the watershed hydrology.

ACKNOWLEDGEMENTS

This work was possible thanks to the funding provided by the Great Lakes Tributary Modeling Program – Section 516(e) of the Water Resources Development Act and the assistance of the stakeholder groups of the Knife River watershed.

MIDDLE MISSISSIPPI RIVER SEDIMENTATION ANALYSIS AT TRIBUTARY JUNCTIONS

Lisa C. Andes, Graduate Research Assistant; Parks College of Engineering, Aviation and Technology, Saint Louis University, St. Louis, MO, andes@slu.edu; Amanda L. Cox, Assistant Professor, Parks College of Engineering, Aviation and Technology, Saint Louis University, St. Louis, MO, coxal@slu.edu

INTRODUCTION

The Mississippi River System (MRS) has a cumulative length of 6100 miles and connects 17 inland rivers. In 2012, MRS transported 1,402 million short tons of cargo through over 100 inland ports primarily through vessel traffic on federally-authorized navigation channels (U.S. Army Corps of Engineers (USACE), 2013). The Middle Mississippi River (MMR) is an integral piece of the MRS, beginning at the confluence of the Ohio River near Cario, IL and extending 300 miles upstream to just below Lock and Dam 22 as shown in Figure 1 (USACE, 2015).

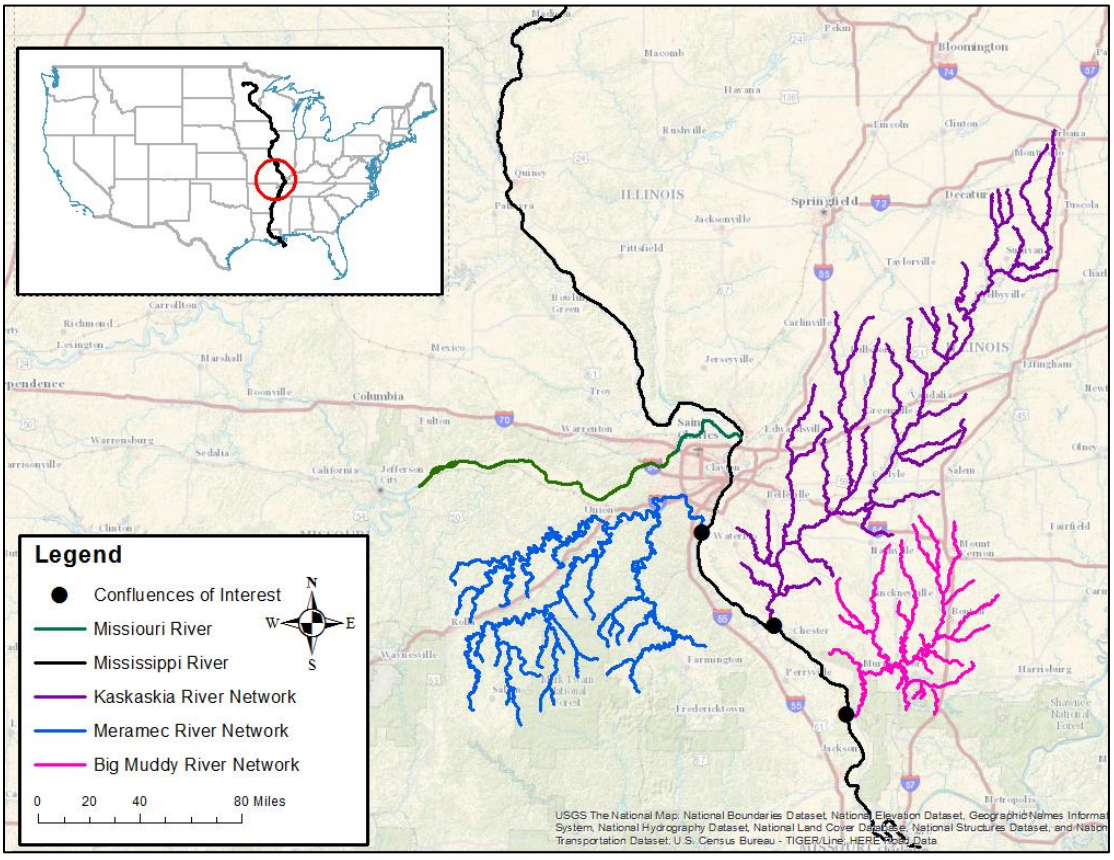

Figure 1 Middle Mississippi River study area

The MMR reach of the MRS marks a change in river management at the confluence of the Missouri River, where the Mississippi River transitions from an open river downstream to a slack-water navigation system upstream that continues through the Upper Mississippi River

(UMR). A slack-water navigation system requires construction of a series of Locks and Dams that create navigable pools to maintain channel depth. These operations may require routine maintenance dredging. The open river portion of the MMR maintains safe channel depths through routine maintenance dredging. Some characteristic descriptors of the open river portion of the MMR are crescent-shaped point bars, an atypically uniform width, and low to moderate sinuosity (Brauer et al., 2005).

Pinter et al. (2004) reviewed reported dredge volumes per river mile between 1964 and 1997, a 34-year record, of the UMR and MMR and noted that the open portion of the river had persistent sedimentation at tributary junctions. The MMR has four river confluences in the open channel reach, namely the Big Muddy River (BMR) confluence, Kaskaskia River (KR) confluence, Meramec River (MER) confluence, and Missouri River (MOR) confluence. Sedimentation rates and patterns described by Pinter et al. (2004) are briefly summarized here. Cumulative dredge volume near the BMR junction was 4.6 million cubic yards (mcy). Sedimentation occurred over a 3.1-mile reach of the MMR just downstream of the tributary junction. Dredge volumes and shoal formation size were along the downstream reach of the KR and not explicitly noted in the study; however, they were described as being a larger volume than both the MER and BMR. Pinter et al. (2004) also noted that sediment discharge from the KR is declining due to upstream Lock and Dam structures. Dredge volumes reported at MER totaled 4.8 mcy, occurring over a 4.1-mile distance of the MMR downstream of the junction. Dredge volumes reported at the MOR were an order of magnitude smaller (0.8 mcy covering 1.3 miles downstream of the junction). Pinter et al. (2004) speculated that the reduced sedimentation at the MOR was attributed to the upstream river training structures that may trap sediment. Due to the lack of similarity between MOR and BMR, KR and MER, the MOR was not included as part of this study.

The spatial distribution of cumulative dredge volumes per river mile provides essential insight into morphologic features of the MMR that continue to promote recurrent sedimentation and required routine maintenance to sustain navigable waters. An in-depth analysis of the temporal and spatial variability of these shoals as a function of the local hydraulic and sediment dynamics is needed to provide insight and yield innovative solutions to improve current dredge practices. Understanding the variability and physical mechanisms behind shoal development is a key step in developing science-based strategies that reduce routine dredge maintenance volumes.

There are two primary objectives of this study: (1) describe the temporal and spatial evolution of shoal formations downstream of tributary junctions using a collection of continuous hydrographic surveys of the navigation channel, and (2) examine the relationship between the morphologic evolution and variation in bulk hydrodynamic parameters.

CLASSICAL MODEL OF TRIBUTARY JUNCTION MORPHOLOGY

The classic morphologic model of asymmetric channel confluences has three main components: tributary mouth bars, a scour hole, and a sediment bar formed downstream of the junction (Best, 1986) (Figure 2). The tributary mouth bars develop at the entrance of one or both tributaries into the confluence. Tributary bars form primarily through bed load transport from the tributaries to the junction, and prograde and recede as a function of relative discharge of the tributaries (Biron,

1996). Presence of only one tributary bar is commonly observed when discharge from the main stream of the junction is highly dominant, typically due to a depth differential, i.e. discordant bed geometry, between both tributary mouths (Ashmore et al., 1983; Kennedy, 1984).

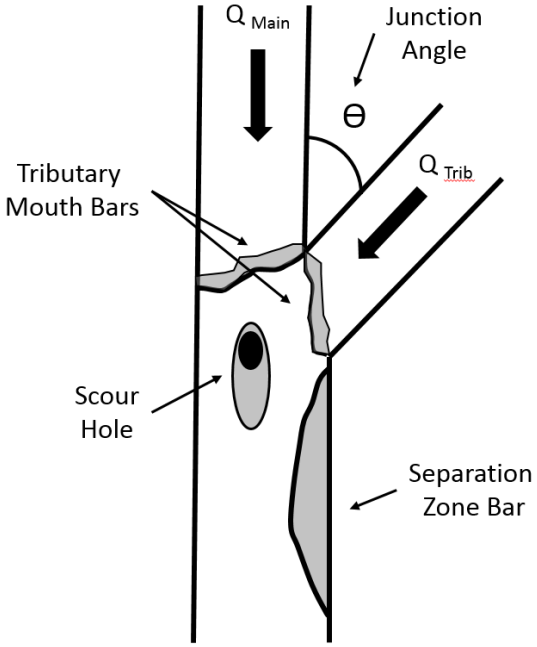

Figure 2 Asymmetrical confluence schematic

Scour holes form slightly downstream of the junction apex and typically bisect the junction angle where the two flows converge and there is downward directed momentum and increased turbulent kinetic energy from secondary circulation (Best, 1986; Rhoads and Kenworthy, 1998). Position of the scour hole can be inferred visually from the observed position of surficial flow convergence (Rhoads et al., 2009). However, in discordant systems such as the confluences of the MER, KR and BMR, scour hole morphology maybe not be easily observed (Biron et al., 1996; Biron et al., 1993; Bristow et al.,1993). One mechanism that could lead to the absence of a scour hole is a prograding tributary bar that has aggraded over the scour hole and essentially buried the hole.

A bank-attached sediment bar formation downstream of a tributary junction is often due to flow separation of the converging tributary flow around the downstream confluence junction. The confluence angle and its degree of confluence symmetry dictate the size and position of the downstream bar (Best, 1986). Confluence symmetry is defined by the confluence planform, where symmetric confluences are more "Y" shaped and asymmetrical confluences occur when the tributary channel joins the flow path of the main channel as shown in Figure 2 (Mosely, 1976). The bank-attached bar forms at the downstream junction corner of the tributary due to flow separation and is composed of fine sediment primarily from the tributary drainage network (Best, 1984; Best, 1986; Bristow et al., 1993). Bank-attached separation-zone bars increase in size when discharge of the tributary channel is comparable or greater than discharge of the main channel through creation a large low-flow, depositional zone and have the potential to deflect

flow from the main channel around the bar due to flow constriction around the bar (Best, 1986; Kenworth and Rhoads, 1995).

The tributary mouth bars, scour hole, and bank-attached tributary bar are dynamic in nature and migrate as a function of planform symmetry, junction angle (Figure 2), depth ratio, discharge ratio, and momentum flux ratio described in Equation 1 through Equation 3,

$$D_r = \frac{D_{Trib}}{D_{Main}} \tag{1}$$

$$Q_r = \frac{Q_{Trib}}{Q_{Main}} \tag{2}$$

$$M_r = \frac{\rho_{Trib} Q_{Trib} v_{Trib}}{\rho_{Trib} Q_{Trib} v_{Trib}} \tag{3}$$

where D_r is the dimensionless depth ratio; D_{main} and D_{trib} are the mean cross-sectional depths of the main and tributary channels [L]; Q_{main} and Q_{trib} are the discharges of the main and tributary channels [L^3T^{-1}]; ρ_{main} and ρ_{trib} are the density of the main and tributary channels [ML^{-3}]; and v_{main} and v_{trib} are the mean cross-sectional velocities of the main and tributary channels [LT^{-1}].

PRELIMINARY RESULTS AND SUMMARY

This study investigates the spatial and temporal variability of sedimentation downstream of the MER, KR and BMR confluences of the MMR. Preliminary results of sedimentation on the MMR downstream of the KR confluence are described in the following section. It is the intent of this effort to analyze a detailed record of hydrographic survey data for the BMR, KR, and MER to identify sedimentation near their confluences with the MMR. These efforts will be summarized in detail during the presentation. The presentation will also include an analysis of bulk hydraulic parameters in efforts to quantify the physical processes that yield sedimentation in these regions.

Preliminary Results – Kaskaskia River Confluence: The Kaskaskia River junction occurs at River Mile 161 along the MMR (Figure 1). Figure 3 compares a before and after dredge survey taken at the confluence (USACE, 2015). Both surveys were collected the USACE, Saint Louis District. Before-Dredge (BD) surveys are often conducted in regions that typically have recurrent sedimentation and are likely to require routine dredging to maintain navigation. The BD survey presented in Figure 3 was conducted on 5 August 2014. Qualitatively from the BD survey there appears to be notable sedimentation at two locations: (1) on the left bank (looking downstream) between the downstream junction corner of the KR and the first downstream weir, i.e. Weir 117.2(L), and (2) across the channel (right bank looking downstream) extending from Weir 117.5(R) downstream of Weir 117.1(R). Sedimentation occurring on the right bank appears to accumulate laterally into the navigation channel.

The After-Dredge (AD) survey was performed on 17 September 2014. AD surveys are used to ensure that after dredging occurs problematic sedimentation has been removed. From the AD

survey presented in Figure 3, it can be observed that the sediment accumulation on the right bank was removed and a wider channel was established. Sediment accumulation on the left bank downstream of the junction appears to have a slight accumulation, but does not appear to be impeding the navigation channel. The AD survey also shows sediment excavation from the KR channel allowing for deeper draft vessel traffic.

INNOVATIVE SEDIMENT MANAGEMENT METHOD TO REDUCE DREDGING

Randall Tucker, President, Streamside Technology LLC., Findlay, OH, (419) 348-5167, rltucker@streamsidetechnologyllc.com; Tim Welp, Research Hydraulic Engineer, U.S. Army Corps Engineer Research and Development Center, Vicksburg, MS, (601) 634-2083, Timothy.L.Welp@usace.army.mil; Robert Thomas, Chief, Hydrology and Hydraulics/Water Management Branch, U.S. Army Corps of Engineers Galveston District, Galveston, TX, (409) 766-3975, Robert.C.Thomas@usace.army.mil

INTRODUCTION

An innovative sediment management method, a 30-ft wide, high capacity, Sediment Collector™, is currently installed in Fountain Creek, Pueblo, Colorado upstream of the confluence with the Arkansas River (location shown in Figure 1). This installation is intended to demonstrate a new technology available to reduce the need for dredging. This Sediment Collector™ was installed to demonstrate technology needed to alleviate the need for dredging by lowering the downstream grade to reduce flooding and ultimately reduce sediment deposition as far downstream as John Martin Reservoir, a U.S. Army Corps of Engineers (USACE) managed lake. The system operates on the principle that sediment in bedload can be trapped by gravity and removed at the natural rate of transport, instead of episodically. This technical paper describes the technology and installation at Fountain Creek, other possible applications, lists lessons learned, cost, and provides some general guidance for applying collector technology at other sites.

Figure 1 Location of Sediment Collector™.

SEDIMENT COLLECTOR™ INSTALLATION IN FOUNTAIN CREEK

A 30-ft wide, high capacity Sediment Collector™ was installed in Fountain Creek Pueblo, CO upstream of the confluence with the Arkansas River in July 2011 to demonstrate a one year long trial of the viability of this new technology. The Sediment Collector™ system, as installed in Fountain Creek, consists of 6 main parts:

1. Collector: 30 FT wide Bedload Collector
2. Pump: 50 HP, submersible variable frequency drive (VFD) pump
3. Controller: Electronic controls with internet access and remote interface
4. 6 inch discharge and 8 inch water return DR11 (160 pounds per square inch) high density polyethylene (HDPE) pipelines
5. Sediment separator: 100 tons/hr
6. Stacker: capable of storing approx. 1,000 cu yds.

The primary component of the collector is a steel hopper (Figure 2) placed on the bottom along a sediment transport pathway. A manifold system (see Figure 3) inside the hopper focuses flow across a small region within the hopper, providing high velocities needed to entrain sediment. A dredge pump, housed in the hull with the hopper, pumps water and sediment through the manifold to the placement area. The pump can also be mounted remotely on land, the preferred configuration for maintenance. Booster pumps can be added to increase the pumping distance, as required.

Figure 2 Sediment Collector™ installed in the dry in Fountain Creek.

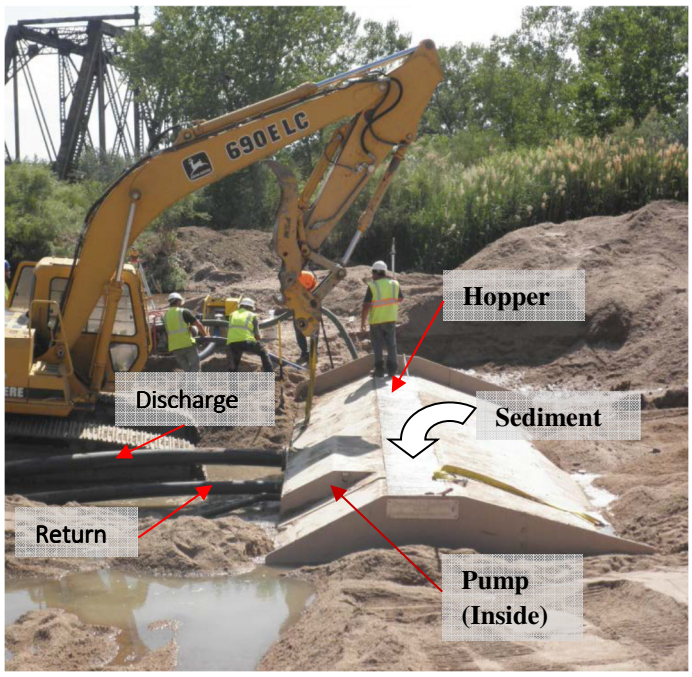

Figure 3 Sediment Collector™ at install.

The system can either be operated in an open or closed cycle. In the open cycle, water is drawn into the Collector manifold from across the screen, since the area of the screen openings is much greater than the area of the manifold orifices, velocity across the screen is very small (<1 ft/s), even though velocity at the manifold is large enough to transport sediment. In the closed cycle, the slurry is discharged into a holding tank and separated from the water, and then the water is returned to the collectors opposite side of the suction manifold, so that water is drawn from the holding tank instead of across the screen; advantages of the closed cycle include minimal impingement velocity (reducing potential for clogging) on the hopper screen, reduced risk of entrainment of aquatic organisms, and greatly reduced consumptive water loss. Sediment is discharged into a bin at the base of the screw separator (Figure 4 left), which separates and drops the coarse sediment onto the stacker (Figure 4 right). Sediment is stockpiled at the stacker until it can be trucked away.

Figure 4 Archimedes screw separator (left) and stacker (right).

Electronic controls (Figure 5) enable automatic or remote operation, reducing or eliminating the cost of labor to supervise operation. The system can be set to run at specified times, as a function of stream gage data, or as a function of hopper capacity (still in development). Dredge pumps, piping, separators, and stackers are all off the shelf technology used in dredging and other industries with documented performance metrics.

Figure 5 Electronic control panel and Archimedes screw separator.

Demonstration Project Cost: Component, installation, and total cost of the system installed at Fountain Creek is shown in Table 1. The project was championed by the City of Pueblo and funded through EPA 319 (Colorado Department of Pueblo Health and Environment, Non-Point Source Office), Pueblo County, Natural Resources Conservation Service (NRCS), and Colorado Water Conservation Board (CWCB) in collaboration with the equipment developer, Streamside Systems, LLC. Since the initiation of the project, the Fountain Creek Watershed, Flood Control, and Greenway District were created. Costs shown in Table 1 are approximate and not intended to represent the actual system cost. Various others have reported the cost to range from $600,000 to $1,000,000, although details associated with the higher estimates of cost are unavailable.

Table 1 Sediment Collector™ cost.

Collector (pumps, controllers, pipe, etc.)	$419,000
Sediment Stacker	$39,000
Installation	$110,000
Approx. Cost of Contract Documents	$50,000
Upgrades/Repairs	$10,000
Total	$628,000

Cost of operating the system has been minimal since it has been operated for short periods of time. The system is capable of being operated remotely; however, because of potential risk to human safety associated with the separator and stacker, the system was only operated under direct supervision. The system uses about 1,000 Watts per hour (1kWh) per minute of operation. If the system were run continuously for 1 year, electricity cost would be about $52,560 (based on cost of $0.10/kWh).

Minor repairs were required after the flood of September 2011. Record breaking rainfall resulted in extreme flooding and record creek flows, but did not damage the Collector. Damage to an exposed junction box required repairs totaling $1,765. The remaining cost for Upgrades/Repairs included a return flow pump and minor modification to the initial layout of the piping. A 1,800 gallon tank was added at the separator along with a pneumatically actuated valve that provides return prime water for the dredge pump at startup to ensure that the specific gravity of the slurry is managed.

Performance: Monitoring of the demonstration project has been underway since installation. Parameters that were planned for measurement included stream bed elevation within ½ mile of the collector, water level, sediment removed, electricity usage, maintenance required, and hours in operation. Specific performance data was collected at various flow rates over approximately 500 hours. Since the system was not operated continuously over many months and with the bedload transport continuing when the system was not in operation, short term stream bed elevation and coarsening impacts were overwhelmed. Therefore, stream bed elevation was not resurveyed at the end of the project.

Record breaking rainfall in September 2011 resulted in extreme flooding and record creek flows of 13,800 cu ft/s. High water damaged the junction box, causing total down time of about 2.5 months while City of Pueblo worked to get a repair contract executed. This flood demonstrated survivability of the system in an extreme event. Repair time was less than one day, once the repair contract was executed. Winterization (heat tracing and freeze protection) was not specified and the system was not operated for about 2 months during the winter months.

Production rate was the key performance parameter measured. Prior to installation of the 30-ft bedload collector, a 2-ft bedload collector (shown in Figure 7 right) was temporarily installed in Fountain Creek to estimate bedload transport extraction rates and assess optimal elevation for collector operation. The 2-ft collector pumped sediment into a drop box (Figure 7 left) that, in turn, allowed a 3 cu ft container to be filled with the subsequent fill time noted to calculate a production rate. Sediment was collected over a three day duration with extraction rates at respective stream flows listed in Table 2. Assuming a linear extraction rate function for a longer collector, respective production rates were estimated for a 30-ft long collector and listed in Table 2 as well.

Figure 7 2-ft collector (right) and drop box (left) used to estimate production rates.

Table 2 Measured 2-ft collector and estimated 30-ft collector extraction rates.

Stream Flow (cu ft/sec)	2-ft Collector Bedload Extraction Rates	Estimated 30-ft Collector Bedload Extraction Rate (cu yds/hr)
120	3 cu ft/26 min	2.8
100	3 cu ft/38 min	2.6
600	3 cu ft/6 min	16.7

Figure 8 plots maximum production rate vs. creek discharge for all data collected, with a second order polynomial trend line fit to the data. Excluding the September 2011 flood, the range of discharge rates captured represents the typical range expected at this site during any year. The figure shows the dependence of bed load on discharge. The estimated production rates in Table 2 (based on the 2-ft collector extraction rates) agree well with the production curve in Figure 8 at the lower flow rates of 100 and 120 cu ft/sec, but less so for the 600 cu ft/sec flow rate condition. Peak measured production rate for the 30 ft Collector is 100 cu yds/hour. At this rate, if sufficient bed load were available, the single 30 ft collector would move 876,000 cu yds/year. The high capacity of a single unit makes it possible to use structures in conjunction with collectors to maximize total capture with fewer collectors.

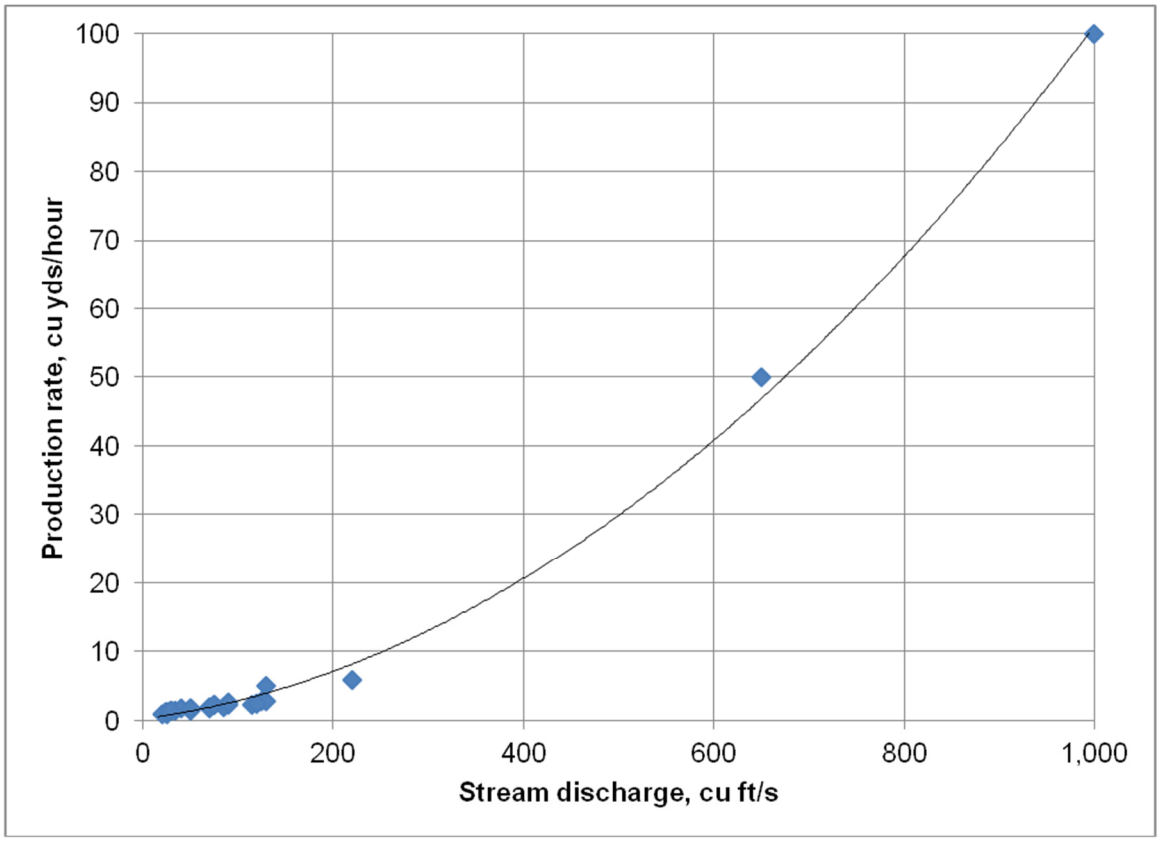

Figure 8 Sediment Collector™ production curve.

Visual inspection of the hopper and other system components were made at least monthly over the course of the year. No significant wear or corrosion is shown on any parts although the

urethane coating on the mild steel hull did sustain scouring and erosion. No repairs have been required other than those associated with initial system configuration, as a result of the flood in September 2011, and vandalism that damaged the power and control conduit leading to the dredge pump. Additional automation and instrumentation was added with the return water tank that included a variable level control and high-level switch that assists with balancing the system.

Lessons Learned: Initial deployment of new systems is an opportunity to inform design and improve installation procedures. The following list describes lessons learned during the demonstration project:

- All electrical components should be well above potential flood water levels.
- Pipelines should be as straight as possible, with no sharp turns; limiting the potential for air to be trapped in the lines.
- When operating the system with return flow, a sufficiently large water storage container should be available at the discharge point to prevent air intrusion during pump start up and to ensure that an acceptable slurry specific gravity is maintained.
- Experience at Fountain Creek suggests that the return flow pump is a worthwhile investment, reducing risk associated with grade control and that the return flow also prevented the Collector from being clogged from surges of sediment that accumulated in the hopper (i.e., the return flow re-fluidizes these sediment "slugs" in the hopper and meters it into the suction ports).
- Accurate survey for grade control during installation is essential both at the discharge point and hopper.
    - Elevation of the hopper directly controls elevation of the bed during operation.
    - Elevation of the pipeline discharge point (relative to the hopper) controls the size of the return flow pump or required head difference if attempting to run without a return flow pump.
- As with any industrial operation, measures must be taken to ensure that unauthorized personnel do not gain access to the material management equipment (Separator and Stacker). The six-foot tall fence around the demonstration project site was insufficient to prevent the curious from gaining access to the dangerous electrical and mechanical equipment. Yard lighting is recommended for night operations.
- Screen configuration and size should be based on the aggregate particle sizes in bedload. This demonstration project selected the standard coarse sand, stainless steel, round bar stock with a 3/8th inch spacing in lieu of recommended vibratory screens. During periods of low flow, larger aggregate can align in the screen apertures - resulting in bridging. Vibrating screens or jet systems could be added to offset this requirement.
- To ensure that stream flow and bedload are delivered across the collector screens, appropriate permanent or temporary cross-vane structures are recommended. Tangential interception of the stream flow by the collector screens can exacerbate the aforementioned screen bridging issues identified.

- Careful collaboration between the technology vendor (or other experts), engineer responsible for system/site design, and construction contractor is essential to avoid additional cost associated with field modifications during installation and initial testing. Design build may be the best procurement mechanism for initial full scale applications.

RECOMMENDED GENERAL APPROACH FOR COLLECTOR PROJECTS

Sediment Collector™ technology should be considered when substantial quantities of sediment selected for removal are being transported as bedload. Recommended key steps in scoping, design, construction, and operation of a Sediment Collector™ project are identified below:

Pre-Design Analysis: Appropriate analyses should be conducted to determine sediment transport processes and expert advice should be solicited to determine if a collector is feasible for each site. Key parameters that should be investigated to determine if a collector project is feasible include:

- Sediment transport (size and rate): typically measured through deployment of a 2' to 6' collector emplaced and operated during varying stream flow conditions (Lipscomb, Darrow and Thornton 2005).
- Transport processes and pathways: typically assessed through combination of expertise, field data and inspection, and application of numerical models.
- Sediment management: Identify potential placement locations and methods of conveyance.
- Operations plan: Identify who will be responsible for operating and maintaining the system after construction.
- Benefits analysis: Compare cost, both financial and environmental, to alternative methods to identify the least cost method of removal.

Design: After the decision to install a Collector has been made, design of the plant should be conducted by an experienced engineer consulting with the system developer or other expert in collector installation. Major components of design analyses include:

- Collector design: Based on data collected and analyses conducted in the Pre-Design phase; consult with the system developer to determine the appropriate configuration of the full scale collector system.
- Placement area design/plan: Design the placement area and plan operations to manage the sediment load anticipated. Contingencies for minimal oversight should be considered.
    - If not conducted during Pre-Design phase, it may be necessary to collect more data or conduct additional analyses to determine the rate of sediment that must be handled.

    - Placement area options range from direct discharge to a complete mechanical separation plant, like the one used at Fountain Creek.
- Pump and pipeline design: Pipeline layout should minimize head loss, prevent air from being trapped, and follow the shortest possible route. Pump size will be a function of sediments, collector size and configuration, placement area design, and pipeline configuration.
- Electronic control and electrical design: Electronic controls and electrical wiring for the collector system must be designed. The Control system should be designed with the collaboration of the system vendor.
- Final site design: Other design features typical of a civil project such as grading, drainage, roads, utilities, lighting, site safety etc.

Construction: The system should be installed by a qualified construction contractor with an expert in collector installation on staff. The demonstration project identified some issues to consider during construction, listed below:

- Construction quality control: Lessons learned during the pilot highlighted the importance of quality control (QC) during construction. Elevation tolerances, pipeline layout, and electrical wiring all had issues at Fountain Creek that could have been eliminated through QC during construction.
- Initial testing: Like any new system, initial testing should be conducted to determine if the system is operating as intended.

Operations and Maintenance: After construction, the system should be monitored to ensure that it is functioning as designed. Some topics for consideration after construction include:

- Monitoring: system components (collectors, pumps, electronics, etc.) and environmental factors (sediment size and transport rate, flow rate, etc.) should both be monitored to assess performance and to inform system maintenance or tuning.
- System tuning: Because of the uncertainty associated with modeling and measuring sediment transport, it is likely that actual production will be different than predicted. It may be possible to modify system configuration to optimize performance; plan to reevaluate system layout after monitoring data has been gathered and analyzed.

Length of monitoring duration necessary to make system tuning decisions will, of course, depend on which system design aspects are being evaluated. The decision to relocate the certain Fountain Creek electrical components well above potential flood water levels happened immediately after the components were flooded, whereas something like a system re-configuration may take longer to more accurately re-assess site specific conditions (e.g., optimum sediment transport volumes and patterns).

OTHER POTENTIAL APPLICATIONS

Collector technology adds two key improvements over other installed dredging systems. This technology can provide selective capture for both the size and quantity of sediment to be removed. Since the system operates with very low or no head across the screen into the hopper, only sediments coarse enough to be transported in bedload are trapped (fine sands to gravels), while finer sediments (silts and clays) remain in suspension. The top size of the sediment is limited by screen opening size. The total volume captured can be modified by controlling the duration of system operation, and by varying the width of the collector installed.

This technology also removes sediment at the natural transport rate. The collector is only capable of trapping sediments when they are supplied by natural forcing (currents or waves). Therefore, the system (when installed at grade) can never exceed natural transport processes. Removing sediment at the natural rate more closely mimics nature, reducing known and potential unforeseen environmental impacts. A permanent Collector serves as a grade-control structure. When installed above grade on a complete cross-section, the Collector will cause aggradation upstream to the desired new elevation. When installed below grade the Collector will initiate a controlled-depth head cut upstream.

The selective capture of bed load at the natural transport rate leads to some specific new capabilities. Although not exhaustive, some potential applications for collector technology are discussed below:

Watershed Management: By actively managing sediments at the watershed level it is possible to drastically reduce sediment load to the area or channel of interest. Managing sediments at many locations throughout the watershed may optimize habitat restoration and protection, and also be more cost effective and environmentally friendly than the traditional practice of dredging at the problem site. This also presents an opportunity to take advantage of flexibility in siting, helping to address issues with property ownership, road access, material handling and transportation, power availability, etc. Collectors are scalable to any stream width, and can be readily retrofitted to existing cross-vane or other structures. They also allow users to actively manage grades in the vicinity of the collector.

Reduce Quantity of Contaminated Sediment Dredging: Coarse sediments can be removed before being deposited in an area known to be contaminated, reducing the total volume of sediment that must be dredged and placed under more stringent requirements typical for removing contaminated sediments.

Sediment Bypassing: At inlets, in tidal systems, or other locations where there is a clearly defined sediment pathway crossing a navigation channel, a Collector could be installed as a sediment bypassing system, allowing sediment to be removed and pumped past the navigation channel, preventing deposition. The system would be installed at reaches where deposition is typical and the discharge located in an area with potential for scour or transport away from the channel.

Reservoir sedimentation can be reduced by capturing and removing bedload at tributary mouths, and either removing the material or reintroducing the sediment below the dam (at the natural transport rate, to offset channel and habitat degradation due to a sediment deficit caused by reservoir trap efficiency). Using collectors to design or retrofit sustainable reservoirs will not only reduce dredging requirements, but will help maintain reservoir storage capacity and related hydroelectric generating capacity, and reduce flood risks that would otherwise increase with a loss of storage.

Sediment Backpassing: On beach locations that experience accretion, the Collector could be installed as a sediment backpassing system allowing sediment to be removed from the accretion area and pumped back to beach erosional "hotspots" within practical pumping distance.

Application in Remote Locations: Since a collector system can be installed with standard truck able equipment, they offer the potential for application in remote locations, where there is a need to control grade in streams, to prevent downstream migration of excess or contaminated sediments, to maintain a navigable channel, or to supply coarse sediment with lower impact than traditional mining practices. In many headwater locations (e.g., first or second-order streams impacted by logging, agriculture, or road construction) stream gradient may allow for Collector clearing on a siphon basis, for continuous operation with no pump or power requirement.

In addition to the potential applications listed above, application of this new technology could result in other benefits not yet fully investigated. Since there is essentially no flow into the hopper (with a closed water cycle), there is little risk of ingesting wildlife or foreign material that might clog the pump. This may help to meet permit requirements or avoid the need for some permits. Closed cycle operations may also be used to address water rights issues by returning water to the hopper. Aesthetic impacts of dredging, and operational limits (e.g., due to Threatened and Endangered species (T&E), or spawning seasons) could be avoided, since there is very low or no flow into the system.

CONCLUSIONS

This paper presented application of Sediment Collector™ technology in Fountain Creek in Pueblo, CO and discusses how it might be applied to reduce USACE navigation dredging. The installation successfully demonstrated the technology; specifically that Collector Technology:

- Works with coarse sediments in a shallow unidirectional flow environment
- Has minimal maintenance costs over a 1-year deployment
- Survives record floods with minimal damage
- Is capable of producing up to 100 cu yds per hour with a single 30-ft collector
- Is relatively inexpensive and easy to deploy without specialized equipment

Further investigation of collector technology through larger scale demonstration at navigation projects is recommended. Future demonstrations should consider testing application in areas

with wave dominated transport, application with finer sediments, application in deeper water, and with different placement options.

HYDROLOGIC ANALYSIS OF MESCAL CANYON WATERSHED AND GEOMORPHIC ASSESSMENT OF LOWER MESCAL ARROYO CONFLUENCE

Vincent Benoit, Hydrologic Technician, Bureau of Reclamation, 555 Broadway NE Ste 100 Albuquerque NM, 8710, Office: 505-462-3628, Cell: 435-757-0936, Email: vbenoit@usbr.gov

INTRODUCTION

Mescal Arroyo empties into the Rio Grande roughly two miles downstream of Elephant Butte Dam. Mescal arroyo is fed by a watershed with a contributing area of roughly 14,000 acres. The vertical relief throughout the watershed ranges from 5,800 feet at the peak of Caballo Cone to an elevation of 4,250 feet at the mouth of the arroyo. The main channel of the Rio Grande above the confluence of the arroyo and river is constrained by natural features and influenced by Mescal Arroyo. Flanked on either side by steep mountainous terrain, the Rio Grande is constricted in width and its channel location is restricted. These constraints are primarily above the confluence of the river and the arroyo, and have a limited effect on the planform around the mouth of Mescal Arroyo. Anthropogenic constraints have a greater effect on the planform of the river channel around the arroyo mouth.

Flows on the Rio Grande in this reach have been controlled by the operation of Elephant Butte Dam since 1916. The channel downstream of Elephant Butte Dam has also been channelized to preserve the conveyance capacity of the channel for delivery of irrigation water downstream and to protect adjacent infrastructure from damage due to high flows. Continuous river maintenance work is performed through the channelized portion of the river downstream of Elephant Butte Dam to maintain the authorized 5,000 cfs channel capacity per the congressional Flood Control Acts of 1948 and 1950.

As is common in ephemeral channels, the slope of the arroyo is greater than that of the river channel. Figure 1 contains two profiles from surveyed data that illustrates the difference in slopes between the arroyo and the river channel, in this case they are an order of magnitude different.

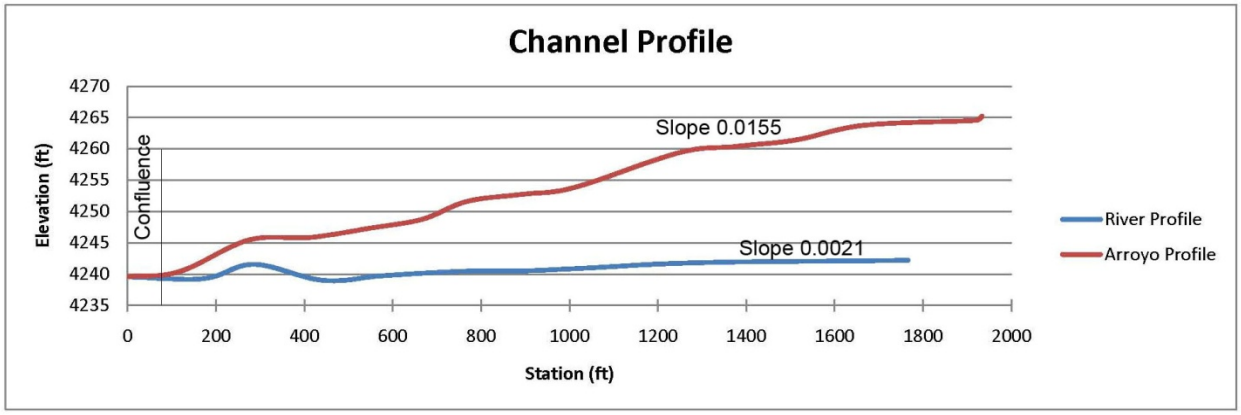

Figure 1 Comparison of Rio Grande Channel slope and Mescal Arroyo slope.

A combination of high runoff potential of the soils and sparse surface vegetation in the upper Mescal Arroyo watershed, high slope of the Arroyo, and a monsoon dominated hydrology, with its periods of intense rainfall result in high rates of sediment transport and deposition during these flashy events. High rates of sediment transport from Mescal Arroyo lead to alluvial fan deposition at the confluence with the Rio Grande that has on occasion both partially and fully blocked river flows, reducing the channel capacity of the Rio Grande below Elephant Butte Dam. The reduction of channel capacity reduces the ability of meeting downstream flow requirements. Deposition also creates a backwater area that impacts the operation of Elephant Butte Dam. Because of the importance of releasing and maintaining the flow downstream to Caballo Reservoir, an analysis of potential solutions to reduce the amount of sediment introduced to the Rio Grande from Mescal Arroyo or increase the sediment transport capacity of the Rio Grande in the vicinity of the arroyo needs to be pursued. Before potential solutions can be decided on it is important to have an understanding of the physical processes at work in the system and how they influence those problems. This geomorphic review presents an analysis of historic channel morphology of the Rio Grande at the confluence with Mescal Arroyo, and a rainfall runoff model to assess the morphological changes occurring in Mescal Arroyo and the effects of storms on the arroyo.

HISTORIC CHANNEL AND FLOODPLAIN ANALYSIS

Rio Grande Channel: The occurrence of high sediment runoff and deposition into the Rio Grande is not solely due to anthropogenic changes, this problem has existed prior to any man-made changes to the river channel. In the 1935 and 1957 aerial photographs shown in Figure 2, sediment deposition is evident at the arroyo's confluence with the river. The 1935 aerial photo was taken before the state road NM 51 was built on the north side of the river, in the photo the red arrow point toward an alluvial fan that has been created by flows from Mescal Arroyo. The blue arrow illustrates the response of the Rio Grande to the sediment influx, with the main channel shifting north. Because the channel is able to shift its location; as shown in the 1935 photo, the additional sediment from the arroyo doesn't impact water flow through the reach. In the 1957 photo, the road embankment and channelization constricted the river to the point where it could no longer alter its course in response to the sediment input from the arroyo. The red arrow on the 1957 aerial shows an alluvial fan that has constricted the channel further.

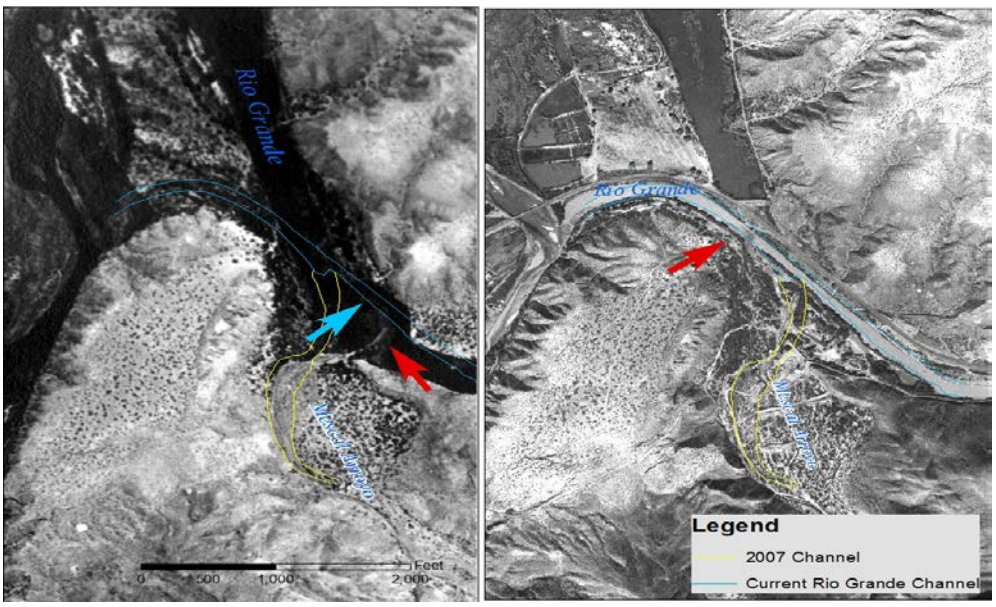

Figure 2 Left aerial photo 1935 and Right aerial photo 1957, blue line illustrates the river channel as of 2012 and yellow line illustrates the 2007 arroyo channel.

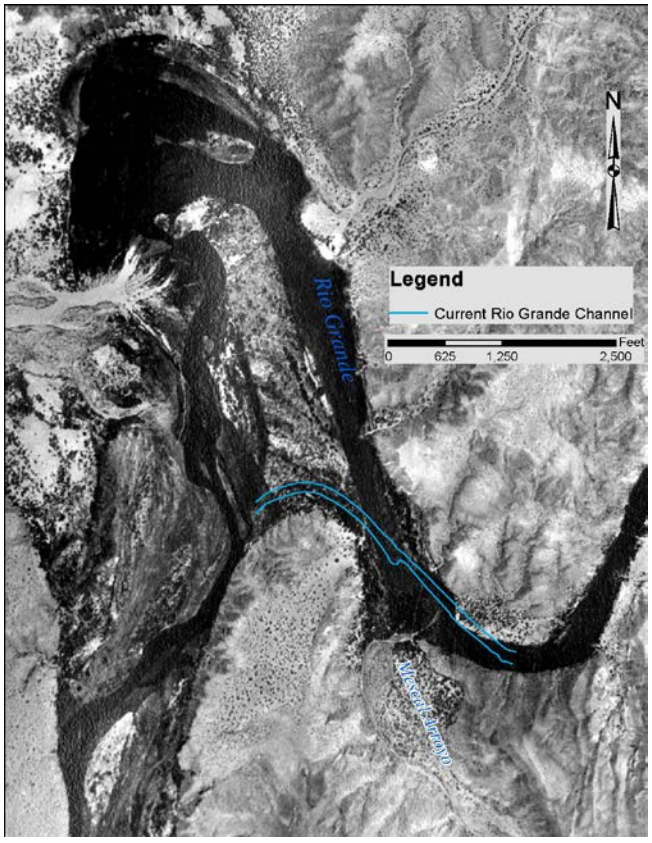

Figure 3 Channel morphology of the Rio Grande prior to anthropomorphic effects.

The Rio Grande was channelized to the location seen in the aerial photograph sometime between 1935 and 1956. Prior to channelization the Rio Grande was constrained by geologic formations to the sinuous planform seen in the 1935 aerial photography (Figure 3). The Rio Grande channel length; illustrated by the blue line in Figure 3 and measured from River Mile 25.2 to River Mile 24.5, was decreased from 8,700 feet in 1935 to 4,100 feet in 1956 through this reach. The active channel was also narrowed in width from an average of 169 feet in 1935 to an average of 98 feet in 1956. The river channel in 1935 also had a floodplain width of 402 feet, which is nonexistent in the 1956 channel. Channel length and widths were estimated using the georectified aerial photography from the corresponding years. The channelization resulted in an increase in the channel's slope by a factor of 1.9. A 1985 channel rehabilitation project was designed to meet the 5,000 cfs channel capacity requirement. The river channel was dredged and drop structures were installed downstream of Mescal Arroyo. (Drew Baird, pers. Comm.).

Post-channelization aerial photos from 1957 illustrate the sensitivity of the channel to the sediment input from Mescal Arroyo due to the loss of floodplain and channel areas for deposition; the red arrow seen on Figure 2 shows an alluvial fan created by the arroyo. Prior to channelization, the river had enough freedom to widen and shift in response to flow and sediment regimes. Both channelization and narrowing efforts led the channel to be more sensitive to sediment input from the arroyo by reducing the width of the river channel. The reduced channel width and the bank protection on the opposite bank has created a situation where the water from the arroyo is deflected and slowed by the highway embankment. The deflection of the western bankline and the river backwater effects on the sediment laden arroyo flow allows for the larger sediment to deposit creating an alluvial fan at the confluence of the river and arroyo. The highway embankment also prevents the river from shifting its course to the west to adjust to additional sediment. Any sediment introduced to the main channel needs to be mobilized by the flows of the Rio Grande, rather than the Rio Grande altering its course in response to the additional sediment.

Figure 4 Left photo taken 7/10/08 and right photo taken 9/10/08

The photos in Figure 4 were taken during one of the rainfall runoff events in the 2008 monsoon season. The line of bubbles; as shown by the red arrows, at the edge of the Rio Grande seen in the leftmost figure delineates the leading edge of the developing fan. The rightmost photo was taken at the same location on 9/10/08 after the monsoon season. Resulting alluvial fan

development has progressed further into the channel where it has constricted the mainstem Rio Grande flow, raising the water surface elevation and creating a backwater condition upstream.

Mescal Arroyo: Anthropomorphic changes at the lower portion of Mescal Arroyo to its confluence with the Rio Grande have altered the way runoff flows move through the arroyo affecting sediment deposition patterns at the confluence. Sometime between 1935 and 1957, the lower portion of Mescal Arroyo was channelized by sediment control embankments on both sides. Prior to the installation of these embankments, storm runoff flows flowed in more of the dendritic pattern exhibited by alluvial fans. These small migrating channels transport runoff water across the alluvial fan. The embankments were likely installed to reduce flow across the alluvial fan to protect the arroyo road crossing. As a result of channelization and flow regulation on the Rio Grande, the alluvial fan of the arroyo extended north (Figure 2) creating a larger alluvial area increasing the arroyo channel length and decreasing the arroyo slope; measured from the 2012 arroyo road crossing location to the river channel, the length of the arroyo increased from 542 ft in 1935 to 1626 ft in 1957. Some of that decrease in slope and increase in arroyo channel length can be attributed to the different location of the Rio Grande channel and the location of the confluence. From 1957 to 2012, the lower arroyo channel was shortened from the 1626 ft to 1199 ft in 2012, due to the relocation of the arroyo's confluence. The current spoil area west of the arroyo mouth existed as a vegetated bar prior to 1956. Currently, the arroyo is constricted near the upper end of the spoil location where rip-rap was installed in 2001 and has mostly been washed away by arroyo flows (Brent Tanzy, Pers. Comm.). Two Wolman pebble counts were performed across the channel in two locations, one cross section further into the arroyo and the second close to the spoil area. The D_{50} for the upstream location was in the range of 6mm or fine gravel and for the downstream location the D_{50} was in the range of 10mm or fine gravel. The coarser downstream size distribution is likely due to the location of the thalweg of the arroyo. At the upper cross section, the active channel was wider and less confined than the downstream cross section. The lower cross section is located below the road crossing and had a more defined active channel consisting of finer material. At the lower cross section there was a bar dominated by coarser sediments likely deposited at higher flows.

Elephant Butte Dam Operations: The operation of the dam and powerplant influences the discharge in the Rio Grande below the dam. Flow releases from the dam are established by the El Paso office in conjunction with the downstream irrigation district's demand (Ben Kalminson, pers. Comm.). Because dam releases are demand driven, there are times where there are no flow releases at all, at these times there is minimal seepage flows in the Rio Grande at the confluence with Mescal Arroyo.

Precipitation/Evaporation: Daily rainfall data from a National Climatic Data Center gauge in Truth or Consequences (35 year record) shows a mean annual rainfall amount of 9.43 inches. Most of the rainfall each year tends to come in the late summer months as short duration but high intensity monsoon storms. Figure 7 consists of average monthly rainfall data for the 35 years of record at the T or C gage and illustrates the meteorology of the monsoon storms. Plotted against the average monthly releases from Elephant Butte, the supply and demand dynamic can be seen. Demand for releases is reduced during monsoon season.

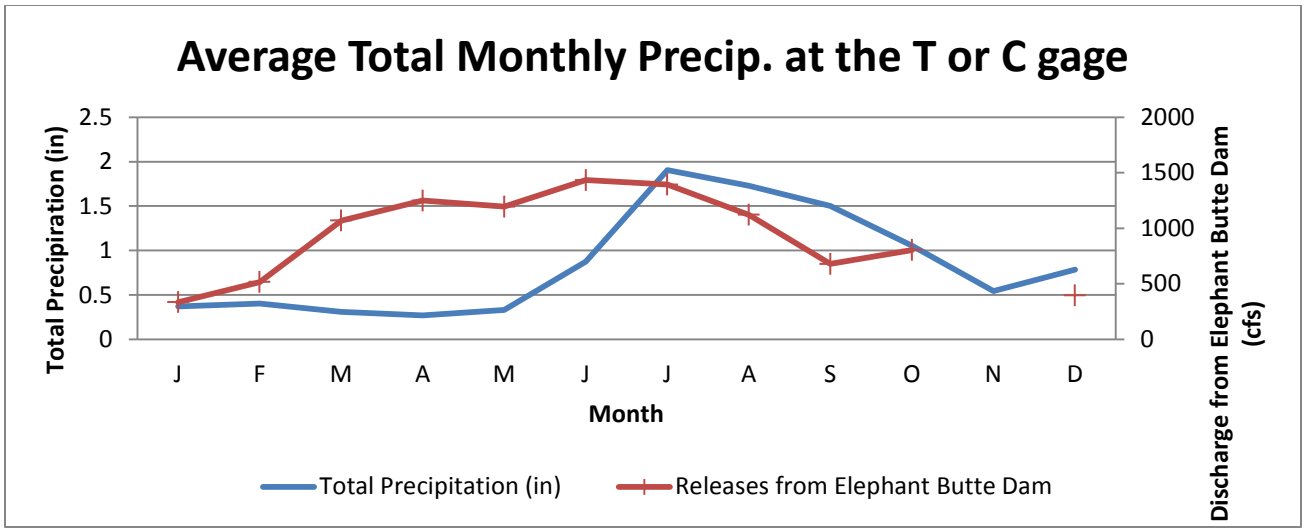

Figure 5 Average Total Monthly Precipitation for all years of record at the NCDC Truth or Consequences gauge compared to average monthly releases from Elephant Butte Dam.

HYDROLOGIC MODEL DEVELOPMENT

Data for the model was processed using the Hec-GeoHMS toolset for ArcGIS 9.3. This toolset aids in the development of model parameters by taking advantage of data published in GIS format. The HEC-GeoHMS toolset takes portions of GIS formatted data and creates model parameters from the data. This model used the 2005 New Mexico Geospatial Data Acquisition Coordination Committee (GDACC) 10 meter enhanced DEM to derive; sub-basin delineation, slopes within the sub-basin, basin centroid, flow path lengths, and channel slopes, for use in modeling the topography of the basin. Once the physical data has been processed through Hec-GeoHMS, the information can be exported to Hec-HMS where additional input values are chosen to describe and make assumptions about the basin model. The additional input values included in the model included soil data, geologic data, estimated evaporation rates and rainfall gage data for Mescal Arroyo. These include the type of basin and meteorologic model, and any specific precipitation gage data that may be available.

HYDROLOGIC MODELING RESULTS

The Mescal Arroyo Hec-HMS model was run for each of the six storm event models representing the different ARIs. Each of the resulting synthetic hydrographs seen in Figure 10 shows a sharp rise in runoff early in the simulation due to the nature of the NOAA precipitation estimates. The attenuation time and peak discharge from the simulations vary as a function of the data used and assumptions made in putting the model together.

Assumptions include:

- The DEM accurately represents the actual ground surface.
- The actual vegetation condition closely matches the assumptions made for the model.
- The precipitation estimates are accurate for the watershed.
- Runoff modeling accurately represents actual runoff in the watershed.

- The precipitation rate closely follows the rainfall curve used in the model.
- Precipitation is distributed equally across the entire watershed.
- Estimated evaporation loss rates are accurate for the watershed.

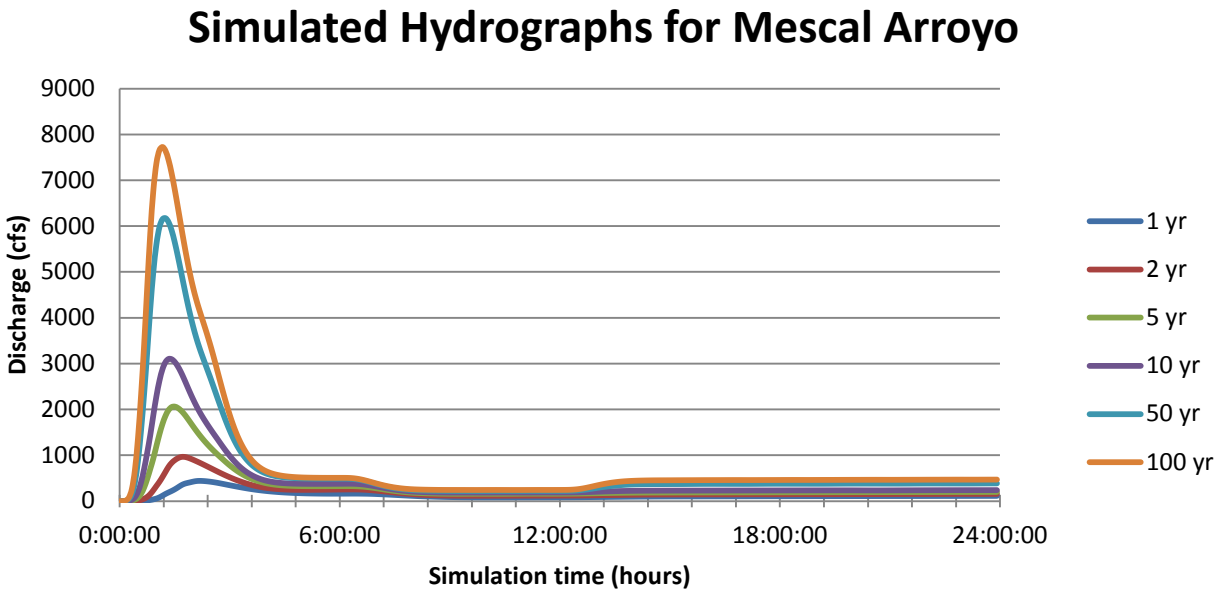

Figure 6 Simulated hydrograph results from the HEC-HMS model

Table 1 Estimated peak discharge and total event runoff for 24 hr return interval storm events.

Return Interval	Estimated Peak Discharge (cfs)	Estimated Event Runoff (ac-ft)
1 yr	450	263
2 yr	975	423
5 yr	2000	657
10 yr	3100	863
50 yr	6100	1458
100 yr	7700	1775

Model results presented in Figure 10 and Table 3, illustrate the high runoff potential in the Mescal Arroyo watershed. The high runoff and the soil types in the watershed have the potential to produce large amounts of sediment runoff. Table 4 provides visual quantity estimates and precipitation data showing the high sediment transport potential of the arroyo.

Table 2 Comparison of sediment removed from the mouth of the arroyo, rainfall through the monsoon season and yearly rainfall data from the Truth or Consequences gage over the yearly period

Estimated Sediment volume removed from Mescal Arroyo and Precipitation data from the T or C gage			
Year	Quantity Removed (cubic yards)	Total Precip for July through September	Total Yearly Precip
2001-2002	3500	3.65	5.48
2002-2003	2200	2.6	5.08
2003-2004	1000	2.85	5.38
2004-2005	5000	5.56	11.19
2005-2006	5000	0.53	3.81
2006-2007	15460	3.56	13.05
2007-2008	1200	3.98	5.42
2008-2009	8400	10.8	11.97
2009-2010	3000	5.44	9.86
2010-2011	3472	8.32	12.36

Table 4 lists an estimate of material removed at the confluence of the arroyo and the mainstem of the Rio Grande by the crew at Elephant Butte compared to the monsoon season precipitation and the total yearly precipitation for that year. Generally, the years with higher precipitation are also years with more sediment removed from the confluence. Aside from water years 2005 and 2006 where the majority of the precipitation occurred in the months January and February for 2005 and in October for 2006, most of the rainfall comes during monsoon season. These two outliers illustrate how variable weather in the arid southwest is. For the Mescal Arroyo model, the precipitation is distributed equally over the entire watershed, this assumption differs from storms in the real world that may be localized and only cover portions of the watershed. This may be one of the sources of poor correlation between yearly rainfall and sediment removed, since a storm of a certain magnitude focused higher in the watershed may yield less channel flow than a storm of the same magnitude closer to the confluence of the arroyo and river.

A PSIAC (Pacific Southwest Inter-Agency Committee) Sediment Yield calculation was performed to gain an idea of the amount of sediment that the arroyo is able to produce. The PSIAC method estimates yearly sediment discharge using a system to rate the arroyo conditions based on a number of parameters including; surface geology, soils, runoff, and land management types. For Mescal Arroyo, there were 9 ratings broken down by soil units. The calculations yielded an estimate of 3.4 ac-ft per square mile per year. Table 5 lists the PSIAC estimate of sediment volume produced by the corresponding geologic soil formation group.

Table 3 Estimates of sediment volume transported through Mescal Arroyo using the PSIAC method.

PSIAC Sediment Yield Estimates			
Unit number	Geomorphic association	Estimated sediment yield (yd^3/ sq-mi/yr)	Estmated sediment yield (AF/sq-mi/yr)
4	Akela	322.67	0.2
21	Bluepoint	387.20	0.24
28	Courthouse rock outcrop	968.00	0.60
30	Delnorte-Cave-Tencee complex	290.40	0.18
34	Albutte- Courthouse complex	806.67	0.50

CONCLUSIONS AND RECOMMENDATIONS

A historic geomorphic assessment of Mescal Arroyo and its confluence with the Rio Grande was done to provide information regarding its condition and history, as well as to illustrate the link between high-intensity rainfall events and the potential for sediment transport through the watershed. At times the arroyo sediment deposition tends to block or partially block flow in the mainstem Rio Grande, disrupting the continuity of flow downstream to Caballo Reservoir. The mainstem Rio Grande channel has been modified for flood control to effectively pass 5,000 cfs and also to meet delivery requirements downstream. Channel location has also been modified for the same reasons plus modification from road and embankment establishment. In addition, dam operations control the Rio Grande releases below Elephant Butte primarily for power and irrigation demand. The combination of these factors creates a situation where the Rio Grande is unable to adjust laterally to sediment input, nor is it able to mobilize most of the sediment deposits at the arroyo outfall with current flow releases.

This geomorphic review presents an analysis of historic channel morphology of the Rio Grande at the confluence with Mescal Arroyo, and a rainfall runoff model to assess the morphological changes occurring in Mescal Arroyo and the effects of storms on the arroyo. The results of the hydrologic analysis and the geomorphic assessment show:

- The alignment of the Rio Grande channel has been channelized to its current location, where it has been narrowed, channel length shortened and excavated to pass the required 5000 cfs. The channel is also restricted from meandering to adjust to sediment inputs.
- Flow regulation due to the dam has disrupted the natural flow regime of the Rio Grande.
- Anthropogenic modifications in the mouth of Mescal Arroyo have channelized the flow into a single channel coming out of the arroyo. The area chosen to spoil material excavated from the Rio Grande channel has further channelized and shortened the arroyo channel.

- The geology of the arroyo consists primarily of sedimentary formations, and geologic processes have left steep slopes within the watershed.
- Soils in the watershed are generally well drained and shallow, with a mostly impermeable substrate. Which have a high runoff potential.
- Monsoon storm meteorology dominates the yearly rainfall amounts in the arroyo. Monsoon storms drop large amounts of rainfall in a short period of time.
- The region is an arid region so vegetation consists of hardy drought tolerant plants.
- A rainfall runoff model was developed for the watershed using existing data for inputs. The results of the model provide an idea of the discharges that are possible from the watershed.
- PSIAC calculations were made to estimate the amount of sediment runoff that can be produced by the arroyo. Estimated total sediment yield is 74 ac-ft of sediment per year over the entire 14,000 acres of Mescal Arroyo.

Addressing the sediment transport problems associated with the arroyo and its confluence will be a continual maintenance concern. Because there are a number of land owners within the area of the arroyo any solution that requires work to be completed in the arroyo will have to consider land ownership issues. The arroyo is an extremely dynamic system any possible solution will have to be designed so that it can withstand the variable flows as well as minimize maintenance. Alternatives should be defined to be designed to withstand the 10 yr flow or about 3000 cfs. Finally, the design alternatives should have no impact on the delivery of water from Elephant Butte downstream. The following is a list of possible solutions to pursue related to sediment management of the arroyo:

- Alteration of dam operations – Operations of the dam could be altered to increase the amount of water in the Rio Grande below Elephant Butte Dam. The idea behind this is that increasing the water flow in the river in response to a rainfall event would be enough to keep the additional sediment mobile, helping to transport excess sediment downstream. This would require rapid response to rainfall events.
- Installation of sediment control structures in lower portion of Mescal Arroyo– Sediment control structures would decrease the amount of sediment introduced to the river. These structures would have to be robust enough that they can withstand the large variations in flow and would require periodic sediment removal. Control structures could include Gabion Baskets, Check Structures and grade control structures. It is important to note that any work in the arroyo is outside of Reclamation's authority under the Middle Rio Grande Project.
- Provide stable transition channel with continued need to remove sediment at confluence – Realignment of the arroyo channel would change the confluence of the arroyo and river to reduce the angle at which the arroyo meets the river. This concept assumes the reduced angle, the additional sediment would most likely be deposited in a location that wouldn't constrain the river channel as much. In addition to the new deposition location, the water velocities at the confluence should be high enough to keep the sediment mobile. Any structures associated with this would have to be robust and periodic removal of deposited sediment would be performed.

INTEGRATING GIS WITH ANNAGNPS WATERSHED MODEL FOR OPTIMAL PLACEMENT OF CONSERVATION PRACTICES IN AGRICULTURAL WATERSHEDS

Henrique G. Momm, Assistant Professor, Middle Tennessee State University, Murfreesboro, TN, 37130, henrique.momm@mtsu.edu; Ronald L. Bingner, Agricultural Engineer, USDA-ARS NSL, Oxford, MS, ron.bingner@ars.usda.gov; Leah Kraemer, Graduate Research Assistant, Middle Tennessee State University, Murfreesboro, TN, 37130, leah.kraemer@amecfw.com; and Robert R. Wells, Research Hydraulic Engineer, USDA-ARS NSL, Oxford, MS, robert.wells@ars.usda.gov

Abstract: The development of technology designed to maximize crop production while minimizing the impact to ecosystems services in agricultural watersheds is a complex undertaking. Integrated and multifaceted relationships exist between multiple systems controlling the transport of non-point source pollution from upstream croplands into downstream water bodies. Some of the known factors controlling non-point source production include: environmental conditions, type and location of sources, selection of farming practices, and implementation of efficient conservation measures. Existing watershed-scale modeling technology, such as the United States Department of Agriculture (USDA) Annualized Agricultural Non-Point Source pollutant loading model, AnnAGNPS, offers the necessary tools to describe existing conditions and even perform simulations of possible suggested scenarios. The challenge resides in the selection of conservation practices (or series of them), their key parameters, and their spatial allocation. This task is difficult due to the integrated nature between erosion sources and conservation systems. For example, implementation of a localized conservation practice upstream can have a positive effect locally; however, it could have a negative effect elsewhere in the watershed (clean water effect). To address this optimization task, a spatial decision support systems (SDSS) based on the AnnAGNPS model, GIS, and genetic algorithms, is being developed to support optimized spatial allocation of conservation practices in agricultural watersheds. In this study, we describe the developed foundational technology to link the optimization algorithm with the riparian filter strips component within the AGNPS system. The technology developed will be integrated with optimization algorithms and will support the long-term objective of determining an optimal alternative that would minimize soil erosion and maximize production area.

INTRODUCTION

In watershed systems, the transport of sediments from croplands to downstream water bodies is influenced by an integrated and multifaceted relationship between farming practices, sediment sources (sheet, rill, gully, and channel), and conservation measures. As the understanding of the impact of each of these factors upon sediment detachment and transport improves, new modeling technologies are being developed to support the decision making process of improving agricultural yield while reducing the ecosystem's pollution.

The Research Service (ARS) and the Natural Conservation Service (NRCS), both branches of the USDA, jointly developed the AnnAGNPS pollution modeling system (Bingner and Theurer, 2001). AnnAGNPS predicts the origin and movement of water, sediment, and chemicals at any

location within the watershed. The model was developed with multiple integrated components, to account for different sediment source areas and sinks, and considers the impacts of conservation practices upon the watershed. Pollutant and sediment tracking provides an important link to their sources enabling valuable insight into the effect and most effective placement of conservation practices. The model is capable of distinguishing between erosion processes (i.e., sheet and rill, tillage-induced ephemeral gullies, classical and edge-of-field gullies processes) and streambed and bank sources.

The challenge resides in the selection of conservation practices (or series of them), their key parameters, and their spatial allocation. Theoretically, there are infinite alternatives on how to implement conservation practices with varying cost and efficiency. However, there is a reduced number of alternatives that minimize sediment output through the implementation of conservation practices at the most critical locations within the watershed while maximizing crop yield through keeping production areas. This problem can be investigated using system-engineering concepts in the form of spatial decision support systems.

The utilization of SDSS can expedite the selection of the most appropriate solution. Our proposed technology integrates modeling (AnnAGNPS), database management, GIS, and optimization algorithms (genetic algorithms). The conservation practice selection and spatial allocation tool is still under development, however, the general linkage between the optimization algorithm, GIS, and the AnnAGNPS model is described in this text.

METHODS

The utilization of riparian vegetation in agricultural fields has been recognized as an effective conservation practice to reduce sediment/nutrients transport from croplands. A riparian buffer component (Momm et al., 2014) has been developed to estimate the influence of riparian vegetation on sediment loadings from sheet, rill, and ephemeral gully sources (Momm et al., 2012). Users can vary basic input parameters used to characterize riparian buffers through the development of a GIS raster grid layer describing the riparian zone spatial extent and vegetation type. This is usually a time consuming task which requires multiple iterations to select the appropriate riparian zone characteristics (width and vegetation type) as well as to spatially allocate riparian zones at the most efficient locations throughout the watershed.

The basic unit of the AnnAGNPS model is the sub-catchment (figure 1A). The entire watershed is sub-divided into sub-catchments and each of them is characterized based on a large number of parameters from multiple databases. To simplify the description of the proposed methods, only one sub-catchment is used (figure 1B). In the AnnAGNPS riparian buffer component (AGBUF), each sub-catchment is intersected with a user-provided riparian buffer layer (figure 1C) and key raster grid cells recorded (figure 1D). A candidate solution in AGBUF is represented as two raster grid layers: one defining the riparian zone extent (figure 1C) and another defining the riparian zone vegetation type.

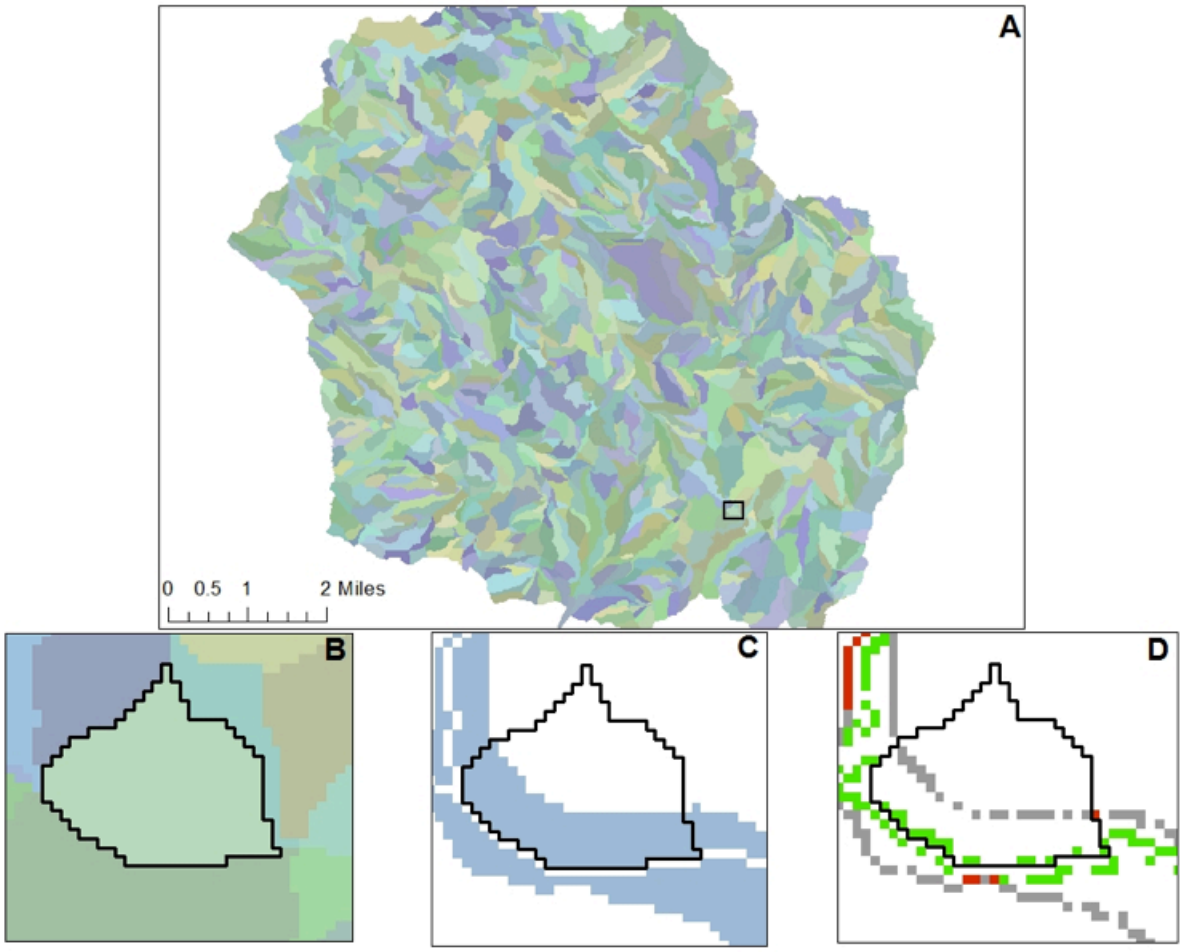

Figure 1 Watershed characterization into sub-catchments (A). Each individual sub-catchment (B) is spatially intersected with land cover layer containing riparian filter strip zone (blue layer in C). The raster grid cells receiving flow from outside the riparian zone (marked in gray in D) and having flow leaving the riparian zone (marked in green in D) are used as input information into the AnnAGNPS buffer GIS technology (AGBUF) described by Momm and others (2014).

The utilization of genetic algorithms (GA) as the optimization engine was sought to streamline the selection process. Genetic algorithms are computer programs inspired by the Darwinian theories of biological evolution, which states that individuals that best fit the environment that they live in will have a higher chance of survival and passing their genes to the next generation (survival of the fittest). During the evolutionary process, the program generates a set of candidate solutions randomly and sorts them based on user-defined fitness criteria. The top fit individuals are selected to form the new set of candidate solutions after crossover and mutation operations are performed. This iterative procedure is repeated until the stopping criteria are reached. For genetic algorithm, the set of candidate solutions is represented by a vector of bits (zeros and ones).

Our contribution was to develop an automated GIS procedure to translate candidate solutions from AGBUF representation (raster grid) into GA representation (vector of bits) and vice versa. The key component in this procedure is the generation of a list of rows and columns of the raster

grid cells marked as downstream edge locations (figure 2). These locations are marked within the grid with a value of 2 and describe raster grid cells located within the riparian zone and with flow exiting the riparian zone (green raster grid cells in figure 3A).

TYPE	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2	2
ROW	1089	1090	1090	1091	1092	1092	1092	1093	1093	1093	1094	1094	1094	1095	1095	1095	1095	1095
COL	1050	1051	1052	1052	1053	1054	1055	1055	1056	1057	1057	1071	1074	1059	1060	1065	1066	1068
	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1	1

Figure 2 The list of raster grid cells marked as upstream riparian zone edge. These vectors are translated into a single vector of bits representing a candidate solution and are understood by the optimization algorithm.

From AGBUF to GA: The user provides a raster grid layer containing the maximum extent of the desired riparian buffer zone throughout the watershed. This is something that would not be practical to implement due to limited resources of conservation agencies and the significant reduction of farming area. However, this layer representing the maximum extent is used to develop a database of row and column information of the raster grid cells marked as riparian downstream edges (green raster grid cells in figure 3A and first three rows in figure 2). The maximum extent raster grid is represented as a vector of ones with the same size (length) as the vectors recording rows and columns of key raster grid cells (fourth row has the same size as the first three rows in figure 2).

From GA to AGBUF: In this part, the program uses the following as input: (i) flow vector layer, (ii) watershed sub-catchment layer, (iii) database of downstream edge raster cells, and (iv) binary vector (GA candidate solution). The algorithm starts by comparing the binary vector with the database of downstream edge raster cells. Only the rows and columns paired with the value of one in the binary vector are marked in the new riparian buffer zone raster grid (green raster grid cells in figure 3). The algorithm then iterates to determine and mark all the raster grid cells flowing into the already marked cells (blue raster grid cells in figure3). Examples of iteration over each buffer raster grid cell labeled 2 (in green) once (A), twice (B), and three times (C) are illustrated in figure 3. The output from the last iteration represents the raster grid layer containing the riparian buffer zone information (used as input into AGBUF).

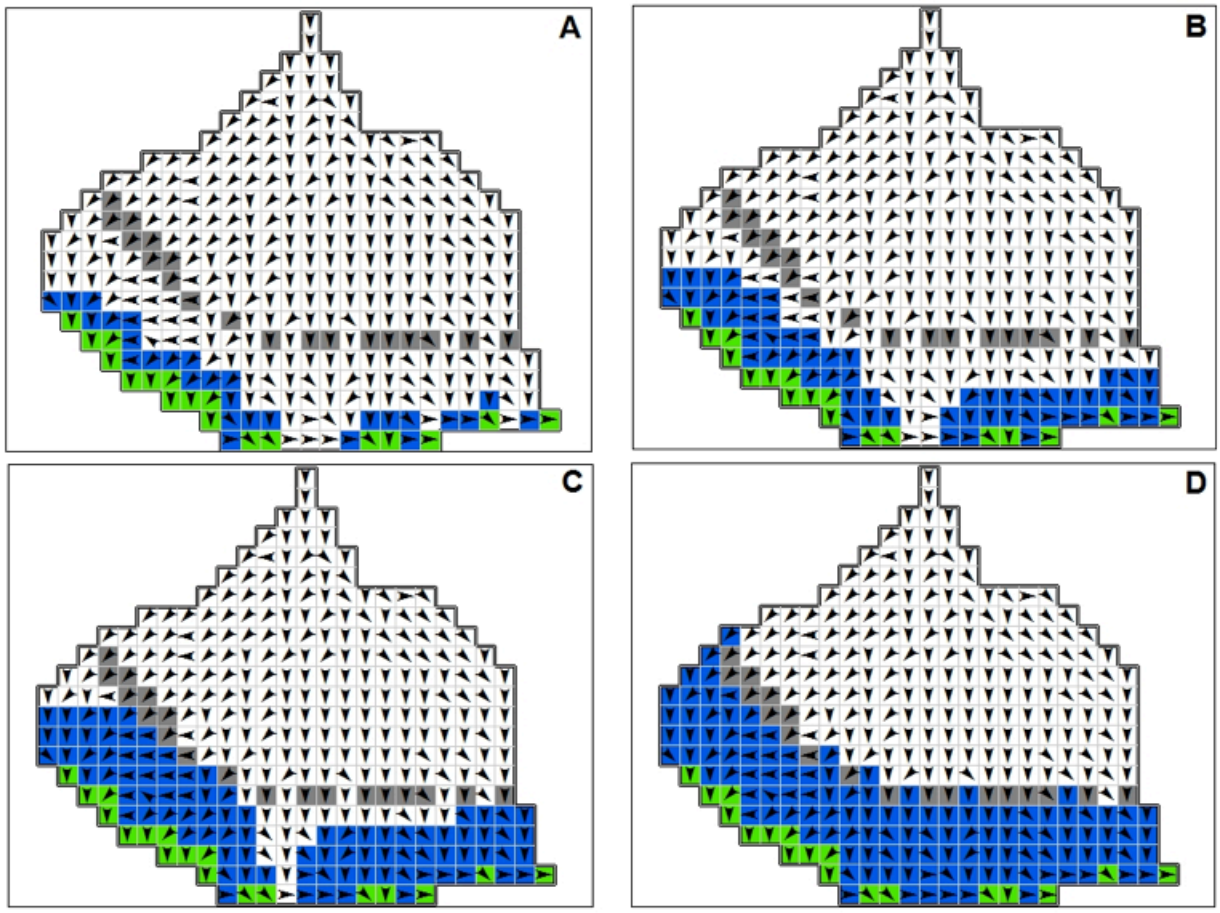

Figure 3 Iterative procedure to translate a candidate solution represented as a vector of bits into a raster grid file. Blue cells show the results of string to raster conversion after one (A), two (B), and three (C) cycles around each green raster grid cell. The final riparian buffer zone is obtained when the maximum width is reached (D).

Evolving Optimal Candidate Solutions: During the evolutionary process, GA generates and combines a large number of different candidate solutions. Different candidate solutions are generated by varying the zero and one values in each binary vector (figure 4). If a binary vector has only zeros, no riparian buffer is generated. A single value of one generates a riparian zone with the only one downstream edge raster grid cell; however its size varies depending upon the drainage pattern into the downstream edge raster grid cell (figure 4A). It is possible that a candidate solution would generate riparian filter strips off from the main concentrated flow paths (figure 4B and 4C), however they would receive poor scoring due to the estimated sediment trapping efficiency being low.

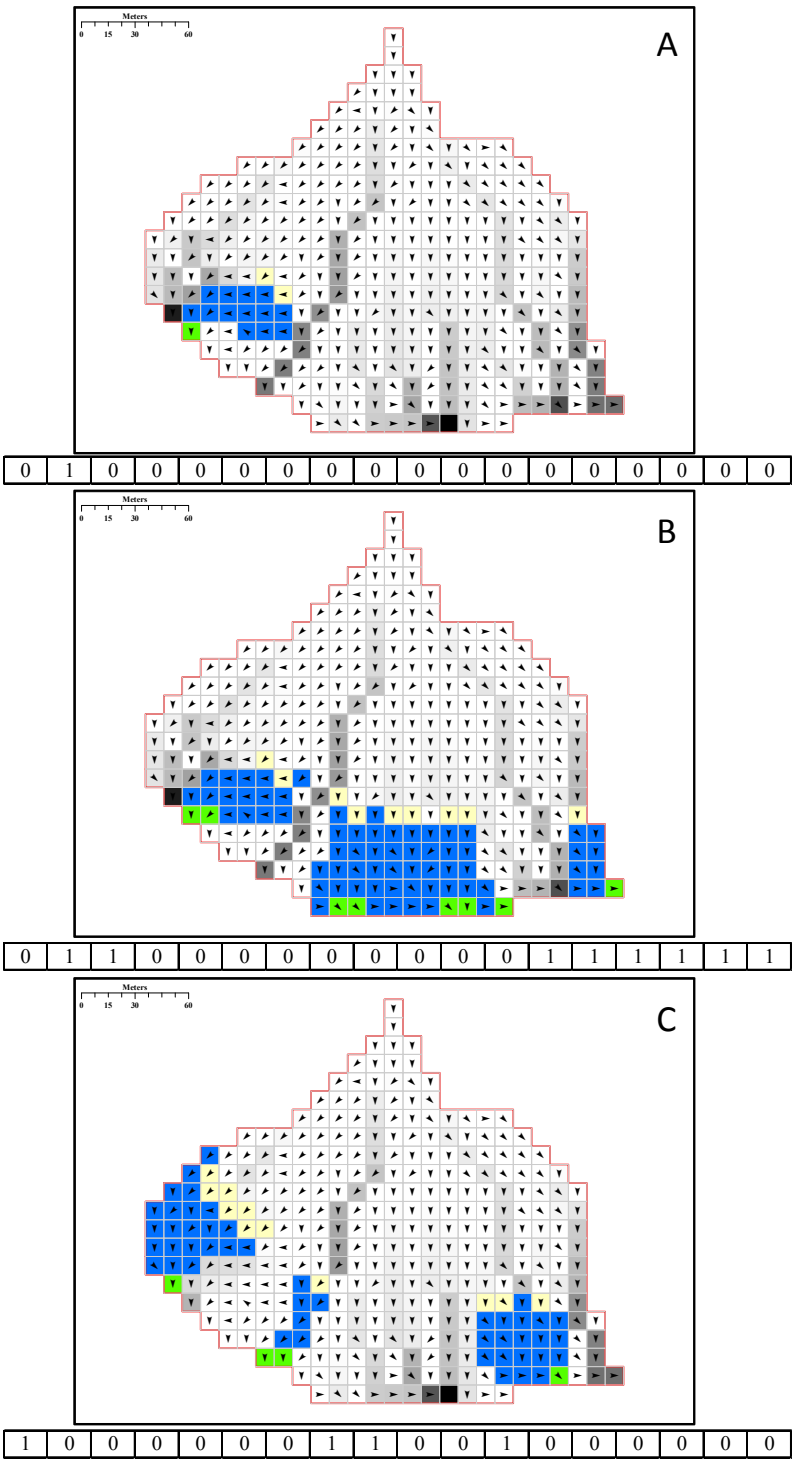

Figure 4 Examples of multiple scenarios in both representation formats: raster grid cell and vector of bits. Raster grid cells marked with gray scale symbology represent flow accumulation and indicate the presence of concentrated flow paths. Green represents downstream edge raster grid cells, yellow upstream raster grid cells, and blue riparian buffer zone raster grid cells. In the first scenario (A) only one of the downstream edge raster grid cells are activated. In the second (B) and third (C) scenarios (B) several downstream edge raster grid cells are activated, displaying the different configurations.

FINAL REMARKS

The described methods serve as the foundation to the development of a comprehensive SDSS integrating a well-established watershed modeling technology (AnnAGNPS), optimization algorithms (genetic algorithm), and GIS. Future developments will encompass the integration of these three components into a single system, with accompanying detailed documentation and easy-to-use graphical user interface.

Our long-term objective is to identify an optimal alternative that spatially locates conservation practices at the most critical locations throughout the watershed and determine their key design parameters. This optimal alternative should minimize nutrient-rich soil losses and, at the same time, maximize production area. Such technology represents an important step in understanding and accounting for the integrated effect of conservation practices and erosion sources by utilizing resources efficiently and promoting sustainable agricultural production.

Abstract: The development of watershed conservation management plans involves many decisions that affect various aspects of a watershed system, with consequences that are difficult to measure. In addition, the efficient placement of practices throughout a watershed as part of an integrated management plan can be difficult without the use of remote sensing data and technology. Watershed modeling technology can use remotely sensed data to evaluate the best placement of edge-of-field buffers and grassed waterways or drop-pipes for gully erosion control for efficient use of conservation resources. This study evaluated the capability of using remotely sensed data and technology for assessments with the USDA Annualized Agricultural Non-Point Source pollutant loading model, AnnAGNPS, in agricultural watersheds. Identification of ephemeral gully and riparian buffers locations and their characteristics were developed using remote sensing components developed as part of AnnAGNPS for comparison to actual locations and characteristics observed in the Goodwin Creek Watershed in North-Central Mississippi that is part of the USDA-ARS Benchmark CEAP-Watershed Assessment Study project. Simulations were performed with AnnAGNPS to assess various levels of conservation practice implementations identified with remotely sensed data and compared to measured loads.

Developing enhanced technology and research to assess conservation management plans is critical for planning and implementing conservation practices specifically designed for erosion and other pollutant control. This study describes the current state of using remote sensed data and research needs for assessing integrated conservation practices and management planning for controlling pollutant loads using the AnnAGNPS watershed model.

Real-Time Forecasting Using HEC-HMS and HEC-MetVue

EXTENDED ABSTRACT

Myles McManus, Hydraulic Engineer, U.S. Army Corps of Engineers, Tulsa District, Myles.B.McManus@usace.army.mil

The procedures and methods used in developing HEC-HMS models by the Corps of Engineers, Tulsa District provide the functionality to predict inflow volumes, rates, and elevations into the reservoirs of the district. This information is used by water managers to make key decisions on the operations of the reservoirs and the consequences of these actions resulting at downstream locations. Tulsa District has been actively pursuing and developing HEC-HMS models for several years to replace the legacy forecast tools with the CWMS (Corps Water Management System) suite of programs by the HEC (Hydrologic Engineering Center). The existing real time rainfall/runoff models are HEC-1 based, in conjunction with various utility programs used for data management.

In order to show how Tulsa District is performing real-time forecasting in lieu of having a complete CWMS package and database setup, a model demonstration using HEC-MetVue, HEC-DSSVue, and HEC-HMS will be shown. The demonstration shows how Tulsa District is extensively testing our HEC-HMS models in preparation for unplugging our legacy WCDS database, programs, and forecasting methods in the interim period while we complete the various tasks involved with completing our full CWMS initiative.

The HEC-HMS models are calibrated using three historical events for each HMS model. Selection of the historical event involves consideration of many factors, such as an isolated storm event, basin wide runoff, variations of rainfall magnitude, observed data availability, and availability of digital precipitation from radar. Archived digital stage III radar files are obtained from the National Weather Service Arkansas-Red River Forecast Center's (ABRFC) office. The program, HEC-MetVue, is used to develop subarea hyetograph data sets using watershed model subbasin shapefiles from the stage III radar files. The hyetographs are used in HEC-HMS to calculate the rainfall runoff volume.

The transform method used is a modified Tulsa regional Snyder's unit hydrograph method. Stream routing methods are primarily Modified Puls routing method for most reach elements. Where Modified Puls storage discharge relationship data is unavailable, the Muskingum routing method is used. Routing lags are also used in the models where there may be significant backwater effects that would cause timing issues with the flow when routing to downstream calibration points. Overall, the routing method chosen is based on available data as well as the most appropriate method for the routing reach.

The base flow method used is Initial Recession, where an initial flow, ratio to peak, and recession constant parameters are used. The reservoirs are modeled using pool routing elements. Paired data for uncontrolled spillway outflow potential is configured using elevation-discharge relationships. Other releases are configured using a user specified controlled release component of the total outflow. Some dams have totally controlled releases, while others have a combination of controlled and uncontrolled releases. This approach allows data for observed inflow, outflow, and elevation to be used in calibration of HEC-HMS models for both historic and real-time events.

Once a full CWMS package is developed and unrolled, we will have HEC-MetVue, HEC-HMS, HEC-ResSim, HEC-RAS, and HEC–FIA, and HEC–CAVI watershed models to use over our entire district. This will allow us to work within the HEC-CAVI program, using a native model implementation approach, to access all the modeling

programs within a single interface. Our current Water Control Data System (WCDS), a database for all our water information including gage and reservoir data, will be transferred onto a new Oracle database to be used with the CWMS system.

The following is a very brief rundown of each piece of software that will be used in CWMS. HEC-MetVue will provide the hyetograph data from radar precipitation data files. HEC-HMS will process the inflow hydrographs at reservoirs and gages, HEC-ResSim will provide reservoir simulation with release logic built for each dam. HEC-RAS will provide in depth flow analysis and inundation mapping. HEC-FIA will provide damage and risk economic assessments. All these programs will be run from inside the HEC-CAVI environment. Any refining or adjustments to observed data in the database will be performed in HEC-CWMSVue, which is very similar to HEC-DSSVue, but has the ability to connect to the CWMS Oracle database and edit that data as well as DSS data.

At this time, Tulsa District is in the model building phase. Recently, CWMS 3.0 was released and is currently being tested with the suite of CWMS models for one of our watersheds. This process is ongoing and will require extensive testing, debugging, time, and effort. Our CWMS Oracle database is also being built at this time. In order to ease the transition to CWMS and ensure we are maintaining all our current abilities to forecast and provide high quality flood control information to the water managers in Tulsa District, we are testing our HEC-HMS models with HEC-Metvue and HEC-DSSVue to compare these results to our legacy software results for the same events and observed data. This allows us to be testing the software and models that are critical to forecasting without having a full CWMS package developed. The current methods and procedures used for real-time forecasting using HEC-HMS models should provide insight on how the hydrological modeling is progressing and evolving within the Corps of Engineers, Tulsa District.

A NEW FRAMEWORK FOR MONITORING THE GREAT LAKES WATER BALANCE ERROR

James W. Lewis, Research Hydraulic Engineer, U.S. Army Engineer Research and Development Center, Coastal and Hydraulics Laboratory, 3909 Halls Ferry Road, Vicksburg, MS 39180, James.W.Lewis@usace.army.mil, (601)634-3895;
Rebecca Bolinger, Postdoctoral Fellow, NOAA Great Lakes Environmental Research Laboratory, 4840 South State Road, Ann Arbor, MI 48108, Becky.Bolinger@noaa.gov, (734)741-2248

Abstract: Agencies across multiple U.S. states and Canadian provinces seek to better understand the hydrologic cycle of the Great Lakes basin. Each estimated hydrologic component, whether based on models or observations, contributes an error to the Great Lakes water balance. A common goal among all agencies is to reduce the water balance error through improved modeling and measurement techniques such that the combined effect of the estimated components matches the water level behavior. Traditionally, different quantities for residual and component net basin supplies have been used to evaluate the Great Lakes water balance. However, these quantities add an unnecessary level of complexity and confusion when cooperating to target primary sources of error in the water balance. A relatively simple framework, based on conservation of mass, is presented in this study that calculates the water balance error for each lake. The primary outcome is a framework where different model estimates can be compared and large contributions to the water balance error can be cooperatively prioritized and targeted. General plots of each lake's error show a number of clear observations suggesting an oscillating seasonal error of precipitation, a potential bias in some connecting channel flow data, and what would happen to the water balance error with the hypothetical inclusion of thermal expansion and contraction. A cooperative reduction in the magnitude of the water balance error will improve Great Lakes water policy and management.

INTRODUCTION

The Great Lakes basin stretches internationally across eight states within the United States of America and two provinces within Canada, containing approximately 20% of the world's volume of fresh water. Water levels and the fluctuations of water levels have significant impact to a broad range of stakeholders, including economic and environmental impacts to both countries. The very important effort of monitoring the hydrologic system of the Great Lakes is cooperative between multiple agencies on each side of the border (Gronewold and Fortin 2012, Fry et al. 2014). There is a growing effort among the Great Lakes community to "close the water balance".

The U.S. Army Corps of Engineers (USACE), Detroit District has developed procedures for monitoring the Great Lakes' water balance and has implemented them as a Corps Division-level International Organization for Standardization (ISO) process. The process provides a standard for review and analysis of the Great Lakes hydrologic and hydraulic (H&H) data that the Division uses in operations and in support of the International Joint Commission (IJC) boards of control. There is a large amount of uncertainty in the current modeling and estimation techniques of each hydrologic component, and although a perfect estimate of each component is

impossible, there is room for improvement among the various techniques. Quantifying the uncertainty in each component as well as the uncertainty in the overall water balance will offer insight about which improvements would be most valuable.

The primary components of the water balance for each Great Lake can be represented by Equation 1. This equation, based on the law of conservation of mass, assumes that the density of water is constant, and is therefore presented as a conservation of volume relationship. In reality, the huge volumes of the lakes can allow for slight differences in density to have an impact, and the ΔS_T term accounts for this. Each term of the equation must have the same units; typically units of volumetric flow, such as m^3/s. The equation is typically used for a specific time period, such as one month or one year. Some terms may not apply to every lake (e.g. Lake Superior does not have a connecting channel inflow).

$$\Delta S = I + P + R - E - O + D + G - C + \Delta S_T \quad (1)$$

where:

ΔS	=	Change in volumetric storage of the lake
I	=	Connecting Channel Inflow
P	=	Precipitation falling directly on the lake surface
R	=	Runoff draining from the land surface to the lake
E	=	Evaporation of water from the lake surface
O	=	Connecting Channel Outflow
D	=	Diversion of water into (+) or out of (-) the lake
G	=	Groundwater flowing to the lake, arriving from below the land surface
C	=	Net effect of consumptive uses (withdrawn water minus returned water)
ΔS_T	=	Change in lake storage due to thermal expansion (+) or contraction (-)

A quantity known as the net basin supply (NBS) is useful for combining the effects of the hydrologic components into one value to represent the general basin conditions for each lake. There are two different ways to calculate the NBS, the residual method and the component method. The component method of calculating NBS is to add/subtract the estimates from each component, hence the name. In practice, the component method is equal to $P + R – E$. The other method is called the residual method, and in practice it is equal to $\Delta S + O – I +/– D$. The final three terms of Equation 1, G, C, and ΔS_T, are significantly smaller than the other terms and are often assumed to have a negligible influence. This assumption introduces some error, though it may be small, whenever it is implemented. Altogether, the residual and component methods of estimating NBS should be relatively similar.

Traditionally, the closure of the water balance has been measured by comparing residual net basin supplies with component net basin supplies (Lee 1992; Neff and Nicholas 2005; DeMarchi, et al. 2009; Deacu, et al. 2012). Although this comparison between component and residual net basin supplies can be informative, it also adds an extra level of explanation and potential confusion when evaluating uncertainty. The framework presented in this paper relates the individual terms directly to the overall water balance error. The analysis of just one overall equation for each lake will provide helpful information about the individual components and clear insight about how well they fit together. This proposed framework deviates from the

traditional analysis and eliminates the need for calculating or evaluating the net basin supplies when analyzing the uncertainty in each component.

Equation 1 can be rearranged such that everything is on the right side of the equation, and the water balance equation in theory should be equal to zero, as shown in Equation 2, for each lake. In reality the equation contains significant uncertainty, as shown by the rearranged Equation 3 representing the typical terms which are used in practice. There are numerous sources of the error in the water balance equation, and each term of Equation 3 contains uncertainty due to measurement errors, spatial and temporal variations, modeling errors, etc.

$$0 = -\Delta S + I + P + R - E - O + D + G - C + \Delta S_T \quad (2)$$

$$Error = -\Delta S_R + I_R + P_R + R_R - E_R - O_R + D_R \quad (3)$$

where:

$Error$	=	Overall error, or gap, in the lake's water balance equation
ΔS_R	=	Recorded/estimated change in volumetric storage of the lake
I_R	=	Recorded/estimated connecting channel inflow
O_R	=	Recorded/estimated connecting channel outflow
P_R	=	Recorded/estimated precipitation falling directly on the lake surface
R_R	=	Recorded/estimated runoff draining from the land surface to the lake
E_R	=	Recorded/estimated evaporation of water from the lake surface
D_R	=	Recorded/estimated diversion of water into (+) or out of (-) the lake

METHODOLOGY

An analysis of the *Error* for each lake was performed using Equation 3. Data sets were organized and converted into common units of m^3/s for each month, using the actual number of days in each month, so that the monthly *Error* could be calculated for each lake. Some of the terms in Equation 3 could be estimated using multiple methods which are available. This analysis chose one of the possible combinations based primarily on the historical availability of the data sets. The following list shows the data set which was used for each term in the water balance for this initial assessment:

Term	Data set used
ΔS_R	Calculated from coordinated beginning-of-month lake-wide average water levels
I_R	USACE records of connecting channel flows
O_R	USACE records of connecting channel flows
P_R	Coordinated over-basin precipitation (other data sets are also compared)
R_R	NOAA GLERL Area Ratio Method
E_R	NOAA GLERL Evaporation
D_R	USACE records of diversion flows

USACE and Environment Canada (EC) coordinate the official historical data set of Great Lakes beginning-of-month (BOM) lake-wide average water levels back to 1900. The network of water level gauges currently used for the lake-wide average levels is shown in Figure 1. Gauges in the United States are operated by the National Oceanic and Atmospheric Administration (NOAA) National Ocean Service (NOS) Center for Operational Oceanographic Products and Services

(CO-OPS). Gauges in Canada are operated by the Canadian Hydrographic Service (CHS). This network of gauges was chosen by the Coordinating Committee on Great Lakes Basic Hydraulic and Hydrology Data (Coordinating Committee), a group composed of representatives from United States and Canadian federal agencies that keep official records of water levels, flows in the connecting channels, and other data related to the Great Lakes hydrologic system for the last fifty years. The difference in BOM water levels from one month to the next is multiplied by the officially coordinated lake surface area (Coordinating Committee, 1977) to determine the change in volume for each lake. This volume is divided by the time duration using the actual number of days for each month to obtain the change in volumetric storage with units of a flow rate, such as m^3/s.

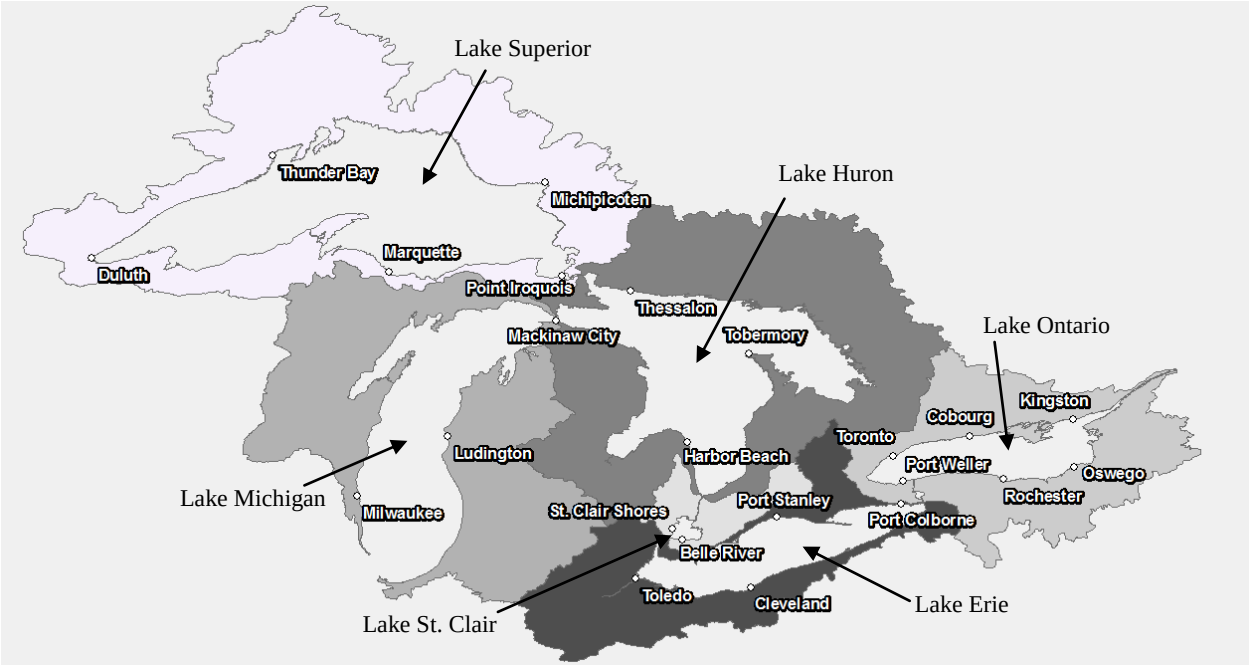

Figure 1 Location of water level gauges used in lake-wide average levels

USACE records of connecting channel flows consist of flows coordinated by the Coordinating Committee and preliminary flows. Preliminary flows are estimated by the Detroit District using a combination of the fall between the upstream and downstream lakes as well as information from NOAA and CHS water levels within the connecting channels. The officially coordinated records of connecting channel flows span 1900 to 2008, with the exception of St. Lawrence River which is coordinated through 2005. Similarly, flow through each of the five diversions (Long Lac, Ogoki, Chicago, the Welland Canal, and the New York State Canal System) is coordinated through the Coordinating Committee, with the official period of record varying for each diversion.

The coordinated over-basin precipitation data is first calculated by the NOAA Great Lakes Environmental Research Laboratory (GLERL) Thiessen Method for estimating precipitation. NOAA CO-OPS then reviews the data and compiles it to be passed on to USACE and EC for coordination. The Coordinating Committee has generally assumed that the over-lake precipitation is better estimated using the over-basin Thiessen method instead of the over-lake

Thiessen method. This assumption may have originated from Croley and Lee 1993, who explain that the Thiessen over-lake precipitation method relies on near-shore meteorology where the lake effects are significant. For this reason, Croley and Lee 1993 used all available meteorological stations throughout the basin to estimate over-lake precipitation, rather than using only near-shore stations. This assumption is investigated near the end of this report, where other data sets produced by the GLERL Thiessen Method were also evaluated; namely Thiessen over-lake and Thiessen over-land. The historical records of all GLERL Thiessen precipitation estimates span 1900 through 2010.

The most complete historical set of runoff data for each of the Great Lakes is the NOAA GLERL Area Ratio Method (ARM). This method extrapolates runoff from gauged drainage areas to un-gauged drainage areas using an area-weighted approach. The window of availability of runoff data varies, with beginning years ranging from 1900 to 1932 depending on the lake.

Evaporation data used in this study are calculated by NOAA GLERL, using their Large Lake Evaporation and Thermodynamics Model. The evaporation data set has the least amount of available data with a historic range going back to 1950.

Using the above data sets, the monthly error (units of m^3/s) is calculated for each lake as well as the annual error (units of m^3/s) from 1950 through 2010. Annual errors are calculated using the time duration of the entire year for each term in Equation 3. In order to perform useful lake-to-lake comparisons of the relative errors, the historical average of all flow into or out of each lake is used for normalizing the errors. This flow is calculated from $I + P + R$ ($+D$, if diversion flows into lake) and should be the same as $O + E$ ($+D$, if diversion flows out of lake) on average. The normalizing flow varies for each lake.

RESULTS

Table 1 shows the calculated annual and monthly average water balance errors for each lake using Equation 3. For interpretation, positive errors are generally caused by the overestimation of any term providing water to the lake or the underestimation of any term removing water from the lake. The converse is true for interpreting negative errors. Each lake's error was normalized by the total average flow into or out of the lake. These normalizing flows were 3700, 8000, 5500, 7000, and 7800 m^3/s for lakes Superior, Michigan-Huron, St. Clair, Erie, and Ontario, respectively, based on each lake's hydrology. Figure 2 shows the chart of average errors in units of m^3/s while Figure 3 shows the normalized percentages.

For more detail on the range of each lake's water balance error for each calendar month, the median, 25% quartile, 75% quartile, maximum and minimum were calculated. These statistical properties are shown in Figure 4 through Figure 8.

Table 1 Average Great Lakes water balance errors

Units of m^3/s													
	Annual	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec

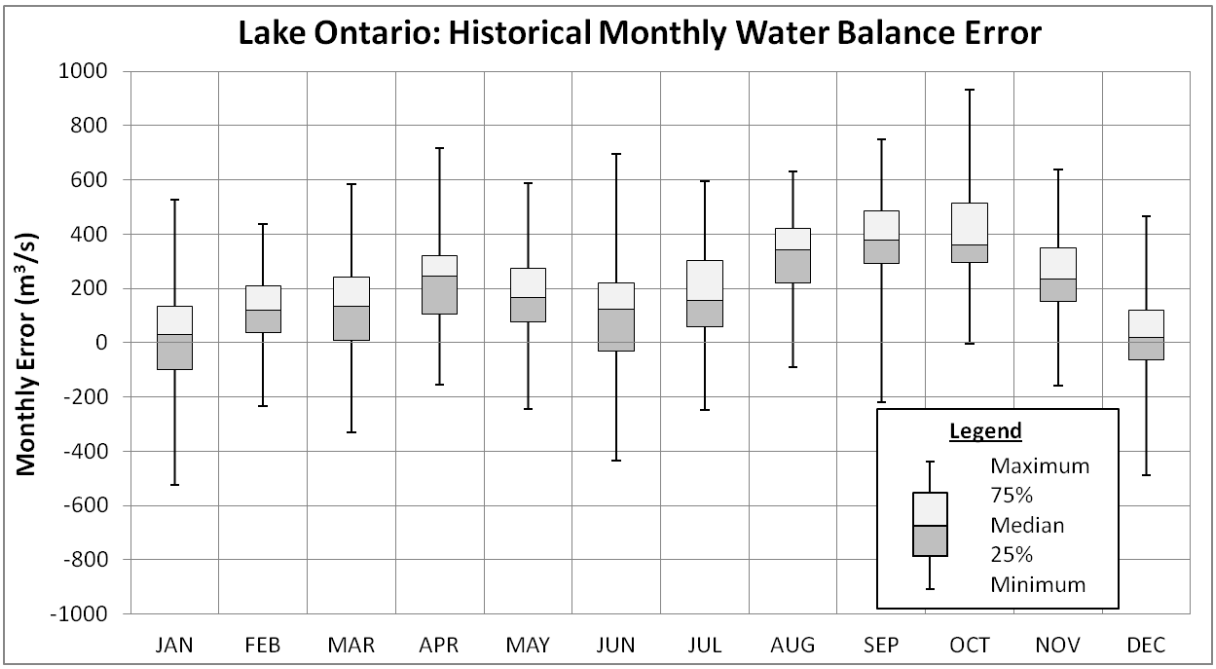

Figure 8 Lake Ontario monthly water balance error statistics

Drawing specific conclusions about errors in individual terms of the water balance requires caution, but these preliminary results reveal many interesting observations. Lakes Superior, Michigan-Huron, and Ontario each had a positive average annual error while lakes St. Clair and Erie had negative errors. In general, the Lake Michigan-Huron water balance errors are the largest while the Lake St. Clair errors are relatively small. This is apparently due to the lake surface area and drainage area of each lake. Since the area is small for Lake St. Clair, the components of *P*, *E*, and *R* are much smaller than the inflow through the St. Clair River and the

outflow through the Detroit River. For Lake Michigan-Huron, however, evaporation is approximately the same magnitude as the inflow from the St. Marys River and the combination of over-lake precipitation and runoff is larger than the outflow through the St. Clair River. A large error suggests that improving the estimates of over-lake precipitation, evaporation, and runoff, especially for Lake Michigan-Huron, should be a priority. A small water balance error for Lake St. Clair implies that the balance between connecting channel flows and water levels is relatively well estimated. However, it is possible that the St. Clair River and Detroit River could both have a bias error in the same direction which would not be detectable when looking at the Lake St. Clair error alone.

Interestingly, errors in the connecting channel flow estimates can influence both the lake upstream and downstream in an opposite manner. For example, decreasing the Niagara River flow estimates would cause both the Lake Erie and the Lake Ontario water balance errors to improve, i.e., move toward zero. Therefore, a re-evaluation of the Niagara River flow estimation method, and/or the investigation of any available hydraulic models, is suggested.

Another interesting observation can be made related to the thermal expansion and contraction of the lakes. In general, the summer water balance errors are positive for the Great Lakes, with the exceptions of lakes St. Clair and Erie. Lake St. Clair is generally below zero for June through August while Lake Erie is near zero for April through August. As the lake water warms in the summer time there is an increase in the lake's water volume due to thermal expansion, creating a positive contribution to the water balance error. Although this would be a more accurate representation of lake storage, it would generally move the Superior, Michigan-Huron, and Ontario errors further away from zero since the errors are already positive, and it would make Lake Erie's error worse as well since it is near zero during those months. This implies that the inclusion of thermal expansion and contraction alone would not perfectly solve the water balance. This is not to suggest that it should be purposefully ignored, but just that it may not be as high of a priority. A proper inclusion of thermal expansion and contraction should be included when available because the goal of monitoring is to have as good of an estimate for each term as possible.

Lakes Superior, Michigan-Huron, and Ontario exhibit some similar seasonal error patterns. The water balance error seems to increase through the summer and then drop significantly at the end of the fall season. This consistent error behavior across multiple lakes may indicate a bias in one or more of the methods used to estimate the components (P, E, or R). Relevant literature (Derecki 1976, Kresge et al. 1964, Holman et al. 2012, and Changnon 1961) acknowledges that the over-lake to over-land precipitation ratio is relatively low in the summer and relatively high in the winter. Since the Thiessen method precipitation estimates are based primarily on gauges over the land, it makes sense that the sign of the seasonal errors shown in the figures could be caused by the over-lake and over-land dynamics. A correction to account for the over-lake and over-land precipitation dynamics would seem to provide significant benefit to the water balance by decreasing the error in the summer months and increasing the error (from a negative value toward zero) in the winter months.

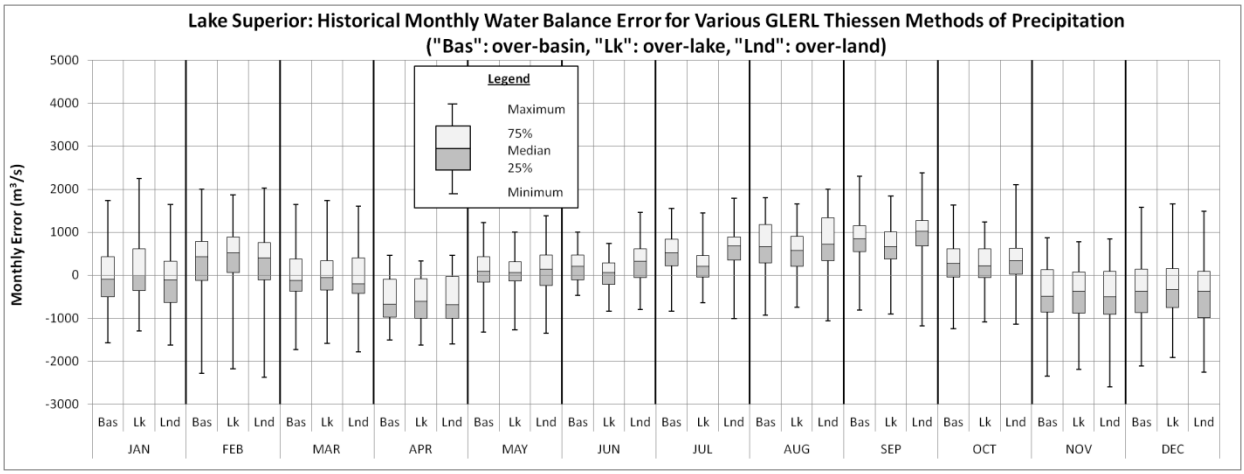

Figure 9 Comparison of GLERL Thiessen precipitation estimates within the framework of the Lake Superior water balance error

As mentioned above, the Thiessen over-basin method is typically used to estimate the over-lake precipitation component of the water balance. Figure 9 presents the side-by-side comparison of GLERL Thiessen Methods for over-basin, over-lake, and over-land precipitation in terms of their influence on the Lake Superior water balance error. In every month except for February, the median Lake Superior water balance error would be improved by using the Thiessen over-lake estimates instead of the over-basin estimates. The month of July is a clear example, where the Lake Superior median error would become 200 m^3/s instead of 500 m^3/s. This indicates that the assumption made by Croley and Lee 1993 appears to be incorrect. It is recommended that this type of comparison be made for each of the other lakes. The Coordinating Committee may wish to consider coordinating Thiessen over-lake precipitation estimates rather than Thiessen over-basin estimates. It is important to note that the Thiessen over-lake estimates are based on near-shore stations, and according to Holman et al. 2012, the seasonal differences between over-lake and over-land precipitation should be much greater than is calculated by the respective GLERL Thiessen methods.

DISCUSSION

The framework for computing the water balance error, presented in Equation 3, will be helpful for relating various sources of uncertainties to one another within the Great Lakes water balance. Comparisons using this basic conservation equation provide more readily apparent observations to a wide audience than the traditional comparisons between residual and component net basin supplies. From a preliminary analysis, which used only one method of estimation for each term of Equation 3, statistical properties were calculated for the monthly and annual water balance errors for each lake. One interesting observation is that the consistent error pattern across multiple lakes suggests that improving the historical precipitation estimates based on seasonal over-lake and over-land dynamics should be a high priority for moving toward "closing the water balance". On the other hand, these preliminary results seem to indicate that although the inclusion of thermal expansion and contraction could provide a more accurate estimate of lake storage, it would not resolve some of the largest magnitudes of water balance error and could even push them further away from zero. Going forward, a comparison using multiple estimation

methods for each term within this framework could provide further insight about individual modeling and estimation techniques.

RIVER RESTORATION DECISION ANALYSIS - 2D HYDRODYNAMIC APPROACH TO PROJECT PRIORITIZATION

David J. Bandrowski, Trinity River Restoration Program, U.S. Bureau of Reclamation, Weaverville, CA, USA, dbandrowski@usbr.gov; Yong G. Lai, Technical Service Center, U.S. Bureau of Reclamation, Denver, CO, USA, ylai@usbr.gov; D. Nathan Bradley; Technical Service Center, U.S. Bureau of Reclamation, Denver, CO, USA, dnbradley@usbr.gov; Josh Murauskas, Anchor QEA LLC, Wenatchee, WA, USA; jmurauskas@anchorqea.com

Abstract: In the field of river restoration sciences there is a growing need for analytical modeling tools and quantitative processes to help identify and prioritize project sites. Two-dimensional (2D) hydraulic models have become more common in recent years and with the availability of robust data sets and computing technology, it is now possible to evaluate large river systems at the reach scale. The Trinity River Restoration Program (TRRP) – Bureau of Reclamation in Northern California is now analyzing a 40 mile segment of the Trinity River to determine priority and implementation sequencing for its Phase II channel rehabilitation projects. A comprehensive approach and quantitative tool has recently been developed to analyze this complex river system. The 2D-Hydrodynamic-Based Logic Modeling (2D-HBLM) tool utilizes various hydraulic output parameters combined with biological, ecological, and physical metrics at user-defined spatial scales and flow discharges to evaluate geomorphic characteristics, riverine processes, and habitat complexity. The habitat metrics are integrated into a comprehensive Logic Model framework to perform statistical analyses to assess project prioritization. The Logic Model will analyze various potential project sites within the 40 mile restoration reach by evaluating connectivity and key response variable drivers. The 2D-HBLM tool will help inform management and decision makers by using a quantitative process to optimize desired response variables with in determining the highest priority locations within the river corridor to implement restoration projects.

Keywords: 2D Hydraulic Modeling, Quantitative Prioritization, Evaluation Metrics, Logic Modeling, Statistical Analysis, and River Restoration

INTRODUCTION

Effective river restoration prioritization starts with well-crafted goals that identify the biological objectives, address underlying causes of habitat change, and recognize that social, economic, and land use issues may constrain restoration options (Beechie et. al. 2008). In addition, effective management actions need to be tied to a Structured Decision Making (SDM) process that connects decisions to objectives (Hammond et al. 1999, Clemen and Reilly 2001). Applying natural resources management actions to the SDM process, like restoration prioritization, is essential for successful project implementation (Conroy and Peterson, 2013; Evers, 2008). This paper describes a river restoration prioritization approach that integrates two-dimensional (2D) hydraulic modeling with desired response and limiting factor metrics into a statistical model framework. This river restoration tool, referred to as two-dimensional hydrodynamic-based logic modeling (2D-HBLM), will analyze and evaluate key biological, physical, and ecological desired responses in relation to various physical and social constraints that may limit restoration options. In this paper, we will demonstrate how this approach can be effectively applied to a large river restoration program to help prioritize projects systematically and objectively.

All too often restoration actions are site specific without considering and evaluating ecosystem scale processes, protection of existing high quality habitats, or an understanding of the effectiveness of specific restoration techniques (Roni et. all. 2002). With over two decades of scientific literature and applied practice, the restoration community has a thorough understanding of the role of channel morphology in the formation of physical habitats (Montgomery and Buffington 1998) and the relationship between flow depth and velocity and habitat quantity and quality (Singh 1989, Lamouroux 1998, Stewart et. al. 2005, Saraeva and Hardy 2009, Goodman et. al. 2014). The understanding of geomorphic processes and physical habitats have been integrated into models to assess hydraulic relationships quantitatively (Schweizer et. al. 2007, Dunbar et. al. 2012) and eco-hydraulic questions through prediction-based simulations (Bovee 1982, Gore et. al. 1998, Milhous et. al. 1989). Model utilization requires restoration science not only to embrace uncertainty (Darby and Sear 2008, Hillman et. al. 2008, Wheaton et. al. 2008), but to integrate bio-physical diversity, variability, and complexity into river management (Brierley and Fryirs 2008). Evaluating tradeoffs and examining alternatives to improve fish habitat through optimization modeling (Null and Lund, 2012) is not just a trend but rather the scientific strategy that management needs to embrace and apply in its decision framework.

The overall approach of this reach-based prioritization is to evaluate the river system through integration of 2D hydraulic modeling, quantitative metric evaluation, and statistical logic modeling within a broader adaptive management and SDM framework. The topics described below include: an overview of 2D hydraulic modeling, the application of the 2D model to the Trinity River, the development of the habitat module quantitative metrics, and the approach to the logic model framework.

OVERVIEW OF 2D HYDRAULIC MODELING

Stream flow modeling is one of the most widely used tools to understand how hydraulic conditions change between discharges and how they are related to fish habitat (Bovee, 1982; Milhous et al., 1989). Building on the early use of one-dimensional (1D) models, 2D hydrodynamic modeling has been widely used for evaluating hydraulic habitat data (e.g. water depth, water velocity, and substrate size). 2D models can be operated on a finer scale than 1D models and they can accurately predict hydraulics in near-shore habitat and across large-scale roughness features (Waddle et al., 2000). 2D models can more accurately predict water velocities and depths at local scales due to the ability to calculate both longitudinal and lateral velocity distributions (Crowder and Diplas, 2000). Sample applications of 2D hydrodynamic models for habitat evaluation include Tharme 2003), Wheaton et al. (2004), Stewart et al. (2005), Mingelbier et al. (2008), Yarnell et al. (2010), Waddle (2010), and Hatten et al. (2013).

In recent years, the trend has been to use a 2D model to represent the roughness elements at the individual boulder scale (e.g., Waddle, 2010), because riverine salmonid species are known to use flow obstructions as velocity shelters in order to minimize energy expenditure while foraging and resting (Bjornn and Reiser, 1991). Boulder placement and the use of large wood are techniques of river restoration commonly used to provide increased diversity of velocity patterns in generally uniform river channels. Accurate modeling of such areas can provide better information about the extent of habitat in rivers and tools for design of constructed habitats.

In this study, we use the U.S. Bureau of Reclamation's Sedimentation and River Hydraulics Two Dimensional depth averaged hydraulic model (SRH-2D). SRH-2D, documented by (Lai 2008; Lai 2010), has been widely used for evaluation of river projects. The robustness and accuracy of SRH-2D have been proven with a wide range of model verifications, as well as many project applications, at both Reclamation and external institutions. SRH-2D has a few unique features which make it ideal for river applications. First, SRH-2D uses a flexible mesh that adopts the arbitrarily shaped element method of Lai et al. (Lai, 2003) for geometric representation. In practice, a hybrid mesh normally uses quadrilaterals in the main stream and near structures and triangles in the floodplain and transition zones. The hybrid mesh achieves the best compromise between accuracy and computing efficiency and such a mesh is relatively easy to generate. Second, SRH-2D adopts very robust (stable) numerical schemes with a seamless wetting-drying algorithm. Reliable solutions may be obtained with the primary tuning parameter of Manning's n. Third, SRH-2D solves the 2D depth-averaged St. Venant dynamic-wave equations using an implicit solution scheme and unstructured meshes with arbitrary mesh cell shapes. It solves both steady and unsteady flows over all flow regimes (subcritical, supercritical or transcritical flows).

APPLICATION OF THE 2D MODEL ON THE TRINITY RIVER

The Trinity River is an ideal location for an applied scientific assessment of a reach based model due to the wealth of robust data sets that span large spatial and temporal scales. The Trinity has been monitored consistently for decades and has been surveyed at high resolution as required for two dimensional hydraulic modeling. A seamless Digital Terrain Model (DTM) that integrates terrestrial and bathymetric topography is the basis of the 40 mile hydraulic model. The DTM for the Trinity consists of airborne LiDAR topography and boat-based sonar bathymetry across the entire reach (Woolpert, 2013) that has been validated within 95% vertical confidence intervals using 0.320-foot RMSEz (Root Mean Square Error) for LiDAR and +/-0.686-foot RMSEz for sonar. This validated accuracy is based on extensive quality control field measurements consisting of 40 channel spanning cross-sections and 849 independent GPS-RTK check shots along the Trinity. The DTM has been certified by a professional licensed land surveyor and exceeds both National Map Accuracy and American Society of Photogrammetry and Remote Sensing (ASPRS) Standards.

In addition to topographic data sets, aerial imagery orthophotography has been collected in multiple years and serves as the foundation data set for geospatial mapping on many projects including the 2D hydraulic model mesh generation. Two model meshes were developed for this project: a coarse mesh to use for model calibration (the calibration mesh) and a denser mesh to use for the actual assessment (the habitat mesh). Both meshes are hybrid meshes that use rectangular elements in the main and side channels and triangular elements in areas that are dry at most flows. The calibration mesh contains one quarter the number of elements as the habitat mesh across the 40 mile reach on the Trinity River.

The calibration mesh was developed from channel bank lines digitized from the aerial imagery data set (Figure 1). The complexity and curvature of the channel dictated the length of elements in a reach. Long straight reaches contain longer elements, Tight bends and areas of complex morphology contain shorter elements.

The width of main channel mesh elements is 1/8 of the local channel width. Side channel

mesh elements are 1/3 of the local side channel width. Calibration mesh elements range from approximately 10 to 50 feet in length and 5 to 25 feet in width. The mean area of calibration mesh elements is 284 square feet.

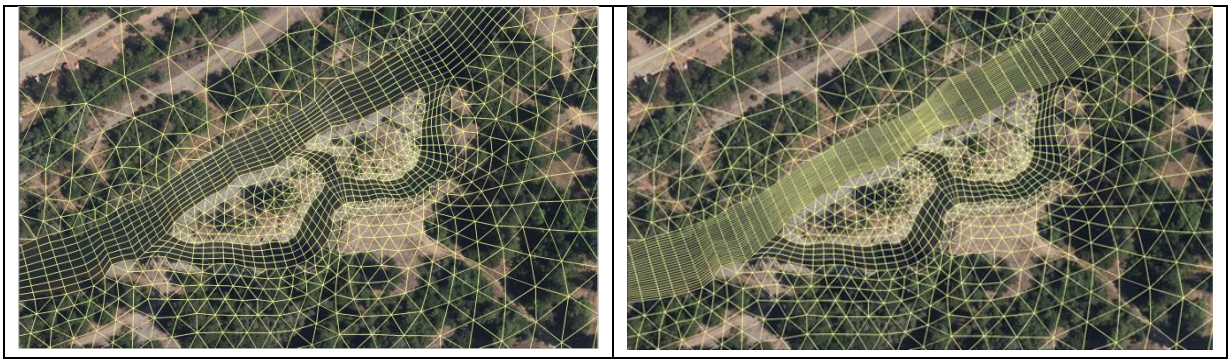

Figure 1 Comparison of the calibration mesh (left) and the habitat mesh (right)

The habitat mesh was developed by dividing each calibration mesh element into four elements. Channel elements in the habitat mesh range in width from approximately 1 foot to 10 feet. The mean area of habitat mesh channel elements is 71 square feet.

The sole calibration parameter available in SRH-2D is the channel roughness, represented by Manning's n. Increasing channel roughness by increasing the value of Manning's n has the effect of raising the water surface elevation and reducing the flow velocity. Decreasing channel roughness has the opposite effect. The calibration data we used are water surface elevations measured during the bathymetric survey at seven different discharges ranging from 500 cfs to 4500 cfs. About 91% of the model error (modelled elevation minus observed elevation) is within +/- 0.5 feet and the error is symmetrically distributed around zero. This error is similar to the error in the bathymetric data collection.

HABITAT MODULE QUANTITATIVE METRICS

The 2D hydraulic model was run for approximately 20 different discharge cases, ranging from 300 cfs to 14,000 cfs. The hydraulic output of the 2D model is used by a tool called the "Habitat Module to evaluate riverine characteristics using a series of biological, ecological, and physical criteria. The Habitat Module uses quantitative algorithms to calculate key hydraulic variables or "metrics" throughout the river. The metrics are grouped into three spatial output types: 1) Panel-Based "Panel"; 2) Cross-Sectional; and 3) Spatially Distributed - across the mesh elements. For this study, the Panel output was the primary type used. The Panels are 200 meter long and are based off a sampling protocol system currently being used on Trinity for system wide monitoring called Generalized Random Tessellation Stratification (GRTS). Across the entire 40 mile reach, there are 319 Panels from upstream to downstream. The Panel system was used to help organize the hydraulic output and metrics into a uniform system to which further statistical analyses can be applied.

The metrics calculated from the hydraulic model are categorized into three types: Biological, Ecological, and Physical. The other types of information used were field collected empirical data from the Trinity. Table 1 below shows all the available metrics calculated and empirical data that was field measured.

Physical Metrics: Restoration activities on the Trinity River include flow and sediment management intended to promote the dynamic fluvial processes that create diverse physical habitat and rejuvenate the aquatic ecosystem. The physical process metrics used in this study were developed to help quantify the existing geomorphic complexity within each Panel. The fluvial processes involved in the maintenance of high-quality habitat are tightly linked to sediment supply and sediment transport capacity. Scour and fill processes, in which the elevation of the steam bed or bar surface changes dynamically through time, create topographic complexity, maintain substrate quality, and rejuvenate riparian vegetation. Lateral erosion of the banks facilitates planform adjustment and contributes to the formation of alcoves, sloughs, and complex bar features. Although the habitat module cannot address questions about sediment supply, its output includes several metrics intended to assess the spatial variability of sediment transport capacity and geomporhic complexity within each Panel. Shear stress and stream power metrics within each Panel represents the rate of energy dissipation against the bed and banks of a river, which can be used as an indicator of local sediment transport capacity. Using the first derivative of the shear stress can provide an additional metric, which helps determine if the stress in the Panel is increasing or decreasing, providing an indication of where local scour or fill might be expected. The Vorticity metric calculates the angular velocity of a fluid particle and is a kinematic property of the flow field which as a measure of river complexity.

Additional physical metrics include: Flow Direction Change Hydraulic Cross-Over, Wetted Edge Length, Sinousity, Thalweg, etc. For example, Edge Length is the total length of wet-dry boundaries within a panel and reflects complexities of flows around islands, boulders, etc. Various physical metrics can be combined into one representative metric to compare and evaluate the system-wide geomorphic potential or its overall physical complexity at applicable flow discharges. Assessing these metrics in combination can be accomplished using a statistical approach called Principal Components Analysis (PCA). A PCA is used to model variation within a set of metrics to produce a smaller number of independent linear combinations (i.e., principal components; JMP ® 11, SAS Institute, Cary, North Carolina). The first principal component of variables related to geomorphic potential at 6,000 cfs—including velocity, average bed shear stress, average first derivative of shear stress, and stream power—was derived to show the most prominent direction of these metrics using a single variable.

Biological Metrics: A deficit of juvenile rearing habitat has been identified as the primary limiting factor of salmonid populations in the Trinity Rivr and many other rivers. Fry and Pre-smolt critical rearing habitat is computed from the hydraulic model output using Habitat Suitability Criteria (HSC) of derived Depth (D), Velocity (V), and Cover (C). These HSC values were developed for the Trinity River specific to the life stage and species (Goodman et al. 2014). The metric for rearing habitat is fry and Pre Smolt area is based on meeting the depth and velocity combinations (DV) and cover requirements determined by field validated HSC values. The cover criteria are based on field-derived values of suitable distance to vegetation, wood, or other escape cover. The HSC values serve as an index or value range to determine if the habitat is within suitable desirable criteria range for rearing habitat. (See Table 2 below)

Table 2 Trinity River binary habitat suitability criteria from Goodman et al. (2014)

Life stage	Depth	Velocity	Cover
Fry (< 50 mm fork length)	≤ 0.6 meter	≤ 0.15 meters/second	≤ 0.6 meters
Presmolt (50 to 100 mm fork length)	≤ 1.0 meter	≤ 0.24 meters/second	≤ 0.6 meters

The Weighted Useable Area (WUA) metric is a method of combining the scores from the above HSC data for depth, velocity, and cover to evaluate the quality of habitat at a range of values rather than using a binary approach of index cut-off values. WUA habitat values were the primary metric used for the evaluation of biological quality throughout the Trinity system.

APPROACH TO THE LOGIC MODEL FRAMEWORK

The objective of the Logic Model is to assimilate professional judgment, 2D modeling outputs, and empirical data to objectively prioritize restoration projects. Once the hydraulic variables and metrics are calculated within the habitat module and synthesized for each of the 319 Panels. The Logic Model is the component within the 2D-HBLM process that analyses the data statistically and links desired responses with limiting factors to prioritize areas of the river for restoration. Quantitative approaches have long been recognized as a key to improving processes (Box and Myer 1986). Modeling, hierarchical ordering of effects, and identifying key relationships and root causes for deficiency is commonplace in manufacturing (Harry and Schroeder 2006) and increasingly in biological sciences (Dassau et al. 2006; Huang et al. 2009). The Logic Model utilizes such approaches to assess key measures and relationships followed by integration of desired responses and limiting factors to inform prioritization.

Measures used in the Logic Model include physical, biological, and ecological based metrics, along with metrics from empirical data selected using professional judgment prior to analysis. Desired responses include improvements to the quality, connectivity, and complexity of salmonid habitat (Roni et al. 2002). Conversely, limiting factors constrain the ability to implement restoration projects (e.g., access or infrastructure). The distinction between desired responses and limiting factors is important in that the Logic Model is intended to prioritize restoration projects where the need, relative benefit, and practicality are optimized.

Data used in the Logic Model were examined prior to statistical modeling. Both desired responses and limiting factors were reduced to a set of uncorrelated variables using Principal Component Analysis (SAS Institute 2008). This step minimizes the issue of multi-collinearity

in further analyses, particularly with predictor variables (Saab 1999). Desired responses and limiting factors were further analyzed for spatial autocorrelation since standard statistical techniques assume independence among observations. For example, preliminary evaluations show that suitable fry habitat has a partial autocorrelation with at least the two preceding panels at 4500 cfs. Quantitative approaches used in the Logic Model compensate for the relationships among neighboring panels to ensure that parameter estimates and significance tests yield reliable results (Isaak et al. 2010).

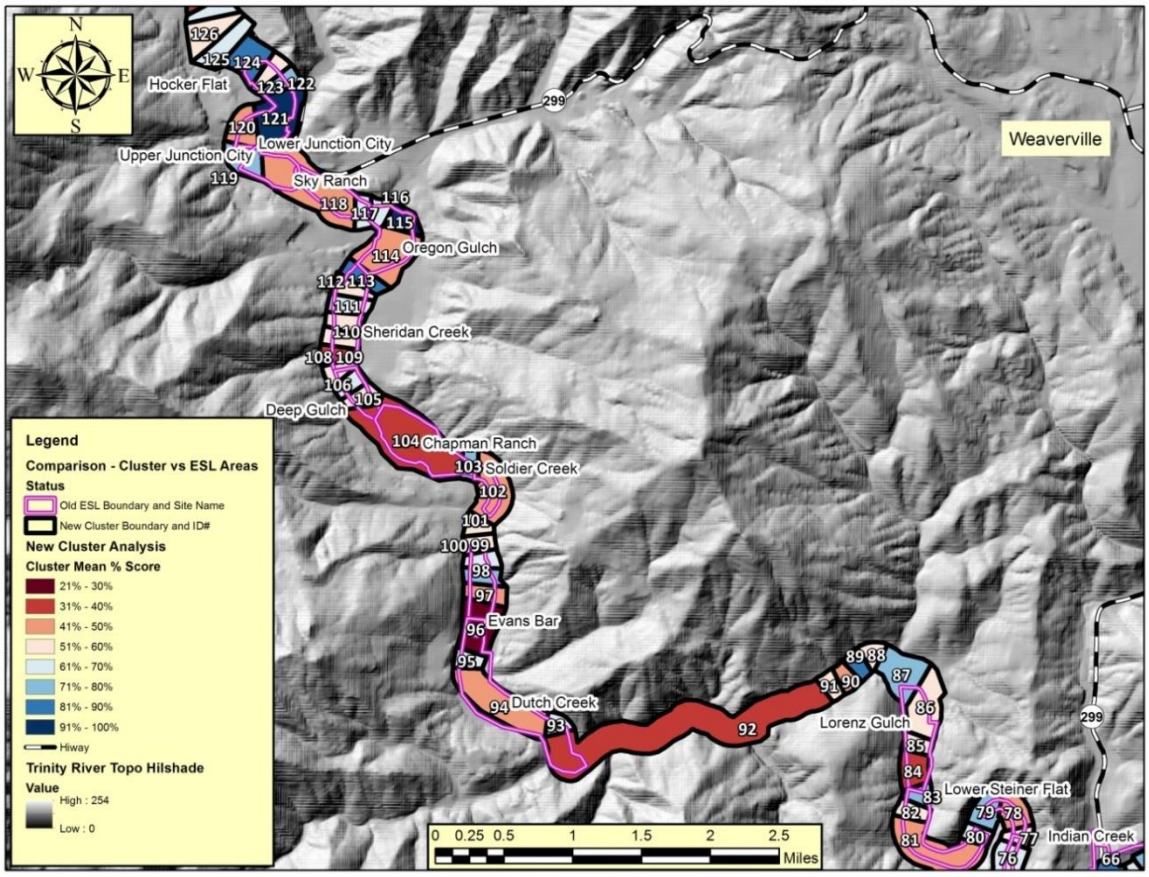
Five metrics were ultimately chosen to be used in the Logic Model analysis to represent biological quality, connectivity, and river complexity, see Table 3 below. Biological quality was defined as the habitat calculated from the weighted usable area (WUA) at winter base flow (300cfs) and at a typical spring flow (1500cfs). Connectivity was defined by the total number of redds observed within each panel and three upstream panels (i.e., a running total of four panels). Complexity was defined by the standard deviation of bed elevation and the standard deviation of stream power at 8,500 cfs. Each panel was ranked relative to the remaining panels (1 to 319) for all five metrics, with ascending ranks for habitat quality and complexity and descending ranks for connectivity (redds). Thus, panels with low WUA values, low variation in complexity, and proximity to a large number of redds would receive lower rankings across the five metrics.

Table 3 Weighting of Metrics Used in the Logic Model in Panel Scoring

Metric	Category	Weight	Relative influence
Rearing Habitat at 300 cfs rank	Habitat Quality (Low Flow)	1.50	0.333
Rearing Habitat at 1,500 cfs rank	Habitat Quality (Mid Flow)	1.00	0.222
Total spawning redds (upstream 3 Panels) rank	Biological Connectivity	1.00	0.222
Standard Deviation of bed elevation (m) rank	Topographic Complexity	0.50	0.111
Standard Deviation of unit stream power (8,500 cfs) rank	Hydraulic Complexity	0.50	0.111

Panels were scored by summing the total ranks across the five metrics, with each metric weighted according to values shown in Table 3. For example, habitat rank at 300 cfs with median accretion has a weighting of 1.50 (33.3% influence), whereas the standard deviation of bed elevation has a weighting of 0.50 (11.1% influence). Each increase in habitat rank and standard deviation of bed elevation rank, therefore, represents a corresponding increase of 1.50 and 0.50 in the total score, respectively. Scores were then scaled relative to the least desirable candidate for a restoration action (i.e., highest score). Scores for each panel, therefore, represent existing habitat quality with the influence of connectivity to spawning habitat and measures of river channel complexity.

Scores across multiple panels were then analyzed to identify segments of the river most suitable for restoration action. First, a cluster analysis (performed by USFWS) was used to identify regions of similar scores that were spatially grouped based on statistical principles from Aldstadt and Getis (2006) and Ord and Getis (1995). The cluster analysis provides a mechanism to evaluate areas desirable for restoration irrespective of arbitrary ESL boundaries. A total of 150 spatially-related clusters of similar scores were identified. The top ten clusters of ascending desirability for restoration action are shown in Table 4 and in Figure 3 below. In addition, these results eliminate any clusters that have less than three adjacent Panels to remove any locations that contain areas that is not practical for restoration actions.



Note: The deeper the color is red the more desirable that location is for restoration; deeper the color is blue the less desirable that location is for restoration. Numbers represent cluster ID that is referenced in the tables below

Figure 2 Map of the new cluster analysis results compared with the old ESL boundaries.

Table 4 Trinity River ESL Segments Ranked by Ascending Desirability for Restoration

Geographic Location	**Evaluation Metric**					**Mean Panel Ranking**	**Additional Considerations for Ranking**				
ESL Name	Rearing Habitat (300cfs)	Rearing Habitat (1500 cfs)	Total Redds (Uprera 3 panels)	SD of Bed Elevation (m)	SD of Unit Stream Power (8,500 cfs)	**Mean Score**	Percent Public Ownership	Adjacent Road Length	Bedrock Area	Topographic Constraint	Geomorphic Potential
Chapman Ranch	85	77	154	69	125	**38.3%**	71%	2,570	0	4.52	-0.46
Below Lorenz (the canyon)	70	59	121	241	217	**43.2%**	58%	2,675	1,084	15.74	1.96
Dutch Creek	103	135	97	149	124	**44.0%**	72%	723	181	7.57	-0.38
Pear Tree Gulch	86	64	173	215	108	**44.2%**	100%	1,354	166	11.95	0.29
Soldier Creek	115	88	150	171	121	**47.0%**	87%	1,151	0	12.39	0.05
Indian Creek (Vitzthum Gulch)	111	115	182	196	103	**51.6%**	64%	2,201	0	7.87	-1.54
Sky Ranch	134	132	97	168	211	**52.2%**	55%	4,464	45	6.34	0.83
Tom Lang Gulch	124	104	176	138	188	**52.9%**	14%	4,426	0	14.59	-0.44
Oregon Gulch	179	177	105	96	114	**55.2%**	60%	3,182	0	3.80	-0.45

Table 4 above, also shows the mean Panel ranking for the five Logic Model metrics along with mean feasibility metrics shown for evaluation. Colors are shaded from red (low scores) to green (high scores) according to ranking scheme described in the approach.

In addition, mean scores were provided across project boundaries (ESLs) to provide context in how river segments used in past evaluations rank under this approach. Metrics judged to be important for assessing project feasibility were calculated based on both clusters and ESLs. These included percent public ownership, road length, bedrock area, topography, and geomorphic potential (the first principal component of velocity, average bed shear stress, average first derivative of shear stress, and stream power at 6,000 cfs). An example of mean feasibility metrics for the identified clusters is shown in Table 5. These metrics are intended to provide additional detail for management's consideration when making final decisions for selecting and prioritizing restoration sites.

Table 5 Top Ten Panel Clusters Ranked by Ascending Desirability for Restoration

Cluster ID	Number of Panels Included	Mean Score	Associated Upstream Project Area (ESL)
96	3	28.7%	Dutch Creek
92	19	35.2%	Below Lorenz (the canyon)
104	7	35.6%	Chapman Ranch
150	7	38.6%	Pear Tree Gulch
60	5	40.2%	Indian Creek (Vitzthum Gulch)
102	4	40.5%	Soldier Creek
114	3	41.3%	Oregon Gulch
94	6	42.7%	Dutch Creek
118	7	45.4%	Sky Ranch
31	4	46.8%	Tom Lang Gulch
Note: See Figure 2 Below for Geographical Representation of the information in this Table			

Table 6 Example of Mean Feasibility Metrics Associated with Clusters

Cluster ID	Associated upstream ESL	Percent Public Ownership	Road Length (ft)	Bedrock Area (ft^3)	Topography ($ft^3 \times 10^6$)	Geomorphic potential (PCA)
96	Dutch Creek	52%	3,719	0	4.6	-0.38
92	Below Lorenz (the canyon)	52%	2,871	1,332	15.8	1.30
104	Chapman Ranch	68%	2,335	0	5.8	-0.52
150	Pear Tree Gulch	100%	2,008	225	12.8	-0.26
60	Indian Creek (Vitzthum Gulch)	89%	1,746	0	7.9	-1.59
102	Soldier Creek	93%	1,052	0	13.3	0.18
114	Oregon Gulch	54%	2,232	0	3.8	-1.43
94	Dutch Creek	77%	-	11	6.3	-0.63
118	Sky Ranch	56%	4,864	153	6.3	0.71
31	Tom Lang Gulch	6%	5,326	0	14.5	-0.70

SUMMARY

The 2D-HBLM process of combining 2D hydraulic modeling output with evaluation metrics and statistical tools is helping bridge new gaps and provide more ways to inform river restoration practitioners and managers. Adaptive Management Processes and Decision Support Systems are often difficult to apply and don't provide the resolution needed for detailed management decisions. 2D-HBLM helps integrate the latest trends in river science and Structured Decision Making processes, allowing for a decision framework that is repeatable, transparent, and quantitative.

Of course, all models have their limitations and therefore the integration between model output and professional judgment is necessary to help validate and ground truth output results. On the Trinity, the entire 2D-HBLM process incorporated many partner organizations and agencies that helped foster a collaborative multi-disciplinary effort. The output results from the cluster analysis were informally validated by technical experts from various disciplines including: fishery biology, geomorphology, and hydraulic engineering with expert knowledge of the Trinity River system. The cluster analysis results matched closely with professional judgment and gave the technical team confidence in making final recommendations to management.

The results from the 2D-HBLM framework were applied to the Trinity River by re-defining the prioritization for channel rehabilitation project sites designs that were being scheduled for the 2015 calendar year. The final 2D-HBLM cluster analysis results were refined based on professional judgment from internal team members. The team members took into account other factors like constructability, site access logistics, as well as, relationship factors such as site interdependence and geographic affiliation. Contiguous projects could help increase design efficiency and create synergy among projects and design teams. Therefore out of the recommended clusters, the Trinity River Restoration Program – Design Team recommended to management to select clusters: 104 through 114 (Chapman Ranch through Oregon Gulch) and the top ranking cluster - 96 (Dutch Creek/Upper Evans Bar). Management agreed to adopt the technical recommendation and therefore the project sites are currently in the design process. This new approach to project prioritization was implemented successfully through the diverse stakeholder partnership of the TRRP and has provided improved technical transparency and decision making defensibility.

TAPER - A REAL-TIME DECISION SUPPORT TOOL FOR BALANCED FLOOD OPERATION OF THE ARKANSAS RIVER IN TULSA DISTRICT

Jennifer Steffen, Hydraulic Engineer, USACE, Tulsa, OK, Jennifer.Steffen@usace.army.mil; Jody Stringer, Hydraulic Engineer, USACE, Tulsa, OK, Jody.Stringer@usace.army.mil; John Daylor, Hydraulic Engineer, Tulsa, OK, John.Daylor@usace.army.mil; David Neumann, University of Colorado Center for Advanced Decision Support for Water and Environmental Systems, david.neumann@Colorado.edu; and Edith Zagona University of Colorado Center for Advanced Decision Support for Water and Environmental Systems, Edith.Zagona@Colorado.edu

Abstract: The U.S. Corps of Engineers Tulsa district is responsible for water management of the Arkansas River as it flows through Kansas and Oklahoma including the operation of numerous flood storage reservoirs and five navigation locks. The goal is to minimize flooding throughout the network with the key regulation control location at Van Buren, Arkansas. Upstream of Van Buren are 13 major flood storage reservoirs (7.6 million acre-feet) with 7,200 sq miles of uncontrolled local runoff that are managed to minimize flooding. The system flood evacuation plan calls for releases that evacuate the flood storage as quickly as possible without causing flooding, while still balancing the system storage and tapering down the flow at Van Buren.

During flood operations, Corp staff use a real-time decision support system named TAPER, implemented in RiverWare, which simulates the river and reservoir network, including all of the reservoir operations. The RiverWare model imports observed and forecasted inflows and local runoff and then uses rulebased simulation to model mandatory surcharge releases, allowable flow at various control locations, and the releases to meet the allowable flow in a balanced manner. The regulation discharge at Van Buren is computed based on a seasonally varying guide curves representing the equivalent percent of basin storage utilized. This algorithm allows higher flows during flooding seasons and when the system is full to recover the flood storage space in the upstream projects. The targets also include a smooth tapered recession to bring the system down to normal operations while allowing for scouring and dredging for navigation.

Given this regulation discharge, the RiverWare model computes a set of proposed release to balance the relative reservoir storages while not exceeding the downstream flow targets. Routing is modeled using the step response routing algorithm. Water managers collectively review the proposed releases and river flows and modify releases based on event specific conditions. RiverWare System Control Tables, plots, and output tools provide a friendly user interface focusing on the key variables in the system. As water managers modify releases, the model is re-run to compute downstream flows and reservoir levels. This process repeats until the managers are satisfied. The final release schedule and other reports are sent to dam operators, other federal agencies, local water managers, power authorities and other interested stakeholders.

RiverWare is a river and reservoir modeling tool developed by the University of Colorado Center for Advanced Decision Support for Water and Environmental Systems (CADSWES) with sponsorship of the Tennessee Valley Authority, the Bureau of Reclamation and the U.S. Army Corp of Engineers.

INTRODUCTION

The Arkansas River originates in central Colorado and flows through Kansas, Oklahoma, and Arkansas to its confluence with the Mississippi River. The U.S. Army Corps of Engineers (USACE) Tulsa District is responsible for water management of the river through Kansas and Oklahoma (Figure 1). During flood events, the system is operated to reduce downstream flooding and then evacuate the flood pool storage as quickly as possible in a balanced manner while still meeting navigation objectives. The Tulsa District has developed a RiverWare operations model called TAPER which helps the District perform this operation on a day-to-day basis as needed. This paper describes the basin and its operations during these flood pool evacuation operations and presents information on the TAPER model.

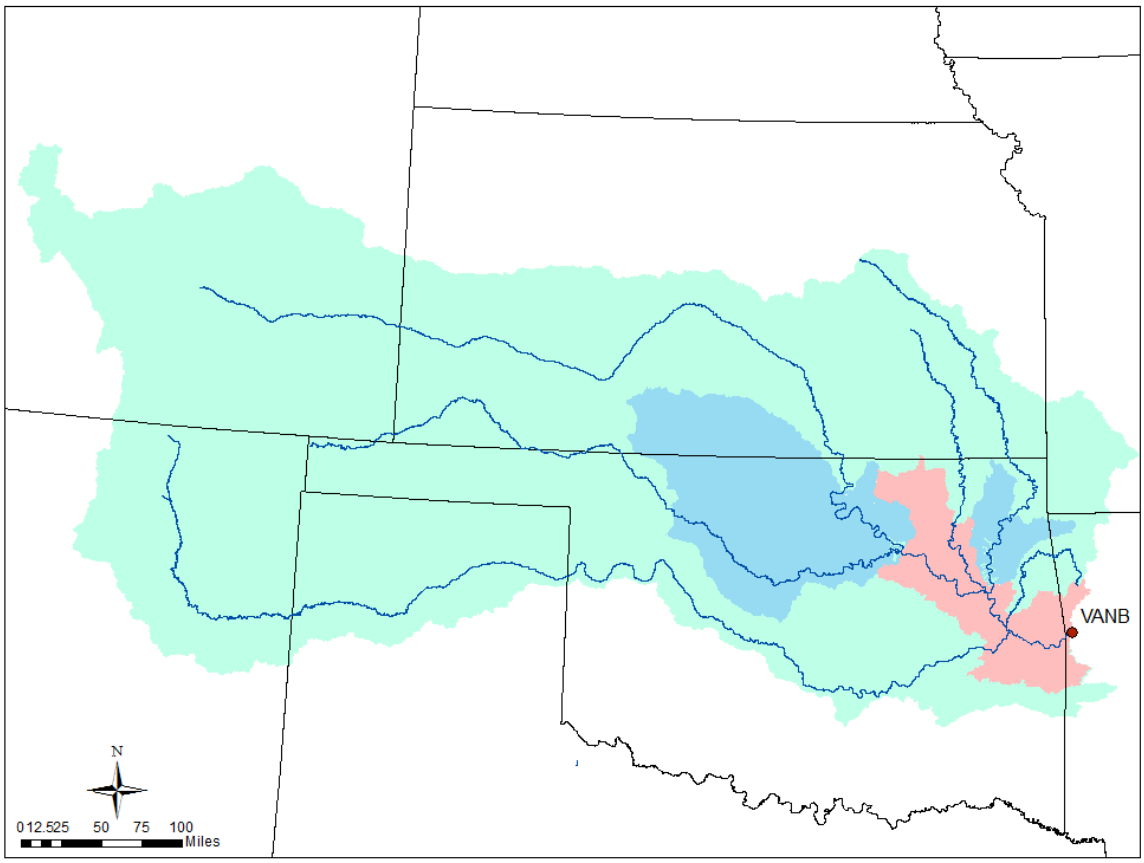

Figure 1 Drainage area (green) for the Arkansas River to Van Buren including locals (above reservoirs (blue), uncontrolled (pink)).

Basin Background: Thirty flood storage reservoirs exist on the Arkansas River and tributary system in Kansas and Oklahoma, including five navigation lock and dams. These reservoirs contribute to a common downstream control point for system regulation at Van Buren, Arkansas (VANB). Thirteen of these reservoirs (Copan, Hulah, Oologah, Birch, Skiatook, Kaw, Keystone, Pensacola, Hudson, Fort Gibson, Tenkiller, Eufaula, and Wister) are all in close proximity to VANB.

The Tulsa District manages the Arkansas River to VANB near Van Buren, Arkansas, and water management policies are specified in the Arkansas River Basin: Water Control Master Manual (USACE Tulsa and Little Rock District). The Arkansas River is managed to keep flows below regulation stage, evacuate flood storage in a timely manner, meet navigation needs, slowly taper flows down to allow for scouring, dredging of navigation channels, and provide for miscellaneous stakeholders needs. When upstream reservoirs are in the flood pools, the Corps is responsible for evacuating this pool. The combined flood pool storage of these lakes is 7.6 million acre-ft and the releases from all 13 reservoirs must be managed along with 7,200 sq miles of uncontrolled local runoff (Figure 2), to meet these multiple objectives, with a max regulation discharge of 150,000 cfs. Based on the percent of flood storage utilized, each reservoir is given an allocation and priority that guides in its releases to meet the flow hydrograph at VANB.

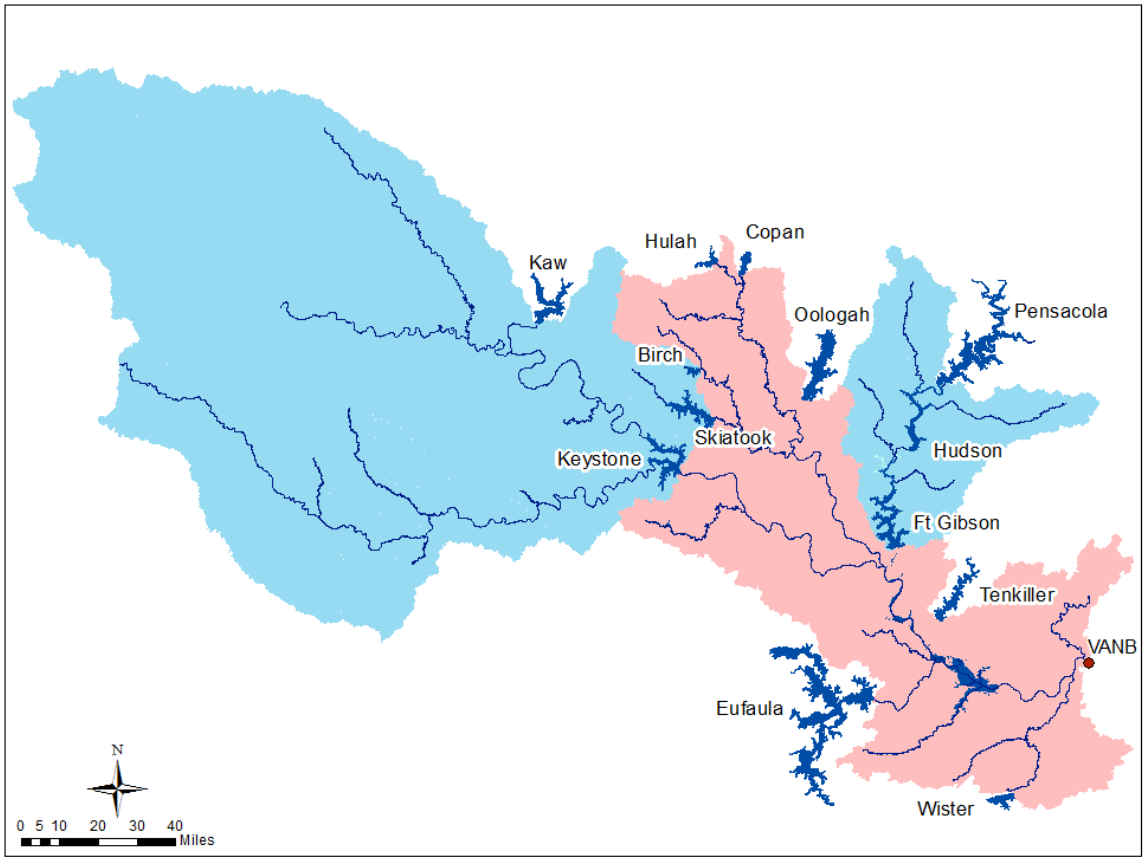

Figure 2 Thirteen reservoirs along Arkansas River and local areas (uncontrolled (pink), above reservoirs (blue))

Taper Operations: Tulsa District uses a procedure called TAPER to balance releases through the Arkansas River to Van Buren. The goal of TAPER is to determine releases using the system flood storage evacuation plan, which correlates system percent full with target flow. The target flow allowed at Van Buren consists of a series of stepped down benches set by a guide curve, which is based on the equivalent percent of basin storage utilized. The benches vary seasonally based on historical flood patterns. Flood water is released quicker during flooding seasons to

increase available flood storage in the upstream projects, and includes a tapered recession for navigation to allow for scour and dredging. A typical evacuation operation period is twenty-one days. To assist with the TAPER operations, Tulsa district uses simulation models to represent the system. The original TAPER program was a daily timestep model, with daily average releases and flows. This caused issues with high and low flow fluctuations in the navigation system. These fluctuations contribute to bank caving and shoaling issues in the system. In order to reduce fluctuations with the old TAPER program the gate changes are entered into a HEC-1 forecast model to route the flows through the Arkansas River. Then gate changes are manipulated to try and reduce fluctuations. This method of operating the system was very time consuming, and was not efficient. A new model was needed with 6-hr timesteps, better routing, and the ability to make a better initial suggestion at the release schedule. RiverWare was selected as the modeling tool in which to implement a new version of TAPER.

The RiverWare TAPER model is a real-time flood management model that imports forecast inflows and local runoff from forecast models. It then uses rulebased simulation to model water management strategies used by the USACE Southwest Division. These rules balance the system by allowing reservoirs to set releases based on priority curves and reservoir fullness, but also by allowing for a smooth flow transitions through reaches, and to not allow rivers to rise above flood stage. RiverWare TAPER produces a set of proposed releases for all reservoirs in the system. Water managers collectively look over proposed releases and modify based on event specific conditions. The final release schedule is sent to stakeholders who have an interest in the reservoirs and river system.

RIVERWARE TAPER MODEL

RiverWare is a river and reservoir modeling tool developed by the University of Colorado Center for Advanced Decision Support for Water and Environmental Systems (CADSWES) with sponsorship of the Tennessee Valley Authority, the Bureau of Reclamation and the U.S. Army Corp of Engineers. RiverWare models operations of the reservoirs and routes releases through routing reaches (CADSWES, 2014). The models consist of reservoirs, control points, confluence objects, routing reaches, and data objects (Figure 3).

Initial Conditions and Inflow Forecasts: To provide an effective evaluation of the river, 30 days of observed pre-simulation release and local inflows are provided to accurately prime the system. For the simulation period, initial elevations, reservoir inflows, and local uncontrolled runoff come from HEC-1 forecast models. HEC-1 is a rainfall runoff model developed by HEC (USACE Hydrologic Engineering Center, 1998). Forecast models are developed for each of the reservoirs and for the local areas. During flood operations, forecast models are calibrated for the specific storm events, using initial and constant loss, Snyder unit hydrograph, and baseflow recession. The corresponding reservoir inflows and local runoffs are imported into RiverWare using RiverWare's Data Management Interface (DMI) tool.

Rules: TAPER uses rules to determine releases that evacuate the flood pool in an efficient manner while not causing flooding downstream and limiting downstream flow for system benches. The goals of the rules are to keep flows at Van Buren below regulation levels determined using system evacuation guide curves, keep all control points below regulation

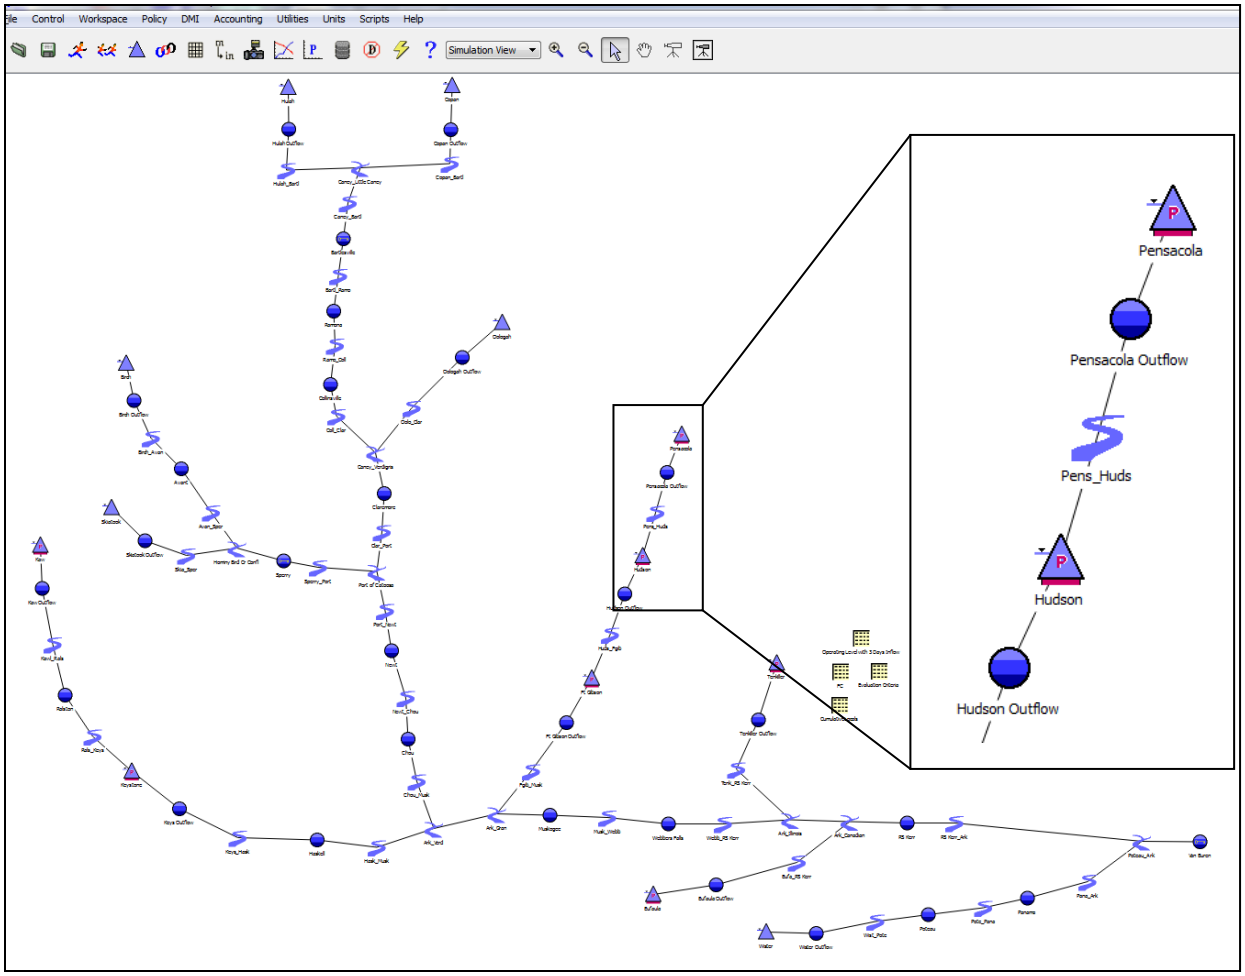

Figure 3 Schematic of RiverWare workspace

limits, and balance the system. The releases are determined using the surcharge, regulation discharge, and flood control rules developed for the USACE Southwest Division, based on the operating policies.

Surcharge: Surcharge occurs when flood water in the lake is above the flood pool and water must be released, regardless of downstream conditions. The surcharge releases are calculated for each reservoir one at a time starting with the most upstream reservoir. In the case where surcharge releases are necessary, they are routed through the system. If the upstream reservoir is above another reservoir, the releases are routed downstream to become inflows to the next reservoir. This reservoir then calculates its surcharge releases. This process continues until surcharge releases have been calculated for every reservoir.

Regulation Discharge: The regulation discharge, which is the maximum flow allowed at Van Buren, varies seasonally and with regard to the percent of basin storage utilized, summarized in the Van Buren Guide Curve (Figure 4).

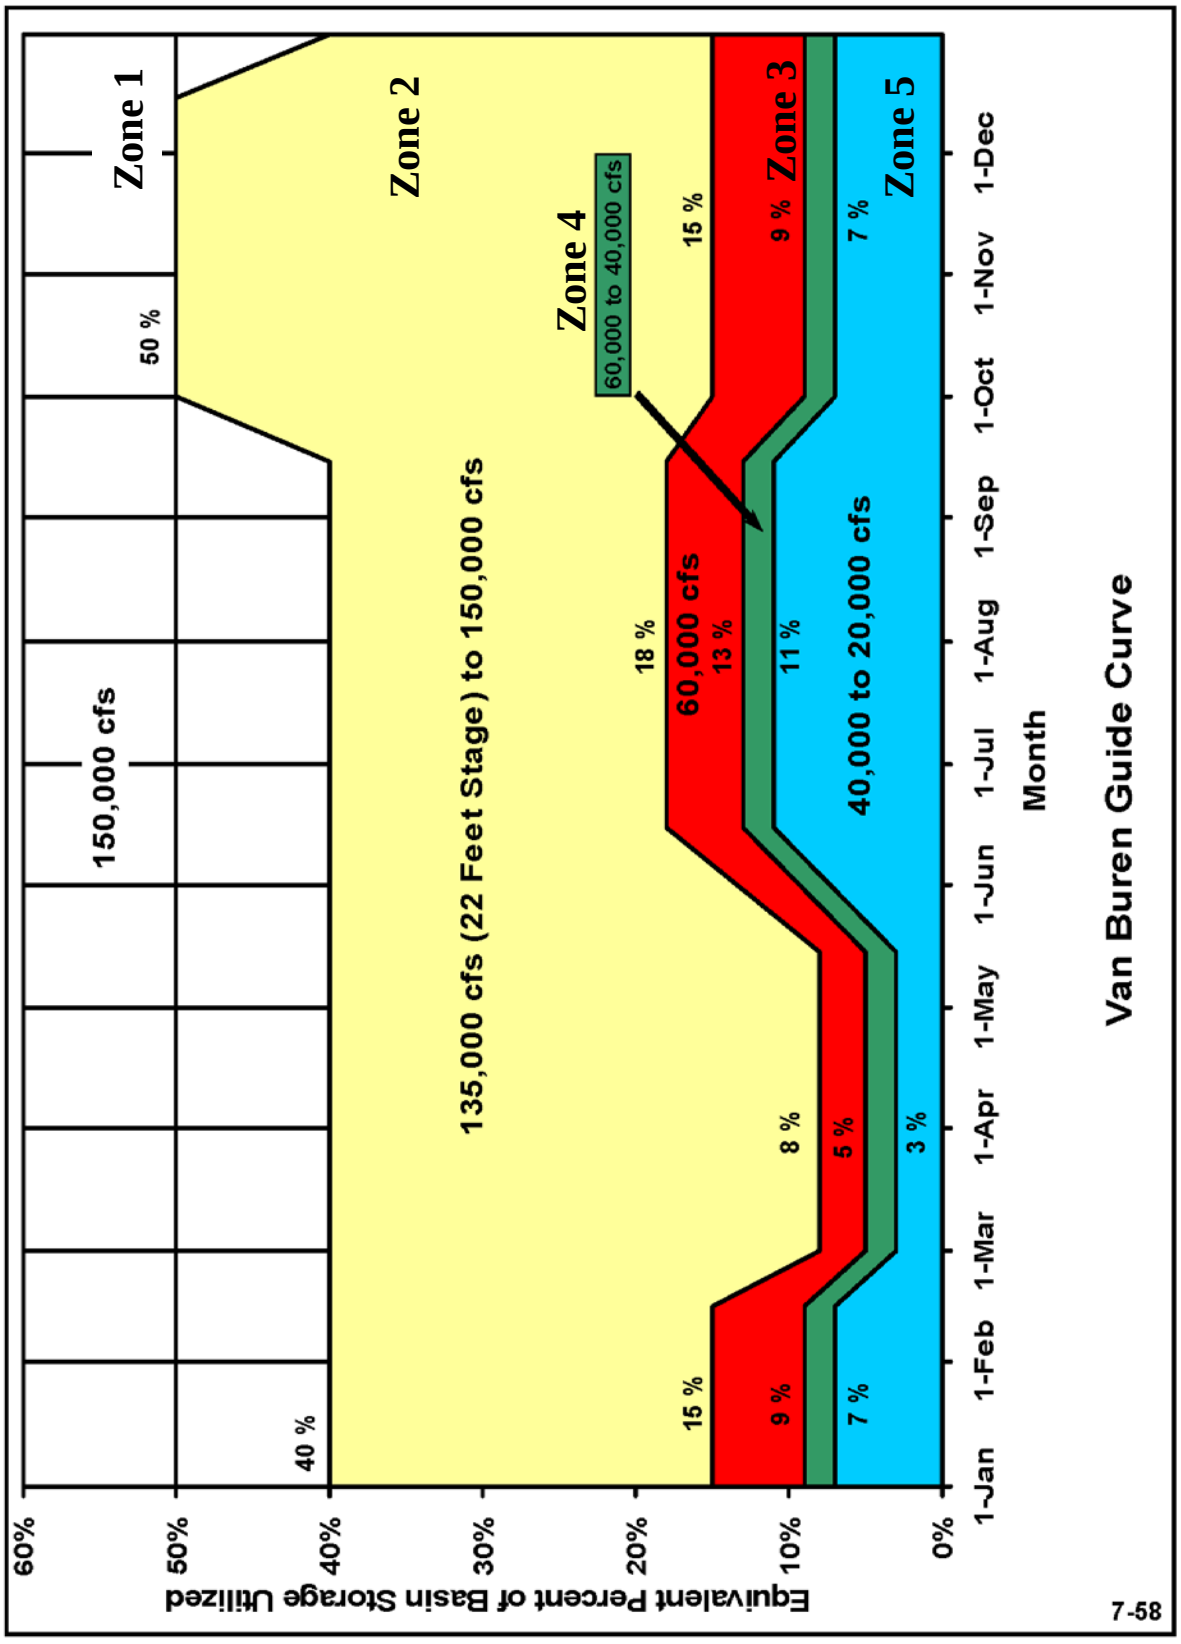

Figure 4 Van Buren Guide Curve with specified regulation discharge flows for five zones.

The Equivalent Percent of Basin Storage Utilized is calculated as

$$\frac{\sum_{@t} S + \left(\sum_{t}^{t+3} I - \sum_{t}^{t+3} O\right)}{\sum_{@t} S_{Total}} * 100 \quad (1)$$

where S is reservoir's flood pool storage utilized, I is reservoir inflow, O is reservoir releases, S_{Total} is the reservoir's total flood pool storage, and t is the current time in days. Depending on the time of year the equivalent percent of basin storage utilized correlates to a regulation discharge at Van Buren, ranging from a high of 150,000 cfs to a low range of 40,000 to 20,000 cfs. There are five zones and each has additional criteria that determines the flow and time period for the range of flows (Figure 4). Some of the zones represent maximum regulation discharge values, while others show a range of flows to transition between. For example Zone 5 requires a tapered recession from 40,000 to 20,000 cfs in 21 days (USACE Tulsa and Little Rock District, Chapter 7). There are also other regulation points in the system such as Bartlesville, Ramona, Collinsville, Claremore, and Muskogee. Each regulation point has a site specific regulation discharge.

Flood Control: The SWD Flood Control rules try to balance the system by reducing each lake to the same balance level/operating level. Tulsa District developed a correlation between percent flood pool storage with a balance level. This allows for a priority assignment for reservoir releases that are competing for downstream channel space. The balance level is based on the system flood storage balance level vs. storage curves (Figure 5). Curve C is the highest priority until the percent of flood storage utilized reaches thirty percent than all lakes have the same priority. Curve B is next in priority followed by Curve A. Each reservoir is assigned a release schedule that will bring all reservoirs to the same operating (balance) level without causing downstream flooding. This process is repeated for each timestep in the forecast time period. The RiverWare rules execute this logic through the use of the predefined Flood Control function which executes the system wide solution. The results are the outflows from each reservoir which are then routed through the system.

Iterative MRM: Since the equivalent percent full equation (1), uses the outflow from the reservoirs, this value will change based on the releases computed in the Flood Control rules. To perform this iteration, RiverWare's Iterative Multiple Run Manager (MRM) is used. This utility allows an entire simulation run to be made and then logic is executed to decide if another simulation is necessary. The logic sets values in the system and another run is executed. For the first pass, the Iterative MRM sets the outflow values in equation (1) to 180,000 acre-ft. For every other run it is set to the computed outflow from the reservoirs. The model runs through three different runs, until the results converge to a solution.

RESULTS

After three iterative runs are made the results are shown in RiverWare's System Control Table (SCT). For each reservoir, the inflow sum, outflow, operating level, pool elevation, percent of flood control pool, and operating level with three days inflow are summarized in a the table (Figure 6). The water managers then look at the model's suggested release schedule and make changes based on engineering experience not captured by the rules and special circumstances.

Figure 6 System Control Table summarizing daily results for 6-hr timestep model

Once the water managers have set their releases, they are locked in as input values for a few days and the model is rerun for the rest of the simulation period. The model determines any unspecified release based on the modified release scenario. The water managers check that gages downstream stay below regulation discharge, and lock in several more days of releases. This process continues until the water managers are satisfied with the final release scenario. Once water managers are satisfied with the results, then html reports, plots (Figure 7), DSS files, and text files are developed for stakeholders. Water managers use the releases plan to make requested gate changes from the dam operators, and coordinate hydropower releases.

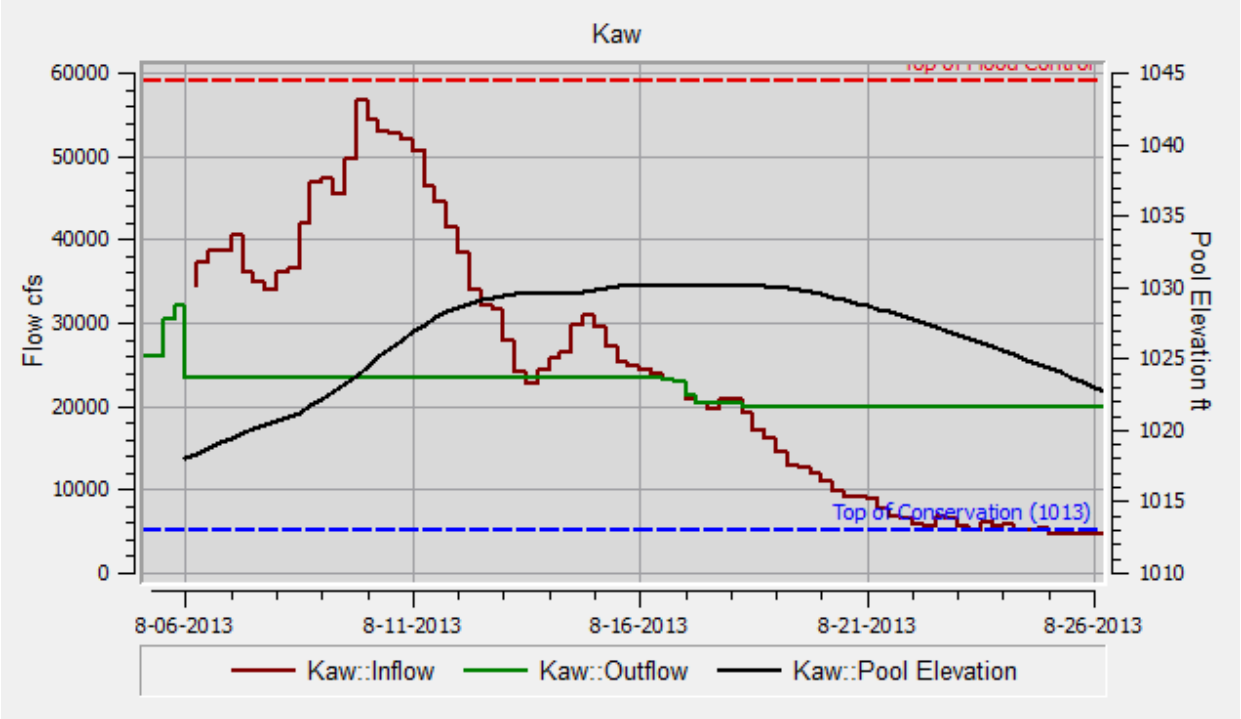

Figure 7 Example of plot sent to stakeholders

CONCLUSION

The U.S. Army Corps of Engineers, Tulsa District manages flows to Van Buren, Arkansas, using a RiverWare model to help with TAPER operations. The model uses operating curves and model constraints to create a recommended release plan that evacuates the flood pool in an efficient manner, while maintaining many stakeholder and navigation needs. The RiverWare model and user interface tools will save water managers time and create a more efficient process to create release plans. The 6-hr model will help to reduce flow fluctuations at the Arkansas River lock and dams, and will allow for one model to create and edit release plans reducing the amount of time spent by water managers.

INTEGRATING HYDROLOGIC AND RIVER OPERATIONS MODELING WITH EXPLICIT SIMULATION OF GROUNDWATER AND SURFACE-WATER EXCHANGE

Eric D. Morway, Hydrologist, U.S. Geological Survey, Carson City, NV emorway@usgs.gov; Richard G. Niswonger, Hydrologist, U.S. Geological Survey, Carson City, NV rniswon@usgs.gov; Enrique Triana, Senior Water Resources Engineer, MWH Global, Fort Collins, CO enrique.triana@mwhglobal.com

Abstract: Existing hydrologic/river-operations model couplings found in the scientific literature adopt a feed-forward approach for updating groundwater surface-water (GW-SW) interactions in the operation component of the coupling, and likewise, for updating simulated diversions (including pumping) in the hydrologic model. In many western US river basins, where GW-SW is a significant component of the overall river budget, it is increasingly important to more accurately account for groundwater returns under increased climate variability and changes in groundwater and surface water management. Because standard functionality available in today's river operation models simulate GW-SW interaction using simplified one-dimensional equations or estimated stream-depletion factors, they do not accurately account for the spatially and temporally distributed influence of groundwater on operations, especially during periods of low-flow. To address this weakness, a generalized river basin Decision Support System and network flow model (MODSIM) is integrated with the modular three-dimensional groundwater flow model (MODFLOW). MODSIM is a river basin management decision support system capable of simulating complex administration of water rights and agreements in large-scale surface-water networks. MODFLOW is a physically-based distributed-parameter finite-difference model used for simulating groundwater systems. The strengths of each code compliment the current weaknesses of the other. That is, MODSIM's inability to simulate spatially-varying GW-SW interaction is a long-standing strength of MODFLOW through the use of the lake (LAK) and stream flow-routing (SFR2) packages. Conversely, MODSIM is well-equipped to administer available river flow and storage accounts among spatially distributed diversions and reservoirs while honoring the constraints of prior appropriation doctrine and in-stream flow requirements. Multiple attempts to inform river operations models with MODFLOW output have been found in the scientific literature, but the feed-forward nature of such attempts fails to synchronize their respective solutions. Recent efforts have focused on iteratively passing information (i.e., GW-SW exchanges, canal diversion amounts, reservoir releases) between MODSIM and MODFLOW in memory to achieve synchronization between the respective model solutions before advancing to the next time-step. To accomplish this goal, the Lake (LAK) and Streamflow-Routing (SFR2) packages available with MODFLOW were integrated with MODSIM. The newly developed code will provide water planners and managers in over-appropriated systems with a more robust decision making support tool than is possible with either model applied independently or run using a feed-forward implementation. A demonstration of third-party injuries (i.e., those not directly involved in the transfer of water use) resulting from proposed alternative management interventions during periods of low-flow is demonstrated with an example model.

WINDAM C EARTHEN EMBANKMENT

INTERNAL EROSION ANALYSIS SOFTWARE

ABSTRACT Two primary causes of dam failure are overtopping and internal erosion. For the purpose of evaluating dam safety for existing earthen embankment dams and proposed earthen embankment dams, WinDAM C software will simulate either internal erosion or erosion resulting from an overtopping event. WinDAM C models erosion failure of a homogeneous embankment. Future expansion includes non-homogeneous embankments, and embankment protection analysis.

The four essential functions of the software are:

1. Hydraulically routes one input hydrograph through, around, and over a single earthen dam.
2. Estimates internal erosion and potential breaching of an earthen embankment dam.
3. Estimates erosion of the earthen embankment caused by overtopping of the dam embankment.
4. Estimates auxiliary spillway erosion in up to three earthen or vegetated auxiliary spillways.

The user imports an inflow hydrograph into WinDAM C and selects either internal erosion analysis or overtopping analysis.

Regarding internal erosion within the earthen embankment, the user sets the elevation and initial size of the internal erosion conduit. WinDAM C initially assumes a horizontal, rectangular conduit shape. The internal erosion conduit grows larger as flow erodes embankment material. The erosion may breach the embankment and drain the reservoir.

Since the research has been completed, USDA and KSU are currently verifying and validating a working version of WinDAM C, which should be released for external evaluation and testing in 2015.

INTRODUCTION

Windows Dam Analysis Modules (WinDAM) is a modular software application to analyze earthen embankments during internal erosion and overtopping. Recently released for testing and evaluation by the dam safety community, WinDAM B (USDA, et al. 2012) includes erosional failure of a homogeneous embankment through overtopping and release of stored water. The alpha version of WinDAM C, currently under development, includes analysis of internal erosion. Future planned development includes non-homogeneous embankments. The US Department of Agriculture – Agricultural Research Service (USDA-ARS), US Department of Agriculture – Natural Resources Conservation Service (USDA-NRCS), and Kansas State University (KSU) are working jointly to develop this software.

For nearly seventy years, the USDA-NRCS has partnered with landowners, municipalities, conservation districts and other sponsors to construct more than 11,000 rural flood control dams. These structures provide $1.5B in annual benefits by providing flood control, municipal and rural water supplies, irrigation water, wetland habitat, and recreation among others. Many of these aging dams were designed with a 50-year service life, and time takes a toll on these structures. Sediment pools fill and encroach upon the flood detention volume. Structure components deteriorate, and hazard creep occurs in urbanizing areas that were once rural cropland areas. As a result, the consequences of dam failure must be considered when evaluating and prioritizing these structures for rehabilitation since the structures may no longer meet NRCS design criteria (USDA, 2005).

Overtopping and internal erosion are the primary causes of dam failures, with each mode attributed to a roughly equal number of failures (Foster, Fell and Spannagle 1998). For a given dam, one (or neither) mode may be more likely. For example, many of the storage reservoirs in arid West have large volumes relative to inflow and are managed such that overtopping is very unlikely. The US Bureau of Reclamation (USBR, 2011) names internal erosion of embankments (or their foundations) as the number one cause of dam failures in the western US. WinDAM C, when completed, will estimate breach erosion of an earthen dam through one of two modes: internal erosion through the embankment or overtopping the embankment. This document describes the WinDAM model currently being developed to examine internal erosion. The model is currently at the alpha stage of development undergoing verification and validation testing by the developers. It is anticipated that additional testing by the dam safety user community will also be required.

WINDAM C CAPABILITIES

PURPOSE OF SOFTWARE The essential functions of WinDAM C software are threefold:

- Hydraulically route (level pool routing) one inflow hydrograph through, around, and over a single earthen dam.
- Estimate auxiliary spillway erosion in up to three earthen or vegetated auxiliary spillways.

- Estimate erosion of the earthen embankment caused by internal erosion or by overtopping of the dam embankment.

Since WinDAM C does not include any hydrology component, the user must create the reservoir inflow hydrograph in other software, such as WinTR-20 (USDA-NRCS, 2009) or SITES (USDA-NRCS, 2012). The user can import the hydrograph or paste the hydrograph points into the user interface. The user has the flexibility to choose the hydrologic software most suitable for analysis of site conditions.

INTERNAL EROSION OF HOMOGENOUS EARTHEN EMBANKMENT WinDAM C models the dam embankment as a homogenous earthen material. Many USDA-NRCS dams are homogenous earthfill, so the WinDAM C model applies. If applied to zoned embankments, the suggested approach is to consider material and geometry that will dominate the process. For computational purposes, the earthen embankment fits into a simplified, rectangular-shaped valley (Figure 1) with vertical abutments and level valley floor.

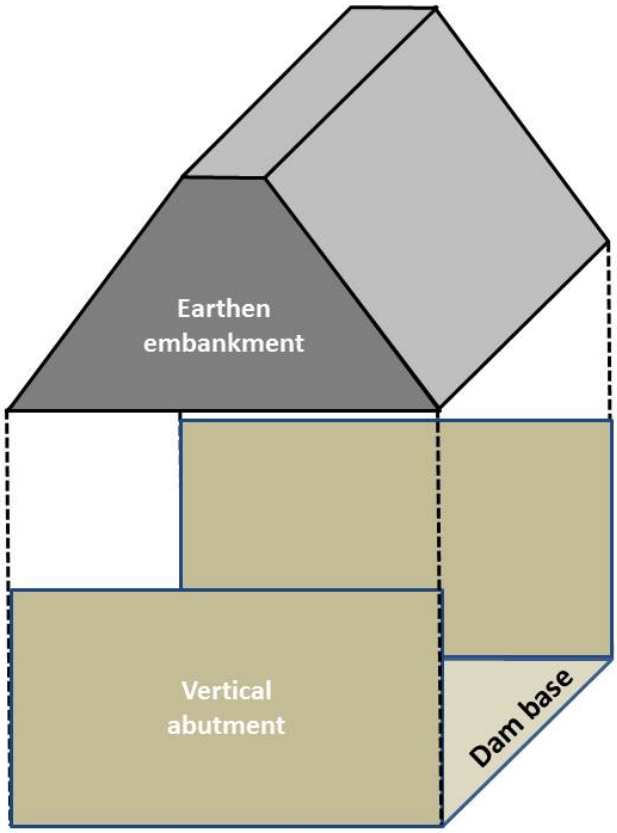

Figure 1 Homogenous earthen embankment in rectangular-shaped valley

INITIAL INTERNAL EROSION CONDUIT For a WinDAM C internal erosion analysis, the user specifies the initial size and location of the internal erosion conduit. To simplify the

analysis, the conduit is horizontal—there is no slope in the upstream-downstream direction through the embankment, as shown in Figure 2. The conduit is assumed to be rectangular. The user must specify the initial conduit dimensions—width and height. The user must input the initial elevation of the conduit invert, as well as the lateral stationing between the left and right abutment.

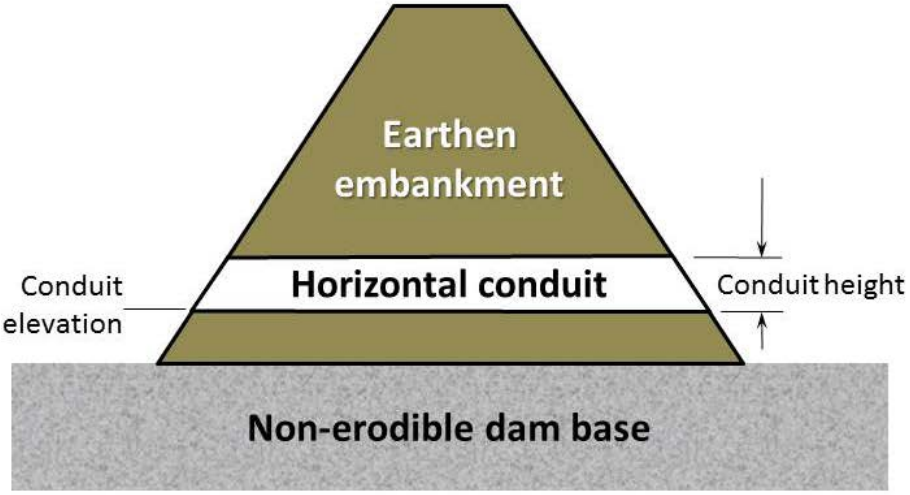

Figure 2 WinDAM C internal erosion horizontal conduit profile

In WinDAM C the left and right abutments are considered to be non-erodible and vertical, as shown in Figure 3. The embankment foundation, or dam base, is non-erodible and level. The dam crest profile is defined as a series of user-entered points (Figure 3).

The internal conduit erodes laterally until it reaches an abutment, as shown in Figure 3. The conduit also erodes vertically between the dam crest profile and the dam base. As long as some portion of the conduit is flowing full and the shear stress is sufficient to erode the embankment material, the conduit expands in all four directions equally. Once conduit erosion reaches one of the embankment boundaries (abutment, dam base, or dam crest), expansion/erosion in that direction stops.

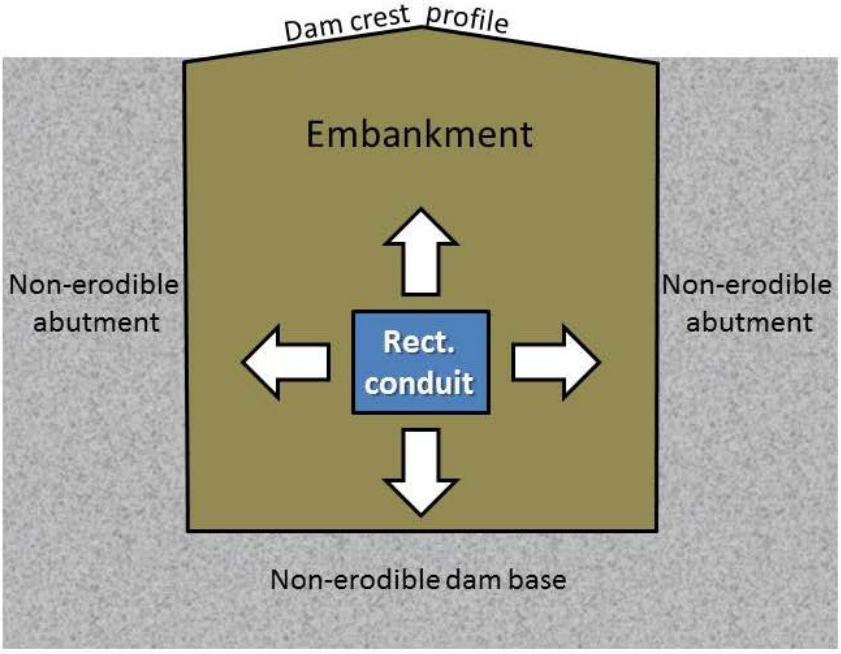

Figure 3 WinDAM C conduit cross-section looking upstream

EROSION PROCESSES Two erosion processes are simulated. The conduit enlarges concentrically due to shear detachment (laterally and vertically in a conduit simplified as having a rectangular cross section); classically this is the only process associated with internal erosion. However, development of a headcut at the outlet and subsequent advance of that headcut also play an important role in breach by internal erosion in some instances, so this process is also modeled.

At the beginning of each time step, the model computes the shear stress produced by flow passing through the rectangular internal erosion conduit. In instances where conduit is full for less than entire length, a backwater curve and resulting average shear stress along conduit length are computed. If the average shear stress is greater than the user-specified critical shear stress, then the amount of erosion is estimated and the conduit expanded accordingly for the next time step.

In addition to simply expanding the internal conduit laterally and vertically, WinDAM C also checks to see if a headcut will form at the downstream invert of the conduit (Figure 4). After this headcut has formed, headcut advance and deepening is computed for each time step using the user-prescribed erosion model (Table 3). This process is simulated much like that of a headcut formed in overtopping with important distinction that width is controlled by the conduit.

TRANSITION FROM INTERNAL CONDUIT EROSION TO BREACH EROSION Once this headcut reaches the upstream face of the embankment the internal conduit has become an

open breach and flow transitions to breach flow. At this point, lateral expansion of the breach is the same as with overtopping flow conditions.

In the early stages of internal erosion, the conduit is usually stable regardless of support by hydrostatic water pressure. As the conduit enlarges, the support provided by water becomes critical. There are three cases when the roof of the conduit is considered to be stable:

1. The conduit is flowing full over the entire length of the conduit.
2. The conduit is flowing full over some part of the conduit length.
3. When flow transitions to free surface flow along the entire length of the conduit and the conduit width is less than twice the overburden height (vertical distance from the dam crest to conduit roof).

As the breach progresses and reservoir drains the roof of the internal erosion conduit will collapse. WinDAM C considers the conduit roof collapsed for these two cases:

1. Erosion of the roof reaches the dam crest profile
2. Free surface flow along the entire conduit length and the conduit width is more than twice the vertical distance from the dam crest to the roof.

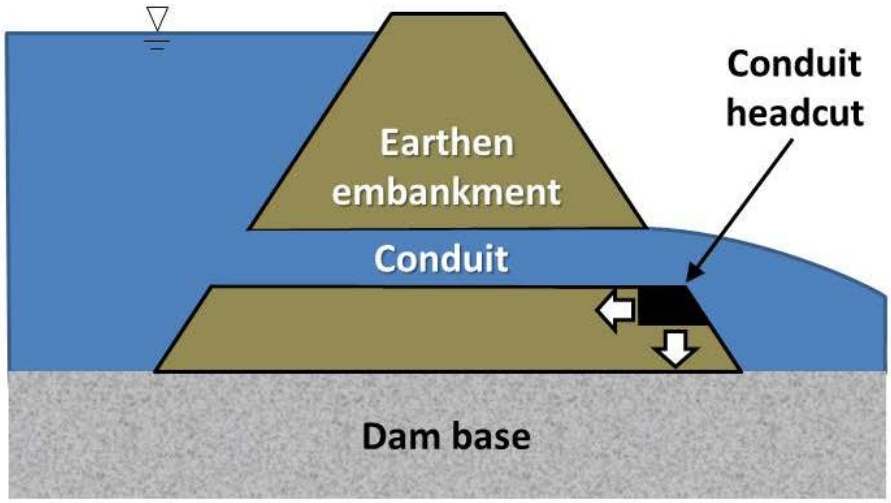

Figure 4 Conduit headcut

NEGLIGIBLE INTERNAL CONDUIT FLOW CASES There are cases where the resulting internal erosion is negligible. These possible cases include:

- Elevation of internal erosion conduit is above maximum water surface in the reservoir, which results in no flow in internal erosion conduit.
- Insufficient time or flow to produce meaningful erosion because the generated stress does not exceed the soil critical stress by sufficient time or amount.
- Highly erosion-resistant embankment materials may not generate shear stresses greater than the soil critical stress.

OVERTOPPING BREACH EROSION If the user selects overtopping erosion analysis in WinDAM C, flow through the breach depends on the eroded breach area and the driving head based on the reservoir water surface, breach elevation, and any downstream tailwater. The four stages of the overtopping breach are described in Table 1.

Table 1 Four stages of WinDAM overtopping breach

Stage 1	Surface protection on downstream embankment slope fails. Headcut forms on downstream face of dam at low point in the crest profile.
Stage 2	Headcut advances through the crest to upstream embankment slope. Breach is initiated when the headcut enters the upstream crest and begins to lower the hydraulic control.
Stage 3	Headcut continues to advance into the reservoir pool releasing stored water.
Stage 4	Headcut continues to widen as reservoir drains following local removal of the embankment in the breach area.

MODELING FLOW THROUGH EMBANKMENT CRACKS Earthen embankments are susceptible to cracking from seismic activity or from desiccation in arid regions. As an overtopping erosion event, the only way to evaluate a crack is to input the crack in the dam crest profile. WinDAM overtopping erosion analysis was not developed for such evaluation and is not appropriate for several reasons. First, crest width in WinDAM is a constant and WinDAM evaluates both stress and erosion strictly from a depth perspective rather than considering the extremely steep profile segments as walls. Second, overtopping is considered on a one-dimensional, unit-discharge basis.

However, analyzing a crack, even one that extends to the dam crest, as an internal erosion event may be appropriate if the user develops a thorough understanding of the computational model and interprets inputs and results accordingly. Cracks have been associated with internal erosion (Bonelli, et al. 2006) (Fell, et al. 2003). The geometry of a crack can be more correctly approximated in an internal erosion simulation in WinDAM C. However, the research program and software were not undertaken to address the early stages of breach development represented by narrow cracks. Users should recognize model constraints and interpret results accordingly, e.g.

- WinDAM C assumes turbulent flow through the internal conduit, whereas flow through narrow cracks may be laminar flow.

- WinDAM C embankment materials properties do not change during the analysis. Over a sufficiently long period of time, flow within small cracks may saturate portions of the embankment and alter its resistance to erosion.

INTERACTION OF EROSION AND HYDRAULICS The hydraulics and erosion are coupled for the embankment breach analysis. In other words, a larger breach in the embankment lets more flow pass through the embankment breach during the next time step. Erosion prediction is relatively straightforward in the homogeneous earth embankment.

Erosion prediction in the auxiliary spillway, however, is much more complex than in the homogenous earth embankment. Hydraulics and erosion are not coupled in the auxiliary spillway because the erosion model only includes information on the weakest unit width subsurface materials in the auxiliary spillway. As a result, WinDAM C does not have the data to estimate the lateral expansion in the auxiliary spillway. Erosion computations in the auxiliary spillway stop when the headcut reaches the upstream edge of the level crest of the auxiliary spillway.

WINDAM VERSIONING

Research is ongoing for future enhancements to WinDAM software, as shown in Table 2. USDA and KSU are currently verifying and validating a working version of WinDAM C, which should be released for evaluation and testing in 2015.

Table 2 WinDAM Versioning

Version	Existing Capabilities or Future Enhancements
WinDAM A+ (2008)	Embankment overtopping analysis (Slope protection evaluation: no embankment erosion analysis)
WinDAM B (2011)	Homogenous fill embankment overtopping and erosion analysis
WinDAM C (2015)	Internal erosion prediction through homogenous fill embankment
WinDAM D (proposed)	Potential failure initiation at toe, berms, and groins. Alternative embankment slope protection materials (i.e. blocks, reinforced vegetation)
WinDAM E (proposed)	Zoned fill embankment overtopping erosion prediction

INPUT DATA

The auxiliary spillway materials in WinDAM C are described with the same data inputs as in SITES (USDA-NRCS, 2012).

WinDAM C requires the user to input one flow hydrograph. This hydrograph input is similar to the SITES input procedure. SITES gives the user the option to input hydrology through a

watershed model, but WinDAM C only allows hydrology input through a single hydrograph. Various design hydrographs will require a different WinDAM C run for each hydrograph.

WinDAM C may be run with or without embankment breach evaluation. When breach evaluation is desired, the earthen embankment must be described so WinDAM C can model either internal erosion or overtopping erosion. The user specifies the embankment slope protection: vegetation, rock riprap, or no cover. The dam embankment crest and slope dimensions are also input.

For the breach analysis option, the user selects one of two headcut models: Temple/Hanson Energy model or Hanson/Robinson Stress Model (Hanson, et al. 2011). The WinDAM C erosion prediction models are designed for estimating erosion of typical NRCS earthen embankments composed of fine-grained, cohesive materials, where the dominant erosion process is the formation, advance, and deepening of a headcut. The soil parameter inputs for each model are listed in Table 3.

Table 3 WinDAM C Erosion Model Soil Inputs

Model	Hanson/Robinson Stress Model	Temple/Hanson Energy Model
Input Parameter *(Units)*	Erodibility (ft/hr)/(lb/ft^2)	Erodibility - (ft/hr)/(lb/ft^2)
	Critical Shear Stress (*lb/ft^2)*	Critical Shear Stress – (*lb/ft^2)*
	Undrained Shear Strength (*lb/ft^2)*	Advance coefficient - *(ft/hr)/(ft/s^3)*
	Total Unit Weight (*lb/ft^3)*	

All four input parameters in the Hanson/Robinson stress model can be measured. In addition this model is recommended for tall dams (> 50 ft high). Since the advance coefficient parameter in the Temple/Hanson cannot be measured directly, most users select the Hanson/Robinson stress model.

A WinDAM C internal erosion analysis covers a few hours or days. The WinDAM model does not account for wetting or drainage of embankment soils during the erosion analysis. Therefore, the material properties of the embankment soil do not change over the period of the breach analysis.

Generally, the outflow from dams is controlled primarily by the hydraulic features of the dam—principal spillway and auxiliary spillway. For these dams where backwater effects are not significant, a single downstream tailwater elevation is sufficient. However, some dams have downstream hydraulic features such as levee or road embankments that impose significant and dynamic backwater effects. WinDAM C incorporates a tailwater rating table to simulate how the outflow from the dam varies with downstream capacity. This backwater is used when analyzing the auxiliary spillway flow, but is not yet utilized when computing the auxiliary spillway erosion.

OUTPUT

WinDAM C has three forms of output; the initial summary screen the user sees upon completion of a valid run, ASCII text output files, and numerous graphical plots. WinDAM C has multiple text output files to describe the expected performance of the embankment and multiple auxiliary spillways. The current list of available output plots in WinDAM C are listed below.

- Conduit/Breach Width
- Dam Cross-section
- Dam Crest Profile
- Conduit Width/Height
- Headcut Advance
- Headcut Position
- Hydrographs
- Reservoir Surface Area
- Reservoir Storage Volume
- Reservoir Water Surface
- Maximum Overtopping / Breach Discharge
- Maximum Overtopping Head
- Overtopping Stress
- All Discharge Ratings
- Auxiliary Spillway Ratings
- Principal Spillway Rating
- Tailwater Elevation
- Tailwater Rating

A sample of the Headcut Advance plot is shown in Figure 5.

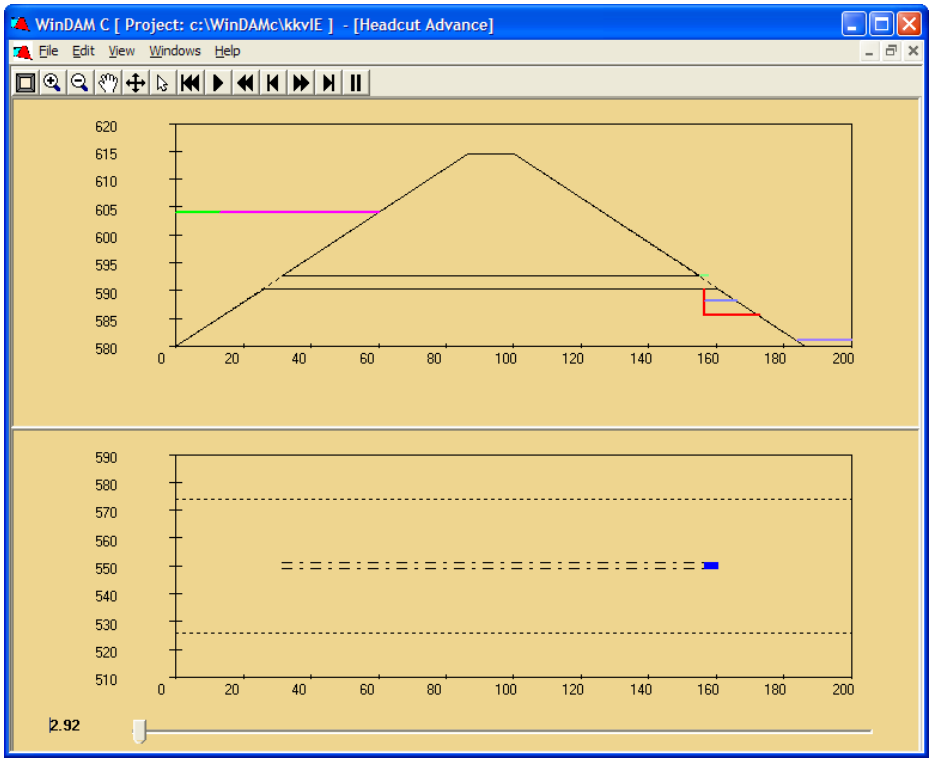

Figure 5 Sample WinDAM C headcut advance plot. Top half is dam cross-section. Bottom half is plan view.

INITIAL MODEL VALIDATION

Four different internal erosion tests on earthen embankments have been conducted at the ARS Hydraulic Engineering Research Unit in Stillwater, OK. Qualitatively, the WinDAM C predicted erosion matches the prototype erosion. The tests indicate that critical shear stress is a key parameter for initiation of erosion and particle detachment, especially for low-head dams. (Tejral, 2014)

CONCLUDING REMARKS

This report contains a preview of the internal erosion modeling capability being developed for WinDAM C. In addition, attention was given to capabilities already available to WinDAM B users—analysis of auxiliary spillways and overtopping breach. WinDAM software download and answers to frequently asked questions can be found at http://go.usa.gov/8Oq.

Abstract

Overtopping erosion accounts for 34 % of earthen dam failures. Grass cover has commonly been used to strengthen slopes and decrease the erodibility of embankment surfaces. Bermuda and Bahia are the most commonly used grasses on embankments and earthen dams due to their dense, deep root systems. A literature review of the acoustics of soils, soil erodibility, and traditional methods for the evaluation of soil surfaces was conducted. The review revealed an acoustic based apparatus capable of measuring mechanical and hydraulic properties that influence soil surface erodibility would be beneficial to soil scientists and engineers. In this study, we investigate the interaction of sound with the ground as a possible technique for assessing the erodibility of embankment surfaces. Physical properties common to both acoustic and erodibility behaviors of soils include: porosity, permeability, bulk density, moisture content, degree of compaction, and mechanical strength. An experiment is currently being conducted on soils with two different types of Bermuda grass, one type of Bahia grass, and one bare soil surface as a control. Acoustic transducers were placed at a depth of four inches to measure the changes in the acoustics behavior of the soil during the grass growth.

INTRODUCTION

In the last 50 years critical infrastructure has evolved to accommodate the steady increase of demand for freshwater and other natural resources. Dam infrastructure systems have assisted in providing an economic supply of freshwater, flood management, and soil conservation Richardson (2001). New technologies for monitoring the performance of the existing dam infrastructure systems must be developed to secure the continued availability of these resources.

Most traditional methods for characterizing erosion resistance involve invasive methods and lab tests. Flume tests have been used to study overtopping on grass covered dams by measuring water flow velocity and shear stress on the soil surface, Powledge et al. (1989). In 1991, a jet erosion test (JET) was developed to characterize erosion resistance on spillways, Hanson (1991).

Soil samples were subjected to varying jet velocities, and erosion was expressed as scour depth divided by time. This study showed that erosion in the site-specific submerged jet testing device may be related to the jet velocity, a time function, and a soil parameter (jet index). The jet index could then be used to provide a common method of expressing erosion resistance. The Erosion Function Apparatus (EFA) is another method to predict erosion rates as a function of shear stress in fine grained soils was designed for scour which could be closely related to the effect of overtopping erosion in earthen embankments. The EFA predicts these erosion rates in a lab by running water over a prepared soil sample at a certain velocity. Scour rate is measured as the height of the sample lost per time and is plotted against water velocity and shear stress on sample, Briaud et al. (2001).

Slot Erosion Test and Hole Erosion Test have been used to study internal soil erosion characteristics in embankment. The Hole Erosion test was used to estimate a priori a coefficient of piping erosion. The radius evolution of the pipe followed a scaling law between critical stress and time of piping erosion, which were a function of the initial hydraulic gradient and the coefficient of erosion. The time of failure and peak flow were related to the coefficient of erosion and the maximum pipe diameter before breaching, Bonelli. (2010). The rate of erosion is shown to be dependent on fines content, plasticity, dispersivity, compaction, water content, density, and saturation. Coarse-grained soils have lower critical shear stressed and erode more rapidly than fine-grained soils Wan et al. (2004).

In recent years acoustic methods have been developed to study soil wetting, compaction and other processes, Berkenhagen. (1998), Lu et al. (2004), Whalley et al. (2012). These acoustic methods utilize mechanical waves to measure soil properties. The acoustic approach has the benefits of being non-invasive and can be performed in the field. Besides the JET, the previously discussed tests require a prepared soil sample in a lab setting.

Acoustic waves traveling through soil interact with the soil particles and fluids. Acoustic parameters are constant-fabric characteristics and can be used to monitor ongoing internal changes of soil properties. Some of the properties that affect the acoustic response include moisture content, soil tension, density, effective stress, and porosity. The velocity of propagation of an acoustic wave can be modeled using

$$V_p = \sqrt{\frac{0.306a\sigma'^{\frac{1}{3}}Z}{\rho n b^{\frac{2}{3}}}} \quad (1)$$

This equation was proposed by Brutsaert et al. (1964) to model the compressional wave (acoustic) velocity in a media of randomly stacked spheres of different sizes as a function of

density (ρ), porosity (n), and effective stress (σ′). Z is a function of saturation, and a and b are adjustable parameters determined from fitting experimental data. Effective stress can then be broken down into 3 stresses. The first is total stress (σ) or overburden pressure which can be expressed as $\rho g h$ where g is the gravitational acceleration and h is the depth of the testing point. The second is the atmospheric pressure (σ_a) which is assumed to be zero. The last stress is soil tension (σ_c), also known as water potential or capillary pressure. This is weighted by saturation (S). These stressed are shown in the equation below.

$$\sigma' = \sigma - \sigma_a - S\sigma_c \quad (2)$$

For near surface areas of low saturation, soil tension is believed to be the main factor that affects sound speed Brutsart et al. (1964). This suction effect draws the soil particles together making the media more elastic which is indicated by increased wave velocities. At intermediate saturation, density and soil tension govern the acoustic behavior and decrease the sound speed. When approaching full saturation, sound speed is known to increase rapidly to the speed of sound in water. Acoustic response is also affected by overburden, but this is not a major parameter in near surface soils. Cohesion is also a factor affecting sound speed. The soil prepared in the current experiment is, for all practical purposes, homogeneous in soil type, so cohesive properties should not vary except due to soil tension. In this paper we discuss the feasibility of a method that estimates mechanical properties that influence soil surface erodibility by observing the changes in the acoustic wave velocity of the soil as a function of grass root growth.

METHODOLOGY

The experimental setup shown in Figure 1 includes a cast acrylic box divided into four quadrants, three quadrants having different grass types and one having a bare soil for control. Each soil quadrant is 1 ft (31 cm) deep with a surface area of 4 sf (0.37 m^2). The soil consists of 1% sand, 67% silt and 32% clay. This material is classified as a silty clay loam commonly used in the construction of earthen embankments. The soil was dried, grinded, and compacted into the box. Compaction was done in 1 inch (2.5 cm) layers with a metal plate. There were a total of 12 layers per quadrant to reach the depth of 1 foot (31 cm). The acoustic sensors consist of bimorph transducers built at The National Center for Physical Acoustics (NCPA) and placed at a depth of 4 inches (10 cm). Each quadrant has three transducers acting as one source and two receivers. This allows for two sets of time of flight measurements. With a known spacing of 6 inches (15 cm) and the travel time, the compressional wave velocity can be calculated.

Figure 1 Experimental setup

After the soil was compacted into the experimental box, time was allowed for relaxation of the initial effective stresses in the soil. The water was then slowly introduced from a drain in the bottom center of the box while the soil was under tension. The water level in an external reservoir was slowly raised to saturate the soil to the surface. Once saturated to the surface, the water in the reservoir was then lowered slowly back to a height of 1 inch (2.5 cm) above the bottom of the soil layer. The common Bermuda sod was donated by a commercial turf company, Tula Turf. The 007 Sumrall Bermuda grass was collected from pasture land, and the wild Bahia mix was collected from a slope covered in Bahia grass.

Grow lights were placed 1 ft (31 cm) above the top of the grass and left on for over 12 hr/day. The grass was cut weekly and fertilized twice a week with 15-30-15 fertilizer to boost root growth. Air temperature and pH of the soil was measured daily. Soil tension was measured at a depth of 6 inches (15 cm) with a tensiometer positioned in the middle of the quadrants. A HydraProbe II was used to measure the dielectric properties of the soil. These dielectric properties were then converted to volumetric moisture content and soil temperature. Figure 2 shows the grass just after the sod was placed on a) September 15, 2014 and later on b) January 16, 2015.

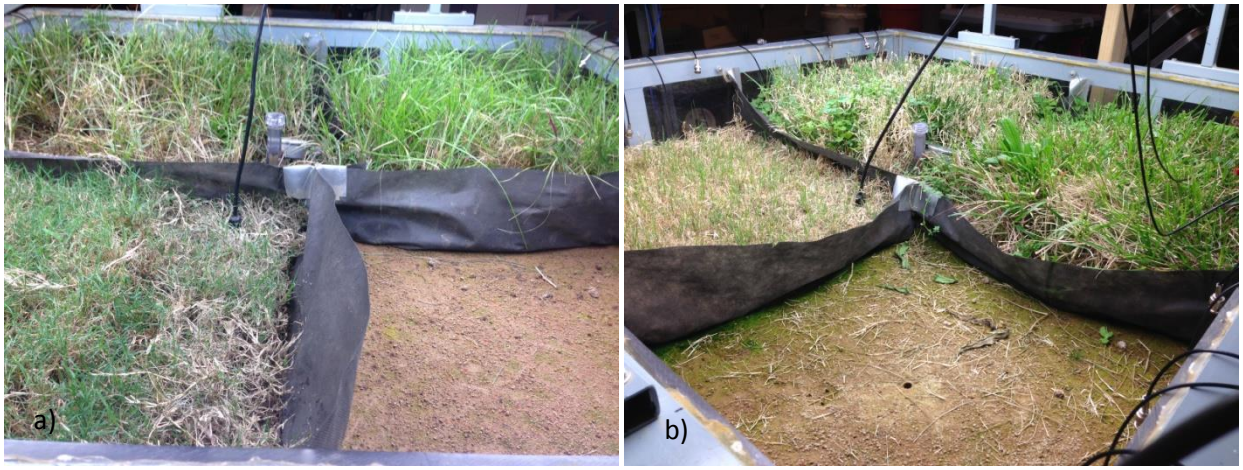

Figure 2 Grass cover on a) September 15, 2014 and b) January 16, 2015

RESULTS

The compressional wave velocities were calculated using Equation 3. The spacing of the transducer pairs (x) is constant at 15 cm (6 inches). The travel time of the sound denoted by Δt was measured using the receiving transducer. A picking routine detected the first arrival on the received waveform.

$$V_p = \frac{x}{\Delta t} \tag{3}$$

The control in this experiment was the bare soil velocities. The velocities in each grass type were compared to the bare soil velocities as a percent change as a function of time. The formula is given by Equation 4.

$$\Delta\% = \frac{V_i - V_b}{V_b} \times 100 \tag{4}$$

V_i is the velocity in the soil of the given grass. V_b is the velocity of the bare soil. The results of the experiment are presented below. Soil tension at the depth of 6 inches (15 cm) as a function of time is shown in Figure 3. The tension has remained very low around 1 – 2 kPa (0.15 – 0.3 psi). By October 4, 2014 the tension increased to 3 – 5 kPa (0.44 – 0.73 psi) before settling back around 1 - 2 kPa (0.15 – 0.3 psi) in November 1, 2014. The tension is moderately low and constant the next month and a half but started to vary more at the start of 2015. Such low tension is a consequence of the high degree of saturation. The soil tension averages about 2 kPa (0.3 psi) and varies ± 1 kPa (0.15 psi).

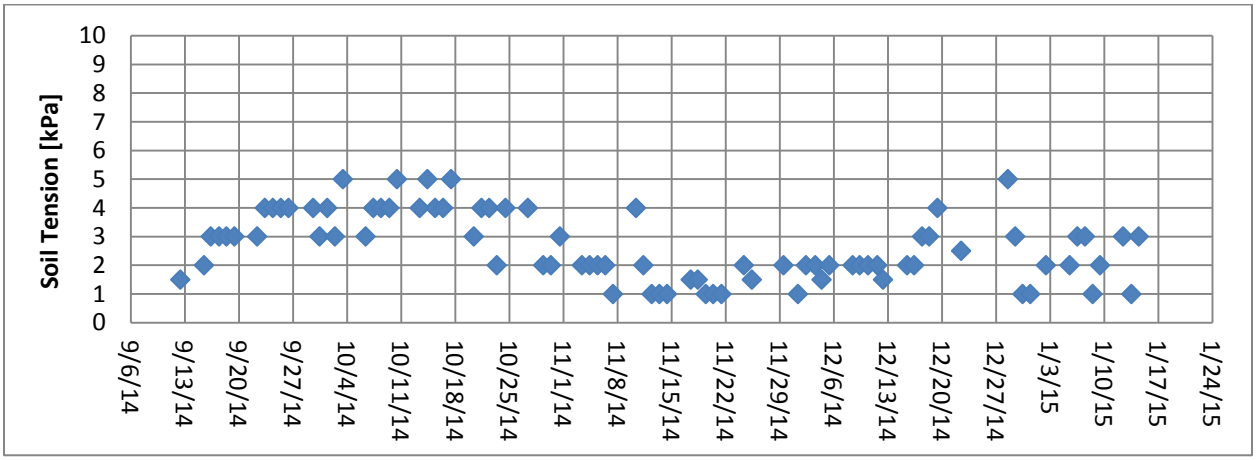

Figure 3 Soil tension since planting sod

The volumetric moisture content is shown as a function of time in Figure 4. It remains rather consistent from 0.51 – 0.54 m^3/m^3 (± 0.03 m^3/m^3). This is near fully saturated for this soil type. It is commonly believed that soil tension would increase with decrease in moisture content due to the soil's capillary rise when the water level is lower. This has not been observed for this experiment. The soil tension decreased with moisture content from October 25, 2014 to November 15, 2014. The accuracy of the HydraProbe II is ± 0.03 m^3/m^3, so this change in moisture content could be negligible. Volumetric moisture content has remained 0.51 m^3/m^3 (± 0.005 m^3/m^3) since December 9, 2014.

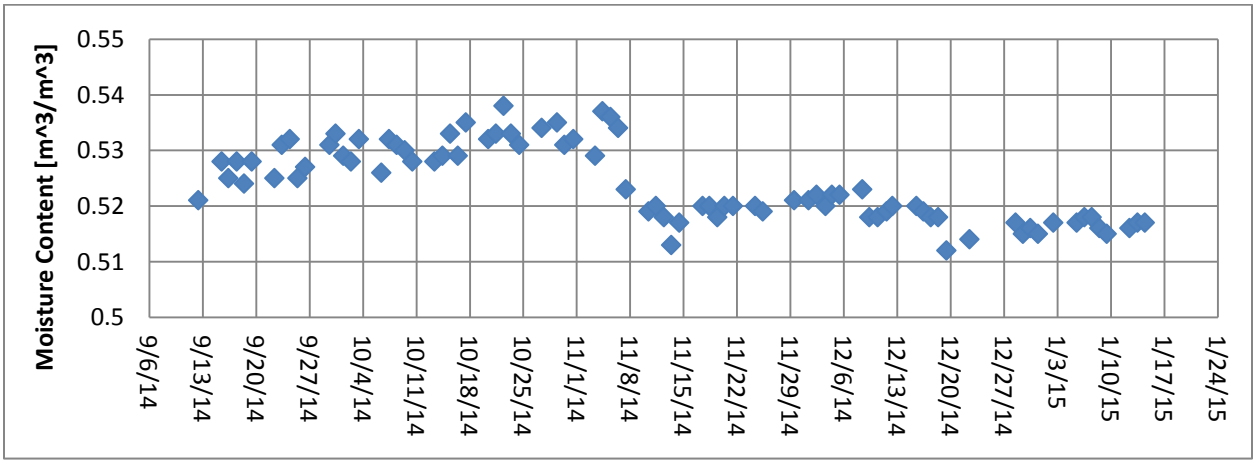

Figure 4 Volumetric moisture content since planting sod

The percent change in velocity with respect to the sound speed in the bare soil as a function of time is plotted in Figure 5. The range of sounds speeds has been from 150 – 260 m/s (492 – 853 ft/s). This is consistent with a soil tension <10 kPa (1.5 psi) and a moisture content around 0.50 m^3/m^3 Lu et al. (2009). Percent change seems to be greatest in the taller grasses. The velocities in the forage Bermuda and the Bahia mix increased approximately 20% compared to the bare soil. The sound speed in the common Bermuda, on the other hand, decreased around 10 – 15 % compared to the bare soil.

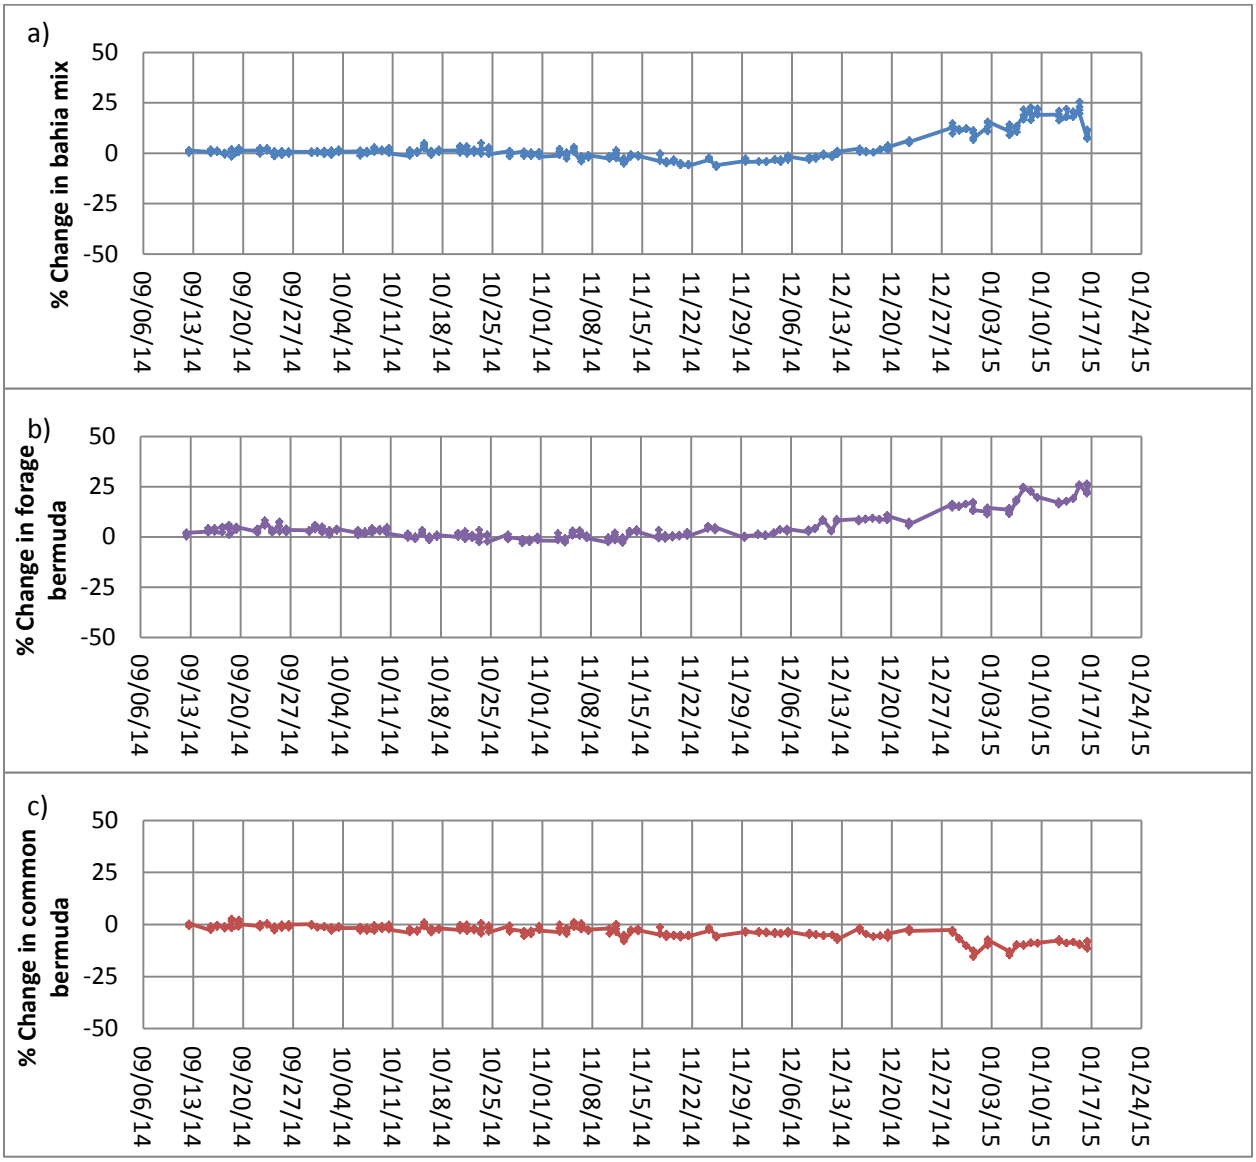

Figure 5 Percent change in sound speed with respect to bare soil for the a) wild Bahia mix, b) forage Bermuda, and c) common Bermuda grasses

The presented measurements to date aim to establish the sensitivity of acoustic measurements with the growth of different grass covers commonly used on earthen dams. In conclusion, an empirical relationship between root growth and sound speed has yet to be determined. More data will be collected over the next months as grass root matrixes become denser. If larger changes in acoustic velocity are observed with the further root growth, the project will be extended to measure the acoustic response as well as erodibility on controlled soil surfaces with several different types of grass covers and cross-plot acoustic, erodibility and grass cover properties to evaluate empirical relationships.

COMPARING PROCESS-BASED BREACH MODELS FOR EARTHEN EMBANKMENTS SUBJECTED TO INTERNAL EROSION

Ronald D. Tejral, Agricultural Engineer, ronald.tejral@ars.usda.gov, and
Sherry L. Hunt, Research Leader and Research Civil Engineer, sherry.hunt@ars.usda.gov,
USDA Agricultural Research Service, Hydraulic Engineering Research Unit, Stillwater, OK

Abstract: A sustainable infrastructure is one for which the risks are understood. Part of understanding the risks for dams is considering the consequences of failure. Predicting the potential flooding from a dam site requires prediction of outflow resulting from breach. Conservative estimates from the assumption of instantaneous breach or from an upper envelope of historical cases are readily computed, but these estimates do not reflect the properties of a specific dam. If it is desired to understand the effects of soil materials, embankment construction, and reservoir characteristics, a process-based model is needed.

WinDAM C is the most recent module of the dam breach software under development by USDA-NRCS in cooperation with USDA-ARS and Kansas State University. It builds on the functionality of previous WinDAM releases (evaluation of embankment surface protection, breach by overtopping, and integrity of auxiliary spillways) by adding the ability to evaluate internal erosion. A process-based model of this type provides an additional tool for the engineer to evaluate the potential impact of site-specific characteristics including erosion process, embankment materials, reservoir storage, and embankment geometry. In addition, this tool may aid in the development of flood warning systems, emergency action plans, and prioritizing dams for rehabilitation.

In this study, results of WinDAM C are compared and contrasted to those obtained using BREACH. A set of hypothetical, synthetic dams was used to represent the range of USDA Small Watershed Structures by varying height and reservoir volume augmented by three variations of detachment/transport rate. Outcomes of historical failure cases and physical model studies were compared to the synthetic set. The work suggests that WinDAM is predicting in the correct order of magnitude and exhibiting appropriate sensitivity to material parameters.

INTRODUCTION

Dams are a component of infrastructure that play many critical roles: supplying municipal and rural water (i.e. for consumption, recreation, agricultural production, etc.), generating or even storing energy, and flood protection for not only populations of residents located downstream but also infrastructure like homes, utilities, and transportation routes. Take for example the subset of flood protection dams that were constructed through the assistance of the USDA Small Watershed Program. These dams were built in partnership with the USDA Natural Resources Conservation Service, formerly the Soil Conservation Service. Even in early projects, sustainability was considered. Careful consideration was given to assure cost was justified by the benefits. Furthermore, federal conservationists and private landowners laid out plans that reduced soil loss, thereby mitigating sediment delivery to the reservoir.

Another facet in the sustainability of dams is risk analysis. The essential questions revolve around 1) identifying incident types and their probabilities and 2) assessing the outcome of each incident type if it were to occur. This report is concerned with the latter, and for that purpose estimates from the assumption of instantaneous breach or from an envelope of historical cases are readily computed. However, the effect is that all dams sharing only the most basic parameters, e.g. height and storage, are predicted to behave identically. Even the limited number of failure cases illustrates this is not true. If it is desired to understand the effects of soil materials, embankment construction, and reservoir characteristics, a process-based model is needed.

Fread (1988) with the National Weather Service developed an early model (BREACH) for breach prediction. Modelers could examine breach by modes of overtopping and internal erosion, which was termed piping. Erosion was computed using the Meyer-Peter and Müller formula as adapted for steep channels by Smart (1984).

WinDAM C is the most recent module of the dam breach software under development by USDA-NRCS in cooperation with USDA-ARS and Kansas State University. Earlier modules supported evaluation of embankment surface protection, breach by overtopping, and integrity of auxiliary spillways. In contrast to BREACH, erosion is computed as detachment-limited and taking the form of a headcut. The headcut behavior is included in the modeling of breach by internal erosion.

To compare these models, a set of inputs was developed which represent the trends of the dams in the USDA Small Watershed Program. Outcomes of historical failure cases and physical model studies were compared to those for representative dams within the synthetic set. This is a part of a more comprehensive and ongoing effort to verify and validate WinDAM C.

METHODS

Because few high quality data sets exist, this exercise was conducted using a synthetic set of dams. This set is derived from existing trends in dams and physical modeling. To aid in assessing the models, other methods of peak breach discharge were used as comparators.

Synthetic Set: The synthetic set of dams consists of a realistic series of dam sizes to evaluate and compare model predictions. A comprehensive database of basic dam parameters is found in the National Inventory of Dams maintained by US Army Corps of Engineers (2007). This database was used to quantify a typical dam built under the USDA Small Watershed Program. Height was selected as the independent variable and median height was found to be 32 ft. A series of heights based on powers of two were selected to include the median and span the range within the USDA Small Watershed Program from 4 to 128 ft.

Reservoir Characteristics: The next step was to define a height to storage relationship. The median trace of maximum storage volumes through these heights with bin boundaries determined by midpoints in logarithmic space was constructed. For example, the representative reservoir storage for 32 ft dams was selected by finding median from within $2^{4.5} \leq h_d < 2^{5.5}$ ft, or $22.6 \leq h_d < 45.3$ ft. A second-degree polynomial was fit to the values:

$$V_{max} = 0.39h_d^2 - 2.5h_d + 220 \quad (1)$$

where V_{max} = maximum storage volume (assumed to correspond to top of dam), ac-ft, and
h_d = dam height, ft.

Storage relationship is plotted in Figure 1; reduced data are shown in Table 1.

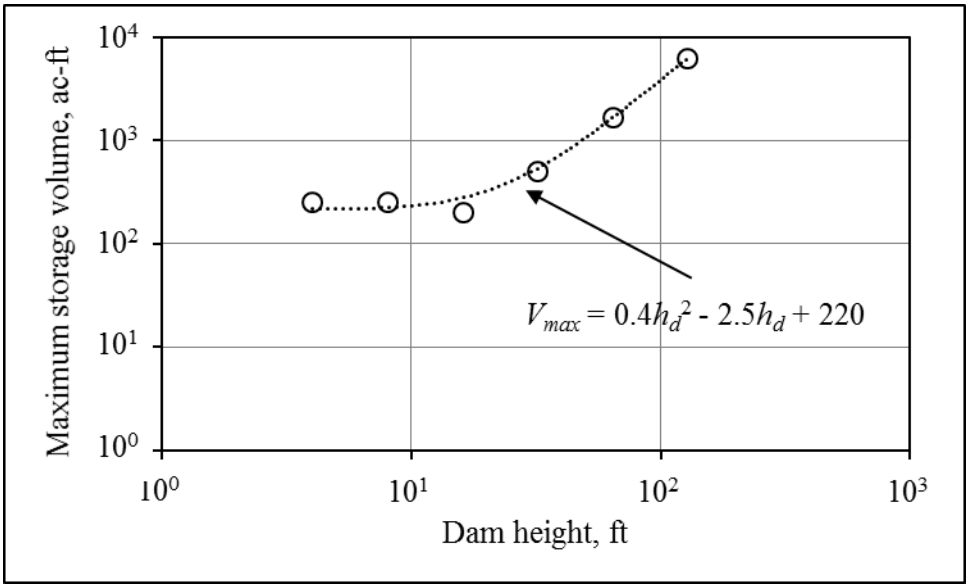

Figure 1 Dam height versus maximum storage volume.

The other reservoir characteristic is shape, which can be described by a hypsometric function. It is presented here similar to Walder and O'Connor (1997):

$$V = V_{max}\left(\frac{h}{h_d}\right)^m \quad (2)$$

Where V = volume of water in reservoir at h, ac-ft,
h = reservoir level, relative to base of dam, ft, and
m = shape parameter.
A fixed shape as defined by m = 3 was used throughout. This reservoir shape may be visualized as a cone as per Clarke (1982) or pyramid (of any base) with vertex at bottom and base defined by water surface.

While WinDAM accepts hypsometry data as height versus either volume or area, BREACH is restricted to area. Equation 2 was differentiated with respect to h to solve for area.

Dam Geometry: Embankment length is included in the NID. In finding the median length for each range of dam height, interesting behaviors are observed and reported in Table 1. Short dams (4 and 8 ft) tend to be long relative to their height. A plausible explanation are NID criteria, which would exclude all low hazard dams in this range unless they are both 6 ft high and store 50 ac-ft

or more; dams that meet inclusion on this criterion alone will tend to be long. From median heights of 16 to 64 ft, the trend is for length to increase linearly with height. This part of the data behaves as one might expect. These expectations are not unreasonable given this is the region in which bulk of data resides, and therefore has shaped our expectations. However, the trend does not continue into the bin with median height of 128 ft. Here, the explanation is likely a combination of topography and design criteria. The authors suspect that in general these dams are located in more steeply incised valleys, and were therefore taller to attain the storage necessary for flood control. This tendency toward a narrower valley led, in turn, to shorter lengths. Despite the lack of a clear trend, the overall variation in length was not extreme: median lengths do not even double (while dam height and maximum volume span one and nearly three orders of magnitude, respectively). For this reason, a single length of all dams was arrived at from average of the median lengths rounded to 1 significant figure: 900 ft.

While length was a field in the NID, other guidance was needed to select top width and slopes. A relationship for varying top width was defined using guidance on minimum top width by USDA-NRCS (2005). While actual top widths may be greater, it was assumed that these minimums were representative. The resulting top widths are reported in Table 1.

The final geometric considerations were upstream and downstream slopes. According to US Bureau of Reclamation (1987) upstream slopes are typically 2.5 or 3 (horizontal) to 1 (vertical). Similarly, Ralston (1987) stated that downstream slopes are usually 2.5:1 or 3:1. For the exercise, 3:1 was selected for both upstream and downstream slopes.

Table 1 Dam heights, medians of maximum storage volume, maximum storage volume of synthetic set, median crest lengths, and top widths.

Dam height, h_d, ft	Bin median of Maximum Storage Volume, ac-ft	Maximum Storage Volume as computed by eqn. 1, V_{max}, ac-ft	Median crest length, ft	Top Width, ft
4	254	220	1231	8
8	253	220	931	8
16	203	280	706	10
32	503	540	840	14
64	1687	1660	1018	14
128	4806	6300	855	16

Material Properties: Each model requires some quantification of the rate at which material comprising the dam will be eroded or transported. In WinDAM C, the notable parameters are erodibility (k_d) and critical shear stress (τ_c). They are obtainable by jet erosion test developed by

Hanson (1991) among other methods. The rate of headcut advance may be increased by slide of the headcut face principally as a function of undrained shear strength (c_u).

BREACH uses the Meyer-Peter and Müller equation as modified for steep slopes by Smart (1984) to model transport. This relation employs descriptors of the material's gradation: uniformity (D_{90}/D_{30}) and median particle size (D_{50}), being more sensitive to the latter. Additionally, the rate of failure can be increased by computations which rely on strength parameters, cohesion (C) and friction angle (ϕ) to predict slope failure. In contrast to WinDAM, these slope failures are of the channel sides.

Rather than arbitrarily varying any or all these parameters, three combinations of these were selected to correspond to physical tests conducted by ARS. The experiments from which they were taken presented a range of failure rates: Breach formation in less than 30 minutes to incomplete breach (initiation, but not formation) at 24 hours. Representative values of the soil test results and estimated parameters are presented in Table 2. For BREACH, gradation was available, but strength parameters were estimated from unconfined compression results.

Soils information also may be used by BREACH to estimate Manning-Strickler roughness. In an example Fread (1988) recommended use of Darcy friction factor and Moody diagram for a soil with median grain size diameter of 1 mm. As all soils represented here were of $D_{50} < 1$ mm, that was the method employed.

Table 2. Soils information.

Soil Property	Synthetic subset		
	High	Medium	Low
Unified Classification	SM	ML	CL
Plasticity Index	non	3	15
Erodibility, k_d, $ft^3\ lb^{-1}\ hr^{-1}$	70	1.3	0.3
Critical shear stress, τ_c, psf	0	0.2	0.2
Undrained shear strength, c_u, psi	300	700	1700
Cohesion, psf	150	400	1000
Friction angle, degrees	32	32	28
D_{50}, mm	0.14	0.04	0.02
Uniformity, D_{90}/D_{30}	4	50	130

Initial Conditions: Both models define the path of internal erosion very simplistically. The user specifies initial dimensions and invert elevation, and it is assumed to be horizontal and perpendicular to the crest. Longitudinally, BREACH models the path as located at center of dam relative to length, while WinDAM allows the station to be specified. For these simulations,

internal erosion was modeled as located at the centerline station and at elevation coinciding with $0.25h_d$ above base of dam base. The internal erosion was assumed to be initiated with a void square in cross section and having dimensions of 0.2 ft high and 0.2 ft wide.

A sunny-day failure is simulated with water surface elevation at $0.75h_d$ above dam base and little or no inflow. BREACH has been known not to run with a hydrograph having zero inflow as experienced by Tejral (2009), and therefore a constant inflow of 1 cfs was used.

Comparators: To provide context for the model results, USDA-NRCS peak discharge criteria and a subset of failure cases and experiments were used as comparators.

TR-60 Peak Breach Discharge: The peak breach discharge as predicted by the criteria in USDA-NRCS (2005) TR-60 was computed for each dam of the synthetic set. Because depth of water for all dams was less than 103 ft, the first equation that applied was

$$Q_{max} = (1{,}100)\left[\frac{(V_s)(H_w)}{A}\right]^{1.35} \quad (3)$$

where Q_{max} = peak discharge, ft^3/s
V_s = reservoir storage at time of failure, ac-ft
H_w = depth of water at time of failure, ft, and
A = cross-sectional area of embankment at breach location, ft^2.

Recall that short dams of the synthetic set had disproportionally large storage relative to population. This brought into play additional criteria that places an upper envelope on peak discharge (when $H_w \leq 103$ ft).

$$Q_{max} = (65){H_w}^{1.85} \quad (4)$$

The effect is that Q_{max} for the dam heights of 4 and 8 ft plot slightly above the trend established by higher dams.

TR-60 additionally considers effect of valley cross section. Here it was assumed that the valley did not constrain peak discharge.

Failure and Experimental Cases: The failed dams cases were selected from Wahl (1998) where piping was identified as the failure mode; rockfill embankments were excluded. There was no further screening of data to match synthetic set characteristics. Added to these failure cases were the three experiments conducted by ARS (and from which soils information was used to construct synthetic set). The testing conditions of these 4-ft high embankments closely matched the synthetic set criteria describe in *initial conditions*. The selected cases and their peak breach discharges are reported in Table 3.

Table 3 Peak breach discharges for earthen dam failures for which piping was mode from Wahl (1998) and experiments conducted by USDA-ARS.

RESULTS AND DISCUSSION

Peak breach discharges were tabulated for the completed model runs. In Figure 2 all results of WinDAM are shown, while the results corresponding to only the medium erodibility dams were plotted for BREACH. This was done because the predictions were essentially identical, and separate series could not be readily perceived on log-log plot.

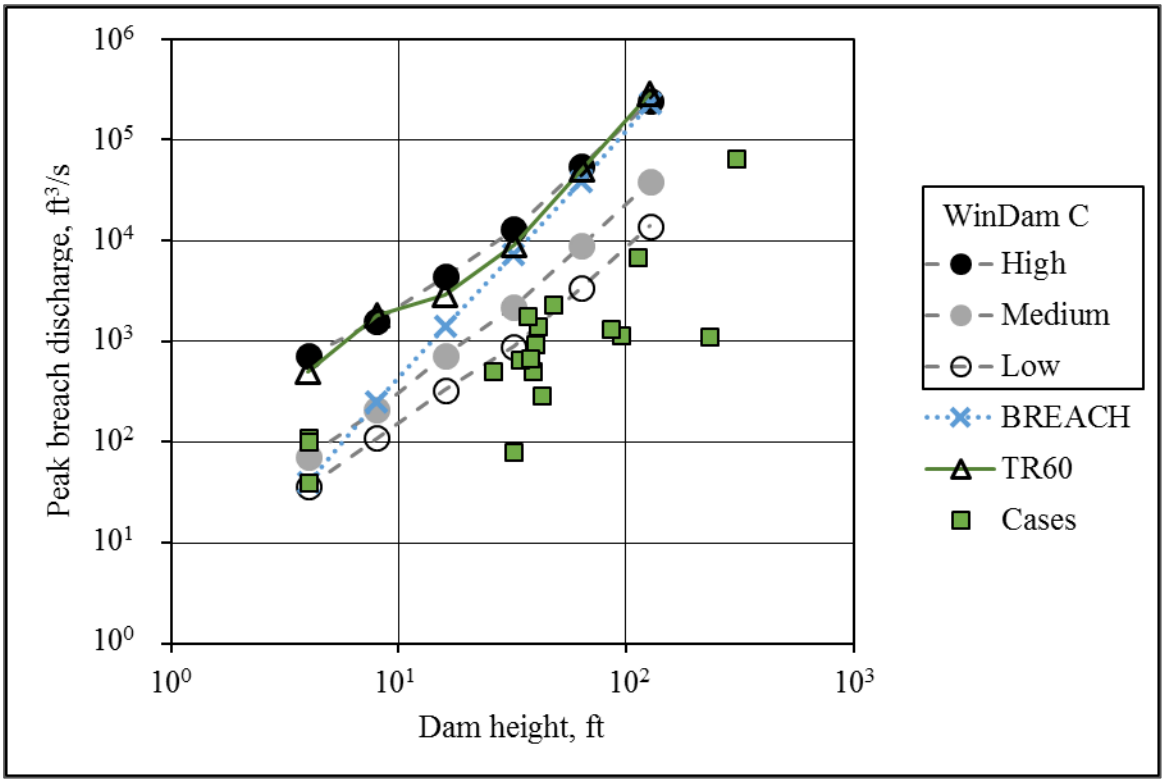

Figure 2 Peak breach discharge versus dam height for synthetic sets as predicted by WinDAM C and BREACH. For context also plotted are peak breach discharge for NRCS TR-60 and selected failure cases from Wahl (1998) and ARS research.

Relative to TR-60, BREACH arrives at very similar predictions for dams from 32 to 128 ft in height. WinDAM results for highly erodible dams track closely to the TR-60 relation throughout the full range of heights. Results for the more erosion resistant subsets (Medium and Low erodibility) roughly parallel the TR-60 series, but fall well below it, approximately an order of magnitude for the Low subset.

While plotted as points, there is often considerable uncertainty in the peak discharge. This uncertainty aside, note that none of the cases from Wahl plots above the Medium subset as predicted by WinDAM.

Times of peak discharge were also examined. While peak discharge exhibited little sensitivity in BREACH, there were discernible differences in time. The model tended to predict peak discharge of the highly erodible dams would occur in about twice the time as for low erodibility dams. For WinDAM, the time to peak was roughly 20 to 30 times greater for the low erodibility dams than the high erodibility dams. This was consistent with the behavior of physical models at USDA ARS.

CONCLUSIONS

Based on WinDAM results, for dams that are near the median storage, highly erodible material would be necessary for maximum discharge to approach that predicted by TR-60 equations. Conversely, if they were to breach under a similar scenario, most of the USDA Small Watershed Program structures would likely exhibit peak discharges well below TR-60.

The soils used to develop the synthetic sets exhibited considerably different erosion rates when tested. Note in the discussion that BREACH predicted the highly erodible dams would reach peak discharge *later* than more erosion resistant dams. For materials of higher plasticity, BREACH computes a critical shear stress similar to that found by jet erosion test. However, the representative diameter dominates the MPM-Smart equation. In BREACH, recall that roughness was estimated using soil gradation. This roughness was likely not representative of the form roughness that is more relevant to modeling flow rate. A user-selected roughness, however, further limits BREACH's sensitivity to a soil's characteristics. Because BREACH is unable to differentiate the behavior for these very different soils, this study further illustrates the difficulty in modeling detachment of cohesive materials as sediment transport.

The TR-60 equations and internal erosion cases suggest WinDAM is predicting in the correct order of magnitude. However, additional testing of the WinDAM model is needed to determine validity and bounds of application.

In closing, it is reiterated that the work presented here is part of the verification and validation testing by the developers. It is anticipated that WinDAM will be made available to a broader group for additional validation testing in the near future. As with any model, the results presented here require sound engineering judgment when applied.

ACKNOWLEDGEMENTS

NONDISCRIMINATION STATEMENT

EFFECTIVENESS OF CHANNEL IMPROVEMENT WORK ON THE MISSISSIPPI RIVER

Richie McComas, Hydraulic Engineer, USACE Vicksburg District, Vicksburg, MS, Richie.McComas@usace.army.mil; and C. Fred Pinkard, Jr., Hydraulic Engineer, USACE, Vicksburg District, Vicksburg, MS, Freddie.Pinkard@usace.army.mil.

Abstract: The Mississippi River has long been a major contributor to the physical and economic development of our nation. However, at the time that the United States was first settled, the Mississippi River was a natural alluvial stream characterized by a wide, shallow channel, numerous shifting sandbars, and large fluctuations in stage. The river was active and freely meandered across its floodplain. In this natural state, the river could not provide a dependable channel to meet the nation's commercial navigation needs nor could it provide for the efficient passing of flood flows.

To meet both navigation and flood control needs, a dependable, low maintenance channel had to be developed. Initially, dredging was conducted to provide adequate depths for navigation and levees were constructed to ease flooding problems. However, these measures alone proved ineffective. Then in 1927, a great flood devastated the entire Mississippi River Valley. As a result of this flood, Congress passed the Flood Control Act of 1928. This legislation authorized the U. S. Army Corps of Engineers to develop a comprehensive system of flood control and navigation improvements for the Lower Mississippi River. To provide an efficient navigation channel and to provide protection for the flood damage reduction levees, the banks of the river had to be locked in place. In response to this need, the Corps of Engineers initiated a comprehensive bank stabilization program. The use of revetment consisting of articulated concrete mattress (ACM) on the lower bank in conjunction with stone paving on the upper bank has proved to be most effective in controlling the erosion of the river's banks. However, revetment alone was not sufficient to provide a low maintenance channel. During low water periods, substantial dredging was required to maintain adequate channel dimensions. As a result of this continued dredging, a system of stone dikes was developed to provide adequate channel dimensions through trouble reaches. Now approximately 85 percent complete, the dike program has greatly reduced the expensive dredging requirements. Dredging within the Vicksburg District is only occasionally required in a limited number of isolated problem reaches.

Even with the proven success of the channel improvement program, additional work is required. With continued construction of the remaining planned channel improvement structures and continued maintenance of existing structures, an efficient navigation channel will continue to be provided on the Lower Mississippi River. During 2001 a paper which summarized the effectiveness of channel improvement work on the Mississippi River was prepared for the 7th Federal Interagency Sedimentation Conference. This current paper provides an update and expands on the information provided in that paper, takes a more detailed look at the project's environmental conservation and enhancement features, and identifies the performance of the channel improvement features during both the historic flood of 2011 and subsequent extreme low water in 2012.

BASIN CHARACTERISTICS

The Mississippi River drainage basin is the third largest in the world, exceeded in size only by the Amazon River in South America and the Congo River in Africa. The Mississippi River drains 41 percent of the lower 48 states, including all or parts of 31 states, extending from New York in the east to Montana in the west. The Ohio, Missouri, Tennessee, Arkansas, and Red River basins are part of the Mississippi River basin. The Mississippi River flows some 2,350 miles from its source at Lake Itasca in Minnesota to the Gulf of Mexico. The Lower Mississippi River Valley extends from just below Cape Girardeau, Missouri for approximately 600 miles to the Gulf of Mexico. The lower valley ranges in width from 30 miles to 125 miles with an average width of 45 miles and includes parts of Missouri, Illinois, Kentucky, Tennessee, Arkansas, Mississippi, and Louisiana. Figure 1 is a map that identifies the boundaries of the Mississippi River basin.

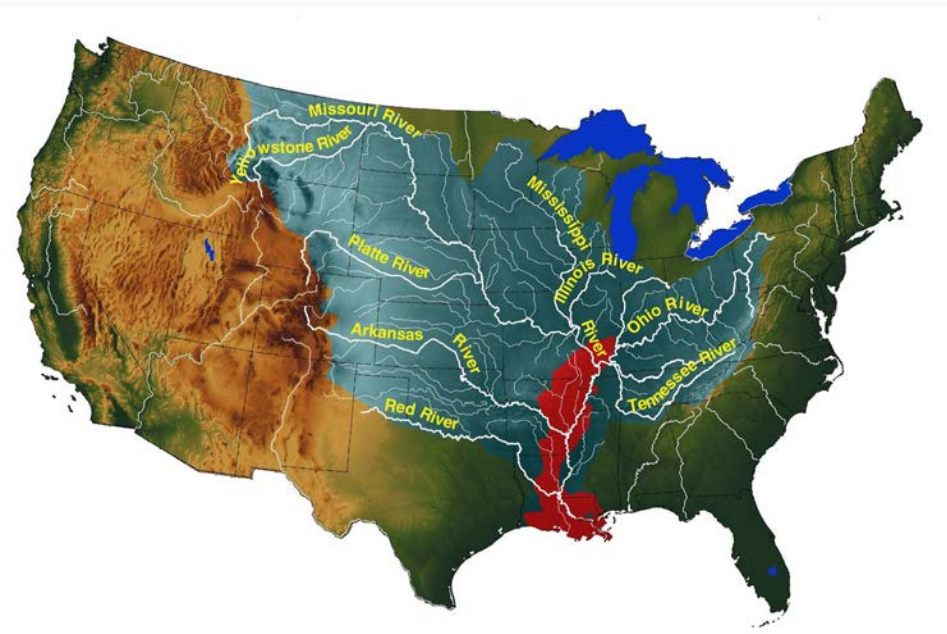

Figure 1. Mississippi River Drainage Basin

On the Mississippi River, flows, stages, and channel velocities vary over a wide range. During the 1943 through 2014 period, the average flow at Vicksburg, Mississippi was 625,000 cubic feet per second (cfs). The minimum recorded flow during this 71-year period was 126,000 cfs during January 1964 while the maximum recorded flow was approximately 2,300,000 during the 2011 flood. During that period, flows ranged on average from a low of around 305,000 cfs to a high of about 1,000,000 cfs. River stages also vary greatly. During the 1943 through 2014 period, the average annual low stage at Vicksburg was 54.1 feet, National Geodetic Vertical Datum (NGVD), the average stage was 66.3 feet, NGVD, and the average annual high stage was 78.4 feet, NGVD. Based on these averages, stages typically varied a little over 24 feet from annual highwater to low water. The lowest stage ever recorded at Vicksburg was 39.2 feet, NGVD during February 1940 while the highest stage recorded was 103.3 feet, NGVD during the 2011

flood. Channel velocities typically range from about 2 to 3 feet per second during low water to over 10 feet per second during highwater.

The Mississippi River is an alluvial river that carries a large and highly variable sediment load. Available data indicates that the annual suspended sediment load at Tarbert Landing, Mississippi (River Mile 306.3) has varied from about 70,000,000 tons to over 575,000,000 tons. Between 1963 and 2005, the average annual measured suspended sediment load was approximately 150,000,000 tons (Thorne et al., 2015). This sediment load equates to 133 tons per square mile of contributing drainage area per year. Sieve analyses indicate that on average, this suspended sediment load consists of about 20 percent sand and 80 percent fine material (silt and clay). Studies have indicated that over time, the measured suspended sediment load on the Mississippi River has significantly decreased primarily due to the construction of the channel improvement features, closure of multipurpose reservoirs, and improved land use management procedures. However, since the measured suspended sediment load is predominantly silt and clay, which are not found in large quantities in the bed, the total measured suspended sediment load could have decreased without any decrease in the bed material load, which is mostly unmeasured. In fact, as pointed out by Biedenharn (1995), the river through much of the Vicksburg and Memphis Districts has a steeper slope and larger stream power (QS) today than it did prior to the 1930's. Therefore, since studies (Nordin and Queen, 1992) show that the bed material size (D50) of the river has not changed significantly since the early 1930's, it is possible that the bed material load in these steeper reaches is higher today than it was prior to that time. This conclusion would suggest that more sediment of the size that deposits in the navigation channel and historically required removal by dredging is carried by the river today.

NAVIGATION DEVELOPMENT HISTORY

The Mississippi River has long been recognized as a valuable transportation benefit. Native Americans traveled the river by canoe for centuries before the European explorers arrived. The Europeans used the river for settlement expansion and small-scale commercial navigation to transport goods such as furs and supplies. The introduction of the steamboat during the early 19th century ignited an explosion of development along the river. However, the river was unpredictable and many steamboats fell victim to hazardous snags, shifting sandbars and high channel velocities. As early as 1820, the Federal Government recognized the importance of improving the Mississippi River for navigation. In that year, Congress appropriated funds for the preparation of a survey, maps, and charts of the Ohio and Mississippi Rivers. In 1824, the Corps of Engineers initiated channel improvement work by removing snags in the Mississippi River below the mouth of the Missouri River. For several years thereafter, channel improvement work was sporadic and limited to localized areas. All channel improvement work halted during the Civil War. As the country began to heal after the war, the need for more substantial Federal involvement in improvements of the river for navigation and flood control was generally recognized. In 1879, Congress established the Mississippi River Commission (MRC) to coordinate engineering operations within the Mississippi River Valley. The MRC was assigned the primary duties "…to take into consideration and mature a plan or plans and estimates as will correct and permanently locate, and deepen the channel and protect the banks of the Mississippi River; improve and give safety and ease to the navigation thereof; prevent destructive floods;

promote and facilitate commerce, trade, and the postal service…". In 1894, dredging began on the river. The success of these dredging operations prompted Congress in 1896 to authorize a 9-foot deep by 250- foot wide navigation channel from Cairo, Illinois to the Gulf of Mexico, to be maintained by dredging alone. However, dredging alone was not entirely effective in providing the required navigation channel and did not provide for the overall development needs of the valley. Then in 1927, the most disastrous flood in the history of the Lower Mississippi River Valley occurred. This flood inundated an area of about 26,000 square miles. During this flood, levees were breached, cities and towns were flooded, industry was paralyzed and crops were destroyed. Over 200 lives were lost and over 600,000 people were displaced. As a result of this flood, Congress passed the Flood Control Act of 1928, the nation's first comprehensive flood control and navigation act. This act increased the authorized navigation channel width to 300 feet and initiated a policy of river improvement and systematic construction of the channel improvement feature. The act also authorized the Mississippi River and Tributaries (MR&T) Project. Every year since the Flood Control Act of 1928 was passed, Congress has appropriated funds for the MR&T Project. The MR&T Project consists of four major components. These components include levees, floodways, tributary basin improvements, and channel improvement. Channel improvement includes stabilization to provide and maintain an efficient navigation alignment, increase the flood carrying capacity of the river, and protect the levee system. To provide for this component, an intense program of revetment and dike construction was initiated and is on-going today. The estimated total construction cost of the Vicksburg District's portion of the MR&T channel improvement program is $1,251,000,000. Through 2014, $1,083,708,129 (87%) has been expended. Maintenance is a critical part of the channel improvement program. Adequate funding must be provided in order to insure the continued functionality of the structures once they are constructed. The Vicksburg District currently receives maintenance funds annually. As more channel improvement works are completed and as existing works continue to age, more maintenance funds are required. However, the availability of funds for maintenance is not increasing resulting in maintenance requirements not being fully met.

Waterborne commerce on the Mississippi River has increased from 30 million tons in 1940 to nearly 500 million tons today. This tonnage includes such commodities as agricultural products including various grains, coal and coke, petroleum products, sand, gravel, and stone, salt, sulphur and other chemicals, among others. Without this valuable transportation system, the railways and highways would have to bear the burden of transporting these commodities. One standard barge that is 35 feet wide and 195 feet long has a capacity of 1,500 tons of cargo. One of these barges has the capacity of 15 railroad cars or 58 18-wheeler trucks. Therefore, it would require approximately 5,000,000 railroad cars or 19,230,000 18-wheeler trucks to transport the tonnage that moves on the Mississippi River today. The Mississippi River also provides an important link in the mobilization of our nation's defense forces. Therefore, the on-going development of the channel improvement program has resulted in the Mississippi River continuing to thrive as a crucial link for the country's economic development.

BANK STABILIAZTION

As is common on natural alluvial rivers, the Mississippi River has historically experienced bankline erosion and resulting migration. As evidenced by the numerous oxbow lakes and meander scars that exist today, the Mississippi River freely meandered across its floodplain. In

this natural state, the river was wide and shallow with numerous shifting sandbars. To provide a dependable navigation channel and to protect the flood damage reduction levees, the banks of the river had to be locked in place along the desired alignment. Therefore, an intense program of bank stabilization was initiated. In the past, several types of revetment have been used including willow, lumber, and asphalt mattresses. While these types of revetment proved somewhat successful, the most economical and effective means of protecting the banks continues to be a revetment composed of articulated concrete mattress (ACM) on the lower bank and stone paving on the upper bank. The current method of ACM placement is unique and is the result of years of research and development.

The use of ACM is restricted to large rivers due to the size of the floating plant required to place the mat. Therefore, in the Vicksburg District, ACM has only been used on the Mississippi River and on the lower Red River below the mouth of the Black River. The mat placement process includes several phases. The first phase involves clearing the bank. Many of the banks on the lower Mississippi River have vegetation that hinders the sinking process. Therefore, a narrow strip is cleared along the top bank to allow anchors to be provided during the sinking process. Caving banks are usually very steep. Therefore, to insure the stability of the revetment, the bank is graded to a flatter stable slope. The banks are graded by a large floating diesel-electric powered dragline. The clearing and grading of the banks are conducted on a schedule so that work is completed as close to the arrival of the mat-sinking unit as possible. This minimizes the potential for erosion of the freshly graded bank, reducing the overall cost of the operation and producing a better product. Natural vegetation re-establishes itself quickly along the stabilized top bank following completion of the revetment construction. Once the banks are graded, ACM is placed (or sunk) by the Mat Sinking Unit. The ACM consist of individual units of mat that are pre-cast and stored at strategically located casting fields along the river. Each unit contains 16 separate concrete blocks that are held together by corrosion-resistant wire embedded in the concrete. Each unit is 25 feet long by 4 feet wide by 3 inches thick and is commonly referred to as a square (100 square feet). Once the revetment season begins, the ACM squares are loaded onto barges and transported to the construction sites. Once on site, the squares are loaded on a specially designed mat-sinking barge. The squares are wired together into a mattress that is 140 feet wide and anchored to the bank with cables. As the mat is assembled, the sinking barge moves out into the river along the mooring barge. As the sinking barge moves, the ACM is launched off the barge and covers the river bottom. Placement of the mat continues to beyond the deepest part of the channel. The mat sinking plant is then moved upstream to lay the next section of mattress. This process continues with each succeeding mattress overlapping the previous mattress in a manner similar to shingles on a roof until the desired length of bank has been revetted. Once the ACM is sunk, placing stone riprap on the graded upper bank completes the revetment process.

ACM is typically placed during the low water season. On the lower Mississippi River, the revetment season usually extends from early September until all scheduled revetment placement is complete, usually in November. The location and amount of revetment placed each year is based on a prioritization of needed stabilization work and available funding. Through 2014, approximately 293 miles of revetment have been placed on the Mississippi River within the Vicksburg District with only 15 miles of revetment remaining to be constructed. Therefore, the revetment construction program is approximately 95 percent complete.

Figure 2. ACM Stacked on the Casting Field

Figure 3. Mat Sinking Unit

During 2011, the flood of record was experienced on much of the Lower Mississippi River with both record stage and discharge set at Vicksburg, Mississippi. During that event, the revetments were severely challenged. While damage did occur to some revetments, no catastrophic failures occurred to any of the revetments within the Vicksburg District. Therefore, during this historic event, the revetments continued to provide protection to the flood damage reduction levees by preventing channel migration due to eroding banks. Congress appropriated supplemental funds after the flood for damage repairs. As of late 2014, the Vicksburg District has completed all flood damage repairs to revetments.

CHANNEL CONTRACTION

The channel improvement feature that has had the greatest impact on dredging is dikes. Dikes are constructed on the Mississippi River to contract the width of the low water channel to provide and maintain adequate channel dimensions for navigation. Historically, dikes have been constructed of timber pile or stone or a combination of the two materials. Since stone is more permanent, this construction material is now used exclusively for dike construction. Dikes on the Mississippi River are constructed to a sufficient height to maintain an efficient low water channel but low enough so as not to hinder the passage of flood flows. Dikes within the

Vicksburg District are typically constructed so as to provide a 2,500-foot width between the riverward end of the dike and the opposite bank of the river. The Vicksburg District has been constructing channel control dikes on the Mississippi River since the early 1960's. As of 2014, 301 dikes totaling approximately 127 miles have been constructed. The dike construction program is approximately 85 percent complete with approximately 23 miles of dikes remaining to be constructed.

As previously mentioned, the Federal Government has been involved in dredging the Mississippi River since the 1890's. As the MR&T bank stabilization and channel control programs progressed, less dredging has been required to provide and maintain an efficient navigation channel. The Mississippi River is dynamic. As river conditions change, dredging is required in trouble reaches. As this occurs, dikes are designed and constructed to greatly reduce or eliminate required dredging.

Figure 4. Mississippi River Dike Field

Records indicate that required dredging within the Vicksburg District often well exceeded 10,000,000 cubic yards per year during the 1960's and the first half of the 1970's. However, during those years, the dike construction program was in its infancy. Figure 5 presents a graphical comparison of the annual dredging conducted on the Mississippi River within the Vicksburg District versus the cumulative amount of completed dike construction. This plot is for channel dredging only and does not include required dredging in the harbors. As the figure shows, in 1970 over 18,000,000 cubic yards were dredged. By that time, a total of less than 35 miles of dikes had been constructed. As the dike construction continued, the amount of dredging required to maintain a dependable low water navigation channel drastically decreased. In 1980, approximately 4,600,000 cubic yards of dredging was required and almost 65 miles of dikes were complete. In 1988, only 4,700,000 cubic yards were dredged even though the basin was experiencing a severe low water with river stages falling lower than had occurred in several decades. At Vicksburg, the low stage recorded in 1988 was the lowest in almost a quarter century. By 1988, just over 75 miles of dikes had been constructed. During the late 1990's and the early 2000's, less than 2,000,000 cubic yards were dredged annually. An increase in dredging was experienced during the later part of the 2000's. This can be primarily attributed to

changing channel conditions at Victoria Bend. The Vicksburg District designed and constructed additional dikes at Victoria Bend during recent years that has lead to a decrease in the need for dredging at this location. In fact, during 2011and 2013, no channel dredging was required in the Vicksburg District and only 282,000 cubic yards were dredged during 2014. Extreme low water occurred during 2012. That year, the lowest stage was recorded at Vicksburg, Mississippi since the extreme low water in 1988. In fact, 86 days with stages below 2 feet were recorded at Vicksburg from July through December 2012. This extreme, long duration low water severely challenged the effectiveness of the channel control dikes especially after many had been damaged during the historic flood experienced the previous year. A combined 6,400,000 cubic yards of channel dredging was required in 2012 at Victoria Bend plus an additional 5 different locations. Since that time, many of the dikes damaged during the 2011 flood have been repaired. However, repair work is still required at approximately 15 dikes. Repairs are being made as funding becomes available. Figure 5 shows the drastic reduction in required dredging as dike construction has progressed. Even during the extreme low water years of 1988 and 2012, channel dredging was limited to manageable amounts. The limited required dredging is a testament to the effectiveness of the channel improvement program.

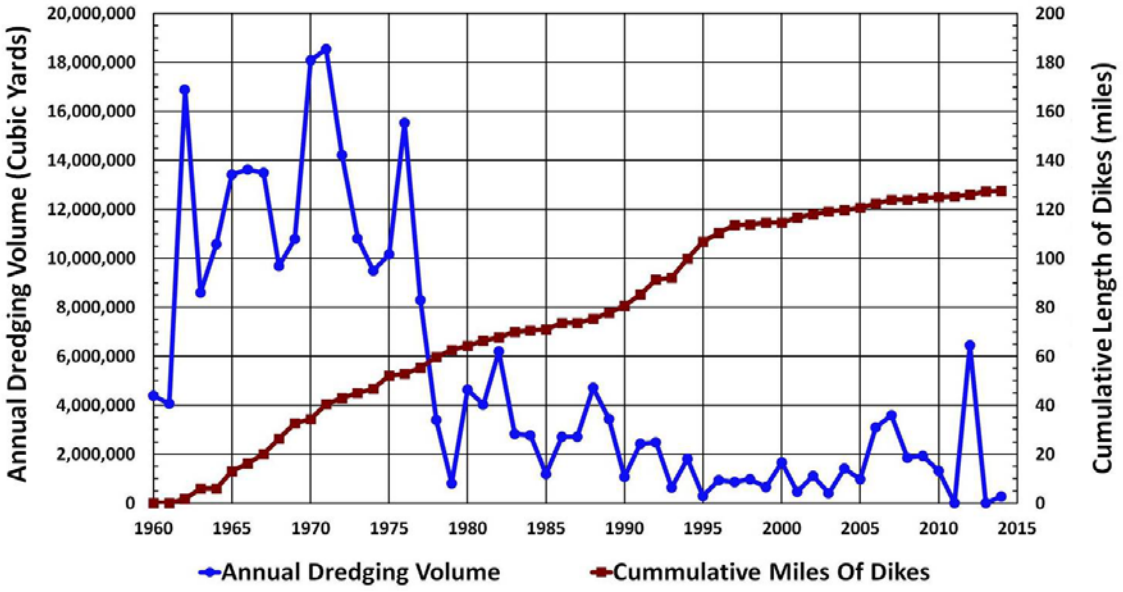

Figure 5. Mississippi River Channel Dredging Versus Cumulative Length of Dikes in Vicksburg District (1960 – 2014)

Environmental Conservation and Enhancement

Since the 1990's, the Vicksburg District has made a concerted effort to provide channel improvement features that not only provide for the authorized missions of flood damage reduction and navigation but also conserve or enhance the environment. For both revetments and dikes, a no work period is provided during April, May, and June for the pallid sturgeon spawning season. Also, restrictions are enforced on both revetment and dike work within set distances from known nesting least terns. Since the mid 1990's, environmental enhancement has

been provided by way of constructing grooves on the surface of the articulated concrete mat. The surface of the mat is grooved during the casting process by dragging a large wire brush type tool over the uncured concrete after it is placed into forms. Use of the grooved mat improves the aquatic habitat provided by the river by increasing the surface area for growth of macro-invertebrates which retain and recycle organic materials that would otherwise be lost from the system. This process provides a food source for fish with recreational, ecological, and economical value.

One of the environmental features currently used by the Corps of Engineers for dikes is the notched concept. By leaving a notch in selected dikes, the navigation channel can be maintained while at the same time provide diverse habitats for a variety of species including fish and the endangered least tern. The intended result is to insure that flow is maintained for longer durations in secondary channels than would otherwise be provided without the notches. The size and location of the notch in dikes is determined by the overall configuration of the river channel at each specific location. The Vicksburg District provides notches with varying widths and bottom elevations of the notch depending on the site. The District's current plan is to notch all future dikes that are constructed across secondary channels. All existing dikes extending across secondary channels that require raising in the future will also be notched at the time they are raised. The Vicksburg District first constructed notched dikes on the Mississippi River during the mid-1980's. Since that time, some 86 notched dikes have been constructed within the District. Figure 6 is an example of a notched dike.

Figure 6. Mississippi River Notched Dike

During 2011 and again in 2013, the Vicksburg District partnered with the U.S. Fish and Wildlife Service, Mississippi River Trust, and the Lower Mississippi River Conservation Committee (LMRCC) to improve habitat for species in the lower Mississippi River without compromising the vital navigation and flood risk reduction systems. The LMRCC is a coalition of 12 state natural resource conservation and environmental quality agencies in Arkansas, Kentucky,

Louisiana, Mississippi, Missouri, and Tennessee. The LMRCC was formed in 1994 and is dedicated to conserving the natural resources of the lower Mississippi River floodplain. This partnership involved the notching of 4 existing dikes at Island 70 and 2 existing dikes at Below Prentiss and another 2 existing dikes at Catfish Point for secondary channel restoration. Each partner agency has a clearly defined role in completing these projects. The Corps of Engineers provides engineering design and construction oversight. The LMRCC secures all necessary permits for regulatory compliance, coordinates all activities and procures the construction contract. Funding for the construction is provided by the USFWS through the Fish Passage Program (Prestwood and Rodgers, 2014). Figure 7 is a photograph of an existing dike at Island 70 being notched.

During July 2013, the Corps of Engineers Mississippi Valley Division in consultation with the U.S. Fish and Wildlife Service (USFWS) developed a conservation plan for three endangered

Figure 7, Dike Notching at Island 70

species on the Lower Mississippi River. Those species include the interior least tern, pallid sturgeon, and the fat pocketbook mussel. Specifically, the conservation plan is a programmatic mechanism by which the channel improvement program of the Mississippi River and Tributaries (MR&T) Project is being utilized to implement conservation measures that maintain and improve habitat values within the Lower Mississippi River for recovery of endangered and other trust species inhabiting the river channel. As a result of the information presented in the conservation plan, the USFWS issued a biological opinion on the channel improvement program on the Lower Mississippi River in December 2013. A biological opinion is required to determine if Federal action (channel improvement program) is likely to jeopardize the existence of a listed (threatened or endangered) species or result in the destruction or adverse modification of critical habitat. The conclusion of the biological opinion was stated by the USFWS as follows: "After reviewing the current status of the interior least tern, pallid sturgeon, and fat pocketbook mussel, the environmental baseline for the action area, the effects of continued operation and maintenance of the channel improvement program, it is the Service's biological opinion that the channel

improvement program is not likely to jeopardize the continued existence of the interior least tern, pallid sturgeon, and fat pocketbook mussel. No critical habitat has been designated for these species; therefore, none will be affected."

CONCLUSIONS

The Mississippi River has been and remains a major contributor to the physical and economic development of the nation. It carries the runoff from rainfall and snow melt for about 41 percent of the contiguous United States plus a small portion of Canada along with about 150,000,000 tons of sediment annually to the Gulf of Mexico. The river also supplies water for millions people and unnumbered industries and power plants. Currently, approximately 500,000,000 tons of commerce are transported on its navigation channel annually. Since their inception, the channel improvement works completed by the Corps of Engineers have contributed significantly to the efficient operation of this mighty river and its service to the nation. More recently, the systematic placement of channel training structures have significantly reduced the need for costly dredging to maintain a dependable navigation channel. The revetment program proved invaluable during the historic 2011 flood in maintaining channel alignment and protecting the flood damage reduction levees from channel migration. Also, the channel improvement program features being utilized to implement conservation measures have proved effective in maintaining and improving habitat values within the Lower Mississippi River for recovery of endangered species that inhabit the river channel.

EXTENDED ABSTRACT

Suspended sediment is one of the most detrimental pollutants to the Chesapeake Bay.; Streams in the Piedmont Physiographic Province have the highest suspended sediment concentrations in the Bay watershed. The Piedmont region has been heavily impacted by historic land uses including land clearing for agriculture, colonial era riparian sedimentation, low-head dam construction, subsequent reforestation in the 20th century, and presently by urbanization including development near Washington, DC and Baltimore, MD. The Piedmont Physiographic Province is developing at a greater rate than any other portion of the Bay watershed while also contributing the highest sediment yield (Gellis et al. 2009).

One of the objectives of our study was to develop a metric for comparing stream function between basins through the quantification of floodplain and bank sediment storage and supply (see Schenk et al. 2013 for the full manuscript). In particular, we developed a floodplain trapping metric to compare streams with variable characteristics and determine the ability of a stream's floodplain to trap and retain sediment transported during flood events. This objective was accomplished by creating a bank and floodplain sediment budget (hereafter referred to as a "sediment budget") for three Piedmont streams tributary to the Chesapeake Bay and comparing these estimations to published sediment yields for the same streams. A second objective was to use this floodplain-bank sediment budget to better understand the processes that govern sediment dynamics within relatively small streams in the Piedmont region of the Chesapeake Bay.

The watersheds of each stream vary in land use from urban to agricultural but have similar catchment areas and annual stream discharges (Table 1). Linganore Creek (LIN) has the highest amount of agriculture in its watershed (Gellis et al. In Press). Little Conestoga Creek (LCC) is influenced by rapid urbanization from nearby Lancaster, PA as well as current and recent low-head dams that have influenced floodplain connectivity (Schenk and Hupp, 2009). Difficult Run (DR) has the highest amount of urbanization resulting in a flashier hydrograph than the other two streams (Hupp et al. 2013).

Table 1. Watershed characteristics of each studied stream. Sediment yield measurements from each stream are from their respective USGS streamgages except DR where an upstream streamgage collected sediment loads (USGS streamgage 01645704). Sediment loads were collected during Water Years 2008-2011, 2003, and 2009 for LIN, LCC, and DR respectively.

		Annual	Annual	Basin			
	USGS	mean discharge	sediment yield	Area	Land Use (%)		
Stream	streamgage	m^3/s (cfs)	$Mg/km^2/yr$	Km^2	Agriculture	Forested	Developed
Linganore Creek (LIN)	01642438	1.4 (50)	43.5	147	71	22	7
Little Conestoga Creek (LCC)	01576712	1.7 (61)	65.1	160	68	10	22
Difficult Run (DR)	01646000	1.8 (62)	163.9	141	6	40	54

Field measurements included cross-sectional surveys extending from the valley headwall to the opposite bank of the channel (one half of the total floodplain as well as the entire channel). Bank height, channel width, floodplain width, and changes in channel morphology were all noted. Three floodplain transects were established per site per stream. Each transect consisted of 1 to 13 artificial marker horizons (feldspar clay) to determine floodplain deposition rates over time. Five bank transects were established per site with 6 bank pins per transect (3 on each side of the channel at low, middle, and high locations on the bank). Catchment area above each study site, elevation, gradient, width-depth ratio, and sinuosity along the reach at each site were determined from LiDAR imagery (0.03m vertical accuracy), digital elevation models (DEMs), topographic maps, and channel cross sections. Relations between fluvial geomorphic variables and both floodplain deposition and bank erosion were tested for significant correlations using Pearson Product-Moments analysis. Within each watershed, site floodplain deposition and bank erosion rates were related to basin area, channel sinuosity, channel gradient, bank height, channel cross-sectional area, and the ratios of bank height to floodplain width, channel width to depth, channel cross-sectional area to floodplain width and channel width to floodplain width. Variables were transformed when necessary to meet the parametric assumptions of the analyses.

Net site sediment budgets were best explained by gradient at Difficult Run, floodplain width at Little Conestoga Creek, and the relation of channel cross-sectional area to floodplain width at Linganore Creek. A correlation for all streams indicated that net site sediment budget was best explained by relative floodplain width (ratio of channel width to floodplain width). A new geomorphic metric, the floodplain trapping factor, was used to compare sediment budgets between streams with differing suspended sediment yields. Site sediment budgets were normalized by floodplain area and divided by the stream's sediment yield to provide a unit-less measure of floodplain sediment trapping. A floodplain trapping factor represents the amount of upland sediment that a particular floodplain site can trap (e.g. a factor of 5 would indicate that a particular floodplain site traps the equivalent of 5 times that area in upland erosional source area). Using this factor we determined that (1) Linganore Creek had the highest gross and net (floodplain deposition minus bank erosion) floodplain trapping factor (107, 46 respectively), (2) that Difficult Run the lowest gross floodplain trapping factor (29), and (3) that Little Conestoga Creek had the lowest net floodplain trapping factor (-14, indicating that study sites were net contributors to the suspended sediment load; Figure 1). The trapping factor is a robust metric for comparing 3 streams of varied watershed and geomorphic character, it promises to be a useful tool for future stream assessments, especially on projects related to stream and floodplain restoration. The trapping factor metric, and the relative floodplain width correlation with net site sediment budgets, is currently being tested at 30 streams in the Piedmont and Valley and Ridge Physiographic Provinces to determine if the metric and geomorphic correlation can be confidently extrapolated to other streams in the Mid-Atlantic region.

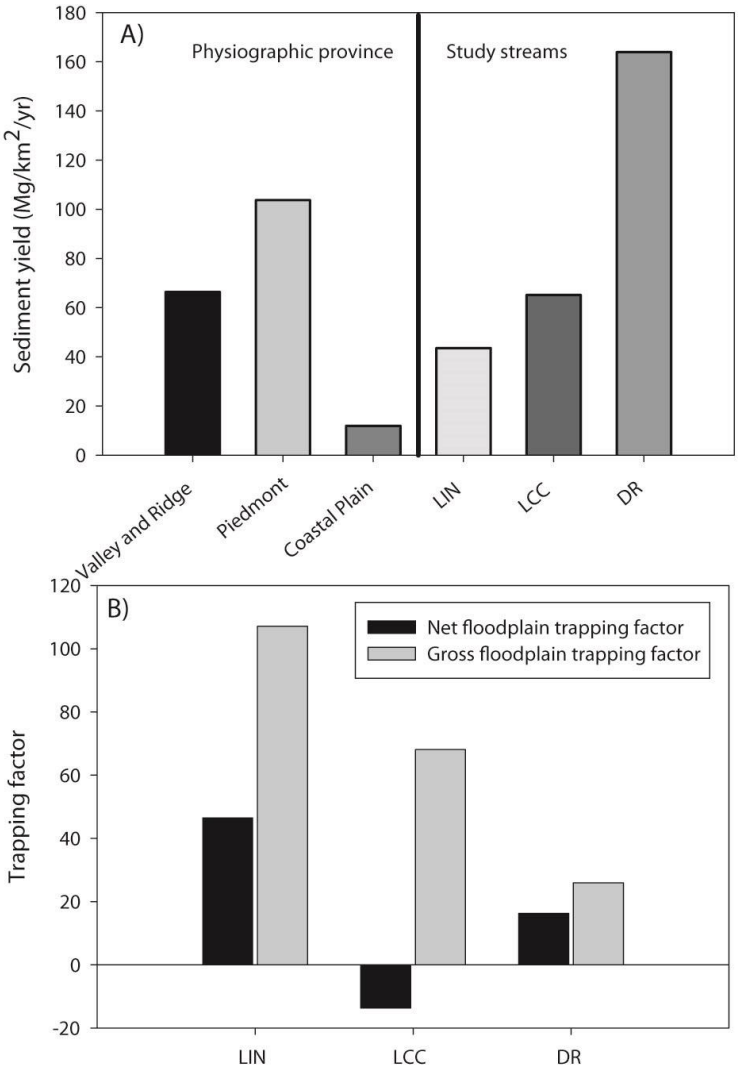

Figure 1. A) Mean sediment yields for select Physiographic provinces of the Chesapeake Bay (Gellis et al. 2009) and sediment yields for the study streams from Table 1. B) Mean gross and net floodplain trapping factor by study stream. LIN, LCC, and DR represent Linganore Creek, Little Conestoga Creek, and Difficult Run respectively.

AUTOMATED UPDATES TO 2D HYDROLOGIC MODELS FOR OPEN-PIT MINING

Christopher Smemoe, PhD, PE, Aquaveo, 3210 N Canyon Rd, Suite 300, Provo UT, csmemoe@aquaveo.com; Clark Barlow, PE, CFM, Aquaveo, 3210 N Canyon Rd, Suite 300, Provo UT, cbarlow@aquaveo.com

Abstract Open-pit mines exhibit complicated hydrologic and sediment transport processes that impact the surrounding environment. Building and calibrating an initial hydrologic model that models these processes is a challenge, and updating this model poses further challenges. Hydrologic models of open-pit mines must be frequently updated because of constant changes to the topography, land use, pumping stations, and settling ponds surrounding the open-pit mine. The Gridded Surface Subsurface Hydrologic Analysis (GSSHA) 2D hydrologic model, developed by the US Army Corps of Engineers (USACE) Engineer Research and Development Center, can be used to analyze the complicated processes in an open-pit mine, among other things. The Watershed Modeling System (WMS) software, developed by Aquaveo, provides graphical tools to develop a GSSHA model and view the model output. We have developed an automated modeling wizard in the WMS that assists GSSHA modelers in updating the topography, land use, pumping stations, settling ponds, and associated model parameters for open-pit mine hydrologic models. This paper describes the procedures followed in automatically updating these model parameters using this wizard.

INTRODUCTION

Open-pit mines exhibit complicated hydrologic and sediment transport processes that impact the surrounding environment. Building and calibrating an initial hydrologic model that models these processes is a challenge, and updating this model poses further challenges. Hydrologic models of open-pit mines must be frequently updated because of constant changes to the topography, land use, pumping stations, and settling ponds surrounding the open-pit mine. This study included developing a semi-automated wizard-based approach for updating hydrologic models in watershed areas surrounding open-pit mines.

The Gridded Surface Subsurface Hydrologic Analysis (GSSHA) hydrologic model, developed by the USACE's Engineer Research and Development Center, was used to model the watershed areas surrounding the open-pit mines described in this study. GSSHA "is a physics-based, distributed, hydrologic, sediment and constituent fate and transport model. Features include two dimensional (2D) overland flow, 1D stream flow, 1D infiltration, 2D groundwater, and full coupling between the groundwater, shallow soils, streams, and overland flow" (Downer and Ogden, 2015). Because GSSHA offers so many processes that can be modeled, it offers an ideal solution for modeling the complex hydrologic processes surrounding open-pit mines.

The Watershed Modeling System (WMS) software, developed by Aquaveo, provides graphical tools to develop a GSSHA model and view the model output. We used WMS to

collect the necessary data and to build, run, and calibrate GSSHA models for this study. Then we read and view the GSSHA results in WMS. Aquaveo developed an automated modeling wizard in WMS that assists GSSHA modelers in updating the topography, land use, pumping stations, settling ponds, and associated model parameters for open-pit mine hydrologic models.

The model study area was the watershed areas surrounding three large open-pit coal mines in Indonesia. Several watersheds surround these mines, and water quality and erosion in the surrounding watersheds are a concern. Aquaveo built and calibrated separate GSSHA models for each of the watersheds surrounding the mines. Aquaveo then tested the wizard on each of these models to determine its usefulness in automatically updating the models of the watersheds surrounding the mines. This paper gives an overview of the model development and shows how the WMS wizard is used to automatically update the hydrologic models for the watersheds surrounding the open-pit mines. The techniques used in this wizard can be used to automatically update other types of hydrologic models and could possibly be used to auto-generate GSSHA hydrologic models sometime in the future.

METHODS

This section first gives an overview of the models that were developed and then describes the processing required to update the various types of data for each of the models in the WMS wizard.

Model Overview: 21 different GSSHA models were built and calibrated to represent the watershed areas surrounding 3 different yet closely-spaced open-pit coal mines. Techniques involved in setting up the initial GSSHA models using WMS are described elsewhere (see Nelson and Smemoe, 2015). A photo of one of the open-pit mines is shown in figure 1.

Ponded water, loose sediment, and drainage are a major problem in the areas surrounding these open-pit mines. Because of the impacts of the mine, there are some areas surrounding the mines where erosion is a major concern (figure 2).

The watershed models determined areas with large amounts of sediment erosion and deposition, areas with high channel velocities, and determined the impacts of sediment mitigation efforts, including adding sediment settling ponds (figure 3) at the downstream end of the watersheds.

Figure 1 One of the open-pit coal mines

Figure 2 An eroded culvert crossing close to one of the mines

Figure 3 A series of sediment settling ponds surrounding one of the open-pit mines.

A plan view of the GSSHA-computed water depths after a storm event is shown in figure 4.

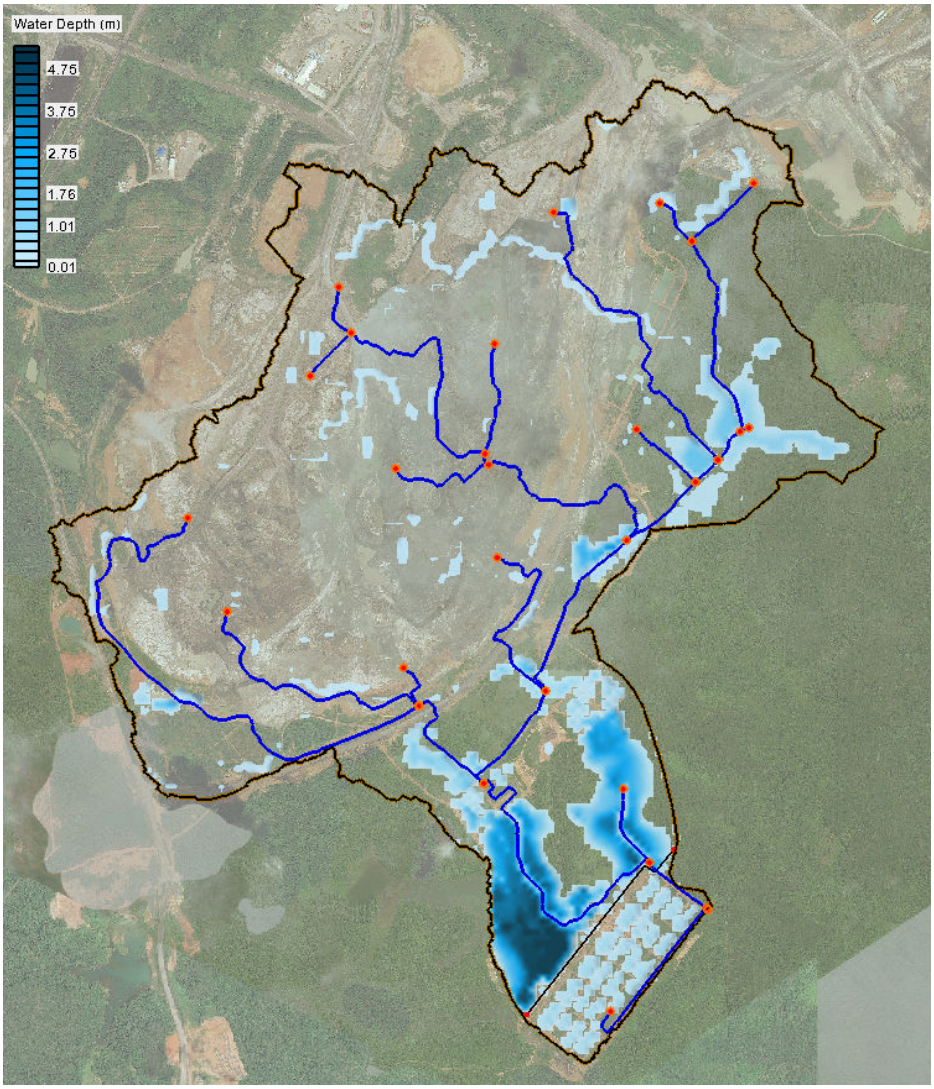

Figure 4 Computed water depths in one of the watersheds surrounding the open-pit mine.

A similar example of the GSSHA-computed erosion/deposition map is shown in figure 5.

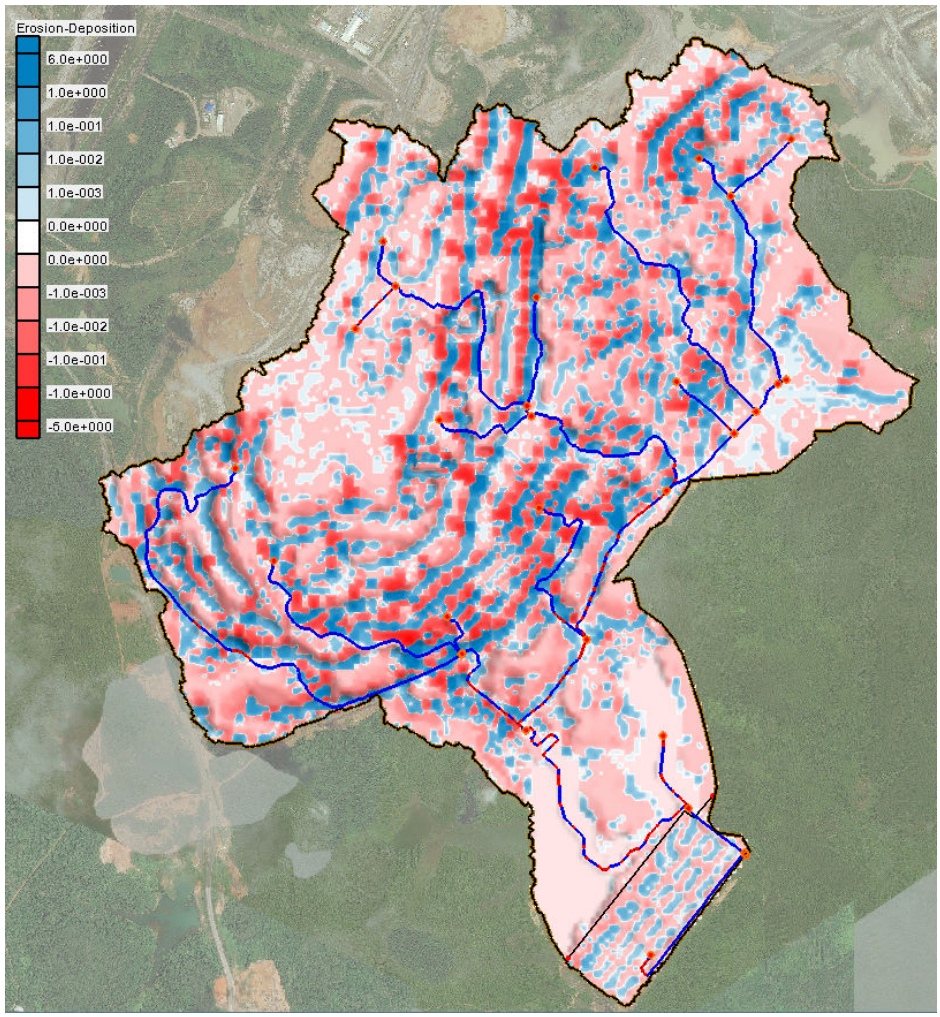

Figure 5 Aerial map showing computed sediment erosion (red-tinted areas) and deposition (blue-tinted areas) in one of the watersheds surrounding the open-pit mine.

The WMS mine wizard can be used to update changing model inputs for the 21 existing GSSHA models and outputs many useful model parameters that are described in the section on model output.

Update Elevation Data: An image showing the GSSHA model update wizard with each of its steps is shown in figure 6.

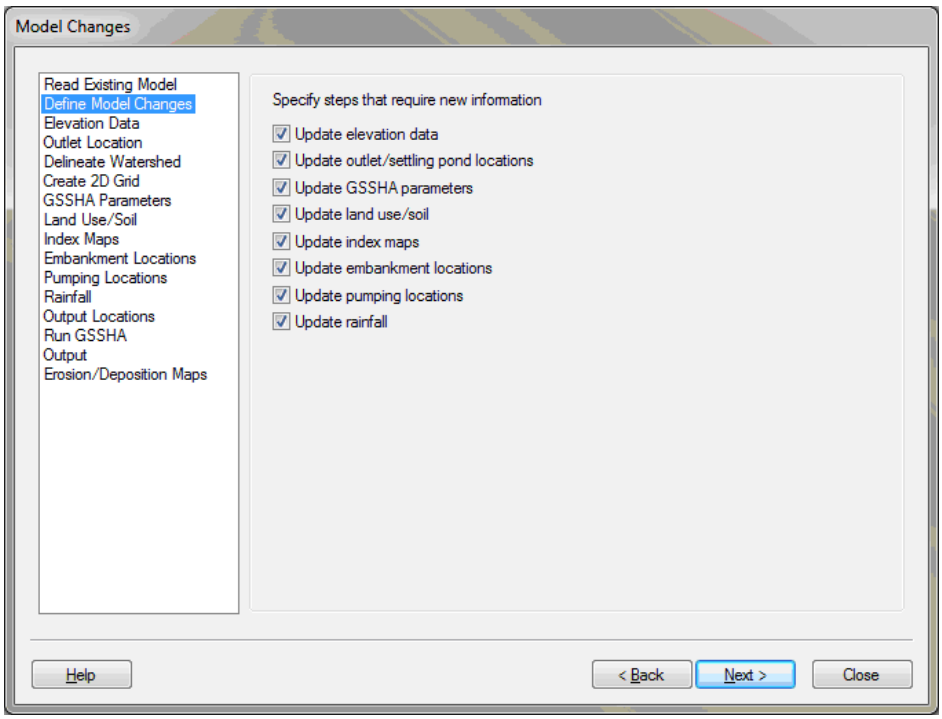

Figure 6 GSSHA mine model update wizard.

You can use the Update Elevation Data step of the wizard to read updated elevation data, if necessary. The updated elevation data is used to delineate the watershed and update the 2D Grid elevations in the GSSHA model. When delineating a watershed, it is important to determine flow directions and flow accumulation values from the elevation data, and this step includes an option to compute these grids from the elevation data.

Update Outlet/Settling Pond Locations: Sometimes, the locations of the settling ponds are changed or new settling ponds or embankments are added to the watershed that change the flow and may require the watershed outlet point and the watershed boundary to be changed. Because of this, we added a step to the wizard to assign a new outlet location. If a drainage coverage (layer) already exists in the model, WMS copies this coverage to a new drainage coverage. If no drainage coverage exists, WMS creates a new drainage coverage so the outlet can be added to that coverage. When assigning a new outlet location, WMS deletes all the geometric data in the coverage and the watershed boundary is re-computed when the watershed is delineated in the next step.

Watershed Delineation: This step determines the watershed boundary based on the flow directions and accumulations and the outlet point in the active drainage coverage.

Update 2D Grid: The Create 2D Grid step is used to update or create a 2D grid for running GSSHA from the delineated watershed boundary. In this step, you select a grid cell size or number of cells, assign an optional depression coverage, and assign an optional coverage containing GSSHA structures (such as detention basin outlets) and select a button to create a 2D grid and initialize your GSSHA model parameters.

WMS does the following when you select the Create 2D Grid button:

1. Convert the delineated drainage coverage to a GSSHA coverage.
2. Intersect the stream arcs (polylines) in the GSSHA coverage with the depression coverage (if this option is on) and split the stream arcs at the intersections.
3. Redistribute stream vertices so the vertex spacing matches the specified 2D grid cell size.
4. Smooth any stream arcs that are outside of depression coverage polygons. If no depression coverage exists, WMS removes all adverse slopes on the streams.
5. Combine the stream arcs so they are no longer split at the intersections of polygons in the depression coverage.
6. Assign default stream attributes to all the streams (Trapezoidal channel with the following attributes: Manning's n = 0.03, depth = 3 m, width = 4 m, and side slope = 0.5.
7. If the option to assign structures from an existing GSSHA coverage is selected, WMS copies the embankments, detention basin nodes, and pumps and their attributes from the selected GSSHA coverage to the new GSSHA coverage.
8. Creates a 2D grid filling the watershed boundary polygon at the specified cell size.
9. Initializes the GSSHA model data and copies the previously defined GSSHA model job control information over to the new GSSHA model.

Update GSSHA Parameters: This step of the wizard is used to specify the GSSHA land use and soil type parameters assigned to the land uses and soil types in WMS. These parameters are later assigned to the GSSHA model after updating the land use and soil data assigned to your model. Default parameter files can be read and used from other projects to parameterize values in the active GSSHA model.

Update Land Use/Soil Data: The define land use and soil data step converts GIS shapefiles to data in the WMS Map module. WMS uses the boundary of the watershed in the GSSHA coverage to clip the shapefile data for the selected files.

Update Index Maps: The index maps step is used to generate GSSHA index maps from the polygons in the WMS land use and soil type coverages. After WMS defines the GSSHA index maps, it generates GSSHA mapping tables from the index map ID's and the GSSHA land use and soil type parameters defined in the GSSHA Parameters step of the wizard.

Update Embankment Locations: The embankment locations step is used to layout or change the locations of GSSHA embankment arcs within a watershed. These embankment arcs could represent structures such as hauling roads, detention basin embankments, or settling pond embankments.

Update Pumping Stations: The pumping locations step of the wizard is used to delete or add pumping stations and to define the pumping rates. Pump stations are where water or sludge is transferred from the open-pit mine to the watershed. These pumping stations can be a major source of sediment load in each of the watersheds surrounding the mines.

Update Rainfall: The model rainfall occasionally needs to be updated to forecast future sediment loads and water depths in each of the watersheds surrounding the open-pit mines.

Output: Several output parameters that are useful for managing the watersheds surrounding the open-pit mine are exported from the model after running the model. Some of the parameters that are output include:

1. Simulation input parameters, such as pumping rates, model duration, and watershed area.
2. General simulation results at each user-specified output point, such as peak flow, runoff volume, volume of water pumped, and total infiltration.
3. Information about the settling ponds, such as their initial storage, volume of rainfall in the ponds, volume of runoff to the ponds, and the peak discharge from the ponds.
4. A sediment summary, including the maximum and average erosion rates, the total sediment eroded and deposited in various parts of the watershed, and sediment concentrations.
5. Discharge and runoff volume are also computed at each user-specified output location in the model.
6. An erosion/deposition plan view map is computed and displayed as part of the output.

DISCUSSION, CONCLUSION, AND FUTURE WORK

Open-pit mines can impact their surrounding watersheds in various ways. The GSSHA model can be used to model some of these impacts on the environment. Some of these impacts include sediment erosion, sediment deposition, and flooding from settling pond embankments and hauling roads. WMS can be used to develop GSSHA models, and the open-pit mine wizard in WMS allows you to update these GSSHA models in a semi-automated fashion.

This paper provided an overview of the GSSHA hydrologic models surrounding three open-pit coal mines and shows how the WMS wizard can automatically update the hydrologic models for the area surrounding the open-pit mine. We would like to extend the techniques used in this wizard to automatically update other types of GSSHA hydrologic models and perhaps to auto-generate hydrologic models for any watershed of interest.

LOW WATER PLANNING IN THE COLUMBIA RIVER BASIN

Thomas Chisholm, Hydraulic Engineer, U. S. Army Corps of Engineers, Northwestern Division, Portland, OR, tom.a.chisholm@usace.army.mil

INTRODUCTION

Storage reservoirs even out variation in river flow. A chief benefit of this function is more reliable supplies of both hydropower and water. For reservoirs that supply power and water perhaps the most basic design question is: how much reservoir capacity is required given natural flow and demand.

In 1961 United States President Dwight Eisenhower and Canadian Prime Minister John Diefenbaker signed the Columbia River Treaty. The Treaty's preamble states: "Recognizing that the greatest benefit to each country can be secured by cooperative measures for hydroelectric power generation and flood control, which will make possible other benefits as well." Thus, the Treaty focuses on flood control and hydropower. During low water conditions attention focuses on hydropower over flood control. Although in many rivers water supply is the primary objective in the Columbia River Treaty it falls into "other benefits". However, attention to ecological processes, which value water supply, has increased since the signing of the Treaty.

The Treaty and its annexes provide guidelines for developing project operating plans and apportioning benefits. Both operating plans and benefit calculations use the critical period concept. Article I of the Treaty entitled Interpretation includes:

(d) "**critical stream flow period**" means the period, beginning with the initial release of stored water from full reservoir conditions and ending with the reservoirs empty, when the water available from reservoir releases plus the natural stream flow is capable of producing the least amount of hydroelectric power in meeting system load requirements.

CRITICAL PERIOD DEVELOPMENT

Critical Period Concept: Considering that Treaty ratification occurred in 1961, the Treaty used methods existing in 1961. In 1961 computers were in their infancy. The concept of critical period arose in water supply engineering. In the water supply context critical period has the same definition as in the Treaty but with water substituted for hydroelectric power. The critical period concept is applied when calculating reservoir capacity required to meet demand and also the demand that a reservoir of a given capacity can meet. The concept may have arisen before the name critical period. Oguz and Bayazit (1991) describe statistical properties of the water supply critical period. They credit Hall, Askew and Yeh (1969) with inventing the concept of critical period, clearly not the case. However, Hall, Askew and Yeh include a modest bibliography and do not cite papers that describe critical periods, but they imply the technique was in use. Like Oguz and Bayazit this author has not located literature with critical period in the title prior to Hall Askew and Yeh's paper. Also, all literature on critical period analysis located by this author treat water supply not hydropower.

Klemes' papers (1979 1984) expound on historical development of the reservoir sizing problem. The seminal paper in this field is Rippl (1883) who proposed the mass curve method. This technique plots a time series of cumulative inflow. The maximum deviations of the plot below a straight line with a slope at the demand for water allow calculation of reservoir size required to support the demand. The time period covered by the line used to size the reservoir is the critical period. The graphical nature of this method made it appealing prior to the advent of computers.

A similar method, which Klemes (1984) credits to Varlet (1923), requires plotting two mass curves separated by the reservoir capacity. This method is commonly called the stretched string method. The yield of the reservoir is the flattest line that extends from the bottom line to the top line. The extent of this line is the critical period. The intuitiveness and graphical nature of this method made it appealing prior to the advent of computers. The author is not aware of this method being applied to the power problem. However, it is conceivable that it was used in analysis leading to development of the Treaty.

Power: The hydropower generation equation is

$$P = e\rho ghQ \tag{1}$$

Where P denotes power, e nondimensional efficiency, ρ density of fluid, g acceleration of gravity, h hydraulic head, and Q volume flow rate. Metric units yield generation in Watts. Efficiency depends on dam and generator physical properties in addition to flow rate and head. Because operating conditions continually vary, long term planning uses average values.

Assuming head scales linearly with impounded volume, V, and generating flow is the sum of inflow, I, and change of impounded volume dV/dt yields

$$P = e\rho g\ aV\left(\frac{dV}{dt} + I\right) \tag{2}$$

This equation indicates that maximizing system generation when decreasing reservoir content primarily requires retaining maximum head in projects that have the highest Q. If two reservoirs, denoted by subscripts one and two, are in series with inflow to the upstream reservoir, generation as the reservoirs draft from full to empty is:

$$G = e\rho g \int_0^T aV_1\left(\frac{dV_1}{dt} + I\right) + bV_2\left(\frac{dV_1}{dt} + \frac{dV_2}{dt} + I\right) \mathrm{dt} \tag{3}$$

The critical period definition includes drafting reservoirs from full to empty. Its power interpretation requires retaining volume in projects that make the largest contribution to head. Note that in many cases inflow originates from an upstream project. Typically headwater projects have lower inflows so drafting them first maximizes generation. As equation 3 illustrates, the downstream project passes all the outflow from the upstream project plus draft

from the downstream project. As power demand continues to require draft, reduced head reduces generation per unit of water. This requires ever-increasing draft to meet generation targets.

Calculating power critical periods using current technology is an optimization problem. But when the Treaty was developed USACOE (1981) describes it as "trial and error." While the principles in the previous paragraph guide an operation, gradient solvers (Fletcher 1987) often struggle because in complex hydrosystems the problem is very nonlinear. Conditions where projects spill are particularly challenging because if discharge is greater than turbine capacity there is no gradient in generation until flow decreases below maximum turbine capability. However, a successfull solution describes a system operation that is useful for planning.

Treaty: The Treaty determines Columbia River Basin hydro operation using a procedure called the Treaty Storage Regulation (TSR). This calculates an operation which meets operational constraints and at least critical period power. Constraints include those described in the Flood Control Operating Plan (2003) along with physical ones. The wide variety of operational constraints serving fish and environmental concerns are not addressed by the TSR because they did not exist when the Treaty was signed. Some are addressed by supplemental agreements negotiated between the United States and Canadian Entities.

The TSR plans an operation which guarantees critical period generation unless water is unavailable. If reservoirs are empty generation becomes limited by inflow. The Treaty uses 30 years of water record from 1929 -1960 as its period of record. With the Treaty based on 30 years of record and Mica Dam completed in 1973 the dams have been in operation for longer than the period of record. Analysis performed by Hicks and Baldrica (1970) using synthetic records give a return period of 385 years for the 1929-1932 critical period. USACOE (1981) refers to a reanalysis performed by the University of Washington which reduces this return period to 164 years. One would think that the long return period of the critical period in the Treaty's period of record would avoid ever drafting reservoirs to empty. But the TSR called for drafting reservoirs to empty in 2001. However Treaty language that allows operation as agreed to by the parties allows ad hoc hedging, which is described in the next section, in actual operations.

Treaty Assumptions: The delivery vs. availability diagram has long been used to describe reservoir operation. Draper and Lund (2004) explain its use but did not invent it. The flat section of line in the unhedged case between 10 and 20 on the horizontal axis shows operations when the reservoir is between full and empty and meets demand for water. To the left, passing inflow plus drafting available water cannot meet demand so the reservoir drafts to empty then passes inflow. To the right of the flat line the reservoir is full so it passes inflow. Both the left and right are undesirable situations. To the left water demand is not met and to the right the reservoir cannot make any contribution to flood reduction.

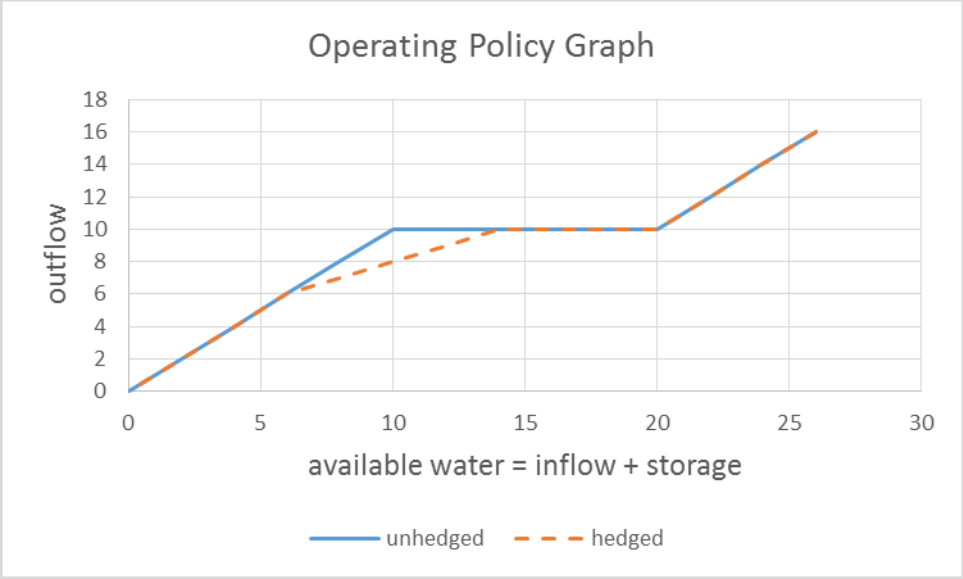

Figure 1 Effect of hedging on outflow.

The hedged line in Figure 1 shows water delivery curtailment before the reservoir drafts to empty. This increases probability of a curtailment but reduces probability of a very severe curtailment. The balance between avoiding curtailments and avoiding empty reservoirs has received attention in the literature recently. For example, Google Scholar indicates J. W. Labadie's (2004) article "Optimal Operation of Multireservior Systems State of the Art Review" has been cited 728 times. Many of these articles apply modern optimization techniques to optimizing reservoir operations. The Treaty makes no attempt to hedge. Hedging theory was developed prior to negotiation of the Treaty. One of the seminal works in optimization, Little (1954), applied dynamic programming to operation of the Columbia River dams. Perhaps the Treaty developers were aware that the unusually dry period in the period of record led to conservative operations.

COLUMBIA RIVER CRITICAL PERIOD

Low Water Periods: Calculating periods of lowest average unregulated inflow of various lengths provides insight. The unregulated flows used for planning in the Columbia River Basin are the modified flows published by the Bonneville Power Administration (2011). These modified flows are essentially flow that would exist if dams did not exist but irrigation withdrawals occurred at 2010 levels. Using modified flows and a spreadsheet one can calculate consecutive rolling averages of increasing lengths. For example, a column of three month averages contains averages of August through October, September through November, October through December and so on until all data are used. Columns going across contain progressively longer periods August through October, August through November, etc. Each column has a minimum value. These minimum values increase as longer periods are averaged. Figure 2 shows periods of lowest average unregulated flow at The Dalles for periods between one and 76

months. Most periods of lowest average flow add one month to the preceding shorter period. However, periods sometimes jump years away. For example the smallest ten month average extends from July 1936 to April 1937, the smallest 11 month average extends from July 1936 to May 1937, but the smallest 12 month average extends from December 1976 to November 1977.

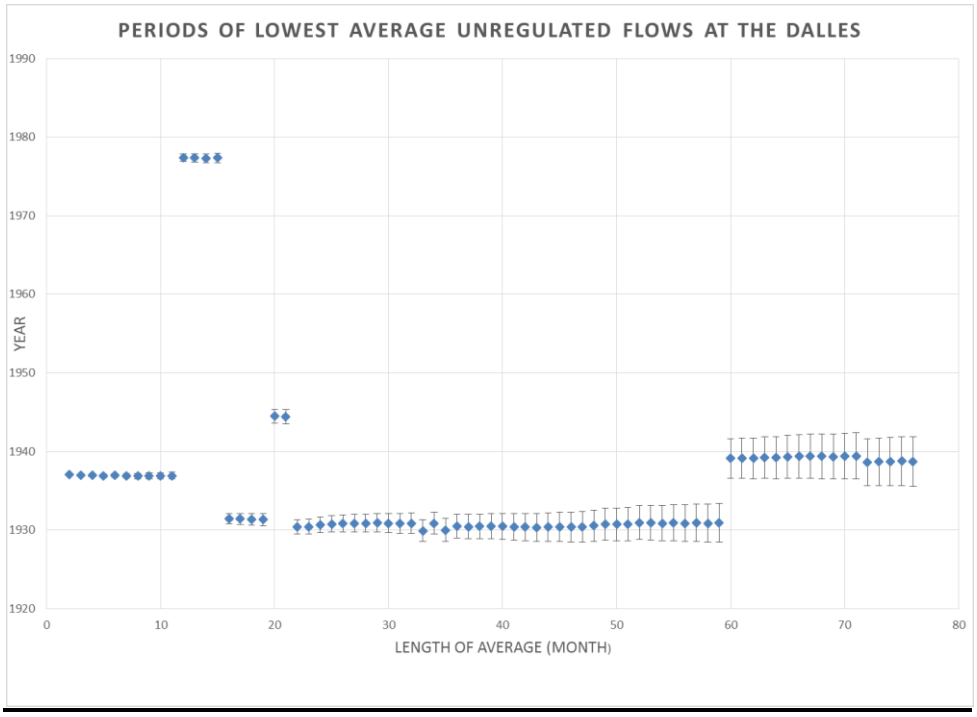

Figure 2 Periods of lowest unregulated flows at The Dalles

Water Supply Critical Period: To include effects of reservoir drafting in critical periods, reservoir content is divided by the number of months averaged and added to the average flow values described in the previous section. Longer periods have reservoir content divided by a larger period length yielding a smaller result. Smaller storage content also yields a smaller value. Over longer periods average reservoir contribution decreases but average stream flow increases. There exists a time where the sum of these two competing effects result in a minimum value. This is the critical period flow. Figure 3 shows average critical period flow with drafting for some storage levels. The periodicity of the plot arises from the seasonality of flow. Higher flow occurs during spring snow melt and lower flow occurs in fall and winter.

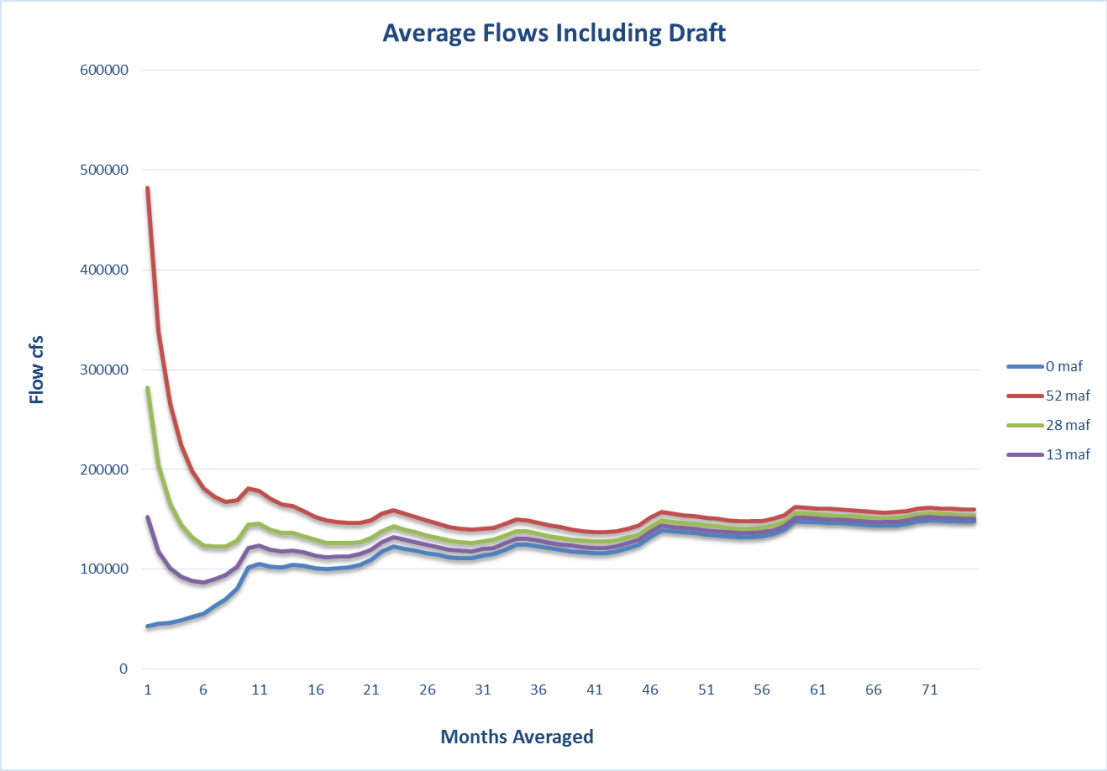

Figure 3 The Dalles average flows with drafting

Comparison of Water and Power Critical Periods: Given the complexity of calculating power critical period it is worth examining the difference between power critical periods and water supply critical periods. The power critical periods come from Columbia River Treaty Operating Committee (2013). Table 1 shows time periods are usually quite similar.

Table 1 Power and flow critical periods.

Storage	Power Critical Period	Water Critical Period
52 maf	Aug 1928 Feb 1932	Sept 1928 – Feb 1932
28 maf	Sept 1943 April 1945	Aug 1936 – March 1937
13 maf	Nov 1936 April 1937	Sept 1936 – March 1937

The power and water critical periods for the 28 maf case appear quite different. However, the two critical periods are eight and 20 months long, respectively. As discussed regarding Figure 3 critical periods with similar values may have lengths differing by 12 months due to the annual shape of flow variation. Figure 2 shows the 20 month flow minimum is near 1945 whereas the eight month minimum is near 1937. Figures 4 and 5 apply the stretched string method to these two periods. The line showing draft in 1945 just barely makes it between the upper and lower lines.

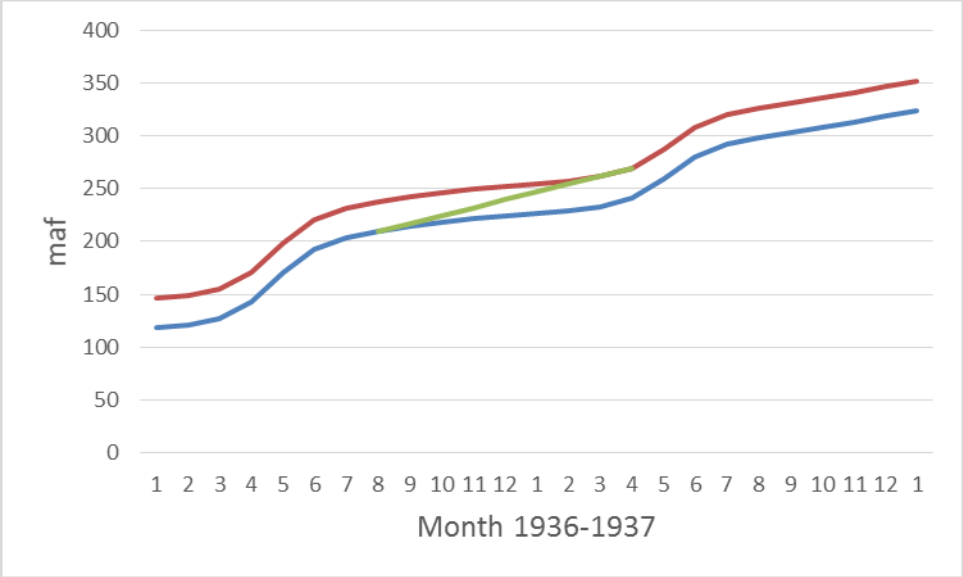

Figure 4 Stretched string approach applied to 1936-1937.

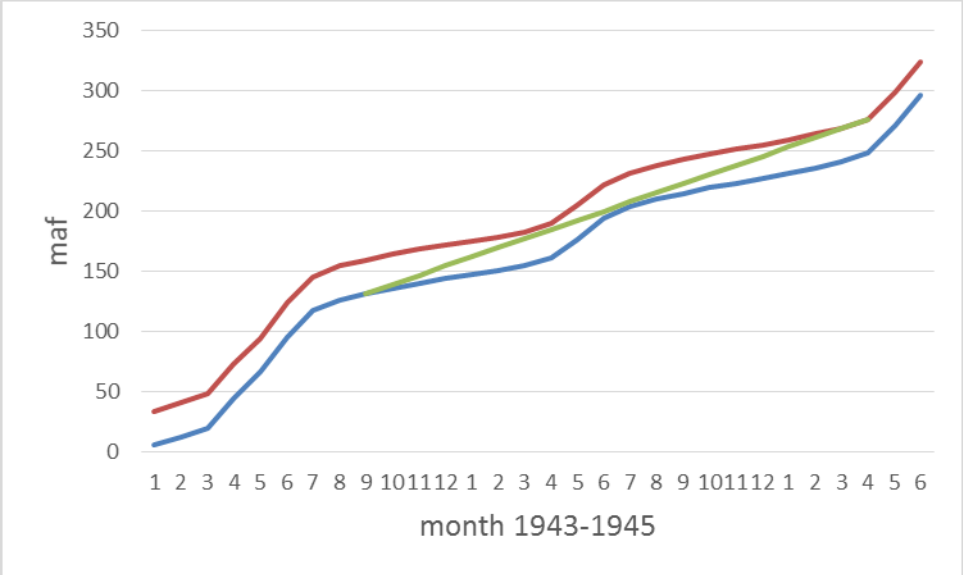

Figure 5 Stretched string approach applied to 1943-1945.

CONCLUSION

The concept of critical period, the period of minimum flow as a reservoir drafts from full to empty, has a long history in reservoir planning. However, critical period is often referred to by other names in the literature. It has been improved by using a stochastic approach to flows and hedging when low flow conditions exist. The Columbia River Treaty used a straight critical period without either of these improvements. However, the Treaty allows for supplemental agreements between parties, so in practice the United States and Canada often implement these improvements.

Power and water supply critical periods are similar. Power critical period calculations require calculating project operation making these calculations more complicated. Portions of a basins often have different critical periods than the basin as a whole. Consequently, power critical periods depend on where hydrogeneration is located in a basin.

RIVER ENGINEERING RESEARCH NEEDS IN THE ARMY CORPS OF ENGINEERS

Meg Jonas, Senior Hydraulic Engineer, USACE Headquarters, Engineering & Construction, Washington, DC, meg.m.jonas@usace.army.mil; John Remus, Chief – Hydrologic Engineering Branch, USACE Omaha District, Omaha, Nebraska, john.i.remus@usace.army.mil

Abstract River engineering is one of the core competencies of the Army Corps of Engineers. As a cross-cutting topic, river engineering research falls under many separate topic areas: sediment transport modeling; ecosystem restoration; dam and levee safety; infrastructure; fluvial geomorphology; design of riverine structures; and others. The Corps expert Committee on Channel Stabilization has reviewed multiple submitted topics and has identified research topics that would advance the discipline of river engineering. Since the field of river engineering is so broad, and many topics cut across traditional program funding lines, it is easy for key needs to lose visibility. This presentation will discuss the priorities identified by the expert Committee.

INTRODUCTION

The importance of river engineering in USACE was described in an earlier paper (Remus and Jonas, 2010). Research was identified as a critical component, with a recommended first step of reviewing the research needs submitted by Corps field personnel. The collected statements form a valuable record of research needs.

In May 2014, the Corps expert Committee on Channel Stabilization reviewed a collated list of river engineering research needs and ranked them as high, medium or low. Ten needs received high rankings from a strong majority of committee members. These ten are listed below. The order does not reflect any priority.

The research needs were drawn from the Flood Risk Management (FRM) Gateway. Any Corps employee can submit an R&D Statement of Need (SON) for consideration for research funding. Submission guidelines and all previously submitted SONs are included at the FRM Gateway: **http://operations.usace.army.mil/flood.cfm**. Corps employees are strongly encouraged to submit SONs.

The Committee did not attempt to identify research needs not included in the list of SONs. Therefore, the rankings below are a preliminary effort to prioritize river engineering needs, based on the needs that were submitted. Additional work will be required to develop a comprehensive, prioritized list.

RIVER ENGINEERING RESEARCH NEEDS – HIGH PRIORITY

The needs below were all ranked high as the consensus of the Committee. The order does not reflect any relative priority. The descriptions are taken from the FRM Gateway website.

1. **Effects of Training Structures on River Stages**.
    a. **Tracking Number** 2008-F-46
    b. **Need that Drives Requirement**. For many years, various river training structures have been constructed on America's rivers to reduce bank caving and to develop and maintain adequate channel dimensions that support commercial navigation. These training structures include various types of bank stabilization techniques as well as various dikes schemes. These structures provide a more efficient channel by eliminating channel migration through the prevention of bank erosion, realigning a river reach, constricting a channel to increase depth, cutting off side channels and chutes, and concentrating braided rivers into single channels. During the recent floods on the Upper Mississippi River, some have purported that the presence of river training structures actually resulted in higher stages. Previous studies/investigations addressing the impacts of river training works on flood stages will serve to reevaluate and update those findings.
    c. **Extent of Need Across USACE**. Training structures are frequently used throughout the United States to develop rivers for storm damage reduction, navigation, water supply, environmental restoration, recreation, and hydropower. In many parts of the country, floods cause extensive damage even with current flood damage reduction projects in place. If training structures result in increased river levels, then the current level of protection provided by storm damage reduction measures (especially levees) is reduced during floods.
    d. **Requirement**. R&D requirement is to develop a methodology and guidance for evaluating river training structures, especially their impact on overall river stages. This effort will include the evaluation of available tools (including models) and the identification of the ones that are most applicable. An often complex combination of various factors influence channel morphology and thus, river stages. A critical step in determining impacts on river stages is to conduct a detailed geomorphic assessment that identifies these factors for a given river system and determines how these factors are integrated to produce channel morphology.
    e. **Consequences if Requirement Not Met**. The consequences of not meeting the requirement include the potential loss of current levels of protection for flood damage reduction measures on rivers that have been developed with channel training structures. A loss in the level of protection prevents the flood damage reduction measures from providing the benefits that the projects were designed to provide resulting in an increased risk of damage.
    f. **Product Recommendation.** A methodology and guidance for the evaluation of river training structures on river stages will be developed. The Upper and Middle Mississippi River will be used as a test case. Applicable data will be collected and the training works evaluated as to their impact on river stages.

2. **The WES Stream Investigation and Streambank Stabilization Handbook**
    a. **Tracking Number** 2014-F-24
    b. **Need that Drives Requirement**. The WES Stream Investigation and Streambank Stabilization Handbook was last updated in 1997. The handbook is widely used

by USACE field offices, other Federal agencies and the public to provide and outline templates for proper investigative, stabilization and restoration techniques.

c. **Extent of Need Across USACE**. The stream investigation, stabilization and restoration community of practice has greatly progressed in the past 15 plus years and practitioners need to have the most current information to address natural resource issues.

d. **Requirement**. Combine the current handbook with updated ERDC Tech Notes and Reports, Bulletins, EM updates, Hydraulic Design Criteria and additional pertinent information.

e. **Consequences if Requirement Not Met**. If the current WES Stream Investigation and Streambank Stabilization Handbook (1997) is not updated the USACE field offices, other Federal Resource Agencies and the public will not have the most current and up to date stream stabilization and restoration methods.

f. **Product Recommendation.** A methodology and guidance for the evaluation of river training structures on river stages will be developed. The Upper and Middle Mississippi River will be used as a test case. Applicable data will be collected and the training works evaluated as to their impact.

3. **Streambank Stabilization and Grade Control Techniques Suitable for Stream and Watershed Restoration Projects (Update of Section 32 Program)**

a. **Tracking Number** 2008-F-43

b. **Need that Drives Requirement**. Engineering design criteria for low-cost, environmentally relevant streambank protection and grade stabilization techniques suitable for stream and watershed restoration projects. The Corps has excellent design guidance for measures such as full bank riprap revetment, but no guidance for innovative and alternative measures increasingly requested by local stakeholders. Methods such as rootwads, Newbury rock riffles, stone barbs, J-hooks, W-weirs and many more are described in the gray literature, without reliable design criteria. Many have only limited design criteria or are emerging techniques. Reviewing the performance of completed projects is complicated by the lack of as-built plans, design computations, or monitoring, and by the use of unique designs, among other considerations. The Corps capability to include innovative stream stabilization measures in the engineering toolbox is critical to our success in stream and watershed restoration, as well as in regional sediment management.

c. **Extent of Need Across USACE**. This need exists through all Corps districts. It applies in particular to smaller watershed and stream restoration projects. It would also be useful in projects where watershed sediment reduction is a goal.

d. **Requirement**. The following R&D efforts would be effective in meeting this need: a. A major step would be an update of the Section 32 program to address stream stabilization measures (bed and bank) suitable for restoration projects. (The original Section 32 demonstration program constructed low-cost innovative streambank stabilization measures, and monitored their performance over time.) Like the original Section 32 program, an updated program should combine district expertise and ERDC and NRCS research capability. b. R&D to evaluate the performance of a wide range of ecologically relevant stabilization measures in

constructed projects, along with available design criteria. The goal would be to come up with relevant design recommendations. (R&D work has been done along these lines for bendway weirs and for stone toe protection, which are only two of numerous techniques in use. This work has been leveraged against work done by the US Bureau of Reclamation.) This work should be coordinated with the efforts of other agencies, such as the US Bureau of Reclamation. c. R&D to compile a comprehensive national list of methods used, with engineering and ecological limitations and benefits. This would be a joint effort with the USBR. It would take a USBR hydraulic engineering report for the Middle Rio Grande, and give it national application by addressing other methods and constraints. (Listings of methods and techniques have been performed in several references, but lack discussion of the engineering design criteria.) This national list of methods is probably the logical first step of the three listed here. It should be performed by ERDC-CHL in conjunction with IWR, ERDC-EL, district personnel, USBR, and NRCS.

e. Consequences if Requirement Not Met. The consequences of not meeting this need are: a. A lack of design guidance for streambank stabilization and grade control measures suitable for stream and watershed restoration projects. b. A lack of leadership in an arena where the Corps has traditionally provided guidance to both Corps districts and the wider community of practice c. A lack of a systems approach to restoration projects. The incorporation of sound engineering criteria for ecologically-friendly techniques is essential to project success.

f. Product Recommendation. This effort would build on several ongoing efforts by ERDC-CHL, USBR, NRCS, USDA, and the Desert Research Institute. The results should be incorporated into Corps guidance.

4. Full Integration of Hydraulic Engineering with Ecological Components of Project Planning and Design

a. Tracking Number 2008-F-49

b. Need that Drives Requirement. Since the Corps has added the mission of aquatic ecosystem restoration, an increasing percentage of projects include restoration goals. Although the restoration objectives are formulated by ecologists, their successful attainment relies on the support of hydraulic engineers (for hydrologic, hydraulic, and sedimentation aspects of design). There is a need for improvements in the planning and design process that would fully integrate Corps engineering and ecological components from the beginning of projects. The need is to ensure that hydrology, hydraulics, and most importantly, sedimentation, are not tacked on at the end of the planning process. The goal is a systems approach that would include all disciplines from start to finish, with a common vision of project goals and processes. The benefits include an improved capability to deliver viable and sustainable projects that meet goals and functions.

c. Extent of Need Across USACE. This need exists through all Corps districts, and covers a majority of projects.

d. Requirement. Extension and coordination of Planning and Engineering guidance and processes to address the gap that currently exists between ecologists and engineers. This should be based on R&D into a) the best engineering methods to

support ecosystem restoration projects, and b) the best metrics for ecologists to furnish to engineers to assure project success. This would focus on integrating design with habitat form, function, and maintenance, since these are physical processes that can be defined. A further step of tying species response to physical changes should not be included in this work unit, since the temporal and spatial variance is too great. This work unit should focus on fully integrating what is currently known in the engineering and ecological disciplines into a coherent approach.

e. **Consequences if Requirement Not Met**. The current consequences of not meeting this requirement include the following: a. Projects which cannot achieve goals in a sustainable manner b. Delays (or in some cases cancellation) of projects due to lack of coordination among disciplines. c. Increased projects costs due to delays, and to lost opportunities in shared data collection and information gathering. d. Decreased customer satisfaction.

f. **Product Recommendation.** This R&D should be conducted jointly by the Institute of Water Resources (IWR), Coastal & Hydraulics Laboratory, and Environmental Laboratory. The hydraulic engineering component should be overseen by a Project Development Team (PDT) using the expert Committee on Channel Stabilization as a nucleus. The results should be included in applicable guidance that is coordinated through both Planning and Engineering functions.

5. **Natural Channel Design Manual**
   a. **Tracking Number** 2008-F-79
   b. **Need that Drives Requirement**. The Corps is presently involved in river restoration projects throughout the country in which the goal is to restore habitat, improve fisheries and stabilize fluvial sediments. While the NRCS National Engineering Handbook does a thorough job of documenting Rosgen's methods for natural channel design, there is presently little Corps guidance for design and construction of river restoration projects using channel design methods that fully utilize our hydraulic engineering modeling capability in sediment transport, hydraulics, and hydrology. The Corps has designed and constructed many stream restoration projects using non-Rosgen methods, but has not documented the methodology in a comprehensive manner. Hydraulic and design engineers need this guidance to improve the likelihood of a stable and functional stream restoration project. (Note: the term "natural channel design" is normally associated with the methodology published by Dave Rosgen. It's used here to describe the design of a channel that has the appearance and function of a natural channel to the maximum extent possible.)
   c. **Extent of Need Across USACE**. This need exists through all Corps districts.
   d. **Requirement**. Perform literature review and critical evaluation of restoration channel design methodologies. Document experiences of field engineers with significant experience in successful natural channel designs. Document lessons learned from constructed stream restoration projects. The final product should be a design manual that has incorporates the results of these investigations into a step-by-step procedure for natural channel design that meets the highest hydraulic engineering standards of the Corps.

e. **Consequences if Requirement Not Met**. Not meeting this need will result in poorly designed and non-functioning river restoration projects. In many cases failure of the project will result in loss of habitat and the production of sediment that will ultimately have to be removed from federal navigation or flood control channels.
f. **Product Recommendation.** This R&D should result in a manual that hydraulic and design engineers can use to guide them though a river restoration project. The Corps expert Committee on Channel Stabilization should be involved in work unit oversight. Division technical experts in sedimentation should be included in the field review.

6. **Watershed Sediment Management: R&D to support engineering assessments**
   a. **Tracking Number** 2008-F-42
   b. **Need that Drives Requirement**. Corps districts need relevant and up-to-date methods for evaluating the technical effectiveness of sediment reduction measures. While these measures are proposed in an increasing number of watershed studies, their benefits (in decreased sediment yield) are not adequately estimated without overall guidance. The accurate technical estimation of the benefit (or impact) of various alternatives on sediment volumes and channel stability is critical to an appropriate plan formulation process. Existing guidance has not been updated to incorporate advances in the understanding and analysis of sedimentation, to address innovative practices, or to discuss current automation tools (such as GIS).
   c. **Extent of Need Across USACE**. This need exists through all Corps districts. An increasing number of studies include sediment reduction as a goal.
   d. **Requirement**. R&D to answer technical questions in several areas, with eventual incorporation in guidance. These areas include an evaluation of current sediment management techniques, recommended software and analysis methods , data collection, quantifying uncertainty in the data used - model selection and results, how to deal with data gaps and unknowns, impacts of region and land use on results, incorporation of current methods such as GIS, and others.
   e. **Consequences if Requirement Not Met**. The consequences of not meeting this need include: a. Delays in approval or requests for reformulation b. Watershed projects that do not deliver the intended benefits due to inaccurate technical estimates of sediment reduction. c. Increased study costs due to data and modeling unknowns.
   f. **Product Recommendation.** The final product should be cost-effective and available for use. It should take advantage of completed and ongoing R&D to the maximum extent possible. This would involve significant coordination with other federal agencies (USGS, NRCS, EPA, etc.), as well as state, local, and non-governmental organizations. The methods developed should be coordinated with field personnel, and should also be demonstrated to ensure utility. Three to five district studies should be selected as demonstration sites; the methods developed should be coordinated with the district personnel implementing these studies. The final products should be incorporated into Corps guidance. The R&D efforts

should be undertaken by ERDC-CHL (and coordinated with IWR through the Regional Sediment Management Program).

7. Evalutaion of Sediment Flushing and Other Means of Sediment Bypass for Reservoirs

a. Tracking Number 2008-F-40

b. Need that Drives Requirement. Sediment deposition reduces the useful life of reservoirs and often severely impacts authorized project purposes. Many USACE reservoirs are nearing the end or have exceeded their project lives and others are experiencing decreased project benefits due to sediment deposition. Flushing and other means of sediment bypass through reservoirs offer potential solutions for reducing the deposition of sediment thereby extending their useful lives. While flushing can be effective in reducing sediment deposition, the effects of sediment that is flushed must also be considered as it relates to water quality and downstream channel morphology. Also, the loss of coastal wetlands and freshwater marshes, particularly along the gulf coast region of the United States, is an ecological problem with far-reaching consequences and may be related to the reduction in available fine grain sediment load of the river system which feeds the wetlands. Fine grain sediment is required for the restoration of degraded wetland areas as well as the long term maintenance of healthy marsh. Reservoirs located along the main stem and tributaries of the upper river system may trap much of the fine grain sediment, preventing the material from ever reaching the coastal boundary. The re-entrainment of fine grain material deposited in reservoir pools through flushing operations, and the bypass of sediment through the reservoir by means of tunnels or conduits are potential solutions for addressing the deposition of fine grain sediment in the reservoirs. The feasibility of these methods to prevent deposition of material in the reservoirs and to supply the material to the river system for potential delivery to the coastal zone needs to be addressed.

c. Extent of Need Across USACE. The USACE maintains and operates more than 380 dams and reservoirs within the United States. Continued sediment deposition within these reservoirs results in the loss of storage allocated for project uses such as flood control, water supply, hydropower, recreation, and environmental purposes. With rising costs, as well as adverse environmental impacts of constructing new dams, the need for extending the useful life of existing reservoirs is becoming increasingly important. Research offers the benefit of developing more universal methods of increasing the useful life of reservoirs by reducing the amount of sediment that is being trapped in our reservoirs and possibly removing portions of the material already deposited, thus preventing additional depletion of storage or recovering storage lost due to sediment deposition. Also, USACE districts, as well as other federal agencies such as the U.S. Bureau of Reclamation, that own/operate reservoirs need effective ways to prevent the retention of fine grain sediment that could potentially be used for wetland restoration and maintenance farther downstream.

d. Requirement. R&D requirement is to develop methodology and necessary models for evaluating the potential for flushing and re-entraining sediment

through reservoir operational techniques/manipulation, and to develop models, physical and numerical, to determine hydraulic functionality and structure configuration of potential sediment bypass systems. Furthermore, analysis needs to be conducted to evaluate the intermediate impacts of bypassed sediment on the geomorphology of the river system between the reservoir and the ultimate destination of the sediment to ensure that no adverse impacts are created.

e. **Consequences if Requirement Not Met**. The consequences of not meeting the requirement include the continued reduction in the useful lives of existing reservoirs and the loss of project benefits due to storage volume depletion. Additional consequences include a lost potential opportunity to increase the available sediment concentrations which could be beneficial to slowing or halting the continued loss of coastal wetlands and marshes.
f. **Product Recommendation.** Methodology and guidance for analysis and design of sediment flushing procedures and sediment bypass systems. Increased understanding and modeling capabilities for assessment of both temporal and spatially varied morphological changes within the entire system.

8. **Sediment Modeling Tools**
   a. **Tracking Number** 2008-F-57
   b. **Need that Drives Requirement**. Watershed erosion and sediment transport modeling are crucial to the Corps' navigation mission and are finding increased application as the Corps takes on environmental rehabilitation work. Dredging of inland waterways, channel restoration, dam removal, bank stabilization, reservoir operation, Total Maximum Daily Load (TMDL) computations and water quality best management practices(BMPs) planning all require significant sediment analysis. Additionally, the Corps is beginning to consider the impact of bed change on levee risk (which can be the result of either erosion or deposition) and certification. Analyses of this type are notoriously complex yet nearly all of the technology available in Corps models is decades old and targeted to historical applications (e.g. dredging). There have been notable advancements in the last 20 years that should be incorporated in the Corps' sediment models. Additionally, there are and other problems require original, innovative R&D solutions. Finally, because of the significant uncertainty associated with sediment data and analysis, it is also imperative that Corps sediment models begin to incorporate stochastic principles in their simulations, allowing users to articulate results in terms of outcome uncertainty.
   c. **Extent of Need Across USACE**. Any Corps of Engineers District with dredging, levee certification, channel modification, river restoration, reservoir management, dam removal or watershed management missions needs to perform sediment transport analyses. Increasingly the Corps of Engineers is asked to perform detailed sediment studies to justify these efforts, select strategies or predict outcomes.
   d. **Requirement**. R&D products (main stream H&H models) that are heavily used in Corps planning studies need to be able to model the detailed aspects of water movement in urban areas. Most Corps of Engineers software products for H&H analyses have only recently added rudimentary sediment capabilities and still

require serious research and development before they are robust enough to answer the kinds of questions district engineers and biologists are likely to pose in the next decade.

e. **Consequences if Requirement Not Met**. The consequences for not meeting this requirement include the inability to perform detailed sediment analysis for Corps planning studies. Consequences of poorly planned sediment management include bank failure, levee risk (from toe scour and aggredation), unplanned or unnecessary dredging costs and habitat degradation.

f. **Product Recommendation.** Specific products to provide this capability should draw on methods and technology available from peer reviewed literature and other research institutions. Design and development of techniques and computer algorithms should be consistent with published standards for sediment transport modeling. However, wherever possible short-comings of existing techniques should be identified, and improved methodologies should be researched and developed wherever possible.

9. Web-based Storage and Retrieval System for Channel Cross-Section Data

a. **Tracking Number** 2014-F-4

b. **Need that Drives Requirement**. USGS gage data is readily accessible via the internet, and accordingly, academic and other research literature extensively utilizes gage data to draw broad conclusions about degradation or aggradation trends. The COE has invested hundreds of millions of dollars in regular bathymetric surveys which, if they were more easily accessible, could likewise be used by academic, Corps of Engineers, and other researchers to develop good science to improve management of our flood control channels. Unfortunately, the hassle involved in requesting data from the Corps of Engineers, plus the time it takes to meet such requests, severely limits the use of the data. The need for better management of large amounts of cross-section data has been so pressing in the Kansas City District that we contracted the development of a tool for querying, displaying, exporting, and generating useful geomorphic information.

c. **Extent of Need Across USACE**. Virtually all districts with flood control or navigation projects use cross-sections as a method for assessing channel degradation or aggradation over time. I know of no district that has made this data easily available for widespread benefit.

d. **Requirement**. The Kansas City District (NWK) has an especially robust dataset, which we have compiled into a single database with tens of thousands of cross-sections. We recently contracted with North Arrow Research to develop a tool for querying, displaying, exporting, and generating useful geomorphic information from the cross-sections. This tool has been developed as a desktop utility, but could easily be implemented on a web platform to allow easy access by researchers outside of the Corps. The architecture for storage, display, and information generation is already built. The tool would need to be adapted to operate in a web browser, the data stored on ERDC servers, and other districts made aware of how to format and upload their own data.

e. **Consequences if Requirement Not Met**. Business as usual means a continued under-utilization of hundreds of millions of dollars in excellent bathymetric data.

Adapting the NWK Cross-section Viewer/Analysis tool for web-based storage and retrieval will allow that data to be used more broadly and help the Corps to better understand and manage our projects.

f. Product Recommendation. An adaptation of the NWK Cross-section Analysis/Viewer tool to allow web-based storage and retrieval of information. Presentation of the tool at the 2015 sediment conference, through webinars, or other appropriate venues for technology transfer to other districts.

10. Sediment Data Collection Techniques and Model Applications

a. Tracking Number 2008-F-42

b. Need that Drives Requirement. Many Corps of Engineers projects have a component which must consider sedimentation effects. These investigations often involve the use of a suite of sediment models. The current and future generation of these sediment models will utilize 1, 2 and 3D hydrodynamics, and will potentially have the highest degree of uncertainty of any models used in H&H work. Successful, cost effective modeling requires the utilization of the correct balance of sediment and bathymetric data, field investigation, and experience. Sediment and bathymetric data are often scarce and expensive to acquire. Some of the newer techniques, such as particle tracking, are quite expensive and represent a substantial project investment. The purpose of this proposal is to develop guidance to assist Corps personnel in making decisions on the value of different data collection strategies, as well as the optimization of data collection and modeling efforts.

c. Extent of Need Across USACE. Most Corps offices require sediment impact assessments and modeling at various degrees of complexity.

d. Requirement. The R&D requirement for this need is to develop a coordinated approach for evaluating data requirements, data collection protocols, optimization of data, effective incorporation of data into sediment models, and value of data for a variety of sediment assessment and transport models utilized in large and small scale applications.

e. Consequences if Requirement Not Met. The consequences for not meeting the requirement are increased cost and uncertainty of results which impact project life cycle performance.

f. Product Recommendation. The products from this work are guidelines and methodologies that will help project managers and engineers make decisions on data collection efforts for a variety of applications, with the intent of optimizing model parameter input. This guidance will help reduce the uncertainty of model input data and therefore reduce the uncertainty of model results. A specific goal of the work should be the development of a PROSPECT course, along with workshops which will describe field data collection techniques, new technologies, and the selection and application of sediment assessment and transport models that are currently available.

OTHER CONSIDERATIONS

Research needs were discussed in both the 2014 conference call held by the Committee and in the 2009 workshop on river engineering capability (Remus and Jonas, 2010). Other considerations related to research are identified below.

- There is a continuing need for river engineering research: not all the work has been done.
- The river engineering community of practice should identify and articulate research needs.
- Training and technology transfer of research products is essential.
- In the past, river engineers at USACE Divisions and Headquarters played a critical role in maintaining the agency's focus on both research and training related to river engineering.

SUMMARY AND CONCLUSIONS

River engineering is one of the essential technical competencies of the Corps of Engineers. Ongoing research is required to answer critical questions and address current topics. This paper discusses submitted SONs in the field of river engineering, and the identification of high priority research needs by the expert committee. A logical next step would be the development of an overall strategic plan for river engineering research needs for the Corps. Ideally, this could be used to coordinate efforts with other federal agencies and entities.

ACKNOWLEDGEMENTS

The authors would also like to express their appreciation to the members of the Corps expert Committee on Channel Stabilization, and to the river engineering community within the Corps. Ms. Jonas would like to express her appreciation to Mr. Bill Curtis and Dr. Cary Talbot of ERDC Coastal and Hydraulics Laboratory, for her liaison assignment in support of the Flood Risk Management Research Area.

MODELING EXTREME FLOOD HYDROLOGY FOR GRAND COULEE DAM

Frank Dworak, Hydrologic Engineer, U.S. Bureau of Reclamation, Denver Federal Center, Bldg. 67, Rm. 580, PO Box 25007 (86-68250), Denver, CO 80225-0007, fdworak@usbr.gov; John England, Hydrologic Engineer, U.S. Bureau of Reclamation, Denver Federal Center, Bldg. 67, Rm. 580, PO Box 25007 (86-68250), Denver, CO 80225-0007, jengland@usbr.gov; Marketa Elsner, Hydrologic Engineer, U.S. Bureau of Reclamation, Denver Federal Center, Bldg. 67, Rm. 580, PO Box 25007 (86-68210), Denver, CO 80225-0007, melsner@usbr.gov; Ralph Klinger, Geologist, U.S. Bureau of Reclamation, Denver Federal Center, Bldg. 67, Rm. 580, PO Box 25007 (86-68330), Denver, CO 80225-0007, rklinger@usbr.gov

Abstract: The Bureau of Reclamation is conducting a Hydrologic Hazard Analysis (HHA) for Grand Coulee Dam to develop probabilistic flood frequency estimates for use in a dam safety risk analysis. The major challenges of this study include: 1) developing methodology capable of modeling hydrology for a 74,100 square mile international drainage basin, of which approximately 39,500 square miles are situated in the province of British Columbia, Canada, and 2) modeling a basin that is regulated by 76 major dams located within the Columbia River Basin (CRB) that are owned and operated by a mix of the U.S. federal, state, provincial, or local government, public utilities, and private entities. Following an extensive literature review and investigation into previous and current studies in the CRB, Reclamation is using a multiple methods approach, leveraging the modeling and data analysis completed by other agencies and universities for operations planning, climate change impacts assessments, and the Columbia River Treaty review. Two methods will be used to characterize hydrologic hazards at Grand Coulee Dam: the Expected Moments Algorithm (EMA) with streamflow and paleoflood data to estimate peak-flow statistics; and applying the Variable Infiltration Capacity (VIC) rainfall-runoff model and one-dimensional hydraulic models to develop flood peak and volume hazard curves. The two methods are used in order to: (1) ensure consistency between the rainfall-runoff model and streamflow data (including historical data and paleofloods); (2) provide data and models to estimate and extrapolate hydrologic hazard curves to annual exceedance probabilities (AEPs) of interest; and (3) include uncertainty estimates for the hydrologic hazard curves. The VIC hydrologic output will be used as input to the U.S. Army Corps of Engineers' (USACE) Hydrologic Engineering Center's Watershed Assessment Tool (HEC-WAT).

INTRODUCTION

The Bureau of Reclamation is conducting a Hydrologic Hazard Analysis (HHA) for Grand Coulee Dam to develop probabilistic flood frequency estimates for use in a dam safety risk analysis. Reclamation uses the most updated data and technology, as available and appropriate, to estimate hydrologic risk at dams. When dam loading estimates do not reflect the current information and technology available at one of its facilities, whether it is hydrologic, seismic, or static loading, it is common practice to perform an Issue Evaluation (IE) study to update the loading parameters. The hydrologic loadings for Grand Coulee Dam are being updated to Reclamation's current standard of practice.

The major challenges of this study include: 1) developing methodology capable of modeling hydrology for a 74,100 mi^2 international drainage basin, of which approximately 39,500 mi^2 are situated in the province of British Columbia, Canada, and 2) modeling a basin that is regulated by 76 major dams located within the Columbia River Basin (CRB) that are owned and operated by a mix of the U.S. federal, state, provincial, or local government, public utilities, and private entities. Most of the dams located within the CRB will not play a direct role in estimating hydrology for Grand Coulee Dam; however they will play an important role in estimating how the CRB will be operated as a system. Figure 1 shows the dams that were modeled in the USACE's Columbia River Treaty (CRT) review including Grand Coulee Dam. The project will rely on maximizing the use of previous and current flood studies for Grand Coulee Dam and the CRB.

Grand Coulee Dam is a concrete gravity structure located on the Columbia River in north-central Washington State, located approximately 75 miles west-northwest from Spokane, Washington. The towns of Grand Coulee and Coulee Dam are located immediately upstream and downstream, respectively, of the dam. The drainage basin is composed of mountainous terrain as well as large expanses of high desert plains in eastern Washington, eastern Oregon, and western Idaho. Elevations range from approximately 1,300 feet at the dam crest to over 13,000 feet in the mountains throughout the drainage basin. The CRB has large variations in mean annual precipitation. West of the Cascade Mountains, many regions receive over 30 inches of precipitation annually, while east of the Cascades precipitation is less than 20 inches, with some areas receiving as little as 7 inches (Climate Impacts Group, 2014). Annual precipitation in the Cascade Mountains can be as much as 100 inches. By several accounts, more than 70% of streamflow in the region originates as mountain snowpack (Hamlet et al. 2005; Elsner et al. 2010). Most of the drainage basin accumulates a snowpack throughout the winter followed by rainy periods in the spring and early summer. The high flow period for the Columbia River is driven by snowmelt during the spring and early summer from warming temperatures and rain.

There are two important large scale studies conducted in the CRB that will provide much of the data, modeling and methodology to conduct this study. The USACE has made a large effort to review the river operations, hydraulics, and hydrology involved in updating the 2014/2024 revision to the Columbia River Treaty between the U.S. and Canada (USACE, 2012). This effort has involved developing a detailed model of the Columbia River System, called the Watershed Assessment Tool (WAT), which includes updated terrain and bathymetry, river operations, routing scenarios, climate change, and potential updates to the Columbia River Treaty. The model is capable of estimating daily and flood control operations for the Columbia River system. The model is also capable of computing Monte Carlos simulations of river routings incorporating multiple forecast, operations and hydrology scenarios.

The northwest report of the Third U.S. National Climate Assessment (Snover et al., 2014) assesses the state of climate change in the northwest United States, including the CRB. This report primarily draws from recent studies, including the Washington State Climate Change Impacts Assessment (2009) and the Oregon Climate Assessment Report (2010). The report represents the key climate change issues in the growing body of regional research. The Washington State Climate Change Impacts Assessment (Miles et al. 2010) used climate projections from the Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment

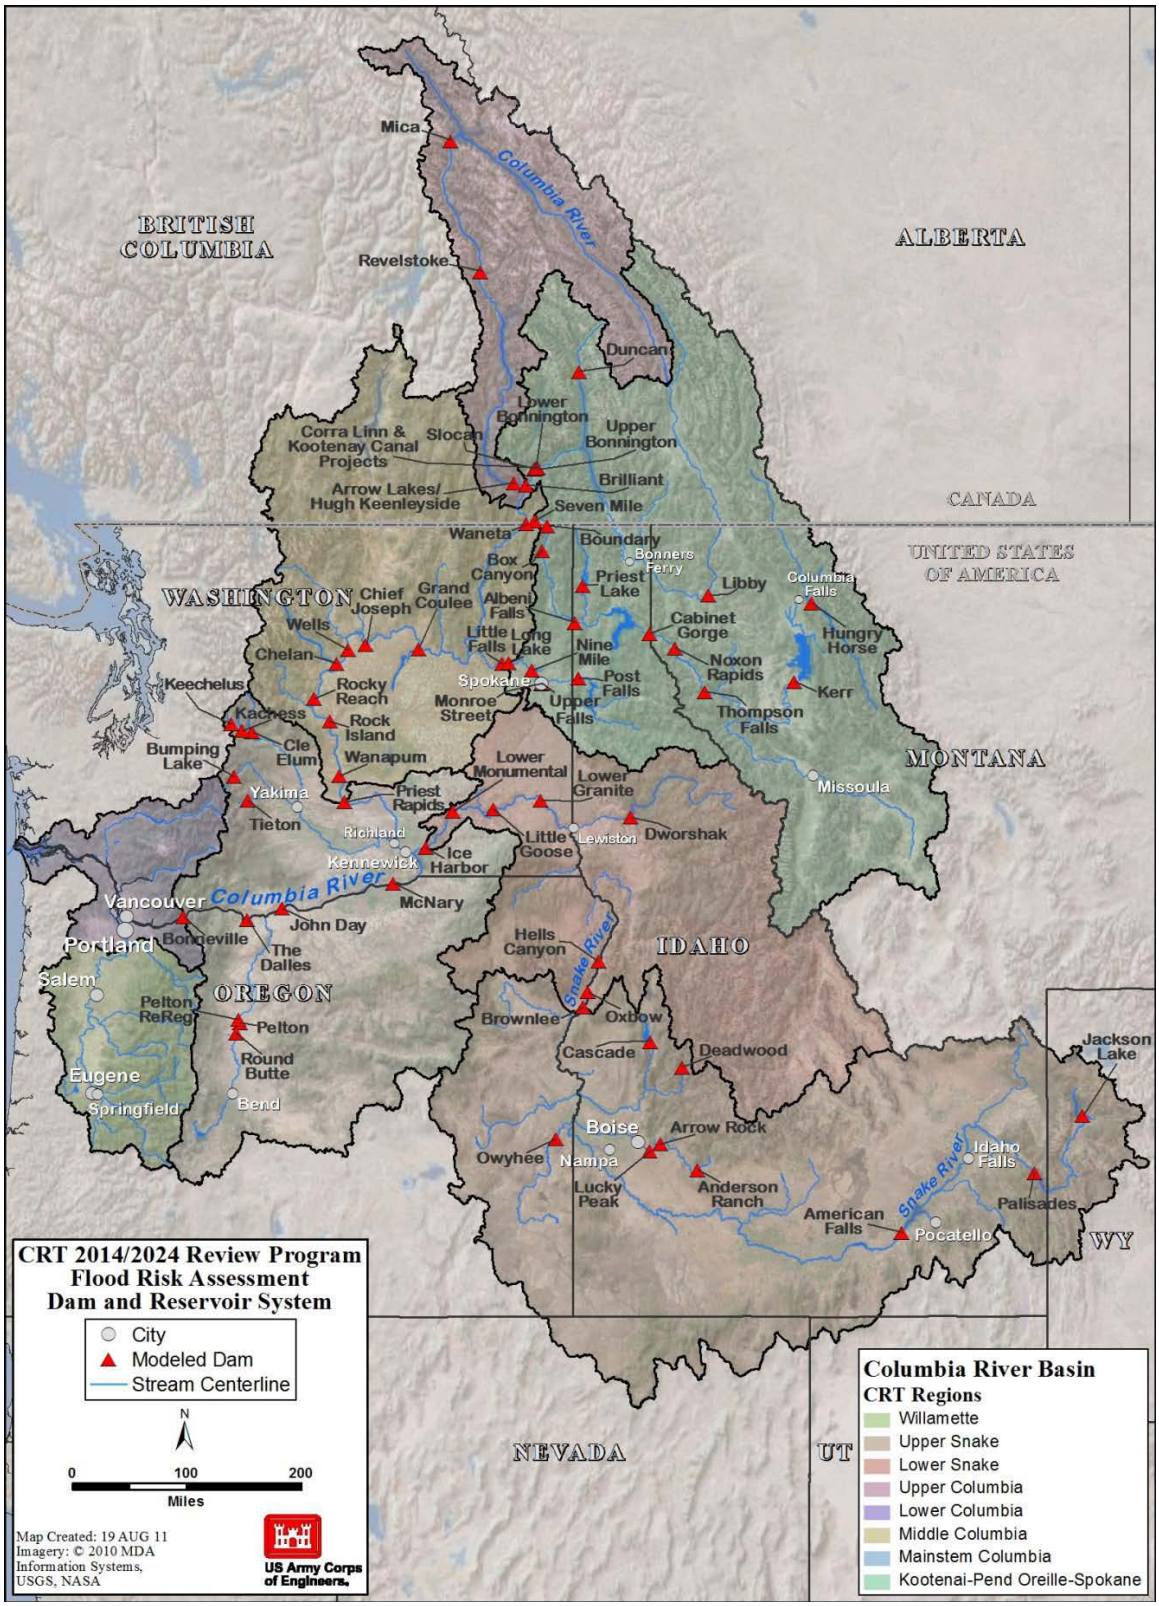

Figure 1 Image illustrating the dams that were modeled as part of the USACE CRT 2014/2024 Review Program, including Grand Coulee Dam (USACE, 2012).

Report (IPCC, 2007). Building on the modeling developed as part of the Washington State Climate Change Impacts Assessment, the Columbia Basin Climate Change Scenarios Project culminated in a comprehensive database of climate and hydrologic scenarios to support climate change analysis and adaptation planning. The intent of work is to provide a range of data for a variety of end users, including planning officials and research scientists. Some advances from this effort include hydrologic model calibration and development of additional climate change scenarios.

HYDROLOGIC HAZARD ANALYSIS

Reclamation uses a multiple methods approach to estimate hydrologic hazard for higher-level dam safety studies, including Issue Evaluations (IE) and Corrective Action Studies (CAS) at specific facilities (Reclamation, 2013). Multiple methods will be used to estimate the hydrologic hazard at Grand Coulee Dam. The approach uses two methods: 1) Expected Moments Algorithm (EMA) streamflow statistics and paleoflood data, and 2) rainfall statistics along with rainfall runoff and hydraulic modeling. The two methods are used in order to: (1) ensure consistency between the rainfall-runoff model and streamflow data (including historical data and paleofloods); (2) provide the data and models to estimate and extrapolate hydrologic hazard curves to AEPs of interest (Swain et al., 2006); and (3) include uncertainty estimates for the hydrologic hazard curves. Both methods will leverage and attempt to incorporate much of the past and ongoing work completed by Reclamation, University of Washington (UW), USACE, and Bonneville Power Administration (BPA).

Streamflow Statistics: EMA (Cohn et al., 1997) is a moments-based parameter estimation procedure that was designed to incorporate many different types of systematic, historical, and paleoflood data into flood frequency analysis. EMA assumes the LP-III distribution best represents the distribution for annual floods. EMA develops approximate confidence intervals using normal theory with and without an adjustment to correct for the correlation between the quantile estimate and its estimated standard deviation (Cohn et al., 2001). EMA has been documented in several journal articles (Cohn et al., 1997; England et al., 2003a; England et al., 2003b; Cohn et al., 2001) and provides a suitable flood frequency model. EMA has been applied by Reclamation at many sites for peak-flow frequency (England et al., 2003b; Swain et al., 2006; England, 2012).

Streamflow statistics will be calculated using EMA and will leverage the hydrology work completed by the USACE for the Columbia River Treaty Review (USACE, 2012). The EMA analysis will use the 2010 no regulation no irrigation (NRNI) dataset (BPA, 2014), synthetic floods developed by the USACE, and paleoflood data. The 2010 NRNI dataset (BPA, USACE, Reclamation) has a period of record (POR) daily from 1929-2008.

The EMA analysis will directly incorporate paleoflood and historic flood estimates into the LPIII analysis. The 1894 flood is the flood of record at most locations along the Columbia River and will be an important parameter in the study. Synthetic floods developed by the USACE may also be used in the EMA analysis or may be used to develop additional synthetic floods specific to flooding at Grand Coulee Dam.

The results of the EMA analysis are flood peak discharges, however the shape and volume of the hydrograph are needed. Flood hydrographs will be developed using several different methods and will then be scaled according to flood peak discharge to represent similar flood patterns. The USACE has developed balanced hydrographs from past large floods. Hydrographs have been developed in the past for historic large floods, such as the 1894 and 1948 floods. These hydrographs may be scaled according to flood peak discharge to represent similar flood patterns. Calibrated rainfall runoff and hydraulic models are part of this hydrologic hazard project and may be used to develop flood hydrographs representative of the runoff patterns for the drainage basin. For a hydrograph scaling approach it may be most appropriate to use a suite of hydrographs that represent historic floods and scale the hydrographs according to peak discharge. Representative hydrographs have been developed for historic large floods on the Columbia River.

Paleoflood Data: Paleoflood information will be used in this study to help extrapolate estimates of the flood frequency beyond the historical record. Paleofloods are past or ancient floods that were not observed by traditional means, but are often preserved in the sedimentary record (Figure 2). Most conventional estimates for the frequency of large floods are based on extrapolations from stream gaging records, and commonly utilize record lengths shorter than 100 years. Paleoflood hydrology ties together estimates associated to peak discharge and age developed from geomorphic and geologic evidence.

The Columbia River, as one of the largest river systems in the U.S. and one famously known as the avenue for the glacial Lake Missoula outburst floods, will require a substantial field effort to develop paleoflood data for this study. Four general locations have currently been proposed as sites to collect paleoflood information: two from the major tributaries that flow into Lake Roosevelt (the mainstem Columbia River and the Spokane River), one at a location downstream of Grand Coulee Dam on the mainstem Columbia River, and the last at a location near The Dalles, OR. The site at The Dalles, OR is intended to serve as a location where paleoflood data

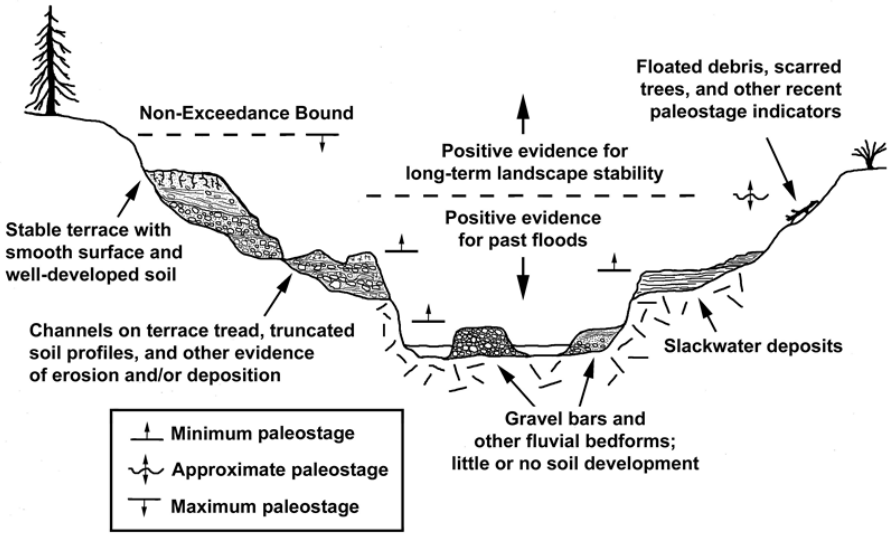

Figure 2 Idealized channel cross-section illustrating the concept of a non-exceedence bound and the fluvial landforms and related deposits associated with paleofloods.

can be developed downstream of the confluence with other major tributaries to the Columbia (i.e., the Yakima and Snake Rivers). The four sites outlined for the study are intended to collect data at key points within the basin that were considered vital and to keep overall study costs downs. A broader range of locations along the mainstem Columbia River upstream of Lake Roosevelt and an additional site on the Clarks Fork may be needed to reconcile the contributions to the reservoir.

Rainfall Statistics and Rainfall Runoff Modeling: The rainfall statistics and runoff modeling approach will use a combination of custom meteorological inputs, stochastic rainfall runoff modeling, hydraulic modeling, and paleoflood data to estimate a range of floods (peaks and volumes) with annual exceedance probabilities (AEPs) from 10^{-3} to 10^{-6}, or as needed for Reclamation dam safety risk-based decision-making. The general concepts that are proposed focus on leveraging the existing Variable Infiltration Capacity (VIC) rainfall-runoff model and the USACE Hydrologic Engineering Center's Watershed Assessment Tool (HEC-WAT) hydraulic model, and their ongoing applications within the Columbia River basin.

Extreme storm rainfall and snowpack data sets will be developed by Reclamation while leveraging the existing work. The custom meteorological inputs will be used as forcings in the VIC Model developed for the Columbia Basin Climate Change Scenarios Project. The VIC model and associated input datasets were developed at 1/16th degree latitude/longitude spatial resolution over the CRB as part of climate change studies. The VIC hydrologic output will be used as input to the HEC-WAT model. The Columbia River HEC-WAT model was developed by the USACE for the CRT Review and is capable of routing flows through the extensively regulated CRB to develop frequency flow estimates for Grand Coulee Dam. This approach will allow for the development of hydrologic hazard estimates at Grand Coulee Dam, and quantify associated uncertainties.

Meteorology: A major effort of this work is to develop custom extreme storm rainfall and snowpack data sets for use as meteorological forcings in the VIC rainfall-runoff model. Some key meteorological assumptions for this study are as follows.

1) Grand Coulee Dam is a major flood control dam with approximately 5.185 million acre-feet (MAF) of dedicated flood storage on the Columbia River system (USACE, 1991), that is operated on a very strong seasonal cycle (USACE, 1997; USACE, 1999; USACE, 2003; USACE, 2012). Meteorological inputs will primarily focus on the late spring and early summer April-May-June (AMJ) season in order to maximize potential CRB inflow volumes.
2) Combined flood control storage within the CRB upstream of Grand Coulee Dam is approximately 33.8 MAF (USACE, 1991; USACE, 2003), including storage at Mica, Arrow, Duncan, Libby, Hungry Horse, and Grand Coulee. In order to examine the potential effects of extreme floods on dam safety at Grand Coulee Dam, estimated extreme storm rainfalls in combination with snowmelt runoff are needed.
3) Snowpack depths and snowmelt runoff potential, in combination with extreme rainfall, are also key meteorological considerations, given the CRB flood storage. The application of season-specific or synoptic mechanism-specific frequency and extreme storm analyses may be investigated to confirm these assumptions are valid.

Meteorology will be developed by leveraging existing data and analyses that use historical and reanalysis data sets, as well as gathering and analyzing new data. It is anticipated that the analysis of 20 individual storm events, including spatial and temporal precipitation distributions, moisture fluxes, storm centering and orientation, will be performed. The main data sets initially include the following:

- the 1/16th degree precipitation and temperature gridded data (1915-2006) from Deems and Hamlet (2010) with consideration of recent updates (Livneh et al., 2013);
- observed point precipitation and temperature from the Global Daily Climatology Network (GDCN) and Global Historical Climatology Network (GHCN)
- daily precipitation, temperature, and related variables from the NRCS SNOTEL network;
- Climate Forecast System Reanalysis (CFSR) data (Saha et al., 2010);
- trajectory analyses and relevant meteorological fields from recent work by Alexander et al. (2013); and
- model runs of individual storms, historical events and ensembles over the CRB using the Weather Research and Forecasting (WRF) regional climate model by University of Washington and U.S. Army Corps of Engineers.

Specific precipitation and temperature perturbations and storm sequencing scenarios will be developed from these data sets. Climate change inputs and hybrid delta scenarios used in the CRB climate change studies commissioned by the State of Washington under House Bill 2860 (Hamlet et al., 2010) will also be considered. Meteorological scenarios may be added to investigate the potential influence of climate change.

Seasonality of extreme storm events will initially focus on analysis of April, May, June (AMJ) rainfall and snowmelt runoff sequences for specific flood years (Table 1). To date, detailed hydrometeorological analyses of the events listed in Table 1, including spatial and temporal patterns, depth-area-duration data, inflow moisture and associated analyses have not been completed. The initial data analysis of the extreme storm season may also be expanded to include warm-season events in summer (July-August) and fall (September-October) after investigation of storm hydrometeorology and snowmelt volume within this large region.

Table 1 Major spring storms in the CRB used for flood risk assessment (USACE, 2012)

Water Year	**Flood Dates**	**Comments**	**Key References**
1894	May 20 - June 15	May rain-on-snow; used as design event for the CRB system-wide flood control (USACE, 1991)	USGS (1949); USACE (1991); USACE (2009)
1948	May 19-23; May 26-29	May rain-on-snow; rainfall	USGS (1949); USACE (1991); USACE (2009)
1956	May 20 – June 6	predominately snowmelt	USACE (2012)
1971	May 31 (peak)	rain may have been predominant	USACE (2012)
1972	May 31 – June 14	snowmelt with some rain	USACE (2012)
1974	May and June	snowmelt	USACE (2012)
1997	May and June	snowmelt with some rain	USACE (2012)

The areal coverage of large precipitation events will be a main driver of extreme flooding. One objective is to develop storm centerings that are capable of producing extreme floods for the project area. The location of the storm centering will drive the possible areal extent of the storm as orographic effects from the Coastal and Cascade Mountains, as well as the aridity of eastern Washington and western Idaho will help to define the possible sizes and locations of storms.

Regional precipitation frequency analysis using L-Moments (Hosking and Wallis, 1997) will be used to estimate extreme storm rainfall point (10 mi^2) probabilities. The storm rainfall inputs will be developed for annual exceedance probabilities (AEPs) ranging from about 10^{-2} to 10^{-6}. Analyses will be done for several (two to three) regions to represent extreme storm rainfall sequences over various combinations of the CRB. The approach that will be developed for this study focuses on partial-area storm rainfall, and existing techniques that are adequate for smaller basins that will need to be modified because of the large CRB watershed.

One critical factor of this study is to couple the storm rainfall sequences in combination with snowmelt runoff. The largest runoff events (to date) have occurred in May and June (Table 1) and are extreme rainfalls in combination with a large snowpack. Spatial coverage of snowpack and snowpack depths are critical components. Scenarios using seasonal snowpack, temperatures, and melt sequences of individual events, such as the record May-June 1948 sequence, will be developed.

Many of the dams within the CRB, including Grand Coulee Dam, are operated for flood control. Seasonal snowmelt forecasting is an important component of flood control and will be examined for potential inclusion in this study. USACE (2012) indicates that forecast error (as well as operations) is a critical aspect to the CRB. The potential to include forecasts and associated forecast errors will be explored.

Rainfall-Runoff Modeling: The Variable Infiltration Capacity (VIC) model (Figure 3) developed for the Columbia Basin Climate Change Scenarios Project (CBCCSP) (Hamlet et al. 2013) will be used to estimate flows from extreme storms, in combination with other meteorological forcings. The CBCCSP came about through a collaboration of the Washington Department of Ecology, the Bonneville Power Administration, the Northwest Power and Conservation Council, the Oregon Water Resources Department and the British Columbia Ministry of the Environment. The project built upon hydrologic model development from the Washington State Climate Change Impacts Assessment (Miles et al. 2010). Specifically, the Variable Infiltration Capacity (VIC) model and associated input datasets were developed at $1/16^{th}$ degree latitude/longitude spatial resolution (approximately 30km^2 or 7400 acres per cell) over the Columbia Basin and coastal drainages within Washington and Oregon. The model was calibrated on a monthly timestep over 12 subbasins of the Columbia Basin. Hydrologic variables such as snowpack, runoff, soil moisture, and evapotranspiration were produced at the grid resolution of the VIC model, and simulated natural streamflow (absent any management effects) was generated at approximately 300 locations throughout the basin.

The VIC model will be used to evaluate the implications of extreme hydrometeorological conditions on the Columbia Basin with respect to flood risk and water management. Frequency precipitation estimates will be used in the historic rainfall database to model extreme floods that

take into account the large drainage basin and multiple sub-basins in the VIC model. A separate interface may be developed to run the perturbed meteorology in a stochastic format with a Monte Carlos method to randomly select the stochastic inputs to the VIC model, run the model, and post processes the results while keeping track of the model parameters for each run. Climate change, and its potential impacts on extreme floods, will also be included in this study. The meteorological forcings to VIC will include appropriate future climate scenarios.

Hydraulics and River Operations Modeling: The USACE developed the HEC-WAT model to integrate the multiple functions of a river system that contribute to flood risk management. The HEC-WAT modeling framework will be used to route flood flows downstream using realistic dam operations. Items such as river regulation, hydropower generation, and structural inventory are modeled and integrated into HEC-WAT to provide an automated approach to develop the metrics necessary to define flood consequences and risk.

High resolution terrain data were collected for both terrestrial and bathymetric conditions. Terrestrial data were collected using LiDAR, which was processed into digital elevation models. Bathymetric data were collected by hydrologic surveys, which resulted in a set of three-dimensional cross-sections. These data were integrated into a seamless terrain model representing elevations on the land and underwater, which was subsequently incorporated into the hydrologic and hydraulic models developed for this study.

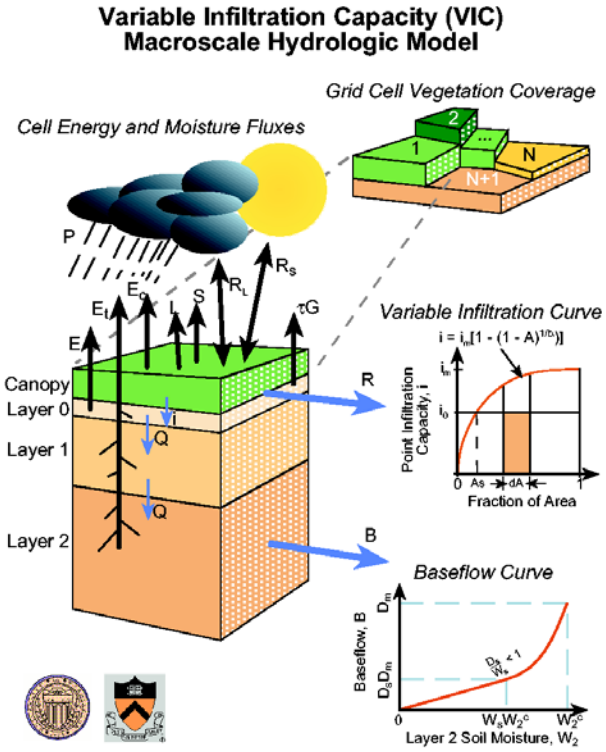

Figure 3 Overview schematic of Variable Infiltration Capacity (VIC) Model.

SUMMARY

Reclamation is performing a HHA for Grand Coulee Dam for use in a Dam Safety risk analysis. Due to the extraordinary large size of the Grand Coulee Dam drainage basin, Reclamation is taking a collaborative approach to the study that leverages the data collection, analyses, and modeling completed by other agencies and universities in both the United States and Canada. A multiple methods approach is being used, that is standard Reclamation practice for high level hydrologic studies, which combines streamflow and rainfall statistics with paleoflood data, hydrograph scaling, rainfall runoff and hydraulic modeling. A detailed HHA of this level has not been completed for Grand Coulee Dam in the past due to the expense and complicated nature of modeling. Leveraging the past and current work being completed in the CRB will allow Reclamation to complete an IE level HHA study for Grand Coulee Dam and help guide dam safety decisions for extreme floods.

DEVELOPMENT OF CCHE2D EMBANKMENT BREAK

Yafei Jia (primary author), National Center for Computational Hydroscience and Engineering, The University of Mississippi, University, Mississippi, jia@ncche.olemiss.edu; Sherry Hunt (co-author), USDA-ARS Hydraulic Engineering Research Unit (HERU) in Stillwater, OK, Sherry.Hunt@ars.usda.gov

Abstract: Flooding due to breaching of earthen embankments often results in detrimental impact on the people and their properties downstream in the flooded zone. The embankment breaching process is often caused by overtopping of excessive water in a reservoir or a river. The purpose of this study is to develop a practical numerical model for simulating overtopping and embankment breaching process. To achieve the goal, the key physical-empirical dam breaching mechanism of earthen embankment is adopted and implemented into CCHE2D surface flow model. A special function describing the shape of the breaching channel profile is introduced which significantly simplifies breach modeling. The developed model is validated using experiment data. The simulated flooding hydrograph, headcut migration, and breaching embankment profiles agree well with the observed data. Because this is a 2D model, the development makes it possible to simulate breaching in more complex conditions and study multiple embankment breaches at the same time. This broadens the applicability of the embankment break model significantly.

Keywords: Dam break, flooding, numerical simulation, two dimensional modeling, WinDAM, cohesive soil, overtopping

INTRODUCTION

Earthen embankments are effective infrastructures constructed across waterways or along rivers as dams or levees for flood protection. Due to aging or extreme hydrological events, embankments may fail and result in detrimental flooding. Embankment breaches have been studied by using physical experiments, numerical model simulations, and field observations. Most publications focus on dam breaching, but studies on the embankment erosion processes are relatively rare. Without considering the gradual breaching process of embankments, one may overestimate the dam break flood discharges. In this study, a numerical model to simulate embankment breaching is developed. Considering the complexity of the breaching process and the resulting flooding, a combination of a two dimensional flow model and a reliable dam break process model would have the potential for the best outcome. One can fully take the advantage of the capabilities of 2D models to accurately and reliably simulate embankment breaches in rivers and reservoirs.

Embankment breaching is often simplified as an instantaneous problem which can be simulated using only numerical flow models. There have been many developments in this area in recent years. Frazão and Zech (2002) measured flood waves in a channel bend and developed a finite volume model to simulate the flood. Aureli et al. (2008) simulated dam breach flooding using a finite volume code, the data were obtained by an imaging technique in a small scale experimental flume. Ying and Wang (2008) have developed a 1D finite volume model for flood wave simulation, where the HLL shock capturing scheme was used to solve the hydrodynamics implicitly. Zhou et al. (2004) validated a 2D model of dam breach flow using physical experiment data, with the complex channel geometry handled using cut-cell technique. Jia et al. (2010)

simulated the 2008 Midwest flood in Mississippi River using CCHE2D, a 2D flood model based on the finite element method. Multiple levee breaches and gradual breach processes have been considered, the simulation results are validated using satellite imagery.

Macchione and Sirangelo (1988) simulated the dam break process by solving 1D Saint Venant and sediment continuity equations. The breaching process was treated similar to that of non-cohesive sediment transport. This model was later applied to simulate multiple dam failures and had reasonable results (Macchione and Sirangelo, 1990). Wu and Wang (2006) simulated dam break processes with a 1D model, small-scaled experimental that considered dams constructed of loose materials. The density of sediment was accounted for in the flow modeling, and the non-equilibrium bed load sediment transport approach was applied. Ying and Wang (2010) have simulated the dam breaching process using a 2D model, simulating the flow using the 2D shallow water model based on the control volume method. The breaching process of an earthen dam composed of cohesive materials is simulated based on the linear model for cohesive soil erosion, which assumes that the erosion rate is proportional to the excessive shear stress acting on the soil surface. Wu (2013) proposed a method to simulate the erosional process causing dam breaching. The dam break slope, connecting the dam crest to the front toe, is assumed to be a straight line for non-cohesive sediment and a vertical drop for cohesive earth dams.

Embankment breaching processes have also been studied using physical experiments. Because embankments are constructed using cohesive materials, it takes extensive efforts to study and quantify the process using large scale physical experiments. Research engineers at the USDA-ARS Hydraulic Engineering Research Unit (HERU) constructed scale models of earthen embankments, and then breached them under controlled conditions. Hanson et al. (2005) conducted several outdoor experiments on large size models constructed of cohesive materials providing a unique set of data for dam breaching analyses and model validation. Their experiments have made significant contributions in collecting detailed observation data. Several other large scale dam break experiments have been carried out in Europe (Hassan, 2008; Vaskinn et al. 2001); in addition to homogeneous cohesive materials, breach processes with composite dam material were also tested.

The computer model Windows Dam Analysis Modules (WinDAM, Temple et al. 2006; Visser et al. 2012) has been developed for evaluation of dam breaching processes subjected to overtopping. It includes a reservoir routing model for the auxiliary spillway and the embankment. The model is capable of evaluating the ability of vegetation or riprap on the downstream face of the dam to withstand the overtopping flow. A homogeneous embankment constructed from cohesive soil materials of simple cross section is assumed.

The objective of this study is to develop an embankment breach model based on a two dimensional model of surface flow and the breach mechanism of the WinDAM model. Because the two–dimensional model is capable of simulating flows in both rivers and reservoirs, it will be applicable to both dam and levee breach cases with general flow conditions. In addition, two dimensional models can provide local flow solutions directly for the overtopping flow and the flow in the downstream flooding zone, the simulation results can be more accurate than one dimensional models. Two-dimensional models make it possible to simulate multiple breaches along a channel at multiple locations and under differing local flow conditions. The finite element method based model CCHE2D (Jia et al. 1999, 2002) has been used for this study.

NUMERICAL MODEL

CCHE2D is a depth-integrated model based on the finite element method for simulating free surface flows, sediment transport, bank erosion, vegetation effect, and water quality, and it is also applicable to coastal processes (Jia and Wang 1999, Jia et al. 2002, 2006, Ding et al. 2003, and Zhu et al. 2008). The model uses a collocation method and quadrilateral mesh system. Velocity-pressure coupling is achieved using a partially staggered grid arrangement. The velocity correction method is used to achieve momentum and mass conservation at each time steps. Temporal integration is of a second order Range-Kutta method. In order to increase computational efficiency, wet-dry capability was developed for handling moving boundary problems in areas with complex topography. It has been applied to a wide range of flow conditions from dam breaches of real scale reservoirs, large rivers such as the Mississippi, to small-scale experimental laminar flows.

EMBANKMENT BREACH MODEL

For cohesive earth embankments, the overtopping flow profile has two segments: a segment at the crest and a segment and the headcut. The conceptual evolution of the geometry of dam and levee breaches is depicted in figure 1.

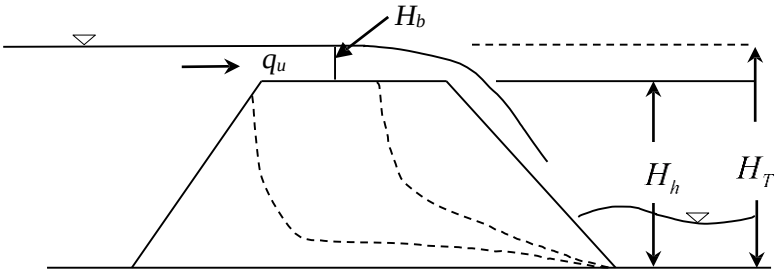

Figure 1 Dam break or levee breaching process sketch

Overtopping induced embankment breach process (figure 1) is normally recognized to have three stages:

1. Overtopping stage: the flow erodes the dam crest surface and front slope surface, these two surfaces lower their elevation almost uniformly. The discharge is relatively small, depending on how much higher the water surface in the reservoir is than that of the crest.
2. Headcut stage: The crest is continuously eroded. Headcut(s) are formed by soil erosion over the front slope and migrate upstream while incising deeper. In this stage the embankment is eroded significantly by the incised channel, but the flow discharge is relatively small because the crest elevation is still quite high. The headcut in the embankment widens due to both lateral erosion and soil mass failure.
3. Embankment breach stage: The headcut migrates to and intercepts with the back of the embankment (upstream slope), the flat dam crest disappeared. Because the remaining embankment is thin and has a sharp crest, its strength to resist flow erosion and water pressure is weakened. The headcut migration rate therefore increases significantly and the discharge increases quickly to the peak flood. The increasing discharge further erodes the remaining embankment crest, deepening and widening this incised channel. The breach

channel widens in this stage with a slower rate. Because the vertical erosion and lateral widening occur at the same time in numerical simulation, the third stage includes the III and IV stages suggested by Hanson (2005).

Because of the complexity of the breaching process, it is difficult to simulate by simply applying a numerical model for hydrodynamics, and sediment erosion and transport. A conceptual model similar to WinDAM was adopted in this study that considered with the following three major processes:

- Frictional erosion on embankment top segment
- Headcut erosion and migration
- Channel widening

Breaching Channel Profile: A simple power function is proposed to represent the headcut profile as indicated in figure 2. The elevation and length of the flat crest is lowered and shortened by top friction erosion and headcut migration. The friction erosion is controlled by the embankment soil property and the flow shear stress. Higher flow rate and more erodible soil would result in faster crest erosion and decrease in elevation. The headcut erosion is physically dominated by frictional erosion and flow plunging impact on soil surface, it is more intensive than crest erosion. One major headcut is considered. In figure 2, (x_T, z_T) is the location of the brink of the dam breach flow or headcut, it connects the two segments and moves in time. (x_b, z_b) is the location of the front toe of the embankment. (x_{tr}, Z_{tr}) and (x_{br}, Z_{br}) is back brink of the embankment crest and embankment back toe. The base line is considered non-erodible in this study.

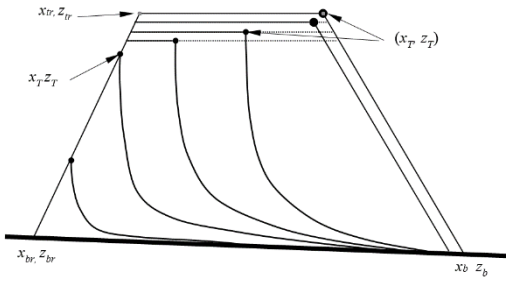

Figure 2 Side view of an overtopping induced dam-break process

It can be seen that the profile across the embankment is mainly represented by three segments:

$$\text{Crest segment}: \quad z = z_T \qquad x \le x_T \tag{1}$$

$$\text{Headcut segment}: \quad \left(\frac{z - z_b}{z_T - z_b}\right)^s = \frac{x - x_b}{x_T - x_b} \qquad x_T \le x \le x_b \tag{2}$$

$$\text{Back slope segment}: \quad \frac{z_T - z_{br}}{z_{tr} - z_{br}} = \frac{x_T - x_{br}}{x_{tr} - x_{br}} \qquad x_{br} < x_T < x_{tr} \tag{3}$$

The crest segment is the horizontal and flat top of the embankment. Its elevation is determined by surface friction erosion; its length can be shortened due to front slope erosion and head cut

migration. The headcut segment is approximated by a function combining the initial straight front slope and the head cut profiles. The shape parameter, *s*, defines a continuous transition from the first stage to second stage of headcuting:

s=1.0 : downstream slope at initial overtopping stage
s>1.0 : headcut stage

Figure 3 illustrates several headcut curves modeled using equation 2, in which *s* varies from 1 to 10.

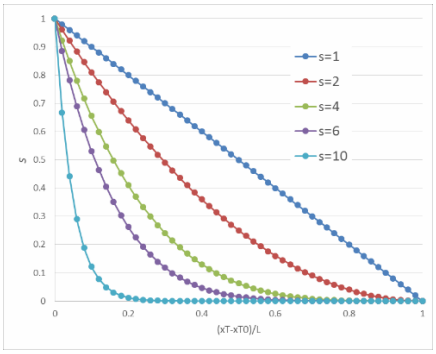

Figure 3 Non-dimensional headcut profile function

The exponent parameter *s* is formulated as a function of x_T and the width of the crest, L_T . It is assumed *s*=1 at the beginning, it increases to its maximum value (*s*=10) when the head cut advances to half of the crest width:

$$\begin{aligned} s &= 1 + 20\frac{(x_{T_0} - x_T)}{L_T}, && (x_T >= x_{T_0} - \tfrac{1}{2}L_T) \\ s &= 10 && (x_T < x_{T_0} - \tfrac{1}{2}L_T) \end{aligned} \quad (4)$$

Equation 4 is a model established to approximate the process of the changing headcut profile. Figure 4 shows this headcut profile parameter changing from the overtopping stage (*s*=1) to the fully advanced headcut stage (*s*=10). This equation assumes that after the headcut has reached a half of the dam crest (0.5L_T), *s* reaches its maximum value, and the headcut steepness remains unchanged in further process. The assumption would not affect the accuracy because the breach is dominated by the location of headcut $[x_T, z_T]$ and less by the shape of the profile.

Equation 3 represents the back slope segment of the embankment which intercepts with the headcut brink (x_T, z_T) when the headcut advance exceeds the back brink of the crest. At this time the remaining embankment becomes a sharp crest and the migration rate will be increased. By inserting x_T into equation 3, one can compute the crest elevation z_T. Inserting the new (x_T, z_T) into equation 2, a headcut profile for the breaching stage can be computed.

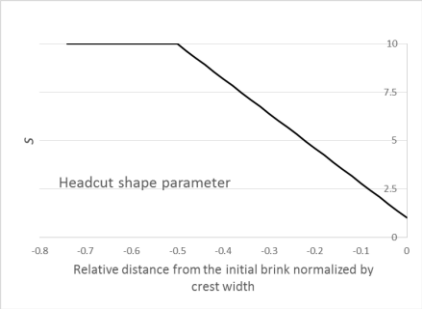

Figure 4 Headcut shape parameter *s*

Embankment Erosion Process: The headcut brink, (x_T, z_T), is the hydraulic control of the entire process. The downward movement of z_T is controlled by friction erosion of the crest. In this study, the crest erosion is governed (Hanson and Cook, 2004 and Hanson and Hunt, 2007) by

$$\frac{dz_T}{dt} = \varepsilon_r = k_d(\tau_e - \tau_c) \tag{5}$$

ε_r is the soil detachment rate in volume per unit time, k_d is the detachment rate coefficient which is an embankment material property parameter, τ_c soil critical shear stress, and τ_e the effective shear stress. Observed data indicate that k_d varies between 0.02~1000 depending on water content, compaction energy and texture of the soil (Henson et al. 2011).

The length of the crest segment will decrease because of the headcut migration. Computing headcut migration is to track the upstream movement of the brink point (x_T, z_T). Temple and Hanson's headcut advance rate model (Temple et al. 2005) is adopted for simulating this process:

$$\frac{dx_T}{dt} = C_h(q_u H_h)^{1/3} \tag{6}$$

where H_h is the headcut height (figure 1), C_h is a calibration parameter for headcut migration rate, q_u is the unit discharge of the overtopping flow. In this study q_u is directly computed by the 2D flow simulation model. The unit discharge would be a constant if the crest is resistant to erosion. In this case, the headcut will advance at a constant rate. If the headcut advances into the reservoir and intercepts the upstream slope of the dam, the brink point will lower its elevation while moving upstream, allowing for more flow to accelerate the breaching process. Experiments indicated that the migration rate would significantly increase when the upstream crest is reached (Hanson et al. 2005). As mentioned earlier, the speed-up is attributed to the weaker embankment condition, the coefficient C_h may have a larger value at the breaching stage. The C_h value is doubled in this study for the headcut migration during the breaching stage.

Widening of the Headcut Channel: In the process of breaching, the breaching channel incises into the embankment, the incision profiles can be computed as indicated in the previous section. However, the incised channel will also be widened due to lateral erosion and mass failure as its bed gets deeper and deeper. The lateral shear force of the flow will erode the materials from the embankment side walls and the steep side slope of the embankment may collapse due to gravity. The widening rate is correlated to the rate of deepening in WinDAM model (Temple et al. 2006): the rate of widening of the breaching channel is of 1.4 times of the rate of deepening. A side wall will therefore retreats 0.7 times of the mean depth erosion in a cross-section. This is equivalent to about 55 degrees along the wet toe of the side slope. In the case of two dimensional modeling, the incised breaching channel is represented by a number of mesh lines and the widening is dominated by the vertical toe erosion of the sidewalls. An effective angle of repose is used to model the channel widening: if the slope near a toe mesh point of the sidewall exceeds this angle due to toe erosion, the sidewall elevation at the higher node is "collapsed" to enforce the angle (figure 5). In the numerical tests, the effective angle of repose is adjusted slightly to fit the observed widening process (Tab. 1).

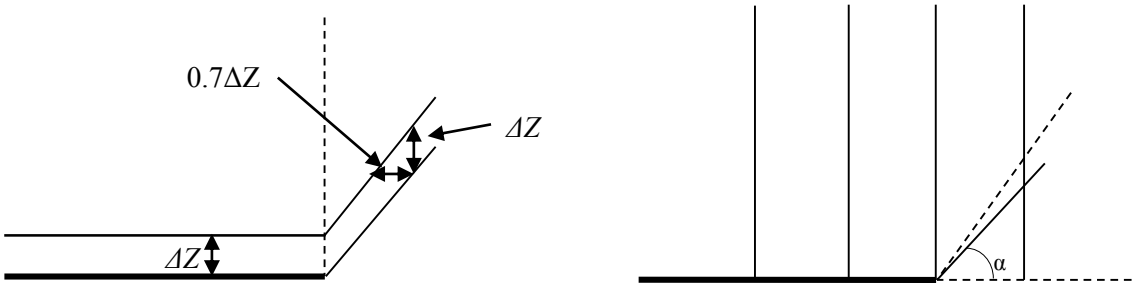

Figure 5 The width increases in time with the lower end being wider.

VALIDATION OF THE IMPLEMENTED CCHE2D DAMBREAK MODEL

Data from the experiment are required to validate the developed model. Large-scale overtopping breach tests on homogenous cohesive embankments conducted by Hanson et al. (2001, 2005) were selected for validation. Three sets of data from the experiments (E1S1, E1S2, and E1S3) were selected for testing. These three tests have the same shape and size of the embankment but built with three different soils. The embankment is 2.3 m high, 22 m long; a 0.46m deep by 1.83m wide notch was opened for the overtopping flow to develop. During the experiments, a flow of 1.0 m3/s is discharged into the reservoir.

Table 1 Parameters used for simulations

	Critical shear stress (Pa)	**Soil erodibility (cm^3/N-S)**	**Headcut coeff C_h**	**Effective angle of repose α(°)**	**Inflow discharge (m^3/s)**	**Soil**
E1S1	0.14	10.3	0.0035	62	1.0	1
E1S2	0.14	2.0	0.000288	50	1.0	2
E1S3	14	0.39	0.00004	55	1.0	3

It is generally recognized that the erosion to the embankment made of cohesive soil is related linearly to an erodibility parameter and the excessive shear stress (Hanson et al. 2001; Hanson, 1989a.) Parameters related to this approach have been calibrated using experimental data to obtain good agreements on comparing the simulated and observed flood process. Table 1 lists the

parameters for the experiments. C_h and α have been calibrated to obtain correct values for headcut advance and breach channel widening.

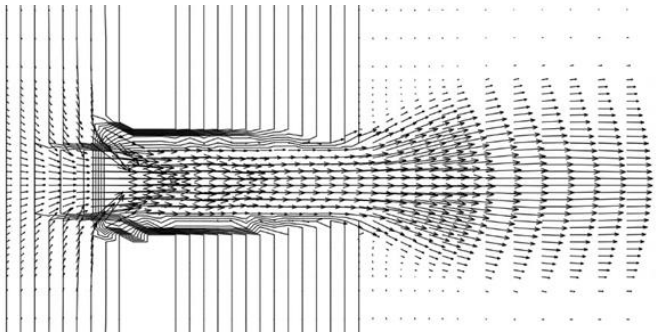

Figure 6 Simulated velocity distribution for E1S1 at t=38 min. Contours indicate the embankment

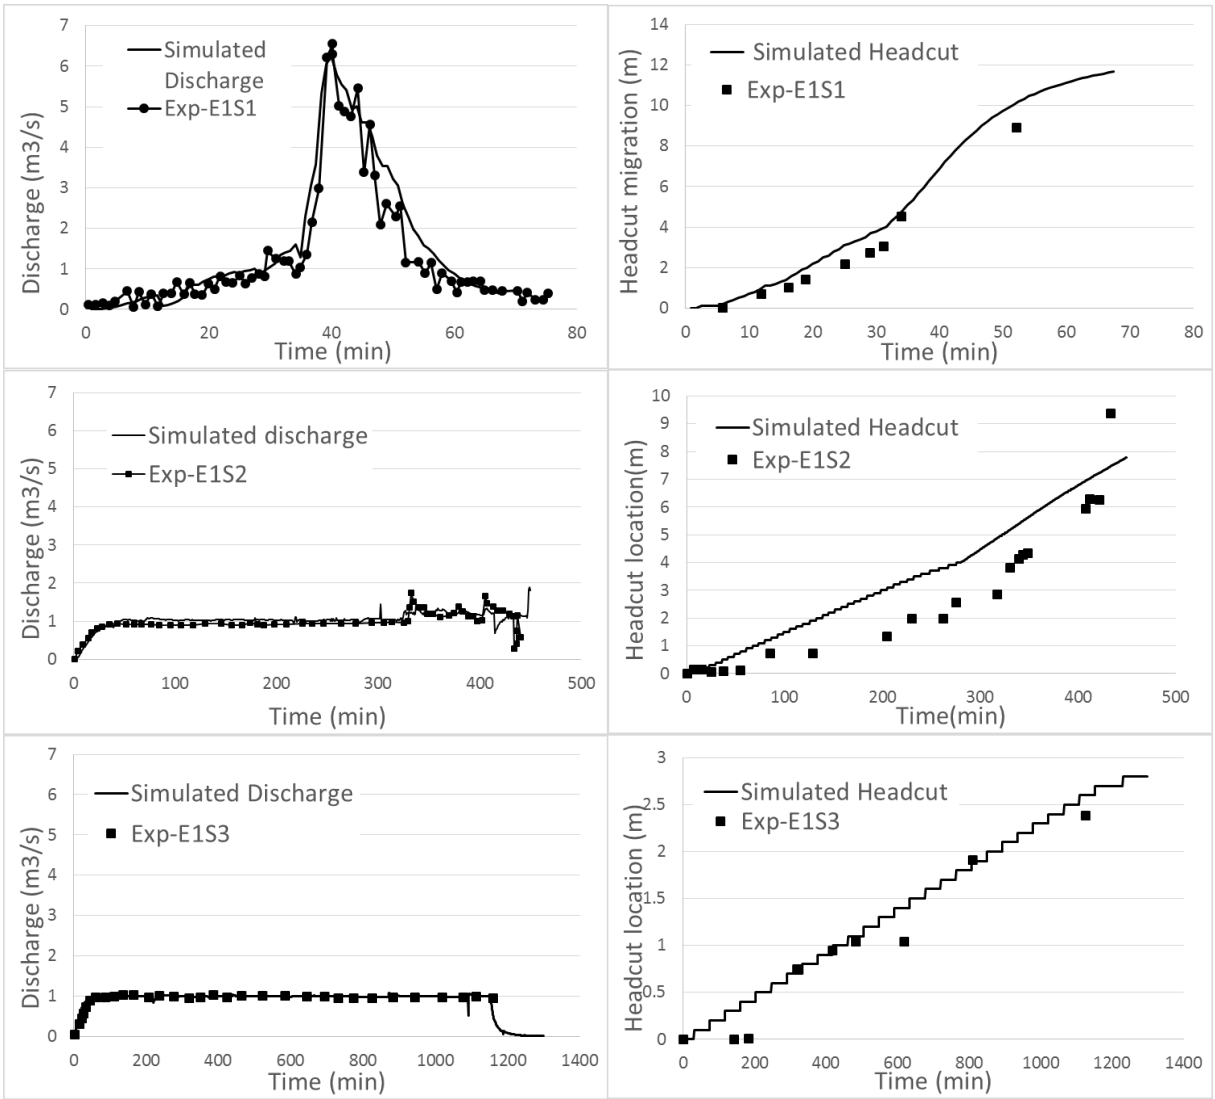

Figure 7 Comparisons of the computed and measured breaching flow discharge and headcut advancement

Figure 6 is a snap shot of the simulated flow field for the case E1S1. The headcut intercepts the back slope of the embankment at t=38 min approximately, the breaching stage starts and flow discharge is increasing rapidly. The vector field indicates the converging flow on the reservoir side and the diverging flow on the outside of the embankment. The variables in equation 5 and 6, τ_c, τ_e, H_h and q_u, are averaged from the simulated two dimensional flow in the friction erosion zone. It is seen the 2D model can represent the hydrodynamics of the breaching flow, the model predicted breaching flood can directly be used for inundation and mitigation analysis.

Figure 7 compares the computed and measured breaching flood discharge and headcut advance of all three test cases. The discharge hydrographs agreed very well including the peak of the flood and the shape of the hydrographs. The simulated headcut migrations also match those observed. Because the advance rate of the headcut is set to be doubled, the simulated migration speed up when the upstream brink of the embankment is reached by the headcut, as seen for E1S1 and E2S2. For the case E1S3, the experiment was terminated before breaching stage, both computed and observed migration are of a constant rate. One notes that the computed headcut location of the case E1S2 is a little ahead of the measured one, about 1 to 2 meters, and the two curves intercept at later time when the observed headcut migration suddenly accelerated.

Figure 8 shows the computed and measured breaching channel profiles of the case E1S2. The general agreement of the two sets of data is very good. The shape of the function-modeled headcut profile at different times are very similar to the measured ones. The 1 minute profile of the simulation has little movement from the initial profile; the measured counterpart has advanced about 1meter. The profiles of 19 minute and 85 minute agreed very well. The simulated profile of 203 minute and 314 minute advanced faster than the measured for about 1-1.5 meters. The agreements for the profiles of 342 minute and 407 minute become good again. These are consistent with headcut advance showing in Fig. 8, that the predicted and measured headcut locations are close at the beginning and near the end, but they have larger differences in the middle of the process.

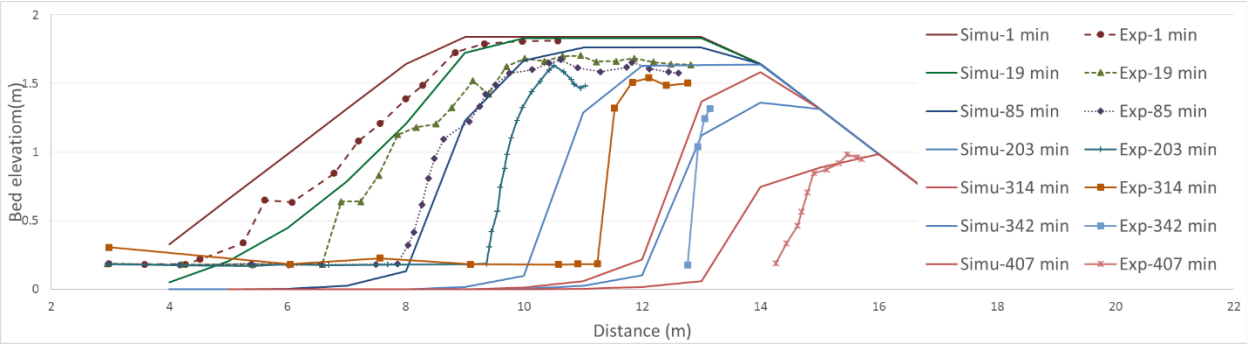

Figure 8. Comparisons of simulated and observed headcut profiles for case E1S2.

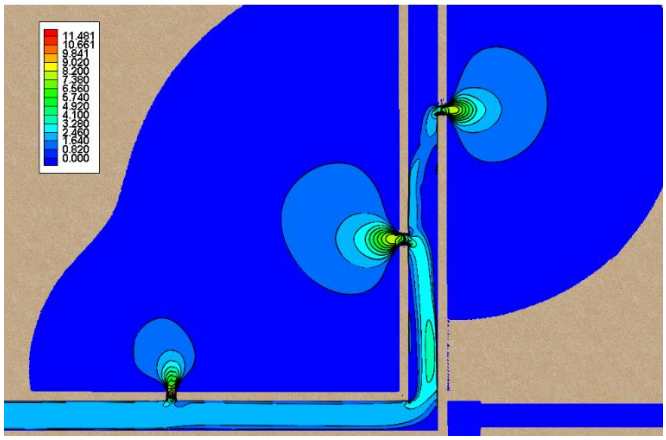

Figure 9 Simulated large scale test case with multiple levee breaching. The horizontal length of the figure is 2 km, the channel width is 100 m.

Figure 9 shows a hypothetical levee embankment breaching test. The flow velocity distribution of the simulated flooding results at about 14 hours is displayed. The maximum velocity exceeds 11m/s. The spatial scale of the simulation is quite large, the width of the domain is 2000 m, the width of the channel is about 100 m, the flow discharge is 1200m^3/s, and the relative levee height is about 7 m. A steady flow is established first, and three notches are made at the breach locations. A continuing run of the model resulted in three breaches along the channel. Because the parameters of the embankment at the three locations are set differently, the flow conditions along the channel and the simulated breach developments are different. This example demonstrates that a two dimensional model can significantly extend the application of the embankment breach model such as WinDAM.

CONCLUSIONS

A two-dimensional embankment breach model is developed by integrating the physical-empirical breach mechanism of the WinDAM model and the general surface flow model, CCHE2D. The new model is capable of simulating one or multiple embankment breaches at the same time in more complicated general surface water conditions. It therefore has a wider potential to be applied for flood prediction and disaster mitigation. A function is proposed to model the breach channel of the headcut which transitions the breach channel profile from the straight line at the beginning to the steep headcut at the end of the process. The function simplifies the computation because no erosion simulation is needed in the area from the headcut brink to the toe of the embankment. Validation tests using three sets of large scale experimental data have had good results indicating the developed model can really predict the physical process of dam breach or levee breaching. In particular, the modeled headcut profiles are very close to those measured. The developed model is embedded in the graphic user interface of the CCHE2D model, making applications of the model very easy.
