Abstract: The accuracy of a model output is, to a large degree, dependent upon the quality of the input data sets including their spatial and temporal resolution. Among those input data sets, precipitation is one of the most important because of its influence on the hydrological model's performance (defined as agreement between measured and simulated values) and its role in determining surface hydrologic processes. Rainfall data are often obtained from rain gage networks, which sometimes may not cover the study area. Usually, precipitation data from the nearest gage stations are used to represent the study area for model hydrological simulations. However, occasionally unusual meteorological conditions can make it necessary to consider precipitation data from gages as far away from the study watershed as the next county. The watershed south of the lake was within 10 miles of two National Oceanic and Atmospheric Administration National Climatic Data Center (NOAA NCDC) precipitation gauges on the north side of the lake, but for year 2010 the SWAT simulated flows using either of these gages as precipitation input data lacked correlation to flows observed at a United States Geology Survey (USGS) gauge on Chickasaw Creek. Due to 2010 being an unusually wet year, an assumption was that additional NOAA NCDC gauges were needed to capture the precipitation events occurred in the watershed; a particular storm occurred in the watershed may be affected by high variability of storm directional paths and variable amounts of rain/snow. By considering additional precipitation gauges within 35 miles of the watershed boundary, model performance as measured by R-squared correlation improved significantly. The nearby precipitation gauges essentially showed no correlation at a coefficient as low as 0.03 for year 2010, but using a combination of the additional gauges to capture the majority of precipitation events raised the coefficient to 0.60 for the same year.

Keywords: Precipitation; Grand Lake St. Marys Watershed; SWAT model; Runoff simulation

INTRODUCTION

The process of transformation of rainfall into runoff over a watershed is very complex, highly non-linear, and exhibits both temporal and spatial variability. Many models have been developed to simulate this process and Soil and Water Assessment Tool (SWAT) is one of these. No matter how complicated a model in simulating this process, the accurate representation of precipitation over the watershed is critical in obtaining the accurate runoff simulation and its transported pollutants.

Rainfall is commonly measured using a rain gauge, which is simply an instrument that is designed to measure the amount of rain that reaches the ground surface during a storm. Rain gauges are considered the most traditional method for measuring rainfall. They have been used historically to provide rainfall quantities and rates at a single point in space. As any measurements, errors can be induced during the measurement processes. One of the common and serious sources of errors in rain gauge measurements is wind-induced error. Another

common problem with rainfall gauge measurements is missing records. This is due to the high probability of gauge mechanical and electrical failures and is also caused by erroneous recording and publishing of rainfall measurements. As a result of measurement error and missing records, researchers and engineers often have to work with incomplete rainfall data from stations where rainfall records might be missing for a day or several days or rainfall data with measurement errors. This will limit most types of rainfall analyses such as calculation of water budgets, determining maximum rainfall intensities, and estimation of area-average rainfall intensities/rainfall amounts.

While rain gauges provide rainfall measurements at individual points, it is more of interest for hydrologic modelling to know rainfall amounts over an area, such as a small drainage basin or a watershed. Usually, the point measurements located in the watershed are assigned to the entire watershed if there is only one rainfall gauge available. The rainfall measurements from the closest rainfall gauge would be assigned to the watershed if there is no rain gauge available in the watershed. If there are more than one rain gauges available in the modelling area, techniques have been proposed to estimate area-average rainfall over an area from point measurements. The most commonly used approaches are based on weighted averaging of rainfall measurements from individual gauges that are located within or close to the area of interest. The Thiessen Polygon method is the most commonly-used method for estimating area-average from point measurements. The weight of a certain station is estimated based on its relative sub-area within the total area of interest. Are rainfall amounts over an area estimated from point measurements representative of the actual amount that happened over that area? How does one get an accurate rainfall estimate over an area based on point measurements (number of point measurements and distance of the point measurement to the interested area)? The overall objective of this study is to explore if common ways of area rainfall estimation provide representative rainfall values for a watershed through comparing SWAT model runoff simulations with field runoff observations.

METHODS AND PROCEDURES

Study Area and Its Background Information: Grand Lake St. Marys is located in Mercer and Auglaize County, northwestern Ohio (Figure 1) and is a very large size lake for its relatively small contributing watershed. The surface area of the lake comprises 17.5 percent of the overall watershed, and much of the remaining watershed is under agricultural production. There are multiple tributaries to the lake within the watershed, with the three largest tributaries making up 63% of lake's upstream drainage. Corn and soybeans are major crops. Other crops include alfalfa (8.5% of the watershed), and winter wheat/ Kentucky bluegrass (6.4% of the watershed) and hay (6.3% of the watershed). Due to the small acreage of farm land available in the watershed, many farmers own animal feeding operations to make a living and sustain local economy.

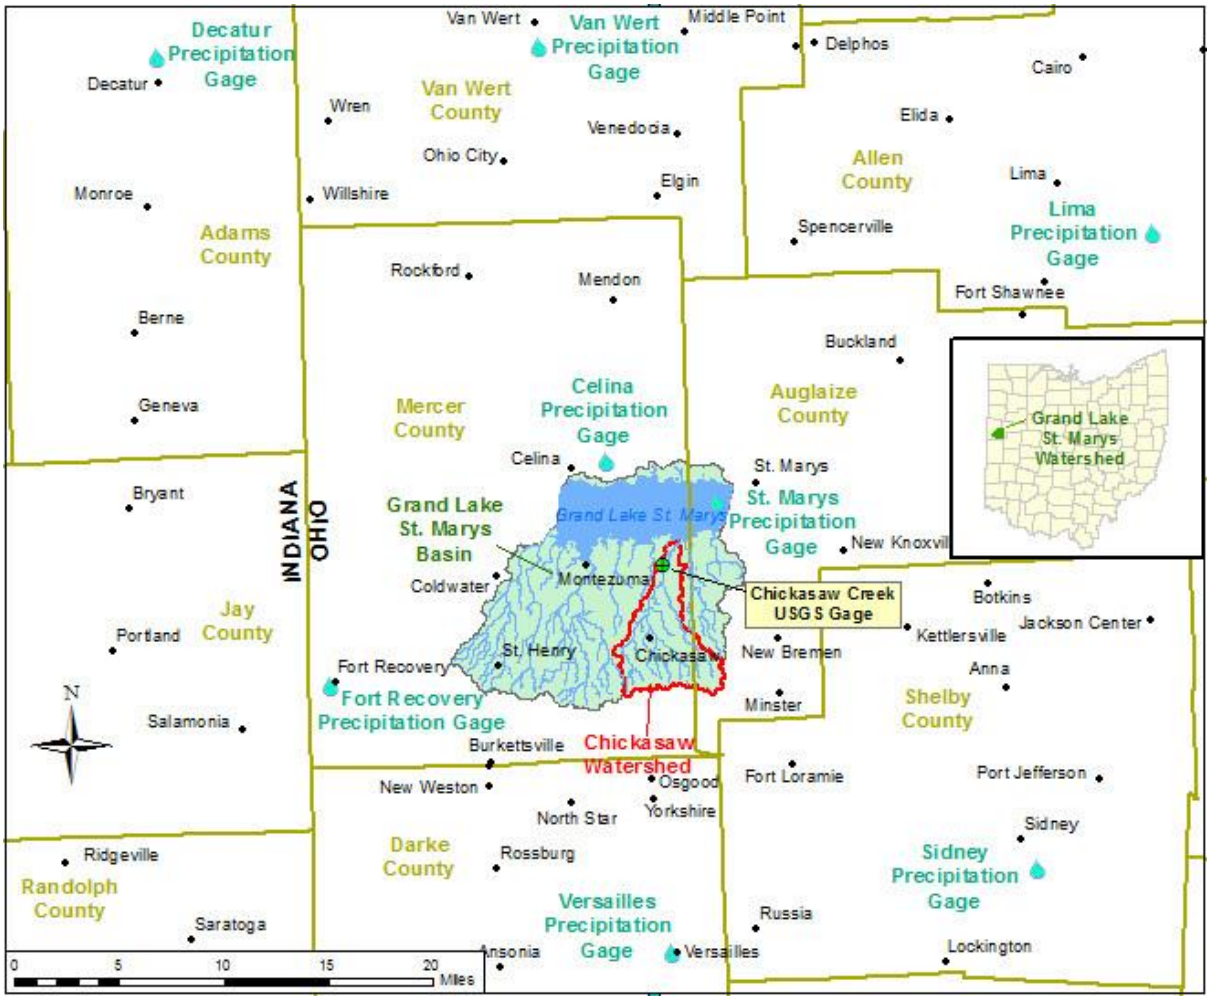

Figure 1 Locations of rural and municipal areas, USGS monitoring gages, and weather stations in the Grand Lake St. Marys Watershed, Mercer and Auglaize County, OH, USA

Grand Lake St. Marys (GLSM) is experiencing toxic levels of algal blooms resulting from phosphorus input from agricultural runoff. Since the outbreak of harmful algae bloom in the summer of 2010, the Ohio Environmental Protection Agency (OEPA) solicited potential short-term remedies from vendors and other interested parties. Thirty-four potential remedies were submitted in response to this solicitation. The submitted potential remedies were reviewed, evaluated and discussed by a technical committee comprised of six environmental scientists. In the absence of other information and from a strictly scientific basis, no single remedy (or proposed combination of remedies) was identified as leading to a probable effective solution. Notably, none of the proposed remedies has been tested on a scale as large as GLSM and therefore the effectiveness of those remedies when applied to GLSM cannot be predicted. The conclusion from this review is that none of the 34 remedies have a better chance for success than the application of alum alone. However, the committee did not believe that the use of alum alone, or any single management practice by itself, could improve the water quality of GLSM except perhaps only over the short term. The most important message from this committee is that the overriding need to improve the lake water quality is to improve the management of the GLSM watershed as a system. Any proposed remedies, however effective they might be in the short term, would be diminished or be completely negated by the continued input of phosphorus, other nutrients and sediment via tributaries. The goal of management of the GLSM watershed as system is implementing

management actions designed to improve the wellness and resiliency of the overall watershed. There is some urgency for the OEPA and EPA Region 5 to seek strategies on both short and long term solutions so as to improve the management of GLSM and its surrounding watershed with respect to sustainability and resilience. One of the questions concerning the longer term restoration of water quality for Grand Lake St Marys is if conservation practices can be adopted to limit nutrient loadings to the lake. The SWAT model is designed to simulate long-term impacts of land use and management on water, sediment and agricultural chemical yields at various temporal and spatial scales in a watershed (Arnold et al., 1998; Arnold and Fohrer, 2005; Gassman et al., 2007). It was chosen to evaluate the impact of conservation practices on nutrient loadings to the lake for this project. Before a model can reasonably simulate nutrient loadings, the runoff has to be reasonably simulated, which would be the first step before a model can be used to simulate nutrient loadings. The first step of the project is to evaluate SWAT runoff simulations.

Since daily flow was monitored at USGS 402913084285400 (Latitude 40°29'13" and Longitude 84°28'54") Chickasaw Creek at St. Marys Ohio (http://waterdata.usgs.gov/usa/nwis/uv?402913084285400). The Chickasaw Creek watershed with a drainage area of 16.4 square miles (42 square kilometers) was chosen as a pilot study.

SWAT Model Description: The Soil and Water Assessment Tool (SWAT) model is a continuous, long-term, physically based semi-distributed model developed to assess impacts of climate and land management on hydrological processes, sediment loading, and pollution transport in watersheds (Arnold et al. 1998). In the SWAT model, a watershed is divided into subwatersheds or subbasins, which are further partitioned into a series of hydrological response units (HRUs). HRUs are uniform units that share unique combinations of soil and land use. Hydrological components, sediment yield, and nutrient cycles are simulated for each HRU and then aggregated for the subbasins.

The hydrological cycle simulated in SWAT is based on the water balance equation:

$$SW_t = SW_0 + \sum_{i-1}^{t} (R_{day} - Q_{surf} - E_a - w_{seep} - Q_{gw})$$

where, SW_t and SW_0 are the final and initial soil water content on day i (mm H_2O), t the time steps on day i, R_{day} the rainfall that reaches the soil surface on day i (mm), Q_{surf} the surface runoff on day i (mm), E_a the evapotranspiration on day i (mm), w_{seep} the interflow on day i (mm), and Q_{gw} is the baseflow on day i (mm) (Neitsch et al. 2005).

The simulated hydrological components include evapotranspiration (ET), surface runoff, percolation, lateral flow, groundwater flow (return flow), transmission losses, ponds, and water yield (Arnold et al. 1998). Evaporation and transpiration are simulated separately in SWAT. Evaporation is computed using exponential functions of soil depth and water content and transpiration is estimated using a linear function of potential evapotranspiration (PET) and leaf area index. Three methods can be used to estimate PET: Hargreaves, Priestley-Taylor, and Penman-Monteith. The Pennman-Monteith method was used to calculate PET in this study. Surface runoff is simulated using a modification of the Soil Conservation Service (now the Natural Resources Conservation Service) Curve Number (SCS-CN) method (USDA, 2004) with daily rainfall. Curve number values used for runoff estimation are based on soil type, LULC, and land management conditions and are adjusted according to soil moisture conditions (Arnold et al. 1993). Percolation is estimated using the combination of a

storage routing technique and a crack-flow model (Arnold et al. 1998). The lateral flow is estimated simultaneously with percolation using a kinematic storage model. The groundwater flow (baseflow) into a channel is calculated based on hydraulic conductivity of shallow aquifer, distance from subbasin to main channel, and water table height. Transmission loss, amount of water removed from tributary channels by transmission, is calculated using procedures described in the SCS Hydrology Handbook. The canopy interception is estimated based on the canopy storage which is a function of vegetation type. Water yield, total amount of water leaving the HRU and entering main channel, is equal to surface runoff plus lateral flow and baseflow, and minus transmission loss and pond abstractions (Neitsch et al. 2005).

Model Input Preparation

The basic SWAT model inputs include a digital elevation model (DEM), Cropland Data Layer, and the Soil Survey Geographic Database (SSURGO) data. Other inputs include daily weather data and field management practices including planting, harvesting, fertilization and tillage information. In addition, streamflow data are also needed for model calibration and validation. The different datasets and their sources are given in Table 1.

The source of the Digital Elevation Model (DEM) data used for the SWAT modeling effort on GLSM was downloaded from USDA Data Gateway. The data is part of the National Elevation Dataset (NED), of which USGS is the original data source. The best horizontal resolution available was 3 meter grid cells, or one-ninth arc second, and this resolution of NED was used in SWAT modeling of GLSM tributary watersheds. Elevation data were converted to ArcGrid format, as required for input elevation data into SWAT. More information about NED can be obtained at http://ned.usgs.gov.

Table 1 Summary of Datasets and their sources used for building the model.

Datasets	Source
Elevation	United States Geological Survey (USGS)
Precipitation	National Climatic Data Center (NCDC)
Soil Classification	Soil Survey Geographic Database (SSURGO)
Landuse	Cropland Data Layer (USDA NASS)
Streamflow	United States Geological Survey (USGS)
Water quality	United States Geological Survey (USGS)

The Cropland Data Layer (CDL) originating from the USDA National Agricultural Statistics Service was used as the input land use/land cover dataset for SWAT modeling of GLSM tributary watersheds. Although SWAT can accommodate other land cover datasets such as the National Land Cover Dataset (NLCD), the CDL was used as it is ideally suited for watersheds that are largely agricultural in land use. The CDL includes information on what crops were planted in a given year on a field level, whereas the NLCD treats cropped fields collectively as a generalized single land use type, regardless of crop type. For modeling efforts in GLSM, the 2009 (56-meter pixel resolution), 2010 (30-meter pixel resolution), and 2011 (30-meter pixel resolution) versions of CDL were used. More information about CDL can be obtained at: http://www.nass.usda.gov/research/Cropland/metadata/meta.htm. As shown in Table 2, Chickasaw watershed is dominated by agricultural crop lands, where corn and soybeans are practiced over 50% of the entire watershed. The entire area of the

watershed is 11960 acres (4840 ha.) and the area draining to the USGS gauges is 10625 acres (4300 ha.).

Table 2 Summary of land use in the Chickasaw watershed

Land use	Area (Acres)	% of watershed area
Corn	4702	39.5
Soybean	2898	24.3
Alfalfa	1010	8.5
Winter wheat/ Kentucky bluegrass	758	6.4
Hay	748	6.3
Forest	384	3.2
Pasture	66	0.6
Urban	342	2.9
Water	11	0.1
Other crops*	1041	8.7
Total	11960	100

*other crops include various crop rotations.

The dominant soil associations in the Chickasaw watershed include Blount, covering 42% of the Chickasaw watershed with 4 soil layers; Pewamo, covering 32% of the watershed with 3 soil layers; and Glynwood, covering 20% of the watershed with 3 soil layers. These 3 soil types altogether comprise 93% of the watershed. The remaining 7% of the watershed is split among 13 soil types, and none of which exceed 3% of the watershed (most are below 1%). The major soil properties are listed in Table 3. Based on the Mercer County Soil Survey, the Blount is somewhat poorly drained, Pewamo is very poorly drained and Glynwood is moderately well drained (http://soils.usda.gov/survey/online_surveys/ohio/mercerOH1979/Mercer.pdf).

Table 3 Soil physical information from SSURGO used in SWAT modeling

Soil Type	Blount				Pewamo			Glynwood		
Layer	1	2	3	4	1	2	3	1	2	3
Depth from the soil surface (mm)	254	635	813	1524	330	940	1524	229	584	1524
Organic carbon content (% soil weight)	1.45	0.29	0.15	0.15	4.36	1.45	0.48	1.16	0.39	0.13
Moist bulk density (g/m^3)	1.45	1.55	1.6	1.73	1.45	1.55	1.6	1.38	1.58	1.75

Weather Data: Daily weather data hosted by the National Oceanic and Atmospheric Administration (NOAA) National Climate Data Center (NCDC) were used to serve as input into the SWAT model. Based on interviews and recommendations from local people, the lake itself appears to have an effect on approaching storms, resulting in different precipitation patterns on the south side of the lake where the Chickasaw watershed is located and on the north side of the lake where two weather stations which are the closest to the watershed are located (in Figure 1). In addition, meteorological observations indicate that the courses that storms travel can be highly variable, especially in relatively wet years. Thus, instead of the

usual modelling approach of just going with the closest gages, precipitation information from various directional precipitation gauges within 35-mile radius from the watershed boundary were collected in the hope of capturing precipitation coming from all directions of the watershed. This was done to explore the possibility of finding the representative precipitation pattern in the watershed.

SWAT Model Simulations and Performance Evaluation: Based on the DEM and selected outlets, the watershed was delineated into subbasins. Subsequently, the subbasins were partitioned into homogeneous units (HRUs), which shared the same land use, soil type, and slope range. In this study, a total of 30 subbasins were delineated, among which 27 subbasins drain to the USGS flow gauge station. HRUs were defined by applying a 10% threshold for land use, soil type, and slope range so any of these components that had a use/type/range less than 10% of a particular subbasin got eliminated from influencing the model result. The net effect of eliminating these minor influences was to significantly improve the efficiency of the model while not significantly affecting the result. Each HRU represents a unique combination of land use, soil type, and slope range, and collectively they provide much of the information needed by the SWAT model to characterize the watershed.

Model simulations were first performed using SWAT default values with precipitation data from the closest gauge (St. Marys). Next, model simulations were performed using SWAT default values with one precipitation gauge at a time for the remaining precipitation gauges from Figure 1. Finally, a hybrid precipitation file was developed to capture precipitation pattern of the watershed by using data from a single gauge to cover a range of consecutive dates based on which gauge best simulated actual precipitation events in term of timing and magnitude within that particular date range. To evaluate the model performance, four statistical measurements were used (Moriasi et al., 2007) including the coefficient of determination (R^2), Nash-Sutcliffe efficiency (NSE), RMSE-observations standard deviation ratio (RSR) and percent bias (PBIAS).

RESULTS AND DISCUSSION

Results from the Closest Precipitation Gauge: The first model simulation was performed using the SWAT default values and precipitation from the closest weather station, St. Marys precipitation gauge in which the missing records were substituted with the precipitation records from the Celina Precipitation gauge (Figure 1). For those two years of the model simulation for which observed flow data were available (2009 and 2010), the R^2 is 0.37 and 0.03 for 2009 and 2010, respectively (Figure 2). The R^2 of 0.37 for 2009 is within the acceptable range for an uncalibrated model simulation, but the R^2 of 0.03 for 2010 is unacceptable. Furthermore, the hydrographs in Figure 2 below show that the simulation did a fairly good job aligning with observed flow peaks for 2009, whereas the simulated peaks essentially aligned very poorly with observed peaks for 2010.

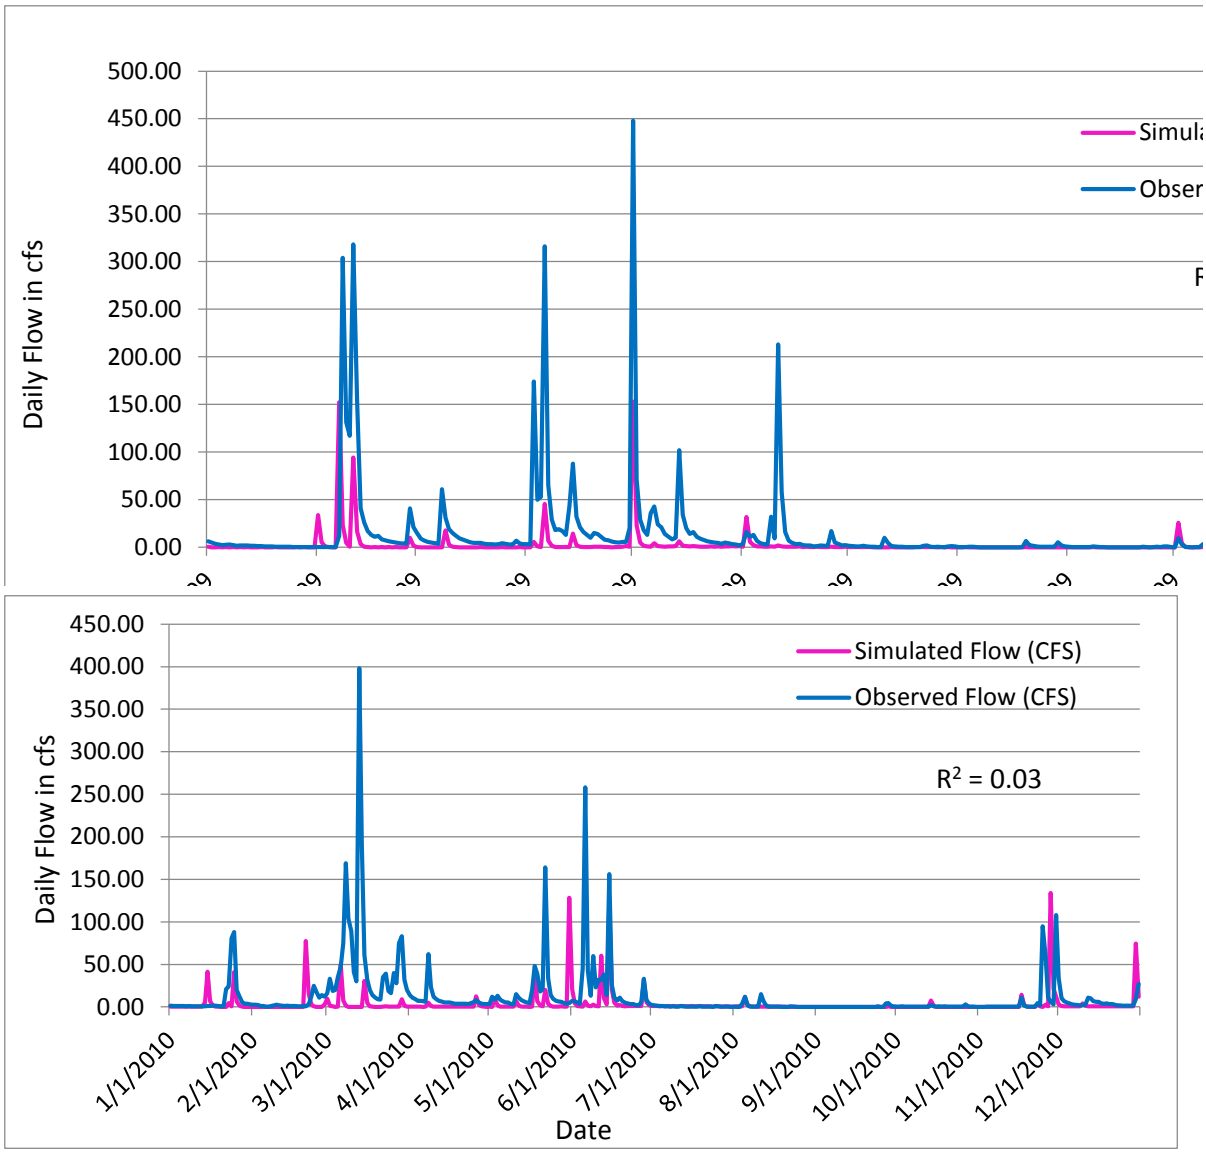

Figure 2 Flow hydrographs for initial uncalibrated model run with SWAT default values using precipitation data from St. Marys precipitation gauge.

The very poor correlation for Year 2010 of the model suggests that improvements to the model might be very difficult. After having tried model developers' recommendations for applying seasonal adjustments to the curve number for the Chickasaw watershed, it was found, unfortunately, very little improvement was achieved on model's performance. The poor correlation between simulated flow and observed flow led us to question the credibility of climate data. How well did the input precipitation dataset at the St. Marys weather station represent actual precipitation conditions in the watershed? The flow correlation coefficients were so low, especially for year 2010 (Figure 2), it seemed that the NOAA precipitation gage used did not match up with actual precipitation in the Chickasaw watershed based on the near-zero correlation of the simulated hydrograph comparing with the observed hydrograph for 2010 (Figure 2). Although the St. Marys precipitation gauge is only a few miles away from the Chickasaw watershed, the zero correlation of the hydrograph indicates that the precipitation gage is totally irrelevant to the flow generated in the watershed.

Results from other Precipitation Gauges: Additional SWAT simulations were performed using the SWAT default values and precipitation data from each of the weather gauges displayed in Figure 1. Table 4 shows the R^2 (correlation coefficients) for each gauge:

Table 4 SWAT model simulations with precipitation data from different precipitation gauges

R-squared	St. Marys	Celina	Decatur	Van Wert	Lima	Sidney	Versailles	Ft. Recov
Year 2009	0.37	0.50	0.17	0.37	0.17	0.14	0.02	0.06
Year 2010	0.03	0.07	0.03	0.07	0.02	0.23	0.04	0.06

As shown in Table 4, using precipitation data from the Sidney precipitation gauge to the southeast of the Grand Lake St. Marys watershed in neighboring Shelby County showed great improvements in correlating daily simulated and observed flows for the year of 2010. Further comparisons on a monthly basis gained more insights on weather patterns of the watershed; for example, in June of 2010, an R^2 of 0.59 was obtained using precipitation data from the Sidney precipitation gauge comparing an R^2 of 0.19 from the St. Marys precipitation gauge (Figure 3). It may be concluded that the first flow peak in this month was caused by a shared precipitation event occurring at both the watershed and the Sidney gauge.

The increased R^2 for June 2010 using precipitation data from the Sidney precipitation gauge is very encouraging, demonstrating that considering a more distant precipitation gauge from the modeled watershed can be promising in capturing the precipitation pattern of the watershed. The hydrograph above demonstrates that the more distant Sidney precipitation gauge might better represent precipitation of the watershed, at least for the first half of June in 2010. However, how well St. Marys precipitation gauge represents the second half of the month can't be overlooked, suggesting that weather experienced at the St. Marys precipitation gauge might better represent the precipitation pattern of the watershed for this time period.

This raised the question: what would be the best way to construct a precipitation file to represent the precipitation happened over the modeled watershed? A precipitation file covering the years 2009 and 2010 was constructed using observed precipitation from all 8 precipitation gauges (Figure 1). For the month of June 2010, it seemed that the Sidney precipitation gauge best represented most of the first half of June, and the St. Mary's precipitation gage represented the second half. Figure 4 illustrates the result of SWAT simulation with such a hybrid precipitation input file.

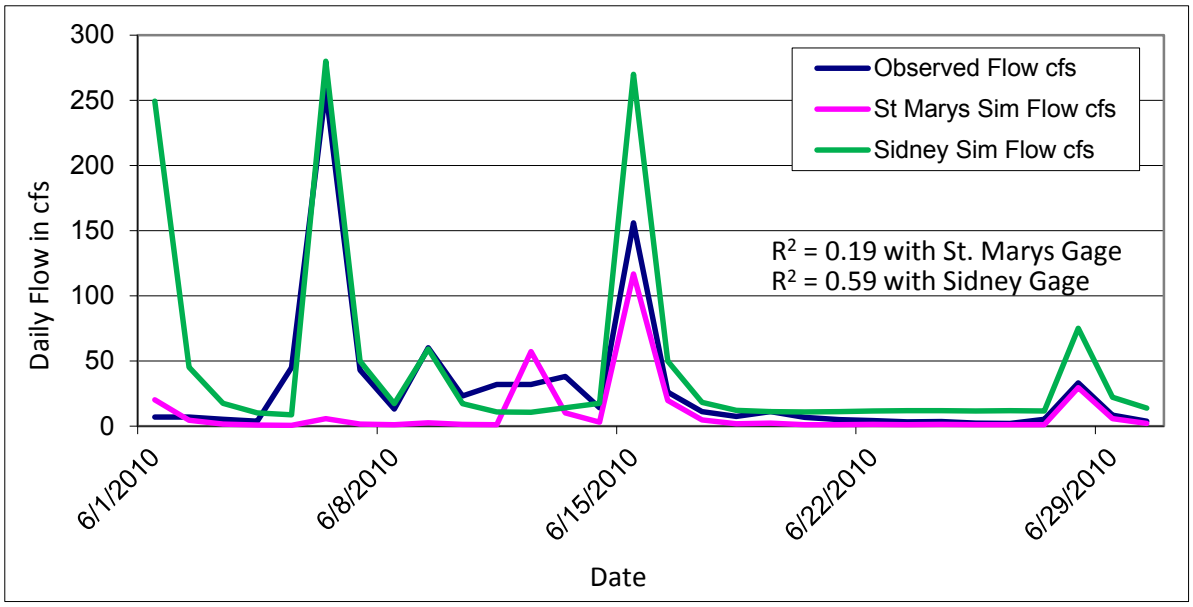

Figure 3 Simulated flow hydrographs using precipitation data from the Sidney precipitation and the St. Marys precipitation gauge vs observed flow hydrograph for June of 2010.

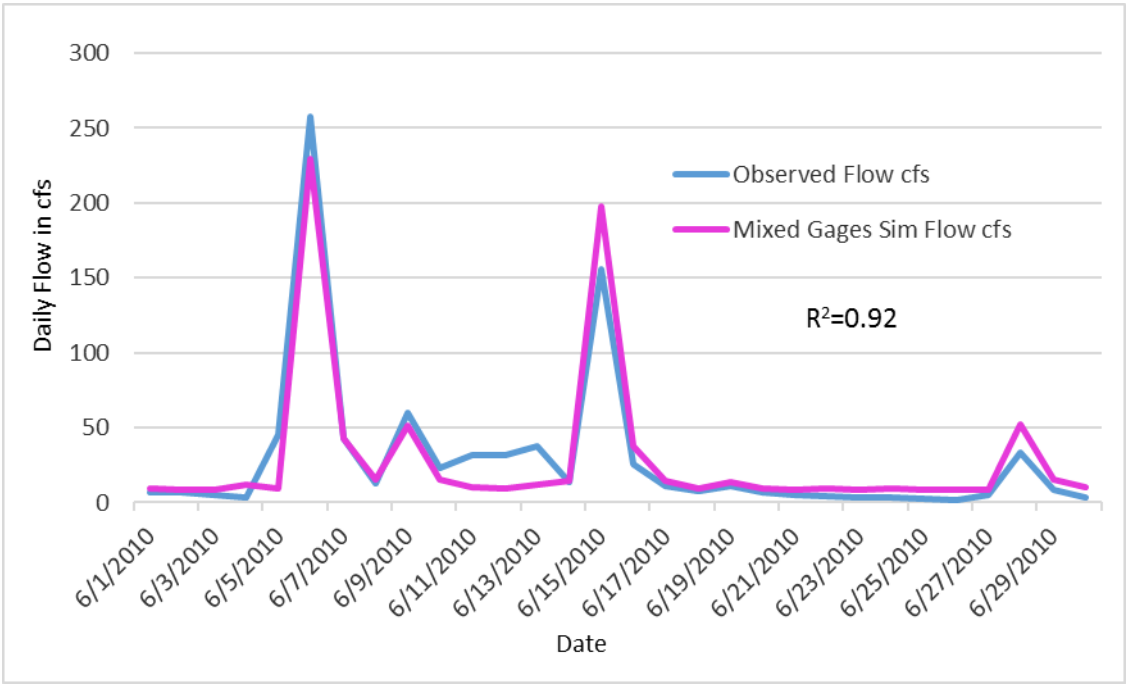

Figure 4 Simulated flow using a hybrid precipitation data from the Sidney precipitation and the St. Marys precipitation gauge vs observed flow for June of 2010.

The excellent result and correlation displayed in Figure 4 provided evidence that constructing a hybrid file from additional precipitation gauges nearby the watershed is necessary to represent the precipitation pattern of the watershed. St. Marys weather data would do a good job at picking up on weather systems coming out of the north, but adding other gages from all directions might pick up weather from all directions.

The result of using a hybrid precipitation input file constructed using a mix of observed daily precipitation data from all 8 precipitation gauges are shown in Table 5. The R^2 of 0.60 between model simulation and field observation displayed in Table 5 can be considered as excellent for an uncalibrated model simulation. The 2010 overall correlation using hybrid precipitation file increased to 0.60 from the dismal 0.03 using just the St. Mary precipitation data and 0.23 using just the Sidney precipitation data.

Table 5 Comparison of model performance using a hybrid precipitation data from all 8 precipitation gauges vs using only St. Marys Weather Station for water year of 2009 and 2010.

Simulated vs. Observed Flow R-squared Correlation	Using St. Marys Weather Station Precipitation Data	Using Hybrid Precipitation Data from All 8 Stations
2009	0.37	0.51
2010	0.03	0.60

Because the results speak so strongly for themselves, a meteorological perspective was sought out. The question of considering precipitation events from multiple gages as far away from the modeled watershed as the next county was posed to someone with a background in meteorology. The meteorologist considered it perhaps a trick question because from a meteorology perspective, it's absolutely appropriate to consider weather data from multiple gages when considering weather for a multi-county area commensurate in size to a major metropolitan area. It's what happens every evening in weather broadcasts in metro areas, or to quote the meteorologist above, "of course it's okay to consider precipitation gages in the next county!"

CONCLUSIONS

Accurate estimation of rainfall amount over a watershed is critical for getting accurate runoff simulation. The common practice of assigning the point measurements located in the watershed to the entire watershed may not represent the precipitation pattern over the watershed. This study shows that a watershed precipitation pattern could be influenced by precipitations from all directions. The closest precipitation gauge, the St. Marys on the north shore of Grand Lake St. Marys experienced a quite different weather pattern than the modeled Chickasaw Creek watershed, which is on the south side of the lake. Thus, it is important to construct a hybrid precipitation file from all 8 precipitation gauges within 35-mile radius from the boundary of the watershed.

Abstract: The establishment, growth, and decline of riparian vegetation within impacted riverine systems is a growing challenge due to the increasing priority of maintaining ecosystem function while sustaining water supply and providing flood protection. A quantitative two-dimensional model is presented for predicting the interactions between flow and vegetation that is currently under development at BOR. The model is based upon the SRH-2D package, which contains a two-dimensional flow and mobile bed sediment transport model. The new SRH-2DV package incorporates a module that simulates the effect of vegetation on river and floodplain hydraulics through spatially distributed roughness. The coupled vegetation-hydraulic solver uses measured vegetation parameters to calculate a spatially-distributed, dynamic Manning's roughness coefficient while simulating the hydrodynamics of the system. Field and modeling work focused on a reach of the San Joaquin River near Fresno, California. Simulation results using the vegetation module are compared with measured water surface elevation and results from a manually-calibrated SRH-2D hydraulics model. We present initial simulation results from application to simple case studies and discuss the utility of expanding the predictive capabilities for application within more complex systems. Results from SRH-2DV will aid the science, economics, and policy of establishing environmental flows by addressing questions regarding the physical interaction of flow and vegetation in rivers and floodplains.

INTRODUCTION

The survival of riparian vegetation within managed river systems is a growing challenge due to the increasing priority of maintaining or restoring ecosystem function while balancing the need for water supply and flood protection. Riparian vegetation plays many important roles in the hydraulic, geomorphic, and ecologic processes of river systems (Naiman, 2010; Gurnell 2014). The ecological services provided by riparian vegetation are beneficial to both the river system and the human population surrounding the system (Groffman et al., 2003). Examples of these services include soil retention (Waters 1995), water quality improvement (Barling and Moore 1994), nutrient cycling (Dahm *et al*. 2002; Hill 1996), habitat provisioning (Keller *et al*. 1993; Stauffer and Best 1980), and flood damage mitigation (Brauman *et al*. 2007). The ecological services associated with riparian areas have been severely degraded in many river systems as the result of river engineering, floodplain development, and watershed development (Sweeney et al., 2004).

At the local scale, riparian vegetation increases flood risk by reducing effective flow areas and increasing hydraulic roughness (Rhee et al., 2008; Wilson et al, 2005; Green 2005). Reducing flow resistance in areas sensitive to flooding has historically been performed by vegetation removal (Darby, 1999; Masterman and Thorne 1992). At the watershed scale, however, vegetation-induced roughness has been

shown to enhance flood wave attenuation (Anderson 2006). Properly characterizing hydraulic roughness at the local scale is important for understanding hydrodynamic heterogeneity at the reach scale, including velocity and shear stress distributions and momentum exchange (Vermaas et al., 2011; Proust et al., 2013; Stone and Hotchkiss, 2007).

Vegetation resists flow due to drag forces on discrete elements and nonlinear interactions between multiple elements (Nepf, 2012). Flow resistance in natural systems is often characterized through the estimation of a dimensionless (e.g., Darcy friction factor *f*) or dimensional (e.g., Chezy coefficient *C* and Manning's *n*) roughness parameter that is used to model the hydraulics. Roughness parameters derive from a combination of empiricism and hydrodynamic theory and are generally interrelated deterministically. The roughness of a vegetated channel is generally a function of both the characteristics of the vegetation (e.g., size, density, flexibility, leaf area) and the flow (depth and velocity; due to streamlining effects). For computational convenience, however, roughness has historically been assumed independent of hydraulic conditions. Chow (1959) produced a list of bracketed roughness values corresponding to various vegetated flow types. Thompson & Roberson (1976) presented an analytical method for predicting roughness due to a flow through vegetation modeled as rigid or flexible cylinders. The method depends on estimation of a drag coefficient, stem spacing and diameter, and flexural rigidity. Kouwen & Li (1980) developed an iterative approach for calculating roughness as a function of vegetation rigidity, and estimated plant deflection in response to forcing exerted by the flow. The Kouwen & Li (1980) approach is generally applicable to grasses, and the authors provid a table with stiffness values for a large variety of grass types. Kouwen & Fathi-Moghadam (2000) describe methodology to estimate resistance due to coniferous trees in open-channel flow by modifying a previously existing model (Fathi-Moghadam & Kouwen, 1997) in order to account for variations in the flexibility between species. The authors obtained species-specific parameters for the equations by conducting intricate laboratory and field experiments to measure drag force on model trees. Darby (1999) presents a simplified cross-section based model for predicting roughness associated with sediment or vegetation. The approach applies one of six different empirically calibrated flow resistance equations at each computational node. An equation similar to the Kouwen & Li (1980) approach is used for flexible vegetation, while an equation similar to the Thompson & Roberson (1976) approach is used for nonflexible vegetation. A procedure for estimating roughness due to flow through stiff or flexible woody vegetation is described by Jarvela (2004). The method, limited to emergent vegetation, incorporates leaf area index (LAI) to account for the effect of leaf distribution on drag resistance. The author also presents (Jarvela, 2005) an analysis of flow structure over submerged flexible vegetation with a focus on velocity profiles and turbulence characteristics. Baptist et al. (2007) derive a Chezy-type formulation for calculating resistance due to submerged or emergent vegetation. The representative resistance coefficient includes contributions from the bed roughness, form drag from flow through the vegetation, and shear due to the velocity profile above the vegetation. Hession and Curran (2013) provide a literature review of trends and research in the topic of vegetation-induced roughness in fluvial systems; the authors discuss the spatio-temporal complexity of processes related to vegetation-flow-sediment interactions. Abu-Aly et al. (2014) present the results of two-dimensional hydraulic modeling using roughness derived from LiDAR. The authors demonstrate the effects of spatially-distributed roughness on hydraulics at the local and reach scale, and underscore the importance of systematically defining roughness at the resolution of the computational grid. The challenge of capturing the complexity of effects due to flow through a broad

range of vegetation types is reflected by the diversity of predictive methods developed during more than five decades of research.

Described herein is a deterministic computational tool for dynamically modeling spatially-distributed flow and vegetation interactions. An existing two-dimensional hydraulic and sediment transport model (SRH-2D) developed at the Bureau of Reclamation (BOR) Technical Service Center (TSC) is used as a basis for the new model development (SRH-2DV). The new SRH-2DV package iteratively computes hydraulic roughness due to vegetated flow as a function of the local hydraulics and vegetation characteristics. The algorithms and parameters applied are drawn from a combination of published literature and collaborative research. Results from SRH-2DV will aid the science, economics, and policy regarding riparian ecosystems by addressing uncertainties such as what impact riparian vegetation has on local flood conditions, how vegetation can be incorporated into restoration projects without increasing flood risks, and how management actions may impact habitat for endangered and threatened species.

METHODS

Model Development: The existing SRH-2D flow solver (Lai, 2010) is used as the computational base for the new SRH-2DV coupled flow and vegetation model. Hydraulic variables are computed by solving the depth-averaged dynamic wave equations using a finite volume numerical method. Solutions can be computed over an unstructured hybrid mesh (Lai, 1997; 2000), and the solver includes a seamless wetting-drying algorithm that is applied at each time step. With appropriate boundary conditions, constant or varying discharge flows may be simulated. The solver can compute subcritical and supercritical flow conditions without special treatment.

Bed shear stresses τ_{bx} and τ_{by} are calculated by the SRH-2D hydraulic solver using the Manning's roughness equation as follows:

$$\begin{pmatrix}\tau_{bx}\\ \tau_{by}\end{pmatrix} = \rho C_f \begin{pmatrix}U_x\\ U_y\end{pmatrix}\sqrt{U_x^2+U_y^2}; \quad C_f = \frac{gn^2}{h^{1/3}} \tag{1}$$

where ρ is water density, U_x and U_y are the x and y velocity components, g is gravity, h is flow depth, and n is the Manning's roughness coefficient. The user-specified Manning's n is generally spatially-distributed yet independent of the computed hydraulic variables, and is a primary "tuning" parameter used during model calibration.

In the SRH-2DV vegetation model, the solver was modified to calculate dynamic Manning's n values at each cell in the computational mesh due to vegetated flow. The approaches of Baptist et al. (2007) and Järvelä (2004) were implemented in the model; the required input parameters could readily be measured in the field and applied within the modeling framework. Additional methods can be built into the modeling framework based on availability of supporting field data and will be investigated in future research.

The Järvelä (2004) approach is valid for emergent, stiff and flexible woody vegetation. The authors proposed the following equation to calculate the friction factor f,

$$f = 4C_{dX}\mathrm{LAI}\left(\frac{U}{U_X}\right)^X \frac{h}{H} \tag{2}$$

where $C_{d\chi}$ is a species-specific drag coefficient, LAI is leaf area index (defined as one-sided leaf area to projected ground surface ratio), U is the flow velocity magnitude, U_χ is a reference velocity (set to 0.1 m/s for this study), and χ is a species-specific exponent (set to -0.57 for this study). The ratio of h (water depth) over H (plant height) is a scaling factor to account for partial submergence ($h<H$). The parameters LAI and H are measured in the field as described below. The variable flow velocity and water depth are obtained from the coupled hydraulic solver, where U is calculated as the resultant of the horizontal velocity components at each mesh cell. The value of the drag parameter $C_{d\chi}$ was based on prior work done by Fathi-Moghadam (1996) and then varied on a species-specific basis in order to calibrate the model response. Thus the friction factor is a function of spatial variation in the plant parameters and spatial and temporal variation in the hydraulic variables. In practice, the Manning's n is used by the hydraulic solver (Equation 1) and is computed from the friction factor as

$$n = h^{\frac{1}{6}}\sqrt{\frac{f}{8g}} \tag{3}$$

Roughness can alternatively be calculated using the Baptist (2007) approach according to

$$C_r = \sqrt{\frac{1}{(1/C_b^2) + (C_d mDH/2g)}} + \frac{\sqrt{g}}{\kappa}\ln\left(\frac{h}{H}\right) \tag{4}$$

where C_b is the Chezy bed coefficient, C_d is the drag coefficient, m is plant density, D is stem diameter, H is plant height, κ = 0.41 is the von Karman constant, and h is the flow depth. Thus the composite resistance coefficient C_r includes the effects of bed resistance, form drag of flow through the vegetation, and the boundary layer formed above the vegetation. For emergent vegetation, the logarithmic term in Equation 4 is dropped since the resistance is only a function of the bed roughness and vegetative form drag. For dense vegetation, the contribution of the bed roughness term may be considered insignificant compared to the contribution of the vegetative drag term (C_b =80 for this study). The water depth h is obtained from the coupled hydraulic solver and the parameters m, D, and H are measured in the field. The drag coefficient C_d was initially set to unity (Baptist, et al., 2007) and then varied on a species-specific basis in order to calibrate the model response. The resistance in Equation 4 is converted to Manning's n as

$$n = \frac{1}{C_r}h^{1/6} \tag{5}$$

Study Reach: The SRH-2DV vegetation model was tested by simulating the hydraulics in a reach of the San Joaquin River west of Fresno, California located between Friant Dam and the Chowchilla Bifurcation structure. This section was selected due to the presence of diverse riparian vegetation types and the availability of pre-existing field data.

Floodplain vegetation in the study reach was classified by Moise and Hendrickson (2002) to have 30 different dominant vegetation classes (Holland, 1986). To further classify woody types, Moise and Hendrickson added a numerical value from 1 to 6 indicating branch density (high to low) based on Hink and Omhart's work (1984). Moise and Hendrickson (2002) found eleven classes that covered 92% of the vegetated area within the study reach: (1) cottonwood riparian of branch density 3; (2) cottonwood riparian low density of branch density 4; (3) and (4) herbaceous, mixed riparian of branch densities 1 and 3; (5) mixed riparian low density of branch density 6; (6) riparian scrub; (7) and (8) willow riparian of branch densities 3 and 4; (9) and (10) willow scrub of branch densities 5 and 6; and (11) willow scrub low density of branch density 6. The vegetation classifications were compiled into a GIS shapefile comprised of polygons delineating the spatial extent of the dominant classes within the study reach.

A computational mesh with boundary conditions was available for the reach from previous hydraulic modeling in support of the San Joaquin River Restoration Project (Dombroski, Greimann, & Gordon, 2012). The existing model was calibrated by comparing simulated water surface elevation to measured water surface elevation at a similar discharge. The Manning's *n* was then manually adjusted in the channel and floodplain areas in order to bring the simulated water surface elevation in better agreement with the measurements. Manually adjusting the Manning's *n* in order to effect the water surface elevation is generally successful in reproducing the gross effect of bed and form roughness; however, the approach includes no explicit treatment of roughness due to vegetation, which limits the capability of the model in predicting vegetative effects.

Empirical Data and Field Work: Development and testing of the SRH-2DV vegetation model was dependent on data reconnaissance in support of the parameterized physical processes. A field study was conducted (Gillihan, 2013) at six 1000 ft^2 sites along the San Joaquin River, producing measurements of vegetation height, stem diameter, stem density, and leaf area index. Vegetation height and stem diameter was measured with a hypsometer (Nikon Forestry Pro Laser) and caliper, respectively. LAI was measured using a photosynthetically active radiation (PAR) sensor (Decagon AccuPAR model LP-80). The field measurement sites were selected as representative samples of the dominant vegetation classes identified by Moise and Hendrickson (2002); the measured vegetation parameters were then applied to all instances of the delineated vegetation classes within the shapefile. An attribute table was constructed to contain the input data required to parameterize the model for each vegetation classification. The shapefile in conjunction with the attribute table defines the spatial distribution of vegetation and corresponding parameters throughout the study reach. The shapefile and attribute table are read directly by the SRH-2DV model and the vegetation information is mapped to the computational mesh over which the hydraulic variables are solved.

Table 1 and Table 2 contain a summary of the parameter values and sources used in the Jarvela (2004) and Baptist (2007) approaches, respectively. Values listed as Variable generally may depend on vegetation class and location, and are used to tune the model response during calibration. Values listed as Measured were taken from the results of the field campaign, and Dynamic indicates quantities calculated by the hydraulic solver that may vary in space and time. The values of fixed parameters are given with reference to a source in the published literature.

For regions within the computational mesh where a vegetation-based roughness was not applicable (e.g., in-channel, no-grow, and anthropogenically disturbed areas) or not physically reasonable, a static value of n=0.035 was assigned by default.

Table 1 Identification of parameters used in the Jarvela (2004) approach for computing hydraulic roughness.

Parameter	Value	Source
C_{dX}	Variable	Model Calibration
X	-0.57	Aberle & Jarvela, 2013
U_x	0.1 m/s (0.328 ft/s)	Aberle & Jarvela, 2013
LAI	Measured	Gillihan, 2013
H	Measured	Gillihan, 2013
U	Dynamic	Hydraulic Solver
h	Dynamic	Hydraulic Solver

Table 2 Identification of parameters used in the Baptist (2007) approach for computing hydraulic roughness.

Parameter	Value	Source
C_D	Variable	Model Calibration
C_b	80	Gillihan, 2013
m	Measured	Gillihan, 2013
D	Measured	Gillihan, 2013
H	Measured	Gillihan, 2013
h	Dynamic	Hydraulic Solver

RESULTS

The SRH-2DV vegetated flow solver was tested by simulating the hydraulics within a reach of the San Joaquin River at flow rates Q = 1100 (31), 2500 (71), 4000 (113), and 7500 (212) cfs (cms). The capability of the hydraulic roughness module in estimating roughness due to vegetation was evaluated by comparing computed Manning's n to manually calibrated Manning's n and by comparing computed water surface elevation to measured water surface elevation at a similar discharge. Also available for comparison is simulated water surface elevation from the manually calibrated model (Dombroski, Greimann, & Gordon, 2012). Figures 1 and 2 show comparisons of water surface elevation results using the Baptist (2007) approach and Jarvela (2004) approach for calculating hydraulic roughness due to vegetation. Also shown is water surface elevation from a simulation using manually calibrated roughness and field measurements of water surface elevation for a similar discharge. The results indicate that the Jarvela (2004) approach, although resulting in under predicted water surface elevation, performs better than the Baptist (2007) approach, and compares favorably with the performance of the manually calibrated model for large extents of the model reach.

The simulated water surface elevation is in part determined by the distribution of Manning's n values computed by the model for each vegetation type. Compiled in Figure 3 and 4 are distributions of

Manning's *n* values for well-represented vegetation types in the modeled reach of the San Joaquin River. The distributions are compiled from the Manning's *n* value at each cell in the computational mesh as designated by the vegetation type polygons. The distributions shown in each figure include (A) the calculated values for wetted cells using the Jarvela (2004) approach, (B) the polygon values including those calculated in wet cells and the default value of n=0.035 in dry cells, and (C) the values taken from the manually calibrated model. Also shown in each plot are the mean (solid line) and standard deviation from the mean (dashed line) of the calculated Manning's *n* values for wetted cells. The distribution of calculated Manning's *n* values (blue) in each plot is representative of cells that are directly coupled to the hydraulics through Equation 2. For Mixed Riparian (Figure 3) and Willow Riparian (Figure 4) vegetation types, the compilation of Manning's *n* values are approximately normally distributed around the mean value. Manning's *n* values calculated for the Willow Scrub (not shown) vegetation type do not appear to be normally distributed, possibly due to species-specific parameters that are causing the calculated roughness values to be biased low. The cumulative count of a distribution of Manning's *n* values provides an indication of the relative influence a given vegetation type has in the hydraulic computations the model is performing. The gross effects of vegetative roughness in the hydraulic model will be driven by vegetation types that are largely inundated for the flow simulated. In the model reach of the San Joaquin River, many cells within the computational mesh are classified as Agricultural Field. The count of calculated Manning's values is far less, however, indicating that the portion of inundated agricultural field (and therefore the effect of agricultural vegetation on the hydraulics within the reach) is small.

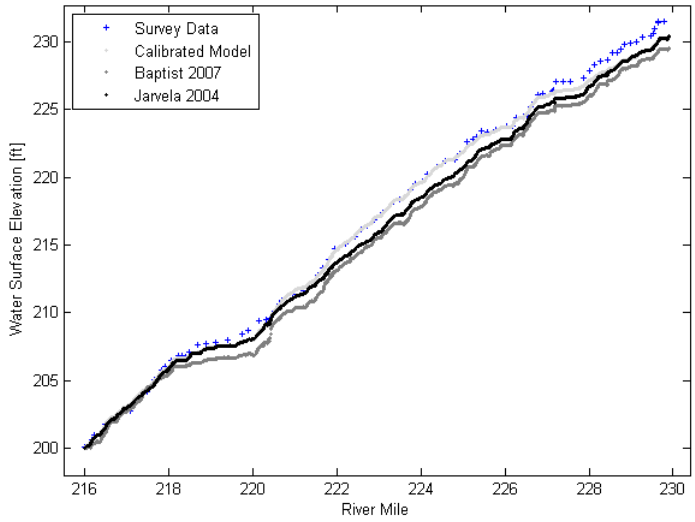

Figure 1 Simulated water surface elevation (ft) as a function of river mile (mi) for Q = 4000 cfs in a reach of the San Joaquin River. Shown for comparison are measured water surface elevation (blue), manually calibrated simulation results (light grey), simulation results using the Baptist (2007) approach (grey), and simulation results using the Jarvela (2004) approach (black). The figure demonstrates that the Jarvela (2004) approach performs better than the Baptist (2007) approach, although falls short of the performance of the manually calibrated model.

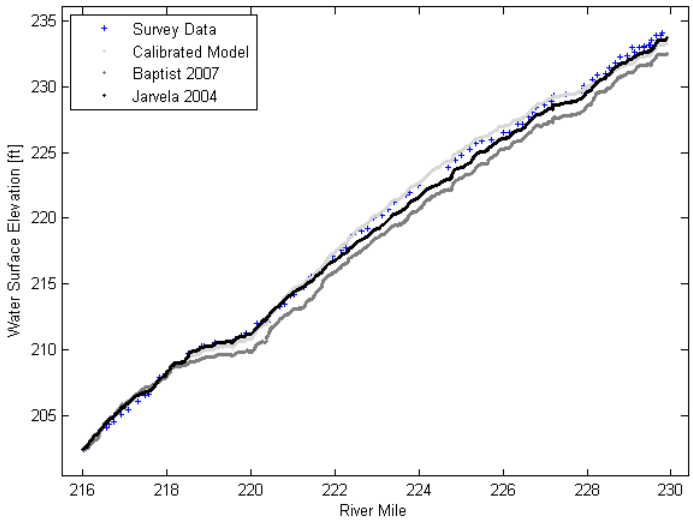

Figure 2 Simulated water surface elevation (ft) as a function of river mile (mi) for Q = 7500 cfs in a reach of the San Joaquin River. Shown for comparison are measured water surface elevation (blue), manually calibrated simulation results (light grey), simulation results using the Baptist (2007) approach (grey), and simulation results using the Jarvela (2004) approach (black). The figure demonstrates that the Jarvela (2004) approach performs better than the Baptist (2007) approach, although falls short of the performance of the manually calibrated model.

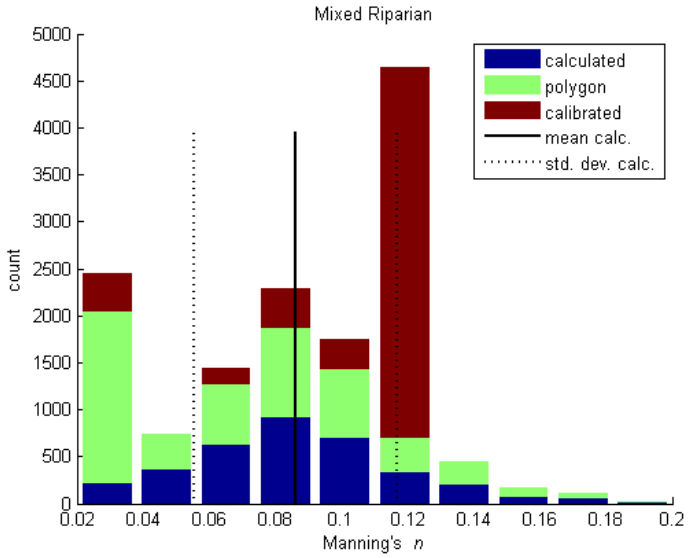

Figure 3 Distribution of Manning's *n* values for Mixed Riparian vegetation in the computational mesh of the modeled reach of the San Joaquin River. Shown in the figure are the calculated values for wetted cells using the Jarvela (2004) approach (blue), the polygon values including those calculated in wet cells and default values in dry cells (green), and the values taken from the manually calibrated model (red). Also shown are the mean (solid line) and standard deviation from the mean (dashed line) of the calculated Manning's *n* values for wetted cells.

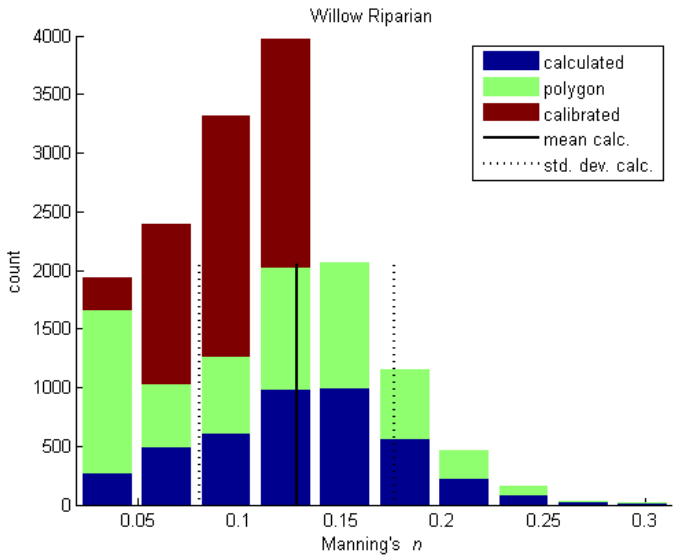

Figure 4 Distribution of Manning's *n* values for Willow Riparian vegetation in the computational mesh of the modeled reach of the San Joaquin River. Shown in the figure are the calculated values for wetted cells using the Jarvela (2004) approach (blue), the polygon values including those calculated in wet cells and default values in dry cells (green), and the values taken from the manually calibrated model (red). Also shown are the mean (solid line) and standard deviation from the mean (dashed line) of the calculated Manning's *n* values for wetted cells.

The comparisons in Figure 1 and 2 show that water surface elevation is underestimated in approximately the upper 2/3 of the model reach using the Jarvela (2004) approach for calculating roughness. This suggests that preferentially increasing the roughness in the upper portion of the model reach may produce simulated hydraulics that better match observed conditions. The mean calculated roughness values for the mixed riparian (Figure 3) and willow scrub (not shown) vegetation types tend lower than the bulk of calibrated roughness values for the same types, which suggests that the spatial distribution of mixed riparian and willow scrub vegetation types may be correlated to the underestimation of water surface elevation in the upper portion of the model reach. Upon inspection of the spatial distribution of mixed riparian and willow scrub vegetation types within the model reach, it is apparent that there is greater spatial coverage in the upper 2/3 of the reach. It was therefore hypothesized that tuning the parameters for the mixed riparian and willow scrub vegetation in order to increase calculated roughness for these types would result in simulated hydraulics that better match the observed conditions. The species-specific drag coefficient C_{dX} was increased from 0.43 to 0.75 for only the mixed riparian and willow scrub types and the model was run again using the Jarvela (2004) approach for calculating roughness. A comparison of water surface elevation for variation in the parameter C_{dX} for a simulated discharge of Q = 7500 cfs is shown in Figure 5. The comparison demonstrates that increasing the species-specific drag coefficient C_{dX} for the mixed riparian and willow scrub vegetation positively affected the simulated hydraulics by preferentially increasing water surface elevation through regions of the modeled reach that were underestimated using a constant value C_{dX}. The variation in parameter C_{dX} resulted in a shift in the distribution of calculated roughness towards larger values. Another test of parameter sensitivity was conducted by varying the exponent X in Equation 2 for the mixed riparian and willow scrub vegetation types. Increasing the fractional exponent X has the effect of increasing roughness, however, with a less than linear sensitivity. For the trial simulation, X was increased from -0.57 to -0.35 for the mixed riparian and willow scrub vegetation types, however the effect on the simulated water surface elevation was small

compared to the effect when varying the drag coefficient, C_{dX}. Comparison of water surface elevation at additional discharges and sensitivity analysis for varying input parameters is provided in Gillihan (2013).

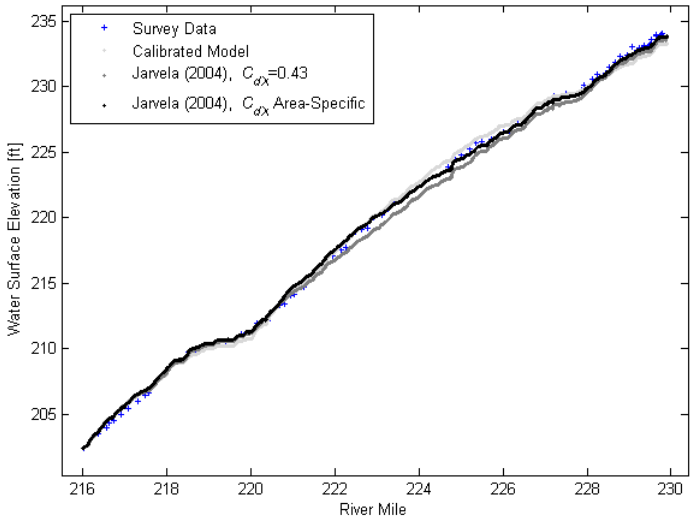

Figure 5 Simulated water surface elevation (ft) as a function of river mile for Q=7500 cfs in a reach of the San Joaquin River. Simulation results are shown for the Jarvela (2004) approach using constant C_{dX}=0.43 (grey) for all vegetation and C_{dX}=0.75 (black) for mixed riparian and willow scrub vegetation. Shown for comparison are measured water surface elevation (blue) and manually calibrated simulation results (light grey). The comparison demonstrates that increasing the species-specific drag coefficient C_{dX} for the mixed riparian and willow scrub vegetation positively affected the simulated hydraulics by preferentially increasing water surface elevation through regions of the modeled reach that were underestimated using a constant value C_{dX}.

DISCUSSION

The results demonstrate that the SRH-2DV model for simulating vegetated flow is generally successful in reproducing the effect of riparian vegetation on water surface elevation as compared to that of measurements and manually calibrated simulations. Distributions of calculated roughness values due to vegetation were generally consistent with values compiled in the literature (Hession & Curran, 2013). The Jarvela (2004) and Baptist (2007) approaches for computing roughness were both implemented in the model. The calibration procedure assumed variables computed by the hydraulic solver (U, h), vegetation characteristics measured in the field (LAI, H, m, D), and parameter values borrowed from published literature (X, U_X) to be known quantities; the parameters C_{dX} and C_d were assumed uncertain and subject to variation.

A likely source of significant error in the modeling is due to limitations imposed by applying locally measured vegetation parameters to spatially disparate zones within the computational mesh. Identical vegetation classes are likely only qualitatively equivalent and so it is predicted that accuracy improvements would be realized by comprehensive measurement of vegetation characteristics throughout the model domain.

The leaf area index is generally a convenient physically-based metric for quantifying vegetal density and area (Jalonen, Jarvela, & Aberle, 2013), and can be estimated by in situ observation or remote sensing. Further, the Jarvela (2004) approach incorporates water depth and velocity information, both of which are directly computed by the hydraulic solver. Given the spatially-detailed information that a two-dimensional hydraulic model can provide, it would be desirable to map measured vegetation parameters at similar scale and resolution (Abu-Aly, Pasternack, Wyrick, Barker, Massa, & Johnson, 2014), which would necessitate the use of remote sensing technologies.

The distributions of calculated roughness values produced by the model and the effect of varying the parameter C_{dX} in Equation 1 indicate that predicting the effects of vegetation on hydraulics is dependent on quantifying complicated species-specific coupling between the vegetation characteristics and local hydraulics. Further exploration of input parameter values and species dependency, a topic of active research (Aberle & Jarvela, 2013), will be useful in gauging applicability and evaluating performance of the algorithms.

Despite the uncertainties identified in the measured and parameterized vegetation characteristics applied in the SRH-2DV model, the simulation results demonstrate good qualitative performance as compared to observed conditions and calibrated results. It is anticipated that the model will serve as a useful tool for predicting the effects of projected vegetation changes and for use as a design tool in restoring riparian vegetation. As the challenges associated with measurement of vegetation characteristics over large spatial scales are overcome through developing remote-sensing techniques, the practicality and accuracy of vegetated-flow modeling will increase.

Abstract: The empirical dataset of surveyed sand bar volumes in Marble Canyon on the Colorado River downstream of Glen Canyon Dam is analyzed. A subset of the empirical dataset is established based on bar and survey date consistency, resulting in the calibration dataset. The sand bar calibration dataset is represented by both the mean and median of the sand bar volume.

A conceptual model describing erosive and depositional processes for sand bars in Marble Canyon is described. A series of model formulations (termed Model V0 through V5) are developed and Model V3 is selected based on model performance calculated as the normalized sum of squared errors and adjusted R-squared. Confidence intervals are developed for the parameters and for the predicted bar volumes coinciding with calibration data survey dates.

Median and mean versions of Model V3 show similar percent improvement over the model V0 performance (86% for median, 89% for mean). The prediction confidence intervals contain 19 of the 28 observed bar volumes for both the mean and median V3 models. Deposition and erosion trends between survey dates are correctly predicted 25 out of 28 times for both the mean and median V3 models. The mean V3 model tended to perform better in the vicinity of high flow experiments (HFEs) as compared to the median V3 model.

INTRODUCTION

The Department of the Interior, through the Bureau of Reclamation (Reclamation) and the National Park Service (NPS) are preparing an environmental impact statement (EIS) for the adoption of a long-term experimental and management plan (LTEMP) for the operation of Glen Canyon Dam on the Colorado River. The EIS will fully evaluate dam operations and identify management actions and experimental options that will provide a framework for adaptively managing Glen Canyon Dam over the next 15 to 20 years.

The Sand Bar Volume Model (SBVM) was developed by Reclamation's Technical Service Center specifically for performing alternative analysis during the LTEMP EIS process. The sediment resource goal for the LTEMP EIS is "to increase and retain fine sediment volume, area, and distribution in the Glen, Marble and Grand Canyon reaches above the elevation of the average base flow for ecological, cultural, and recreational purposes." The Sand Budget Model (Wright et al., 2010) is useful for quantifying the overall sand budget within a reach, but does not consider the proportion of that sediment in the bed versus bars, and therefore does not explicitly reflect the sediment resource goal. The intent of SBVM is to represent a time series of all the bars in Marble Canyon by incorporating the empirical sand bar data, which is described in terms of sediment volumes relative to different reference elevations, into an analysis that more directly reflects the sediment resource goal. SBVM is only applicable to the Colorado River downstream of Glen Canyon Dam, and has currently been calibrated to the dataset consisting of sand bars in Marble Canyon (Figure 1).

REVIEW OF EMPIRICAL DATA

The U.S. Geological Survey's Grand Canyon Monitoring and Research Center (GCMRC) in collaboration with Northern Arizona University (NAU) have been performing repeat surveys of select bars throughout Marble and Grand Canyon for decades (Mueller et al., 2014). There are 25 bars in Marble Canyon, eight in Upper Marble Canyon (RM 0 to RM 30) and 17 in Lower Marble Canyon (RM 30 to RM 61) with 42 survey dates reported between 9/15/1990 and 9/21/2013. Data collected quantify the sediment area and volume relative to the water surface elevations (WSE) associated with a flow of 8,000 cubic feet per second (ft^3/s) and 25,000 ft^3/s (Grams, 2013). Data were binned as volume/area less than the 8,000 ft^3/s WSE, between the 8,000 and 25,000 ft^3/s WSE, and greater than the 25,000 ft^3/s WSE. To reflect the sediment resource goal of the LTEMP EIS, the sand bar data above the 8,000 ft^3/s WSE (8,000-25,000 ft^3/s and greater than 25,000 ft^3/s) is considered to represent the sediment above the elevation of the average base flow. The sediment below the 8,000 ft^3/s WSE is addressed with the Sand

Budget Model (Wright et al., 2010); the SBVM focuses on the portion of sediment referenced in the sediment resource goal of the LTEMP EIS.

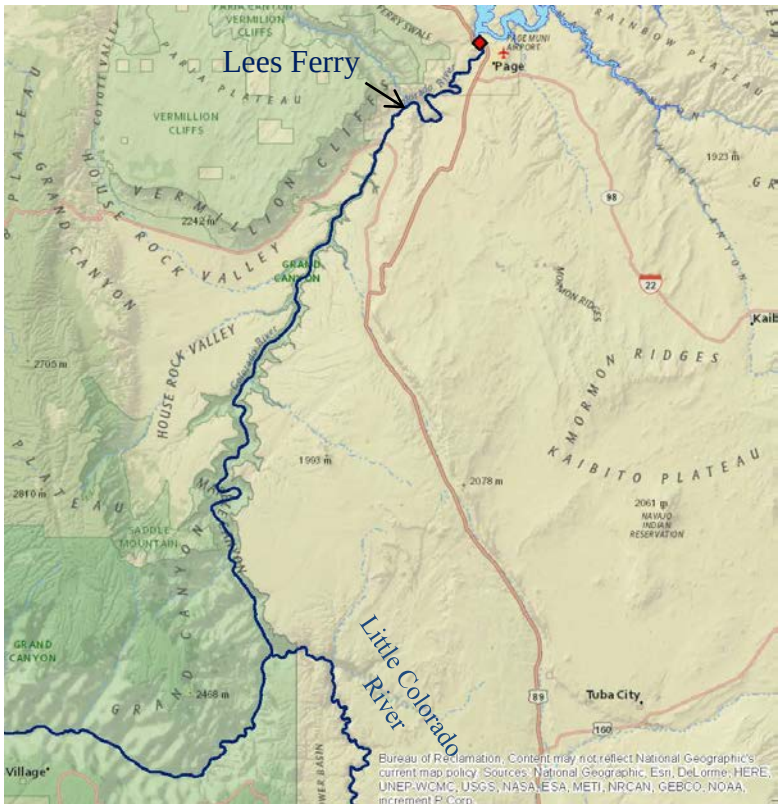

Figure 1 Location map: primary area of interest is Marble Canyon (Lees Ferry to Little Colorado River)

A consistent set of sand bars and survey dates was developed to be used as the calibration dataset. The development of the calibration dataset attempted to maximize the time span of observations but also maintain a consistent set of the highest number of sand bars possible. This approach yielded a calibration dataset of 29 dates (out of 42) and 14 sand bars (out of 25) from 7/26/1991 to 9/21/2013.

The SBVM represents a time series of all the bars in Marble Canyon, where the conglomeration of bars is represented by a single value; either the mean or median volume of those bars. Figure 2 is the distribution of bar volumes above the 8,000 ft^3/s WSE for a reported survey date. Note that the mean is always greater than the median, and that there is more variability in the median through time as compared to variability in the mean. The minimum and maximum bar volume is also shown in the graph; the maximum is always associated with 51-mile bar, the minimum is either 3-mile or 16-mile bar. An overarching assumption of the SBVM is that GCMRC selected bars to survey because those bars represent the variability in morphology and type found in the canyons, and that any inferences made via calibration to the surveyed bars would be representative of all of the sand bars, surveyed or not.

The surveys immediately after HFE events (1996, 2004, and 2008) all have mean volumes greater than 290,000 cubic feet (ft^3). Note that the HFE signal is not as pronounced in the median record; the surveys post-2004 and 2008 HFEs register a median value less than the survey that is approximately five months after the 1996 HFE. The time series of mean bar data likely represents the average conditions in the reach more accurately than the median, but both time series will be used as calibration datasets during model selection.

The trends in the mean and median data generally are the same except for the period from the late 1990s to the early 2000s. Figure 3 presents the correlation between the mean and median bar volume of the calibration dataset.

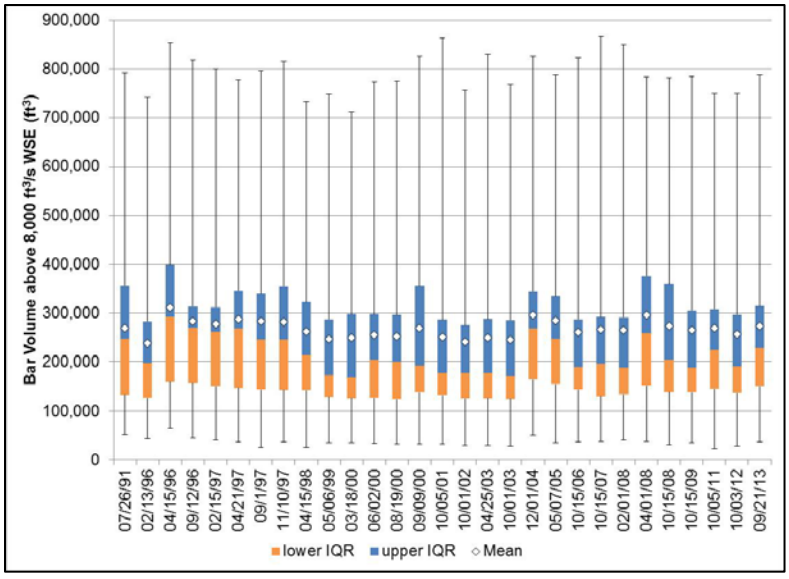

Figure 2 Calibration dataset statistics by date; bars identify minima and maxima and lower IQR refers to the 25th to 50th percentile and upper IQR refers to the 50th to 75th percentile.

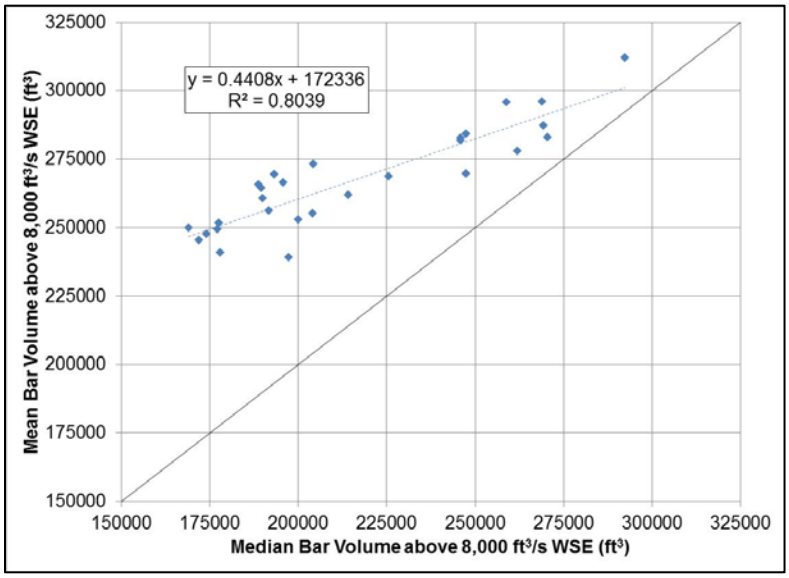

Figure 3 Correlation between mean and median bar volumes of the calibration dataset.

CONCEPTUAL MODEL AND MODELS TESTED FOR SELECTION

The impetus of model development was to find a way to predict bar responses to High Flow Experiments (HFE), sometimes referred to as controlled floods. The controlled high flow releases are meant to mimic natural flooding to an extent and benefit sediment-dependent resources such as sandbars. Building on the body of knowledge of sand bar behavior in Glen, Marble, and Grand Canyon – largely developed by GCMRC (Wiele et al., 2007; Wright and Kaplinski, 2011) – a general conceptual model was developed. The two fundamental processes which need to be captured are bar building (deposition) and bar erosion.

Sand bar deposition and bar building occur at high discharge and with high sediment concentration. The rate of bar building is largest during the early stages of an HFE, and tapers off as the bar becomes more 'full'; there is a physically reasonable maximum bar volume for each bar (Wiele and Torizzo, 2005). Also, the more 'empty' a bar

is, the higher the potential volume of deposition. An important aspect of deposition is the potential volume of sediment which a bar may contain.

The rate of sand bar erosion tends to be large during the first few to six months after a significant bar building event, then tapers off to a fairly constant rate. Early SBVM formulation experimented with combining depositional and erosional processes into a single term to capture bar volume change, but it soon became apparent that these two processes are governed by different processes under different conditions. The following discusses the model as consisting of two terms: one for depositional processes and one for erosional processes.

The general model formulation for a tool that can be used to predict bar volumes is presented in equation 1. There is a deposition rate and an erosion rate calculated at each time step in the model. The equation can be time-integrated get equation (2). A change in bar volume for a given time step is calculated by taking the difference between the erosion and deposition rates and converting to a volume by multiplying by time step and a porosity term. The bar volume for the next time step is the sum of the current time steps bar volume and the change in bar volume calculated at that time step (equation 3).

$$\frac{dS_b(1-\eta)}{dt} = Q_d - Q_e \tag{1}$$

where:

S_b = mean sand bar volume (ft^3) above a base flow rate water surface elevation
η = porosity of sediment (-)
Q_d = depositional flux of sediment into sand bar (ft^3/s)
Q_e = erosional flux of sediment from sand bars (ft^3/s)
t = time (s)

$$\Delta S_b(1-\eta) = \int_{t_1}^{t_2}(Q_d - Q_e)dt \tag{2}$$

$$S_{b(i+1)} = S_{b(i)} + \Delta S_{b(i)} \tag{3}$$

Five different sets of depositional and erosional terms are presented below. These five sets represent different models of depositional and erosional behavior; the erosion term Q_e in models V3 – V5 are identical and are paired with different depositional equations. Models V1-V5 can be compared to the average bar volume, identified as V0. That is, V0 assumes that the predicted bar volume for any time step is simply the average (mean or median as appropriate) bar volume. The model error associated with V0 will be a benchmark to which the model performance for V1-V5 can be compared.

Model V1: Flow only

$$Q_d = a_d {Q_x}^{b_d}$$
$$Q_e = a_e {Q_x}^{b_e}$$

Model V2: Storage only (*Q* is used indirectly to calculate S_{bv}, see below)

$$Q_d = a_d \left(\frac{S_{bv}}{S_b}\right)^m$$
$$Q_e = a_e \left(\frac{S_b}{S_{bv,max}}\right)^n$$

Model V3: Flow and Storage (no concentration term)

$$Q_d = a_d {Q_x}^{b_d} \left(\frac{S_{bv}}{S_b}\right)^m$$
$$Q_e = a_e {Q_x}^{b_e} \left(\frac{S_b}{S_{bv,max}}\right)^n$$

Model V4: Flow, Storage, Concentration (exponent on *Q*)

$$Q_d = a_d C {Q_x}^{b_d} \left(\frac{S_{bv}}{S_b}\right)^m$$

$$Q_e = a_e {Q_x}^{b_e} \left(\frac{S_b}{S_{bv,max}}\right)^n$$

Model V5: Flow, Storage, Concentration (exponent on product of *QC*)

$$Q_d = a_d (CQ_x)^{b_d} \left(\frac{S_{bv}}{S_b}\right)^m$$

$$Q_e = a_e {Q_x}^{b_e} \left(\frac{S_b}{S_{bv,max}}\right)^n$$

Where:

Q_d = deposition rate at time step i (ft^3/s)
Q_e = erosion rate at the time step i (ft^3/s)
Q_x = volumetric water discharge in Colorado River (ft^3/s) at River Mile 30 divided by 2,000 ft^3/s (-);
C = volumetric sand-sized sediment concentration within the Colorado River at River Mile 30 (-)
a_d, b_d, m = calibration parameters (ft^3/s), (-), (-), respectively
a_e, b_e, n = calibration parameters (ft^3/s), (-), (-), respectively.
S_{bv} = maximum available sand bar volume below the WSE at specific flow rate, Q (ft^3).
$S_{bv,max}$ = available sand bar volume at maximum flow rate of 45,000 ft^3/s (ft^3)

The calibration parameters are collectively called a calibration parameter set and include a_d, b_d, m, a_e, b_e, and n. The variable S_{bv} is derived from the empirical volume data for all available survey dates for the 14 bars used in the calibration dataset. S_{bv} is a variable describing the maximum potential sand bar volume at different flow rates. We currently have three data points to which to fit a curve and these points were developed as such:

- A zero sand bar volume was assigned to a discharge of 8,000 ft^3/s, as we are only concerned with the volume of sand above the 8,000 ft^3/s WSE.
- The maximum volume for each of the 14 bars associated as being between the 8,000-25,000 ft^3/s WSE were averaged (mean and median) and assigned to being the potential bar volume at 25,000 ft^3/s.
- The volume between the 8,000-25,000 ft^3/s WSE and the volume above the 25,000 ft^3/s WSE were summed for each survey date, and the maximum of those sums for each of the 14 bars were averaged (mean and median) and assigned to being the potential bar volume at 45,000 ft^3/s, which is the maximum planned release flow rate under the interim guidelines barring an excessively wet hydrologic year.

It is assumed for the sake of the S_{bv} equation that the available sand bar volume at a particular flow rate does not change in time. Further, a continuous function for the S_{bv} equation was desirable for optimization purposes. A logistic function was found to fit the data well and be continuous, once the discharge was scaled. Dividing the discharge by 2,000 ft^3/s provided the logistic functions for mean and median data (Figure 4).

As described in the presentation of the deposition and erosion models, the flow terms use the scaled discharge Q_x (Q/2000) and not the discharge Q, based on general early observations that a smaller base upon which an exponent is placed improves model performance. Also, dividing the flow by 2,000 ft^3/s is consistent with the flow terms in the model.

All models were implemented into the Mathworks® Matlab software. The modified Sand Budget Model (Wright et al., 2010; Russell and Huang, 2010) was developed as a sediment budget for Marble and Eastern Grand Canyon. Because we are focusing on the bars in Marble Canyon, the discharge and concentration time series at the middle of the canyon (RM30) is used as input to SBVM. The initial condition 7/26/1991 for the SBVM model is the average bar volume of 269,809 ft^3 for the mean and 247,433 ft^3 for the median of the calibration data. Because there are multiple parameters and the model is non-linear, optimization is dependent on the initial guess of parameter values. To increase the confidence in the results, a brute force grid search was employed for all models to locate the region of the global maximum, not just a local maximum. Parameter search domains for the mean and median model simulations were: 1E-20 to 1E20 for a_d and a_e; 0 to 30 for m and n; and at least -8 to 6 for b_d and b_e, although the search domain for b_d and b_e tended to be extended from -12 to 12 because the solution domain showed good performance near the bounds of the initial search domain.

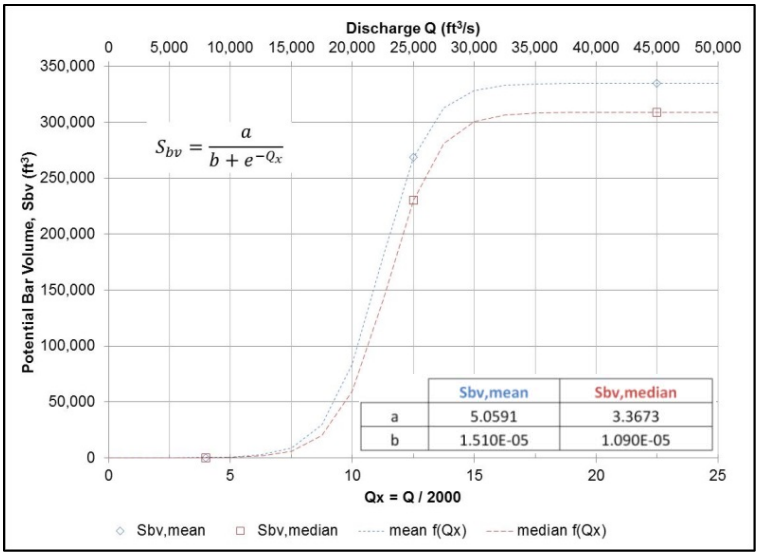

Figure 4 S_{bv} equation for the mean and median datasets

MODEL SEARCH DOMAINS

The bounded search optimization routine "Fminsearch" in Matlab was utilized once the best performing parameter sets were identified from the grid search. Multiple initial guess parameter sets were optimized for each model based on the results of the grid search.

OPTIMIZATION AND MODEL PERFORMANCE

Model V0; Average of calibration dataset This is the simplest model and is used as a benchmark to assess the results of models V1-V5. In this model, the predicted bar volumes are constant through time and are the mean for the mean bar volumes, and the median for the median bar volumes. Model performance is assessed as the sum of squared error (SSE) normalized to the appropriate average bar volume. The SSE for a mean bar volume of 267,754 ft^3 (normalized to this mean) is 0.125, and for a median bar volume of 204,013 ft^3 (normalized to this median) is 0.958. Figure 5 depicts the observed and the model V0 predicted bar volume above the 8,000 ft^3/s WSE.

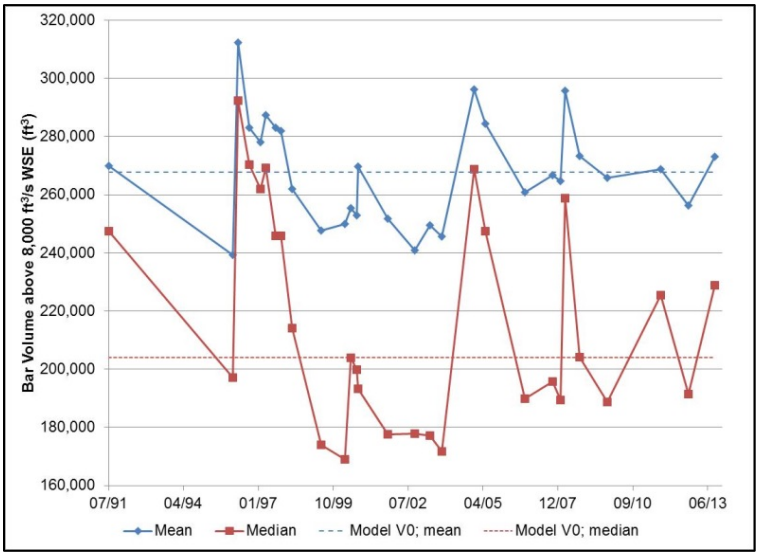

Figure 5 Model V0 depicted against the calibration datasets

Model V1; Flow Only This model uses only a flow term to predict erosion and deposition. There are no history effects accounted for in the erosion and deposition rates, meaning the bar volume existing at a given time step does not inform the rates of erosion and deposition. There is also no utilization of the S_{bv} curve relating the flow rate in the river to the presumed potential bar volume associated with that flow rate.

For both the mean and median cases, the top performing parameter sets (combinations of b_d, b_e, a_d, a_e) resulting from the grid search were used as initial guesses for the bounded Matlab optimization routine "Fminsearch", with the bounds coinciding with the step size specified during the grid search. For example, the grid search for this model had a step size of two for the exponents (b_d, b_e) and for the coefficients (a_d, a_e) the step size was two orders of magnitude. During the optimization for each parameter set, the search bounds were set to ±2 on the exponents and ±2 orders of magnitude on the coefficients.

The parameter sets resulting from the bounded optimization were plotted against their performance (Figure 6). The median optimization plot shows the behavior one would expect; the range for a given parameter decreases as the SSE decreases (performance increases). This behavior appeared for the V1 mean model as well, and gives greater confidence in the optimal parameter set than if the opposite were true (larger range for a given parameter as performance increased).

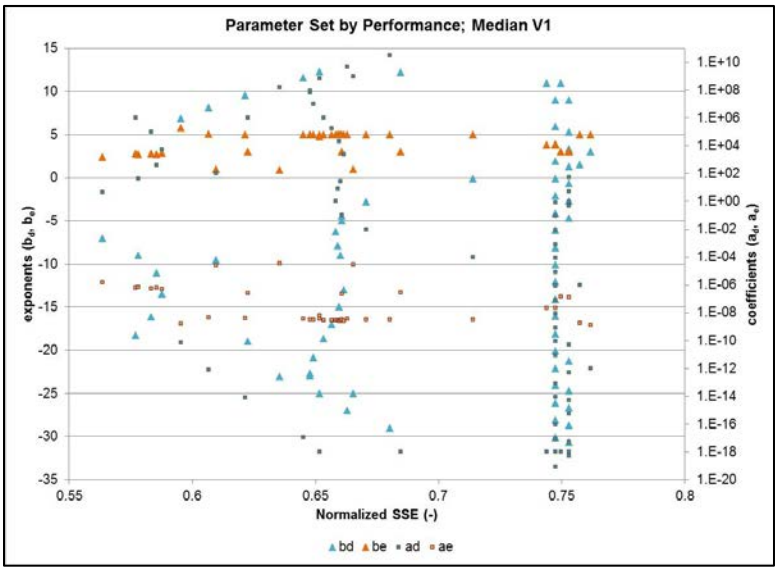

Figure 6 Parameter set performance after optimization for median V1 model

Model V2; Storage Only This model uses only a storage term to predict erosion and deposition. The flow rate at a given time step does not inform the rates of erosion and deposition, except for indirectly, where the flow rate selects the potential bar volume, S_{bv}, and thus the deposition is indirectly associated with flow rate. The erosion rate is simply calculated as a ratio of the current time step bar volume relative to the maximum bar volume; the smaller the bar gets, the slower the rate of erosion.

For the median case, the top performing parameter sets (combinations of m, n, a_d, and a_e) were used as initial guesses for the Matlab optimization routine "Fminsearch" with the bounds coinciding with the step size specified during the grid search as described for model V1. Due to the smooth nature of the mean performance surface, only one optimization was run.

The parameter sets resulting from the bounded optimization for the median data were plotted against their performance. The median optimization plot showed a different pattern than the median optimization plot for model V1; namely, there does not appear to be a convergent solution as the performance increases. Less confidence should be given to this model due to the non-convergent nature of the parameter sets relative to performance. The grid

search for Model V2 mean produced a smooth solution surface that leads to greater confidence in the optimized solution.

Model V3; Flow and Storage This model uses a flow term and a storage term to predict both erosion and deposition. This model is a combination of models V1 and V2. Flow rate and current bar volume inform the rates of erosion and deposition for that time step.

Only those parameter sets from the grid search for the mean model that resulted in an SSE less than or equal to one-half the SSE from model V0 were carried forward to optimization (n=429). If the same selection criteria was applied to the results of the grid search for the median model (using those that had an SSE equal to one-half the model V0 SSE), only about 1% of the parameter sets for the median model would have moved forward to optimization. To increase the sample set, the slope of a Weibull-distribution cumulative distribution function (CDF) was investigated. In the vicinity of an SSE = 0.577 the slope of the CDF transitions from variable to relatively constant. This location corresponds to 6% on the CDF, so the top 6% performing parameters sets from the median grid search (n=1226) moved forward to optimization.

The top performing parameter sets were used as initial guesses for the Matlab optimization routine "Fminsearch" with the bounds coinciding with the step size specified during the grid search as described for models V1. The parameter sets resulting from the bounded optimization were plotted against their performance (Figure 7). The optimization plot shows a pattern that would be expected in optimization; each parameter appears to converge as the performance increases (SSE decreases). This behavior suggests more confidence in the model and the optimized parameter set.

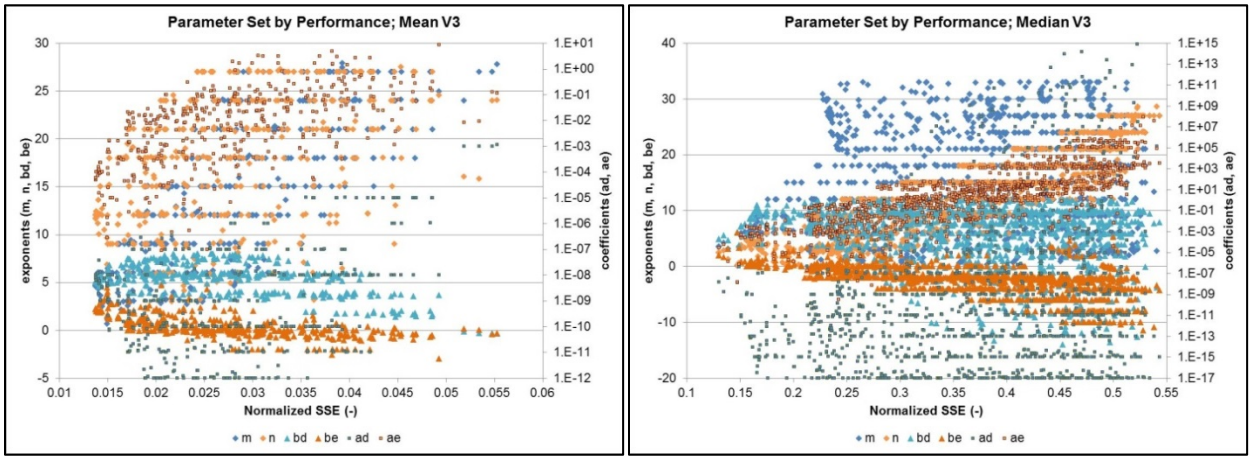

Figure 7 Parameter set performance for Model V3 mean (left) and median (right)

Model V4; Flow, Storage, and Concentration (linear) This model uses a flow term and a storage term to predict both erosion and deposition, much like Model V3, except that the addition of a concentration term is included to predict deposition rates. The exponent on the concentration term is fixed at 1.

Only those parameter sets from the grid search for the mean model that resulted in an SSE less than or equal to one-half the SSE from model V0 were carried forward to optimization (n=1410). If the same selection criteria was applied to the results of the grid search for the median model, (using those that had an SSE equal to one-half the model V0 SSE), only about 3% of the parameter sets for the median model would have moved forward to optimization. To increase the sample set, the slope of the CDF was investigated. In the vicinity of an SSE = 0.517 the slope of the CDF transitions from variable to relatively constant. This location corresponds to 5% on the CDF, so the top 5% performing parameters sets from the median grid search (n=1021) moved forward to optimization.

The top performing parameter sets were used as initial guesses for the Matlab optimization routine "Fminsearch" with the bounds coinciding with the step size specified during the grid search, as discussed in model V1. The parameter sets resulting from the bounded optimization for the median data are plotted against their performance

similar to Figure 6 and Figure 7. The median and mean optimization plot shows a similar convergence of the erosion parameters (n, b_e, and a_e) as for model V3. However, the deposition parameters (m, b_d, and a_d) do not appear to be converging with improved performance. In addition, the performance for model V4 does not achieve the same level as model V3, whether mean or median. This behavior not only reduces the confidence in the optimized parameter sets but also reduces the confidence in the model. The following model (V5) will allow the exponent on the concentration parameter to vary in an attempt to improve performance.

Model V5; Flow, Storage, and Concentration (power) This model uses a flow term and a storage term to predict both erosion and deposition, with the addition of a concentration term in the prediction of deposition rates. Unlike model V4, the concentration term has an exponent that is allowed to vary. The exponent is defined to equal the exponent on the flow term (b_d) so that the number of parameters does not increase.

Only those parameter sets from the grid search for the mean model that resulted in an SSE less than or equal to ½ the SSE from model V0 were carried forward to optimization (n=380). If the same selection criteria was applied to the results of the grid search for the median model, (using those that had an SSE equal to ½ the model V0 SSE), only about 1.3% of the parameter sets for the median model would have moved forward to optimization. To increase the sample set, the slope of the CDF was investigated. In the vicinity of an SSE = 0.617 the slope of the CDF has a noticeable break. This location corresponds to 6% on the CDF, so the top 6% performing parameters sets from the median grid search (n=1226) moved forward to optimization.

The top performing parameter sets were used as initial guesses for the Matlab optimization routine "Fminsearch" with the bounds coinciding with the step size specified during the grid search as described for models V1. The parameter sets resulting from the bounded optimization are plotted against their performance and the median and mean optimization plot showed convergence of the erosion and deposition parameters. The performance for model V5 does not achieve the same level as model V4, whether mean or median. This behavior reduces the confidence in the model.

Summary of Optimized Models Figure 8 presents a summary of the model performance for the mean and median dataset as a progression through models V0-V5. The percent improvement of the models compare models V1-V5 relative to the initial V0 model.

In both the mean and median cases, model performance improves from V0 through V3. Adding the concentration term reduces model performance. It is plausible that the explanation for this lies with the fact that the concentration used is a time series output from the modified Sand Budget Model rather than the actual measured data. Figure 6 from the Wright et al. (2010) paper showing that a significant amount of scatter exists in a concentration vs. discharge plot (not atypical) at River Mile 30. It is possible that using the measured (not model) concentration would improve model performance when including the concentration time series. However, the approach of using measured data means the model is no longer predictive under future flow and operational scenarios.

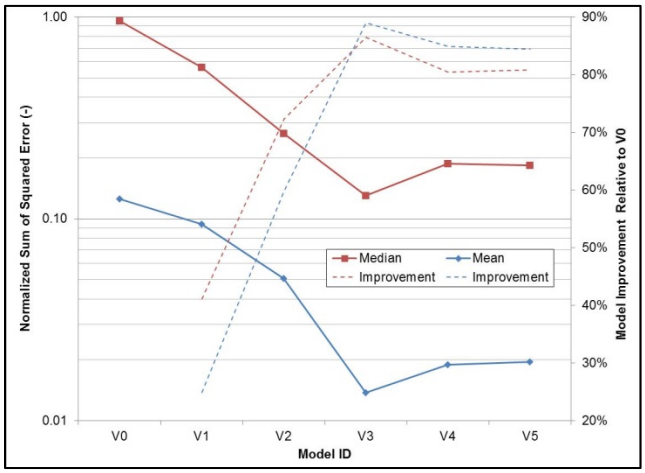

Figure 8 Summary of model performance (SSE) and percent improvement relative to model V0

It is apparent that model V3 is the best for both the mean and median datasets. It is the first model in the progression from V1-V5 that has six regressors, (models V1 and V2 had 4 each). Calculating an adjusted R^2 (or $\bar{R}^2$, r-bar squared) can help assess whether the added complexity is justifiable (http://www.mathworks.com/help/curvefit/evaluating-goodness-of-fit.html). Equation 4 presents the equation used to calculate the adjusted R^2 and Table 1 presents the results by model.

$$\bar{R}^2 = 1 - \frac{SSE(n-1)}{SST(v)} \quad (4)$$

Where:

SSE = sum of squared error (or sum of squared residuals)
SST = total sum of squares (= regression sum of squares + residual sum of squares)
n = number of response values
v = residual degrees of freedom = n-m
m = number of fitted coefficients

Table 1 Adjusted R-squared for models V1-V5; mean and median

	Model				
	V1	**V2**	**V3**	**V4**	**V5**
n	28	28	28	28	28
m	4	4	6	6	6
v = n-m	24	24	22	22	22
$\bar{R}^2$, median	0.27	0.66	0.82	0.74	0.74
$\bar{R}^2$, mean	0.16	0.55	0.87	0.81	0.81

The adjusted R-square values justify the additional complexity of transitioning from model V2 (with 4 regressors) to V3 (with 6 regressors), and suggest that models V4 or V5 do not offer improvement over V3.

CONFIDENCE INTERVALS

The Mathworks Matlab functions "nlparci" and "nlpredci" were used to develop the parameter confidence intervals and the prediction confidence intervals, respectively, both at the 95% confidence level. Table 2 presents the parameter confidence intervals for the median and mean datasets for model V3. Figure 9 presents the predicted sand bar volumes along with the predicted confidence intervals at the time steps corresponding to the observations.

Table 2 Parameter confidence intervals (CI) for model V3

	mean model			**median model**		
	Lower CI	**optimized**	**Upper CI**	**Lower CI**	**optimized**	**Upper CI**
a_d	-3.00E-08	9.86E-09	4.97E-08	-5.97E-08	1.49E-08	8.95E-08
a_e	-1.12E-04	4.83E-05	2.09E-04	-9.12E-05	2.78E-05	1.47E-04
b_d	3.593	5.015	6.437	3.283	4.917	6.550
b_e	0.924	2.272	3.620	0.140	1.965	3.789
m	0.993	4.697	8.400	1.074	3.569	6.063
n	7.105	11.664	16.224	-0.174	2.481	5.135

Both the mean and median prediction confidence intervals contain 19 of the 28 observed bar volumes (the first of the 29 observations – 7/26/1991 – was used as an initial condition for the model). The notable errors of the mean model are that it generally does not capture the cluster of measurements in summer/fall 1997, it under-predicts the erosion after the small depositional event in Fall 2000, and under-predicts the small depositional event in Fall 2007.

The notable errors of the median model are that it over-predicts the erosion before the 1996 HFE, under-predicts the deposition during the 2004 HFE, and under-predicts the erosion after the 2008 HFE.

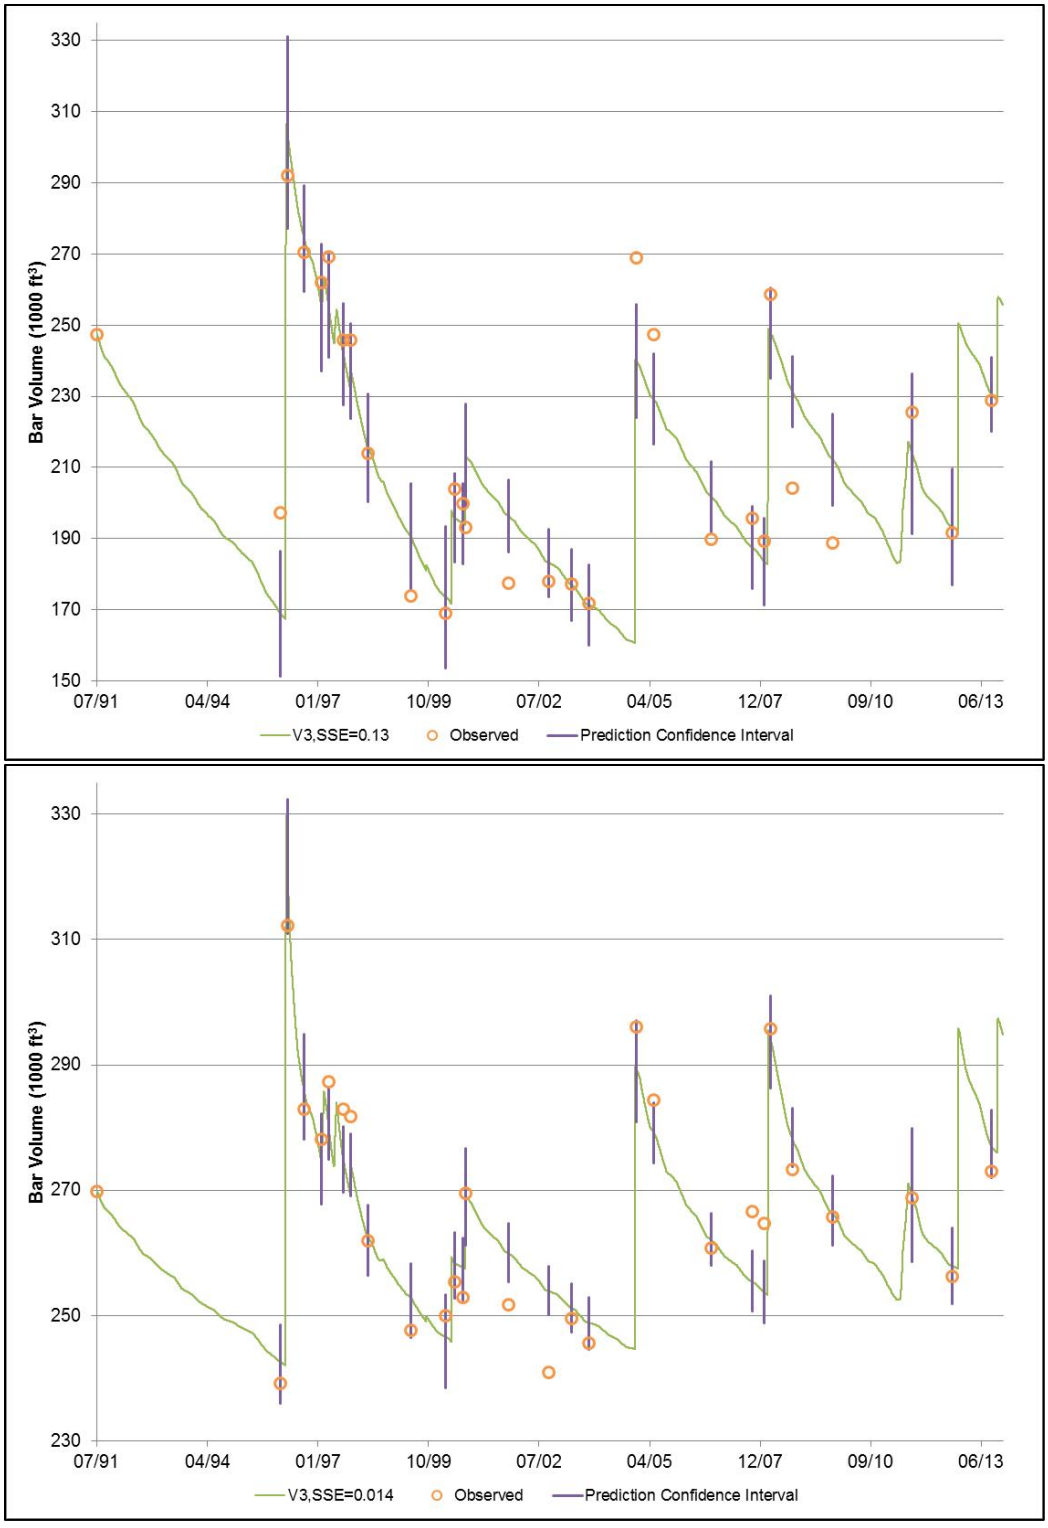

Figure 9 Model V3 predicted bar volume time series and prediction confidence intervals (median above, mean below)

Comparing observed vs. predicted trends of deposition or erosion between survey dates show that both models predict the trend correctly 25 out of 28 times. Both models miss the apparently mild depositional event between October 2006 and October 2007. The remaining trend errors for both the mean and median models occur in the 2000 to 2003 time frame.

Some parameter confidence intervals bound zero. The parameter confidence intervals developed by Matlab assume a normal parameter distribution, and this is likely not the case for the nonlinear model. Also, regression typically assumes that parameters are not correlated. An investigation of the optimized parameters shows that there is a correlation between the coefficients (a_d, a_e) and the flow exponents (b_e, b_e) respectively, as well as correlation between the coefficient a_e and the storage exponent n. No apparent correlation exists between the coefficient a_d and the storage exponent m. For physically practical purposes, a lower bound of zero should be imposed on all confidence intervals in Table 2.

SUMMARY

The empirical dataset of surveyed sand bar volumes in Marble Canyon on the Colorado River downstream of Glen Canyon Dam was analyzed. A subset of the empirical dataset was established based on bar and survey date consistency, resulting in the calibration dataset. The sand bar calibration dataset is represented by both the mean and median of the sand bar volume.

A conceptual model describing erosive and depositional processes for sand bars in Marble Canyon is described. A series of model formulations (termed Model V0 through V5) were developed and Model V3 is selected based on model performance calculated as the normalized sum of squared errors and adjusted R-squared. Confidence intervals were developed for the parameters and for the predicted bar volumes coinciding with calibration data survey dates.

Median and mean versions of Model V3 show similar percent improvement over the model V0 performance (86% for median, 89% for mean). The prediction confidence intervals contain 19 of the 28 observed bar volumes for both the mean and median V3 models. Deposition and erosion trends between survey dates are correctly predicted 25 out of 28 times for both the mean and median V3 models. The mean V3 model tended to perform better in the vicinity of HFEs as compared to the median V3 model.

PROCESSES LIMITING DEPTH OF ARROYO INCISION: EXAMPLES FROM THE RIO PUERCO, NEW MEXICO

Eleanor Griffin, Research Hydrologist, U.S. Geological Survey, Boulder, CO, egriffin@usgs.gov; and Jonathan Friedman, Research Hydrologist, U.S. Geological Survey, Fort Collins, CO, friedmanj@usgs.gov

Abstract: We examined channel flow and suspended sediment transport processes within the lower Rio Puerco arroyo, located in semi-arid north-central New Mexico, in an attempt to answer the question: Why did arroyo incision stop by about 1936? Channel flow model results show that in the narrow, incised channel of 1936, the boundary shear stress during a large flood was highest over the lower banks and bank toes, causing a higher potential for erosion of these surfaces than of the channel bed. This would have caused the channel (and arroyo) to widen, and the higher sediment fluxes from those surfaces would have inhibited the capacity of the flow to erode the bed. We found that volumes of sediment delivered to the channel from local erosion of the arroyo wall did not exceed the capacity of the flow to transport sediment, including sand, in suspension. However, sediment supplied from erosion upstream of our study reach may have reduced the capacity of the flow to erode the bed. Our results suggest that arroyo incision ended with the observed reduction in flood peak magnitude, frequency, and duration after 1941.

INTRODUCTION

Channel incision in the semi-arid southwestern United States in the mid- to late-1800s through early 1900s led to the development of arroyos, which are steep-sided, narrow gullies in which flood flows no longer overtop the walls (Hovey, 1902; Bryan and Post, 1927). Arroyos created hazards for travel and to livestock, and downcutting of the channel eliminated opportunities for flow diversion for irrigation (Bryan, 1928). Large volumes of sediment transported in the Rio Puerco downstream to the mouth between 1929 and the mid-1940s contributed to channel bed aggradation and increased flooding in the middle Rio Grande (Happ, 1948; Welsh, 1985). In addition, the high rate of sediment delivery to the Rio Grande decreased storage capacity of Elephant Butte Reservoir (Figure 1; Bryan and Post, 1927).

Between 1927 and 1936, the 55-km-long lower Rio Puerco arroyo (Figure 1) both widened and incised. Large floods in 1929, 1935 and 1936 contributed to an increase in arroyo volume by about 44.5 x 10^6 m^3 during this period (Friedman et al., 2014). Average arroyo width in this reach nearly doubled, increasing from 118 m in 1927 to 212 m by 1935 (Friedman et al., 2014). In the first 10 valley km (vk) downstream from Highway 6, arroyo depth increased from an average of about 12.1 m in 1927 (Bryan, 1928) to about 14.6 m by 1936 (Friedman et al., 2014). Arroyo volume can increase either by: 1) channel bed incision; 2) block failure of an arroyo wall undercut by channel or floodplain flow; or 3) erosion of inset terraces by meander migration. Eroded sediment can be redistributed within the arroyo, but some fraction of that sediment must be transported down-valley to the mouth in order to have a net increase in arroyo volume through time. In the lower 55 km of the Rio Puerco arroyo, we know that channel bed incision continued until shortly after the flood of record in 1929 and reached a maximum near Highway 6 by about 1936 (Elliott et al., 1999; Friedman et al., 2014). Much of the sediment eroded from the arroyo walls, channel bed, or inset terraces was transported down-valley and either deposited near the mouth, forming a delta, or transported into the Rio Grande (Bryan and Post, 1927; Tuan, 1966).

We examined the processes that caused incision of the channel bed and erosion of the arroyo walls in the first 10 km down-valley from the concrete sill near the Highway 6 crossing (Figure 1). A single arroyo cross section surveyed by K. Bryan in August 1936 (Elliott et al., 1999), located at vk 0.76, provides an example of the shape of the incising arroyo and inset active channel. At this location, the arroyo depth (height of the pre-arroyo valley floor above the channel bed) increased from 13.0 m in 1927 to 15.6 m in 1936, and subsequent aggradation on the bed reduced the depth to 14.9 m by August 1972 (Elliott et al., 1999). Dated sediment deposits in a trench excavated across the arroyo bottom at vk 0.84 km (the Highway 6 trench) indicate that the arroyo bottom has been aggrading since at least the early 1960s (Friedman et al., 2014). The question we address here is: Why did incision stop by about 1936?

Background: The Rio Puerco is an ephemeral tributary of the Rio Grande incised in fine valley-fill sediment, dominantly sand, silt and clay (Heath, 1983; Love, 1986). The watershed occupies 19,040 km^2 dominated by easily eroded sedimentary rocks (Heath, 1983). Elevation ranges from 3444 m at the summit of Mount Taylor, near the

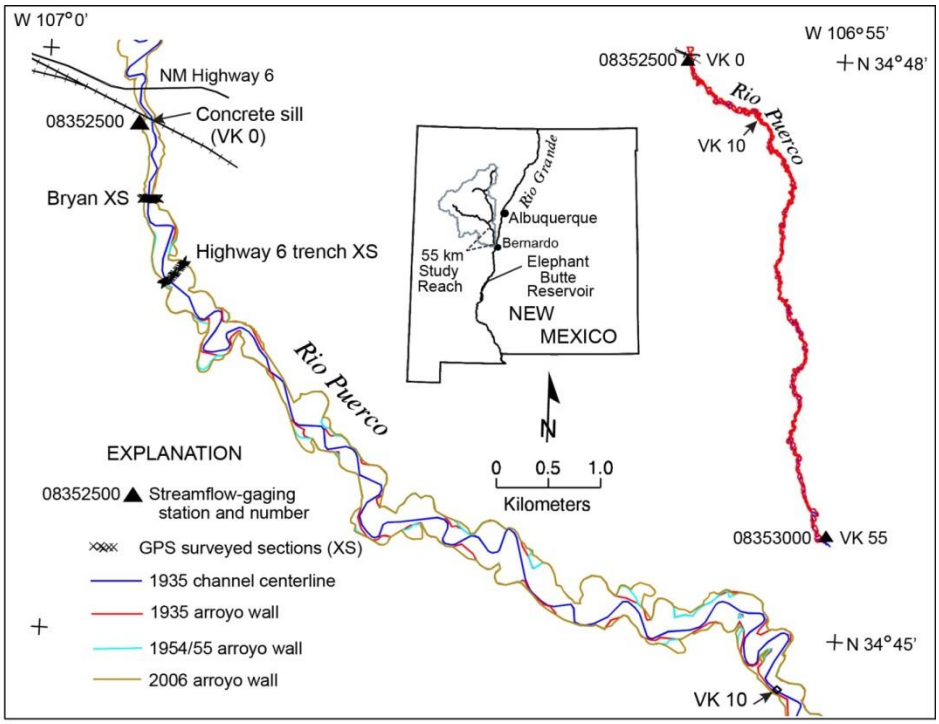

Figure 1 Map of the study reach. We focused this study on incision and arroyo wall erosion processes in the first 10 km downstream from the concrete sill on the downstream side of the railroad bridge near the Highway 6 crossing. Locations of two historical streamflow-gaging stations within the lower Rio Puerco arroyo are shown. Arroyo wall locations in 1935 (red line), the 1950s (light blue line), and 2006 (tan line) show the extent of arroyo widening since 1935. Where lines representing the 1935 and 1954/55 arroyo walls are visible, the arroyo has widened.

center of the watershed, to 1440 m at the mouth of the Rio Puerco near Bernardo (Figure 1). Floods usually are the result of sequences of summer to early fall monsoonal thunderstorms (Heath, 1983; Griffin et al., 2010). Mean annual precipitation varies from about 323 mm in the northeastern highlands to 212 mm at Bernardo, NM (1948 to 1997; Molnár and Ramírez, 2001).

Records available from the U.S. Geological Survey (USGS) streamflow-gaging stations Rio Puerco at Rio Puerco, NM (#08352500), located at vk 0 (Figure 1), and Rio Puerco near Bernardo, NM (#08353000), located at vk 55, indicate that annual peak flows have declined since the flood of record in September 1929 (Friedman et al., 2014). The magnitude of the peak flow on 23 September 1929 was 1,070 m^3/s at Rio Puerco (New Mexico State Engineer, 1930). This event was preceded by a flood with a peak discharge of 880 m^3/s in August 1929. The 1929 floods damaged the Atchison, Topeka, and Santa Fe (AT&SF) Railway Company railroad bridge at the Highway 6 crossing (Figure 1). During the bridge reconstruction in 1930, the concrete sill on the downstream side of the bridge was extended to the full width between abutments, and four concrete steps were added with a total drop from the sill to the downstream channel bed of 4.7 m (Powell, L.H., Chief Engineer, AT&SF Railway Company, written commun., 1953).

The Rio Puerco is known to carry high concentrations of sediment in suspension and to convey high suspended sediment loads (Nordin, 1963; Elliott et al., 1999; Bierman et al., 2005). More than 50% of 524 suspended sediment samples collected at the gage Rio Puerco near Bernardo between October 1947 and September 2002 had concentrations >100,000 mg/L (volume concentration (vol. conc.) > 0.0377; USGS Water-Quality data, 2014a). All samples with concentrations higher than 199,000 mg/L (vol. conc. 0.0751; n = 59) contained sand (Griffin et al., 2014).

The capacity of open channel flow to erode a surface is dependent in part on the sediment load already carried in the flow. Flow entering a reach that already is carrying the maximum sediment load cannot erode a surface unless there is an increase in the shear stress, which can be caused by a constriction in the channel or an increase in slope, for

example. In contrast, if the upstream sediment supply has been cut off by dam construction, then the magnitude of incision and widening can be extreme (Xia et al., 2014). Sand in suspension is transported at about the mean velocity of the fluid, whereas sand transported as bedload moves at the much lower velocity of the near-bed region of the flow. Suspended sediment samples collected by Nordin (1963) and annual suspended sediment loads (Elliott et al., 1999; Bierman et al., 2005) indicate that the dominant mode of sediment transport in this river is in suspension, and we assume that bedload transport is negligible.

Erosion of the Rio Puerco channel bed and arroyo walls is initiated by flow with locally increasing shear stress and increasing capacity to transport sediment, including the fine to very fine sand found in this system (Friedman et al., 2014). The process of wall erosion is dominated by undercutting of the cohesive wall by fluvial erosion along the exposed base of the wall (Figure 2). Layers of clay within the pre-arroyo valley-fill sediment provide cohesion that supports a steep wall face despite heights of more than 10 m. Field observations indicate that block mass failures occur when the wall has been undercut by 1.5 m or more. A single mass failure can deliver a large volume of sediment to the arroyo bottom. Sediment deposited on the arroyo bottom from wall mass failures temporarily protects the base of the wall from erosion. These failures also increase the local availability of sediment for transport, reducing the capacity of the flow to erode the bed.

Any geomorphic, hydrologic, or vegetative change that reduces the magnitude and duration of shear stress acting on the sediment surface can reduce the rate of incision. Possible changes include a reduction in runoff magnitude or duration through time, geomorphic changes that cause a reduction in bed gradient or an increase in flow width, or vegetative changes that add drag to the flow, reducing the shear stress on the sediment surface (see Simon et al., 2000). An increasing sediment load from erosion upstream also can reduce the capacity of flow to erode the bed.

We examined historical flow data (USGS, 2014a,b) and observed geomorphic changes in the arroyo (Friedman et al., 2014) to identify possible causes of the termination of incision in the lower Rio Puerco. We applied a physically based model for flow (Kean and Smith, 2004) to determine how observed widening of the arroyo bottom affected the boundary shear stress distribution during a large flood and the capacity of the flow to transport sediment in suspension. We compared the capacity of the flow to transport sediment with the available record of suspended sediment load transported past the gage near Bernardo (USGS, 2014a). Finally, we compared the extent of arroyo wall erosion determined from wall locations mapped from aerial imagery and LiDAR data covering the reach from vk 0 – 10 for four time intervals between 1935 and 2010.

Progression of incision and widening upstream from the study reach may have contributed to high sediment loads entering the reach, which could have limited the capacity of the flow to erode the bed in the study reach. Using available topographic data (Friedman et al., 2014), we can estimate the volumes of erosion and deposition within the

Figure 2 Example of a sharp bend in which channel flow has undercut the arroyo wall. The pre-arroyo valley-floor surface is about 10.5 m above the channel bed. The thickness of the undercut wall segment is about 7.6 m. Channel flow direction is from bottom of photo to middle left. (Photo taken April 3, 2010 by E. Griffin.)

study reach through time, but have no knowledge of volumes of sediment transported into the reach from upstream. Therefore, we can only infer the possible effects of increased incoming sediment loads on erosion of the arroyo bottom through time.

METHODS

Historical Flow and Suspended Sediment Transport: The streamflow-gaging station Rio Puerco at Rio Puerco, NM, located at the upstream end of our study reach (Figure 1), was operated from Water Year (WY) 1935 through 1976. Additional annual peak flows were determined from peak gage height and indirect discharge measurements at this station through WY 1991 (USGS, 2014b). Limited sediment data were collected at this site. The streamflow-gaging station Rio Puerco near Bernardo, NM, has been in continuous operation since WY 1941, and suspended sediment data are available beginning for WY 1956. We computed annual flow volumes at Rio Puerco for WY 1935 through 1976 and near Bernardo for WY 1941 through 2013 to examine changes through time. By the mid-1970s, the Rio Puerco channel had narrowed and woody vegetation canopy covered 47% of the arroyo bottom (Friedman et al., 2014), changing the flow distribution within the arroyo. Therefore, we applied linear regressions to determine the average relations between annual flow volume and suspended sediment load for the periods 1956 to 1975 and 1976 to 2013, and we estimated the sediment load for WY 1941 using the regression equation for the first period.

Topographic and Imagery Data Sources: Available topographic and imagery data include data from aerial Light Detection and Ranging (LiDAR) surveys conducted in April and July 2005 (Vincent et al., 2009) and March 2010 (Perignon et al., 2013). Arroyo features were mapped from imagery collected in 1935, 1954/55, 1975/79, and 2005 (Friedman et al., 2014). Bryan and Post (1927) and Bryan (1928) provided arroyo width and depth data collected in the late 1800s and early 1900s. All data have been referenced to the North American Datum of 1983 (NAD 83; horizontal datum) and to the North American Vertical Datum of 1988 (NAVD 88).

Channel Shape: Arroyo geomorphic data for the period of incision are almost entirely limited to measurements of arroyo width and depth. Channel width in 1935 determined from aerial imagery (Friedman et al., 2014) ranged from about 30 to 65 m, with an average of 41.1 m. The arroyo cross section surveyed by Bryan in August 1936 (Figure 3; Elliott et al., 1999) provides an example of the incised channel geometry near the end of the phase of incision. Top width of the inset channel in the 1936 Bryan cross section was 41.5 m, center depth was 4.6 m, cross-sectional area was 129 m^2, and the average bank angle was 20.3°.

Previous studies (Kean et al., 2009; Griffin et al., 2010) have shown that the sharp corners between the recently eroded channel bed and bank are areas of high shear stress, causing them to be short-duration, transient features. Therefore, we applied the Kean and Smith (2004) model using a channel shape similar to the 1936 Bryan cross section with a slightly rounded bank toe (**Case A**; Figure 3). We computed flow in the inset channel only, neglecting the terrace area to the right of the channel, artificially extending the banks upward in order to simulate flow in the early, narrow arroyo. For subsequent cases (B and C), we progressively widened the channel and reduced the bank angle as described below.

Nordin's (1963) cross sections surveyed in August and September 1961 near vk 55 provide examples of the channel that widened after initial incision. **Case B** is the channel shape from Case A, widened to match the width of the channel surveyed by Nordin (1963) on 19 August 1961, when measured discharge was 40.5 m^3/s. At a center depth of 1.89 m, top width was 35.9 m (36.5% wider than the channel shape in Case A at the same depth), cross-sectional area was 52.4 m^2, and the average bank angle was 15.3°. Again, for flow modeling purposes, the banks were extended upward at the same angle to accommodate the target flow.

Case C has the same bank geometry as Case B, but with the relatively flat segment in the center of the channel widened by 10 m. This channel shape simulates the wide, braided channel within the arroyo following the large floods of the 1930s and early 1940s (Friedman et al., 2014). Shrub canopy covered an average of only 9% of the arroyo bottom in 1935, and, in many cases, the shrubs present in 1935 were far from the channel (Friedman et al., 2014). In addition, frequent large floods between 1929 and 1936 prevented the establishment of vegetation on the channel bed (arroyo bottom). Therefore, we did not include drag on woody vegetation in these calculations.

Arroyo Wall Erosion: Erosion of the arroyo wall increases planimetric area of the arroyo, which can be used to estimate eroded sediment volumes. We mapped the 2010 arroyo wall locations from the 2010 LiDAR DTM

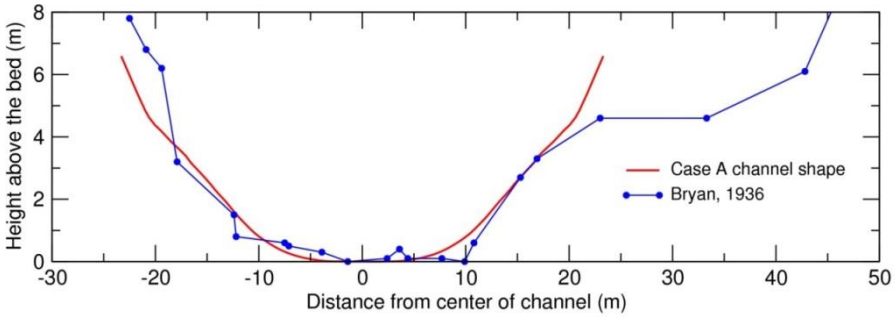

Figure 3 Initial modeled channel shape (Case A; red line), compared to the cross section surveyed by K. Bryan on 5 August 1936 (blue line; Elliott et al., 1999).

(Perignon et al., 2013) in the reach vk 0 – 10 for comparison with previously mapped wall locations in 1935, 1955, 1979, and 2005. We then mapped extents of wall erosion in each of four time intervals: from 1935 to 1955 (length = 20 yr); from 1955 to 1979 (length = 24 yr); from 1979 to 2005 (length = 26 yr); and from 2005 to 2010 (length = 5 yr). Although the last interval is considerably shorter than the others, there was a large flood within this interval (Vincent et al., 2009). For each of the four time intervals we identified: 1) average channel sinuosity; 2) the length of arroyo wall at the start of the interval exposed to channel flow at the base; 3) the length of arroyo wall at the start of the interval that was eroded by the end of the interval; 4) the total planimetric area eroded; and 5) the average wall erosion rate. The average arroyo wall erosion rate (m/yr) was computed by dividing the plan area eroded (m^2) by the length of wall eroded (m) and the number of years in the interval (yr). The computed erosion rates give the average movement of the arroyo wall through time at sites where the mapped change in wall location was >2 m (the minimum detectible movement; Friedman et al., 2014). The volume of sediment eroded from the arroyo wall between 1935 and 1955 was estimated by multiplying the eroded planimetric area by the estimated average height of the valley floor above the channel bed in 1955, about 14.4 m in this reach (Friedman et al., 2014).

Channel Flow Model Application: In a wide, unvegetated channel, the perimeter-averaged boundary shear stress, τ_b, is ρgRS, where ρ is the density of water in a clear-water flow (1,000 kg/m^3), or it is the bulk density of the fluid, ρ_f, in a sediment-laden flow, g is acceleration due to gravity (9.81 m/s^2), R is the hydraulic radius (m), and S is the water-surface slope, estimated here as the average bed slope. We assumed an average sediment density, ρ_s = 2,650 kg/m^3, and computed ρ_f using the equation

$$\rho_f = (1 - C_s)\rho_w + C_s \rho_s , \quad (1)$$

where C_s is the volume concentration of sediment in suspension and ρ_w is the density of water. We assumed that flow was quasi-steady and locally uniform in the down-valley direction and computed flow in the incised channel using the Kean and Smith (2004) model. This model includes the effects of friction on the lateral boundaries in the computation of the flow and boundary shear stress distributions. The model has been applied previously to compute flow in the narrow Rio Puerco channel of 2002 – 2007 in a reach with vegetated banks (Griffin et al., 2005) and in a reach in which bank vegetation had been killed by herbicide and removed by a flood (Griffin et al., 2010). This study is the first application of the model to compute flow in a narrow, deeply incised channel with large capacity. In all cases, the channel was assumed to be straight, with no secondary circulations in the flow.

We selected the magnitude of the annual peak discharge recorded on 23 September 1941, 480 m^3/s, as the target discharge (USGS, 2014b). This discharge is on the order of the mean annual peak flow for the record of the gage at Rio Puerco, 242 m^3/s, plus one standard deviation, 199 m^3/s (n = 51 yr). After 1941, annual peak flows exceeded 480 m^3/s only in 1972, 2006, and 2013. We applied the model to compute the depth of flow required to convey that discharge for each of the three cases for a narrow (Case A) to wide (Case C) channel.

Elevations of the channel bed determined from field survey data or estimated from trench stratigraphy near Highway 6 and Bernardo (Figure 1) combined with mapped channel centerline lengths through the 55 km-long arroyo segment indicate that an average channel bed slope of 0.0011 has been maintained through time since 1935 (Friedman et al., 2014). This slope is used for all of the calculations below. The average down-valley slope is 0.0016 (Griffin et al., 2014). Average sinuosity in 1935 was 1.33 (Friedman et al., 2014).

We assumed that channel bed roughness for flows with a meter or more depth was similar to that measured by Nordin (1963) in August and September 1961 (n = 0.014 to 0.016) and set the bed roughness, z_0, equal to 0.00016 m (Griffin et al., 2014). In a sand-bed stream, these flows are in the upper plane bed regime (Nordin, 1963; Guy et al., 1966). We estimated roughness of recently eroded banks starting 0.30 m above the bed as 0.005 m (Griffin et al., 2010). In the region of the lower bank and bank toe, we used a length-weighted average of the two values. We then calculated the depth required to convey the target discharge for each channel shape.

Computation of Suspended Sediment Transport: The capacity of the flow in the channel to transport sand and finer material in suspension was computed following the method of McLean (1992) and Smith and McLean (1977). We used the bed material distributions found by Griffin et al. (2014) to result in concentration profiles for each of 5 sediment sizes, ranging from medium silt to medium sand, that matched suspended sediment concentrations measured by Nordin (1963) on 20 September 1961 (Table 1). The transport of sand in suspension is dependent on the availability of sand for transport. Field observations (Nordin, 1963; Griffin et al., 2014) and suspended sediment measurements (USGS, 2014a) indicate that the availability of sand for transport has been highly variable through space and time. We assumed that channel bed porosity was 35%, giving a spatially averaged concentration of sediment in the bed, C_b, of 65%, and compensated for variability in availability of sand for transport by assuming sand covered only 25% of the bed in all cases (Topping et al., 2007; Griffin et al., 2014). Concentration profiles were computed for three segments of the channel flow in each case: 1) the middle of the channel over the nearly flat bed; 2) the lower bank and bank toe; and 3) the upper bank. We used the model-calculated τ_b distribution to determine the average τ_b in each segment, specified flow depth as the average depth in the segment, and computed the unit width sediment and sand fluxes (q_s and q_{sand}) in each segment. The total sediment and total sand fluxes in each case were computed by summing the fluxes in each segment.

In the absence of vegetative drag and form drag on topographic roughness elements, the skin friction shear stress, τ_{sf}, needed to compute the sediment transport, is equal to τ_b. Sediment is carried into suspension by turbulent diffusion, and the transport of sediment in suspension is determined by the ratio of the shear velocity, u_*, = $(\tau_b / \rho_f)^{1/2}$, to the sediment settling velocities (Yalin, 1972; Smith and McLean, 1977). Settling velocities for each particle size were determined using the method of Dietrich (1982). We estimated the near-bed reference concentration, C_a, using the equation

$$C_a = \frac{\gamma_0 C_b (T_* - 1)}{1 + \gamma_0 (T_* - 1)}, \tag{2}$$

(Smith and McLean, 1977) where T_* is the transport stage, equal to τ_b / τ_{cr} , τ_{cr} is the critical shear stress for erosion of sediment of a given size, and γ_0 = 0.004 (P.L. Wiberg, reported by McLean, 1992).

The computation of suspended sediment concentration profiles required iteration in each case, as the concentration of sediment in suspension affects the bulk fluid density (equation 1), which affects the sediment settling velocity (Dietrich, 1982). For each iteration, we modified the sediment settling velocities following the method of Dietrich (1982) and recomputed the suspended sediment concentration until the bulk fluid density from the previous iteration

Table 1 Bed material distribution assumed for suspended sediment calculations.

Sediment size (mm)	Fraction of bed material	Clear-water settling velocity (m/s)	Settling velocity with ρ_f = 1130 kg/m^3 (m/s)
0.016	0.40	0.00020	0.00015
0.050	0.14	0.0020	0.0015
0.065	0.20	0.0032	0.0025
0.13	0.19	0.0102	0.0081
0.26	0.07	0.0267	0.0231

was within 5% of the output bulk fluid density. Examples of the decrease in settling velocity for each grain size are shown in Table 1 for ρ_f = 1,130 kg/m^3 (vol. conc. 0.079).

Change in bed elevation (η) with time (t) is calculated from the 1-dimensional sediment continuity equation:

$$\frac{\partial \eta}{\partial t} = -\frac{1}{C_b}\left(\frac{\partial q_s}{\partial x}\right), \tag{3}$$

where x is distance downstream. Erosion of the bed can occur when there is an increase in the sediment flux through time, as during the rising limb of a flood, or with distance downstream. However, the capacity of a flow to erode the bed is strongly dependent on the sediment concentration already in suspension in the flow, which we cannot determine for the early 1900s floods in the study reach.

High concentrations of sand in suspension can cause a density gradient that dampens the turbulent mixing (Gelfenbaum and Smith, 1986; McLean, 1992). Data from Nordin (1963) and our field observations (Griffin et al., 2010) suggest that topographic irregularities in the Rio Puerco inhibit the development of a stable density-stratified flow, and we neglect that process here.

RESULTS

Annual Flow Volume and Suspended Sediment Load: Annual flow volumes from both gages (Figure 4) show a declining trend through time. Continuous flow data are not available for 1929, but the combined August and September flood magnitudes suggest that flow volume in that year was likely higher than in any year of the record. Floods in 1935 and 1936 produced high runoff volumes, but the largest flow volume in the period of record was in WY 1941, when high rainfall caused floods in May, September, and October (Heath, 1983). During the period of overlap in operation of the two gages from WY 1941 to 1976, the volume measured at Bernardo was an average of 94% of the volume measured at the upstream gage. Suspended sediment data from the gage near Bernardo also show a declining trend through time (Figure 5), with the relation between annual suspended sediment load and annual flow volume returning a higher load for a given flow volume in WY 1956 to 1975 than for the same flow volume in WY 1976 to 2013. Extrapolation of the regression for the early period to estimate flow volume in WY 1941 gives a total sediment load of 16.9 x10^6 metric tons (t), about the same as that in WY 1957.

Comparing the average annual sediment load for the period WY 1956 to 1975, 5.05 x 10^6 t/yr (sd = 2.80 x 10^6 t/yr; n = 19) to that for the period WY 1976 to 2013, 1.64 x 10^6 t/yr (sd = 1.01 x 10^6 t/yr; n = 37) shows a 66% decrease in the average annual load. Average annual flow volume also decreased, but only by 37%, from 40.0 x 10^6 m^3/yr (sd = 29.1 x 10^6 m^3/yr; n = 19) to 25.3 x 10^6 m^3/yr (sd = 19.3 x 10^6 m^3/yr; n = 37).

Channel Flow, Boundary Shear Stress, and Suspended Sediment Transport: Channel flow model results for **Case A** (Figure 6) show that as stage (center depth), h, increases from 1.10 to 5.10 m, the τ_b distribution changes from being relatively uniform across the bed and lower banks to showing areas of high stress over the bank toe and lower bank. Discharge increases from 33.0 m^3/s at h = 1.10 m to 480 m^3/s at h = 5.10 m, and the perimeter-averaged τ_b increases from 8.9 to 36.3 N/m^2. When h = 1.10 m, the model-calculated τ_b in the center of the channel is the same as ρghS. As flow depth increases, the difference between τ_b and ρghS in the middle of the channel increases, with a 30% difference between the two values when h = 5.10 m.

At h = 5.10 m, the average τ_b in the 7-m-wide zone of high stress over the bank toe is 51.5 N/m^2, 43% higher than the average in the middle of the channel, 35.9 N/m^2 (Figure 7A). The computed volume concentration of sediment in suspension, 0.0829, gives a total sediment flux of 39.8 m^3/s, and the computed sand flux is 13.4 m^3/s (Table 2). If the flow discharge were sustained at 480 m^3/s for one day and an unlimited supply of sediment, including sand, were readily available for transport, then the total sediment volume transported in a day could have been 3.44 x 10^6 m^3, and the sediment load could have been 9.11 x 10^6 t.

Flow depth in the wider channel of **Case B** required to convey 480 m^3/s is 4.16 m, 18% less than the depth in Case A. The maximum τ_b is reduced by 18%, and the difference between the average τ_b over the bank toe and τ_b in the

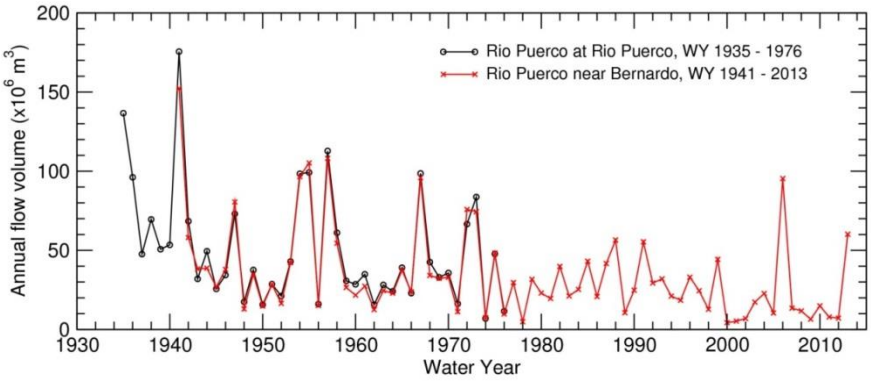

Figure 4 Annual flow volumes at the streamflow-gaging stations Rio Puerco at Rio Puerco (#08352500) and Rio Puerco near Bernardo, NM (#08353000). Declining trends in annual flow volumes are correlated with declining trends in annual peak flows.

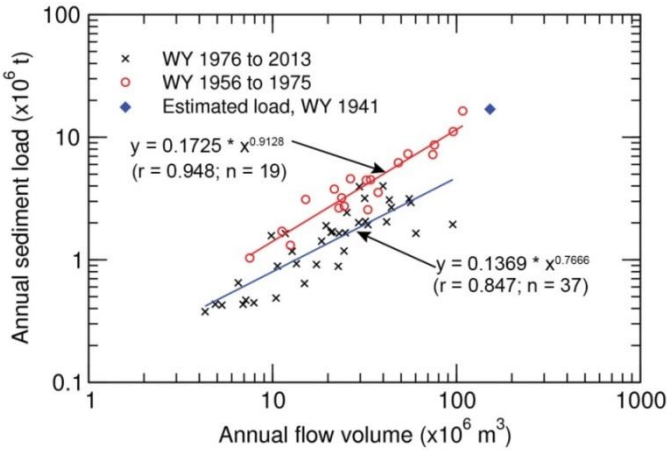

Figure 5 Annual sediment load as a function of annual flow volume from the record of the gaging station Rio Puerco near Bernardo, NM. Red circles are data for WY 1956 (the start of the sediment record) through 1975. Black xs are data for WY 1976 to 2013. The blue diamond is an estimate of the sediment load for WY 1941 based on the regression for WY 1956 through 1975 (red line).

middle of the channel is reduced by 17% (Figure 7). The computed τ_b in the middle of the channel is 11% less than the value of ρghS. The total sediment flux in this channel, 38.0 m^3/s, and sand flux, 12.7 m^3/s, are only 5% less than the computed fluxes in Case A (Table 2).

In the final example, **Case C**, the flow depth required to convey 480 m^3/s is reduced to 3.61 m, 29% less than depth in Case A, and the τ_b distribution approaches the more uniform pattern over the lower banks and bed, similar to the low-flow example of Case A. The maximum τ_b is 29% less than that in Case A, the average τ_b over the bank toe, 38.4 N/m^2, is only 11% greater than the average τ_b in the middle of the channel, and τ_b in the middle of the channel is only 4% less than ρghS. The total sediment flux is only 6.8% less than that in Case A, and the sand flux is 8.2% less (Table 2). The maximum τ_b in the middle of the channel is nearly the same in all 3 cases (Figure 7), ranging from 37.4 N/m^2 in Case C to 39.8 N/m^2 in case B despite the differences in flow depth.

The maximum q_s and q_{sand} (Table 2) are in the region of high τ_b over the lower bank and toe in each case. The maximum unit width fluxes are highest in the narrow channel and lowest in the wide channel, with q_s 24% lower and q_{sand} 27% lower in Case C than in Case A.

Wall Erosion: The extent of wall erosion from one point in time to another is related to the extent of unprotected arroyo wall exposed to channel flow at the start of the time interval (Table 3). In the reach from vk 0 to 10, the total

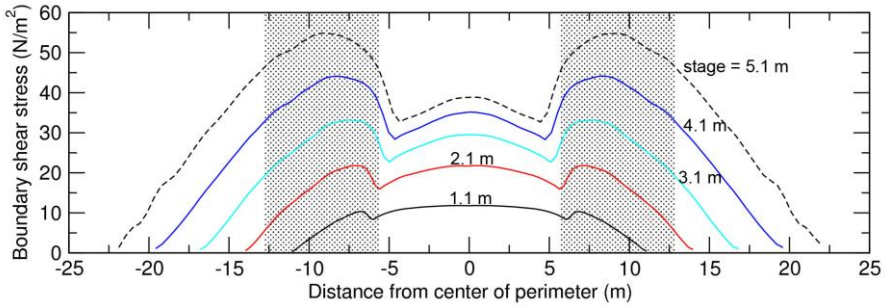

Figure 6 Change in boundary shear stress distribution with increasing flow stage from 1.1 to 5.1 m, Case A channel shape. The shading indicates areas of shear stress over the lower bank and toe.

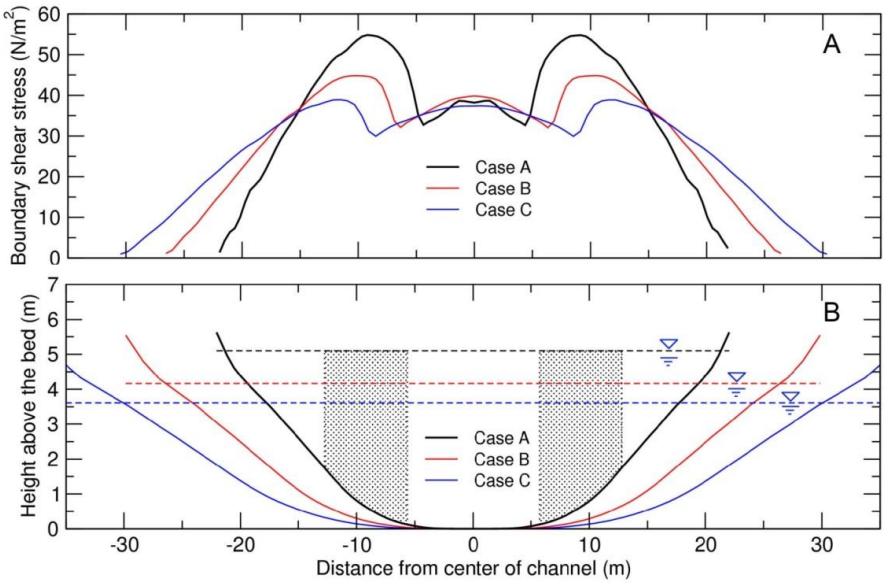

Figure 7 Model-calculated boundary shear stress (**A**) and channel shapes (**B**), with flow center depths that resulted in model-calculated discharge of 480 m^3/s. The shaded areas in B are the regions of high shear stress over the bank toe and lower bank in Case A.

length of wall segments exposed to channel flow at the base decreased from more than 6.3 km in 1935 to about 1 km by 1979. The total length of arroyo wall segments in 1935 that were eroded by 1955 was 7.9 km. Average arroyo width increased in this reach from 222 m in 1935 to 242 m by 1955. Multiplying the increase in arroyo area by the estimated height of the valley floor above the channel bed in 1955, 14.4 m, gives a volume of 2.85 x 10^6 m^3 eroded from the arroyo walls in this segment between 1935 and 1955. Assuming 35% porosity, the sediment volume eroded would have been about 1.85 x 10^6 m^3, with a total weight of 4.91 x 10^6 t, an average of 0.25 x 10^6 t/yr.

Despite the large decreases through time in annual flow volume and length of the arroyo wall exposed to channel flow at the base, the computed average wall erosion rates at sites that eroded all fall within a narrow range, from a minimum of 1.25 m/yr between 1935 and 1955 to a maximum of about 2.00 m/yr between 1979 and 2005.

DISCUSSION AND CONCLUSIONS

In all of the modeled flow cases, τ_b was above τ_{cr} for fine sand (D = 0.13 mm), 0.127 N/m^2. At the minimum modeled flow depth, h = 1.10 m, the perimeter-averaged τ_b, 8.9 N/m^2, was greater than that required to break up the clay armoring layer of the channel bed during Nordin's (1963) measurements (between 3.2 and 7.6 N/m^2). Therefore, all of the modeled flows potentially had the capacity to erode the arroyo bottom. Increasing the flow depth to 5.10 m in Case A resulted in an average shear stress over the lower bank and toe that was 43% higher than τ_b in the middle of the channel. Widening the channel reduced τ_b over the lower bank and toe so that by Case C,

with h = 3.61 m, τ_b over the lower bank and toe was only 11% greater than the average τ_b in the middle of the channel. The suspended sediment transport capacity of the 480 m^3/s channel flow was a maximum of 39.8 m^3/s in Case A. Despite a 26% reduction in mean τ_b from Case A to Case C, the capacity of the flow to transport sediment in suspension was reduced by only 7%.

The boundary shear stress distributions for Cases A, B, and C give an indication of the likely patterns of erosion during rising flow stage. The unit width sediment flux (q_s) varies with τ_b and h across the channel, and in all three cases, is maximum over the lower bank and toe (Table 2). However, the maximum q_s decreases by 24% as the channel widens from Case A to C, decreasing the potential for erosion (equation 3). During the rising limb of a flood, if the incoming sediment load is not at the capacity of the flow, increasing shear stress with stage would erode the wider channel (Case C) relatively uniformly across the bed. As stage rises in the incised, narrow channel (Case

A), the much higher τ_b over the lower banks and toes would cause erosion of those surfaces at a higher rate than the bed. Higher concentrations of sediment over the lower banks and toe would give rise to a concentration gradient toward the center of the channel, causing mixing of the suspended sediment across the channel and inhibiting the capacity of the flow to erode the bed.

The estimated increase in volume of the lower Rio Puerco arroyo through both incision and widening between 1927 and 1935, 44.5 x 10^6 m^3 (Friedman et al., 2014), contained an estimated sediment volume of 28.9 x 10^6 m^3, or about 76.7 x 10^6 t. This total provides an average load of 9.6 x 10^6 t/yr, which is less than the estimated sediment load for WY 1941 (16.9 x 10^6 t/yr). The calculated potential sediment load for a single day of flow at 480 m^3/s in Case A, 9.11 x 10^6 t, is nearly the same as the average annual sediment load from 1927 to 1935. The sediment eroded from the arroyo walls between 1935 and 1955 in the reach from vk 0 – 10, an average of 0.25 x 10^6 t/yr, was only 5% of the average annual sediment load measured at the gage near Bernardo between 1956 and 1975 (5.05 x 10^6 t/yr). The results suggest that the suspended sediment load in the Rio Puerco often has been less than the capacity of the flow to transport sediment in suspension. Therefore, total sediment transport capacity in this system does not appear to have limited the capacity for incision.

The large reduction in length of wall segments exposed to channel flow (Table 3) was the result of increasing width of the arroyo bottom, increasing channel sinuosity, decreasing channel width after the 1940s, and increasing density of woody vegetation on the arroyo bottom through time (Friedman et al., 2014). The greater length of arroyo wall eroded from 1935 to 1955 than the length of wall exposed to channel flow in 1935 was in part the result of rapid channel migration down-valley, with average rates of up to 12 m/yr found by Friedman et al. (2014). The results indicate that arroyo wall erosion rates at sites of erosion averaged about 1.5 m/yr from 1935 to 2010. Although the trend in annual flow volume decreased through time, narrowing of the channel through time (Friedman et al., 2014) caused an increase in flow depth and τ_b as a function of discharge. In addition, sites of wall erosion between 2005 and 2010 were dominantly within sharp bends, where secondary circulations increased the shear stress along the outside of the bend, at the base of the arroyo wall (Engel and Rhoads, 2012). These changes appear to have compensated for the reduction in flow magnitude and volume through time.

The above results indicate that changes in the total suspended sediment transport capacity through time did not limit the capacity for incision. Instead, increased boundary shear stress over the lower bank and toe caused by friction on the lateral boundaries of the narrow, incised channel of 1936 would have contributed to a tendency to widen the channel (and arroyo) rather than further incise the bed. The decreasing flood peak magnitude, frequency and duration after 1941 also decreased the capacity for erosion in this system. A period of moderately low flows from WY 1948 through 1952 (Figure 4) may have provided an opportunity for widespread establishment of woody vegetation on the arroyo bottom, creating drag on future flows and a further reduction of τ_{sf} and potential to erode the bed.

ABSTRACT

In arid and semi-arid rangelands where vegetation is typically sparse, a synergistic relationship is assumed to exist between spatial distribution of plants and hydrologic and erosion processes. In these environments, an accurate understanding of sediment transport processes is key to developing informed management actions and addressing ecosystem response to global changes. In this study, data from rainfall simulation experiments in saline rangeland communities of the Upper Colorado River Basin were used to improve understanding on various sediment and solute transport processes in field conditions. During these experiments, hydrology, erosion and high-resolution surface microtopography changes were routinely measured, presenting a unique opportunity to answer many sediment transport questions relevant to these saline rangeland and other sparsely vegetated ecosystems. A series of variables were developed to quantify and characterize surface microtopographic changes as a function of hydrology, erodibility and hillslope configuration. Key findings from preliminary analyses include: (1) the dependence of deposition on plot slope and its independence on hydrologic and soil loss variables, (2) data supporting the process of increased downcutting as slope increased, (3) significance of accounting deposition processes in overall runoff energy quantification, (4) evidence of an equilibrium channel geometry with a given discharge that is marginally impacted by runoff duration.

INTRODUCTION

Hillslope runoff and soil erosion processes play a vital role in rangeland ecosystem sustainability due to their control on resource mobility but they also have significant implications in off-site resource transport. Nichols et al. (2013) found for example that hillslope processes contributed to 85% of sediment delivery from a 43.7 ha semi-arid shrub-dominated watershed. The influence of vegetation on hillslope runoff and sediment production forms the basis of current hydrology and erosion modeling technologies on rangelands (Nearing et al., 2011). Early attempts to apply empirical soil erosion models derived primarily from cropland data, such as the Universal Soil Loss Equation – USLE and the Revisited Universal Soil Loss Equation – RUSLE, on rangelands yielded unsatisfactory and contested results (Blackburn, 1980; Foster et al., 1981; Hart, 1984; Johnson et al., 1984; Mitchell and Roundtable, 2010; Spaeth et al., 2003; Trieste and Gifford, 1980). Weltz et al. (1998) point to the lumped nature and rigid structure of these empirical models as a key deficiency when applied to rangelands where biotic and abiotic interactions play a strong control on surficial processes.

The advent of physically-based soil erosion models such as the Water Erosion Prediction Project model-WEPP (Laflen et al., 1991) offered the opportunity to develop the scientific framework necessary to provide insight into the relationship between hydrologic processes and rangeland condition. These research efforts led to the Rangeland Hydrology and Erosion Model (RHEM) (Nearing et al., 2011), developed from experimental data specifically collected on rangeland sites across the Western U.S. As a process-based erosion model, RHEM models erosion and hydrology using the same fundamental principles as WEPP.

Runoff generation and erosion on the hillslope are modeled in response to hydrological inputs and hydraulic parameters that are adjusted based on soil intrinsic properties and land surface conditions.

In both WEPP and RHEM, the hillslope is divided into interrill areas where splash and sheet detachment and transport occur and rills where flow is concentrated and fluvial processes dominate. Accurate partitioning of hillslope erosion into interrill and concentrated-flow-dominated processes has a significant implication on rangeland erosion modelling especially following disturbances. Several studies (e.g, Al-Hamdan et al., 2012; Pierson et al., 2013) have demonstrated a significant increase in concentrated flow erosion when shrub-dominated rangeland are disturbed by fire or woody species encroachment compared to undisturbed conditions.

Concentrated flow erosion is a complex process because rill networks have a dual function of sediment and runoff production and storage as well as that of transport of these resources off-site and these intricately coupled functions are traditionally assumed to be controlled by rill flow hydraulics. The key to accurate concentrated flow erosion has therefore been that of adequate prediction of hydraulic parameters. A great deal of research efforts have been invested into relating rill detachment rate to flow hydraulic parameters such as average shear stress (e.g., Ghebreiyessus et al., 1994; Lyle and Smerdon, 1965; Nearing et al., 1997; Torri et al., 1987), stream power (e.g., Bagnold, 1977; Nearing et al., 1997; Zhang et al., 2003), effective stream power (e.g., Bagnold, 1980). Performance tests of these hydraulic parameters at predicting rill detachment rate in various experimental conditions (Al-Hamdan et al., 2012; Wirtz et al., 2013) resulted in no single parameter consistently best-fitting observed detachment rates, although (Al-Hamdan et al., 2012) found that the stream power performed well with rangeland erosion data. Wirtz et al. (2013) attributed discrepancies between observed and predicted erosions to the inherent emphasis of most hydraulic parameters on fluvial processes incising channel bottoms while diffusive processes such as headcut-retreat and bank-erosion make up a non-negligible portion of rill detachment.

Currently available hydraulic-driven-rill-detachment equations albeit incomplete, offer a widely accepted modeling framework but often rely on a good characterization of the channel network. One of the knowledge gap in process-based soil erosion modeling especially on rangelands is the lack of an adequate framework to characterize spatial extent of concentrated flow network. Another knowledge gap in these process-based modeling approaches concerns the mechanism of deposition.

As part of an effort to quantify salt transport from rangelands to the Upper Colorado River Basin (UCRB), experimental rainfall simulation studies were conducted in saline rangelands communities of this basin. Hydrology, erosion and high-resolution surface microtopography changes were routinely measured during these simulations, presenting a unique opportunity to answer many sediment transport questions relevant to these saline rangelands and other sparsely vegetated rangelands. The aim of this paper was to gain insight into the processes of concentrated flow erosion and deposition on saline rangelands by relating traditionally measured hydrologic and sediment yield data to observed expression of these processes in surface microtopography. This knowledge would provide a predictive framework for hydraulic parameter estimation on saline rangelands for use in physically-based erosion models such as RHEM.

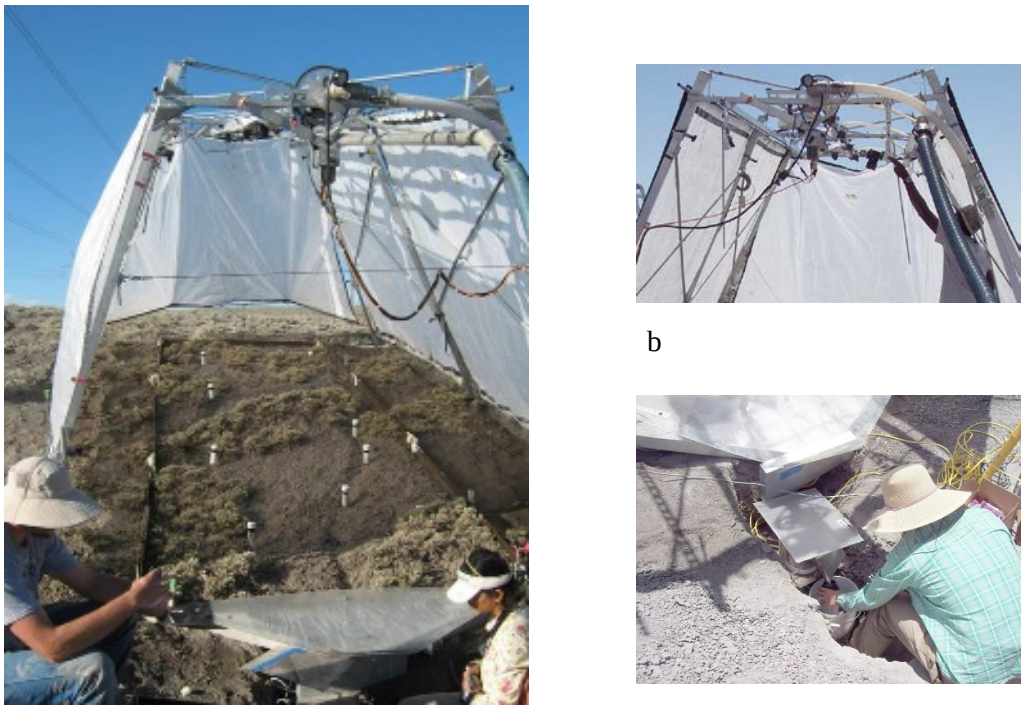
MATERIAL AND METHODS

Study area: This study was part of a broader research effort aimed at quantifying salt transport from rangelands to the Upper Colorado River headwaters. Previous researchers (e.g., Hawkins et al., 1977; Riley et al., 1979; Tuttle and Grauch, 2009) have identified upland areas of the Upper Colorado River Basin in the Mancos Shale and Eagle Valley Evaporite geologic formations as major contributor to the river's salinity. For our study, two sites (Price and DryX hereafter) in the Mancos Shale geologic formation were then selected to conduct rainfall simulation experiments. These sites were selected for their contrasting slope ranges and differences in intrinsic properties of the soil.

The Price site was located near the city of Price, Utah at the geographic coordinates 39° 27' 47.22"N 110° 36' 26.16"W and average elevation of 1649 m. The soil on this site was mapped as a Persayo loam soil series and classified as loamy, mixed, active, calcareous, mesic, shallow, typic torriorthents. Measured slopes on the experimental site ranged from 0.6 to 10%. DryX was located near the city of Ferron, Utah at the geographic coordinates 38°58'38.50"N 111° 7'10.60"W and average elevation of 1893 m. The predominant soil type at DryX was mapped as a complex of Chipeta series soils with Badland areas. The taxonomic classification of the Chipeta series is clayey, mixed, active, calcareous, mesic, shallow, typic torriorthents. Measured slopes at the study area of the DryX site ranged from 11.4% to 24.5%.

Experimental setup

On each experimental site, a series of rainfall simulations were conducted on 6 m x 2 m erosion plots to quantify sediment and salt transport processes during rainfall-driven erosion processes. Erosion and hydrologic responses were assessed by measuring soil loss, runoff and solute transport under four rainfall intensities corresponding to return periods of 2 (50.8 mm/hr), 10 (88.9 mm/hr), 25 (114.3 mm/hr) and 50 (139.7 mm/hr) years. On each plot, a single rainfall event was applied to ensure the capture of the process of salt efflorescence (Bowles et al., 1982; Riley et al., 1982) whereby a salt crust is left at the soil surface by evaporation. Each rainfall intensity on each site was replicated three times leading to a total of twelve plots per site.



a b c

Figure 1 Experimental setup showing (a) rainfall simulator on 6 m x 2 m plot, (b) a close-up view of the camera mount and rail mechanism and (c) the supercritical flume used for runoff discharge measurement and runoff sampling.

A Walnut Gulch Rainfall Simulator (WGRS) (Paige et al., 2004) was used in this study (Figure 1a). A rail mechanism mounted lengthwise on the frame of the simulator supported a camera (Figure 1b) which was used to take overlapping pictures before and after each rainfall event to reconstruct soil surface microtopography at sub-millimeter resolution. A digital Single Lens Reflex (SLR) camera equipped with a

20 mm lens was used for acquiring the surface reconstruction pictures. The average camera-ground distance was 2.4 m and the overlap between adjacent pictures 0.15 m. Pictures were taken along two paths 0.76 m apart on either side of the central boom of the simulator. This image network configuration resulted in 80 to 90 pictures to cover each plot. Translucent side curtains on the simulator served the dual purpose of diffusing light, reducing excessive shadowing in the pictures and limited the effect of wind on rainfall distribution.

Soil surface analysis: Soil surface microtopography was reconstructed using the structure from motion software Agisoft PhotoScan 1.0 (Agisoft Llc, 2013). For each plot, PhotoScan produced pre- and post-rain point clouds which were manually edited to remove vegetation points in the software Cloud Compare (General Public Licence, 2014). Vegetation-free point clouds were then converted in Digital Elevation Models (DEMs) (Figure 2) and analyzed within the ArcGIS system (Esri, 2011).

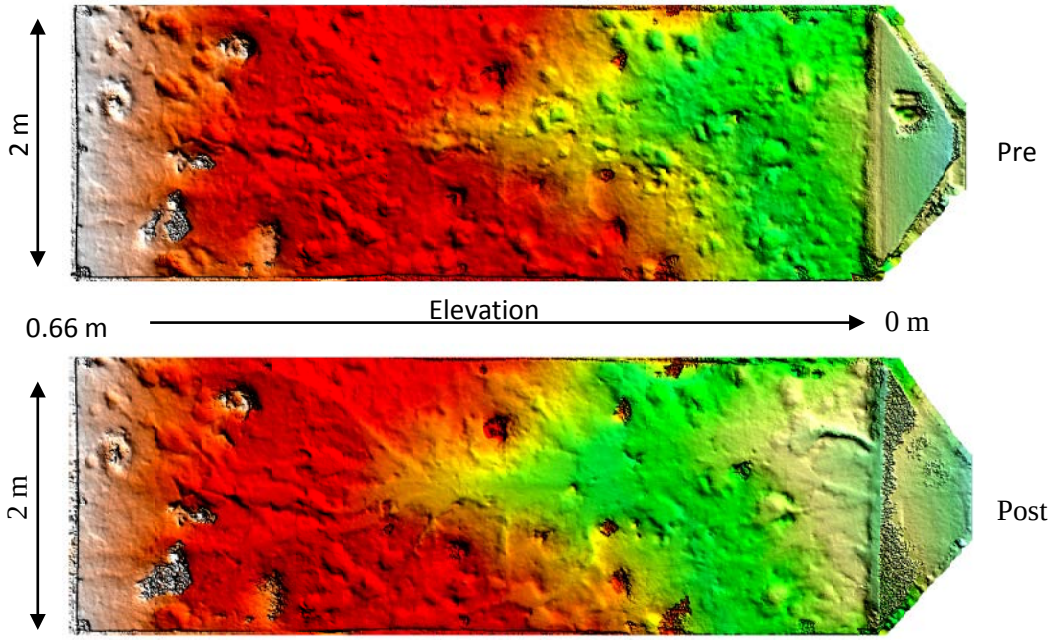


Figure 2 Example of 5-mm resolution DEMs representing soil microtopography reconstructed pre and post rainfall.

In this paper, changes in soil surface microtopography were related to sediment transport mechanisms. Changes to soil surface microtopography were quantified by subtracting post- from pre-rain DEMs, allowing the distinction between erosion areas (negative difference) and deposition areas (positive difference). To characterize soil surface response to erosive events, various areal and volumetric surface metrics were calculated from pre- and post-rain DEMs as well as the difference of DEMs.

Total erosion, deposition and net loss: The overall spatial extents of erosion processes TX_E and deposition TX_D were calculated as

$$TX_E = n \times A \quad (1)$$

$$TX_D = m \times A \quad (2)$$

where n and m are the number of grid cells with respectively negative and positive DEM differences and A is the grid size.

The volumes TV_E, TV_D and TV_N corresponding to erosion and deposition and net loss processes were also quantified as

$$TV_E = \sum_{i=0}^{i=n} \Delta Z_i \times A \tag{3}$$

$$TV_D = \sum_{j=0}^{j=m} \Delta Z_j \times A \tag{4}$$

$$TV_N = TV_E - TV_D \tag{5}$$

where *i* and *j* are respectively grid positions of erosion and deposition and ΔZ is the magnitude of elevation change.

Channel processes: Understanding mechanisms of erosion processes in concentrated flow pathways as they relate to other landscape attributes is crucial to accurate soil erosion modeling. In this study, flow concentration pathways were identified by applying the bottom-hat (also known as the black top-hat) mathematical morphology to the original DEMs. The bottom-hat operator detects local extrema in a two dimensional signals such as images and DEMs. This operator has been successfully applied to digital topographic data to delineate flow network and detect erosional incision (e.g., Rodriguez et al., 2002; Schwanghart et al., 2013). The detail presentation of the bottom-hat implementation is beyond the scope of this paper but in our study, the output of this operator was a spatial function whose minima were areas in the DEMs of local concavities. To minimize the effect of surface roughness in channel network detection, the original DEMs were smoothed using a 0.125 m^2 diamond-shaped structuring element similar to that used in Hyun-Chong et al. (2006). Concentrated flow pathways were considered as areas with bottom-hat responses lower than the plot average. Flow networks corresponding to the conditions pre- (Net_{pre}) and post- (Net_{post}) rain were merged to give a final flow network *Net*.

Spatial extent of erosion and deposition (CX_E and CX_D) that occurred within channels were obtained in a similar manner as TX_E and TX_D.

$$CX_E = n_c \times A \tag{6}$$

$$CX_D = m_c \times A \tag{7}$$

where n_c and m_c are the number of grid cells with respectively negative and positive DEM differences within *Net*. Likewise, CV_E, CV_D and CV_N were calculated by applying Eq. 3-5 to areas within *Net*.

Erosive forces can alter channel networks in both vertical and lateral dimensions depending on hillslope characteristics. These directional changes to the channel network were captured in $Net_{\Delta xy}$ and $Net_{\Delta z}$ for lateral and vertical changes respectively as:

$$Net_{\Delta xy} = Net_{post} \backslash Net_{pre} \tag{8}$$

$$Net_{\Delta z} = Net_{post} \cap Net_{pre} \tag{9}$$

where \ is the set difference operator and ∩ the intersection operator.

From the $Net_{\Delta xy}$ sub-network, spatial and volumetric metrics CX_{xyE}, CX_{xyD}, CV_{xyE}, CV_{xyD} and CV_{xyN} were calculated whereas $Net_{\Delta z}$ was used to obtain CX_{zE}, CX_{zD}, CV_{zE}, CV_{zD} and CV_{zN}.

Other secondary parameters were also calculated:

$$CXR = (CX_E + CX_D)/(TX_E + TX_D) \quad (10)$$

$$CVR_E = CV_E/TV_E \quad (11)$$

$$CVR_N = CV_N/TV_N \quad (12)$$

CXR, CVR_E and CVR_D express the space-based and volume-based ratio of concentrated flow processes that occurred on a plot.

The proportion of concentrated flow energy expenditure in lateral channel expansion versus vertical growth was quantified using two parameters α and α' calculated as:

$$\alpha = CV_{xyE}/CV_E \quad (13)$$

$$\alpha' = CV_{xyN}/CV_N \quad (14)$$

Deposition processes were also examined by calculating the proportion of eroded volume that was re-deposited at the plot level (*TDR*) and in the channels (*CDR*).

$$TDR = TV_D/TV_E \quad (15)$$

$$CDR = CV_D/CV_E \quad (16)$$

These surface changes metrics were related to hydrologic and erosion variables as well as plot slope (SLP). Hydrologic variables used were precipitation (*P*), runoff discharge (*R*), infiltration rate (*IR*), cumulative runoff (SR) and erosion information were sediment concentration (SC) and total sediment loss (S). Throughout this paper, the units are m^2 for spatial metrics (e.g., TX_E, CX_E), m^3 for volumetric surface metrics (e.g., TV_E, CV_E). *P*, *R* and *IR* are in mm, *SR* in 10^{-3} m^3, *SC* in g/L and *S* is in g.

PRELIMINARY RESULTS FROM THE PRICE SITE

Plot-wide erosion and deposition processes: Figure 3 shows the relationships between calculated plot-wide-surface-change metrics and hydrology, erosion and plot slope gradient. For erosion processes, volumetric metrics improved the correlation with hydrology and erosion variables (increased R^2) compared to the spatial metrics (e.g., TX_E vs TV_E), suggesting that incorporating the depth information is crucial to understanding erosion and deposition processes. This improvement in R^2 with the incorporation of depth information was observed throughout the analyses in this study therefore area-based metrics have been excluded as much as possible from other figures for conciseness.

TV_E had the highest correlation in all comparisons except with slope with which TX_E performed better, suggesting that in our experimental conditions at Price, overall eroded volumes were not a function of slope. Cumulative runoff *SR* and runoff rate *R* were better predictors of erosion volumes TV_E with R^2 of 0.60 and 0.74 compared to sediment concentration *SC* and cumulative sediment *S* (R^2 = 0.14 and 0.38 respectively). This finding suggests that a portion of observed sediment loss by weight (especially the colloidal soil fraction) has little contribution to overall surface microtopography. Also, runoff rate R better predicted erosion volumes than cumulative runoff. This finding is consistent with the existence of an equilibrium-channel-network-geometry for a specific runoff discharge with marginal influence of runoff duration. It is also important to note that rainfall events at the Price site did not vary significantly in length which may have masked the effect of runoff duration.

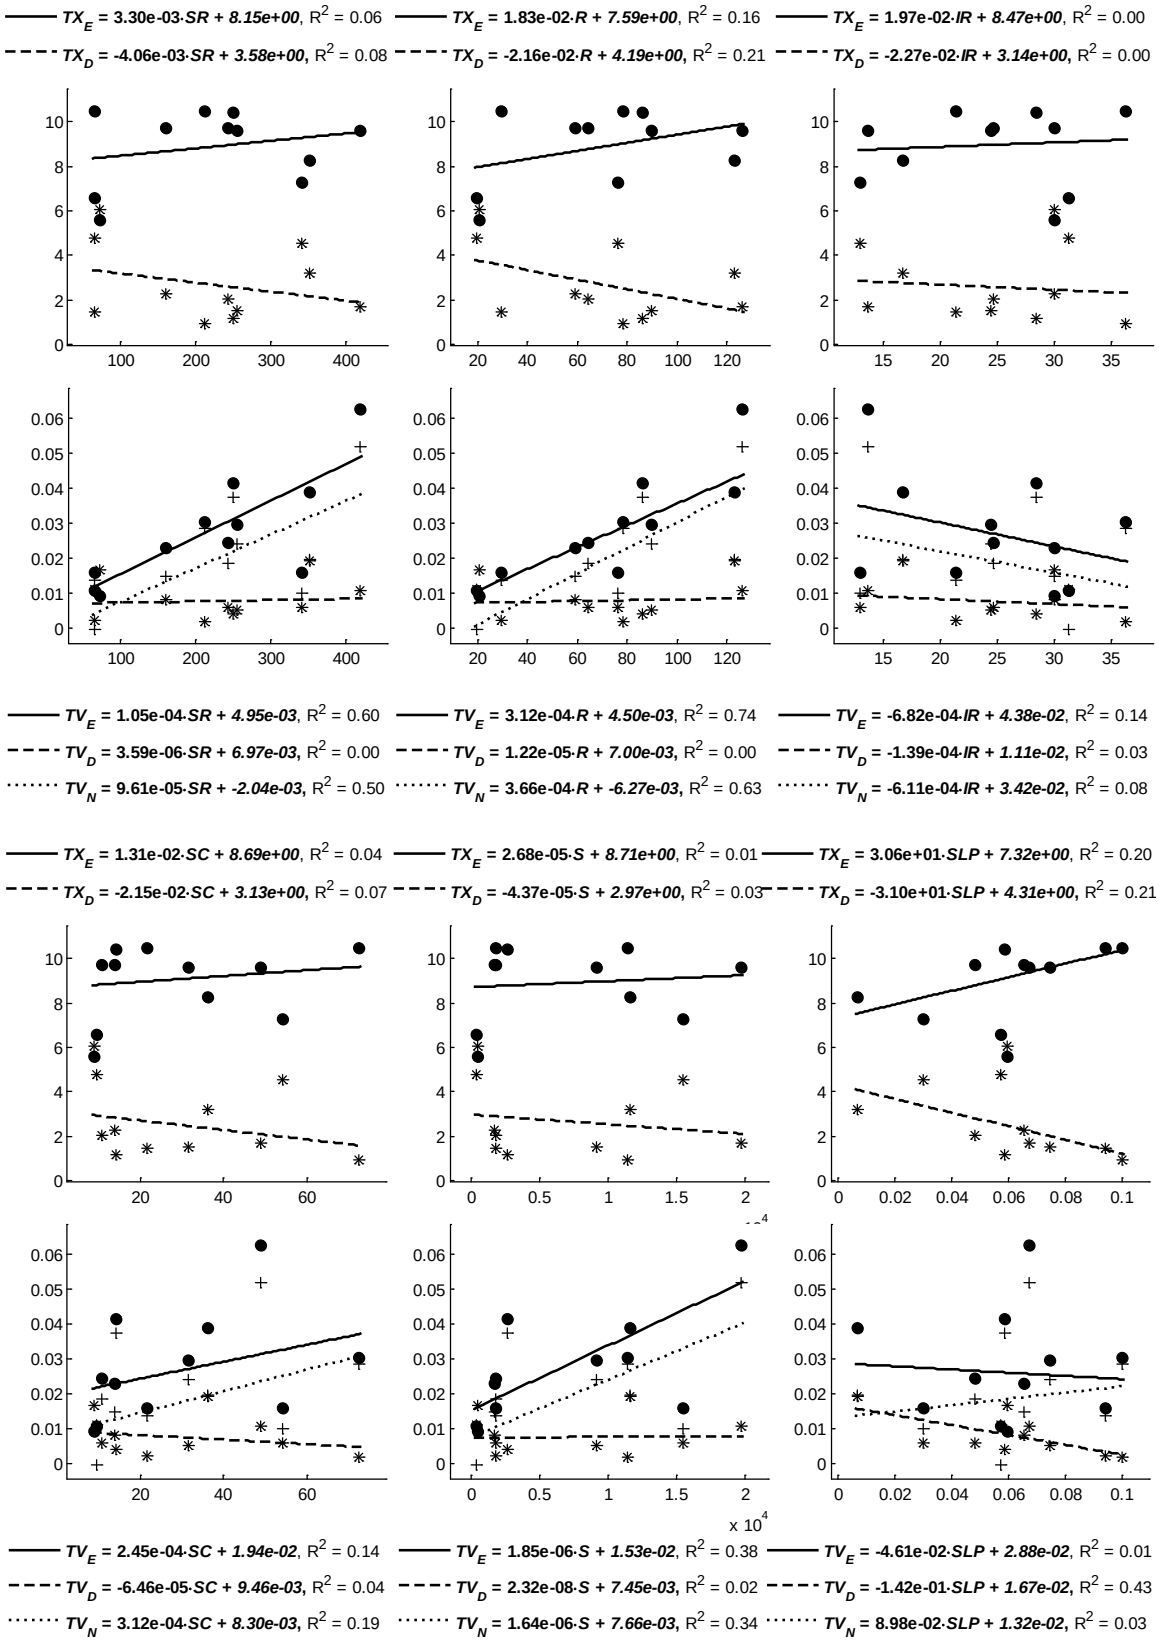

Figure 3 Plot-wide surface change metrics as a function of hydrology, erosion and slope variables.

Deposition processes (TX_D and TV_D) performed poorly against all hydrologic and erosion processes. For hydrologic processes, the largest correlation was found between TX_D and R with an R^2 of 0.21 but it is important to note that TX_D and TX_E are strongly correlated since they are complement of one another on a fixed plot area. This lack of dependence of deposition processes on hydrologic and erosion processes was likely the cause of the decrease in R^2 observed in most cases (except TV_E, TV_N vs. SC) when TV_E was replaced with TV_N. Nevertheless TV_D showed a systematic decreasing trend with slope (R^2 = 0.43), suggesting that sediment deposition volume was mainly controlled by plot slope on this site.

Channel processes: Figure 4 summarizes results of the microtopographic analysis in concentrated flow areas.

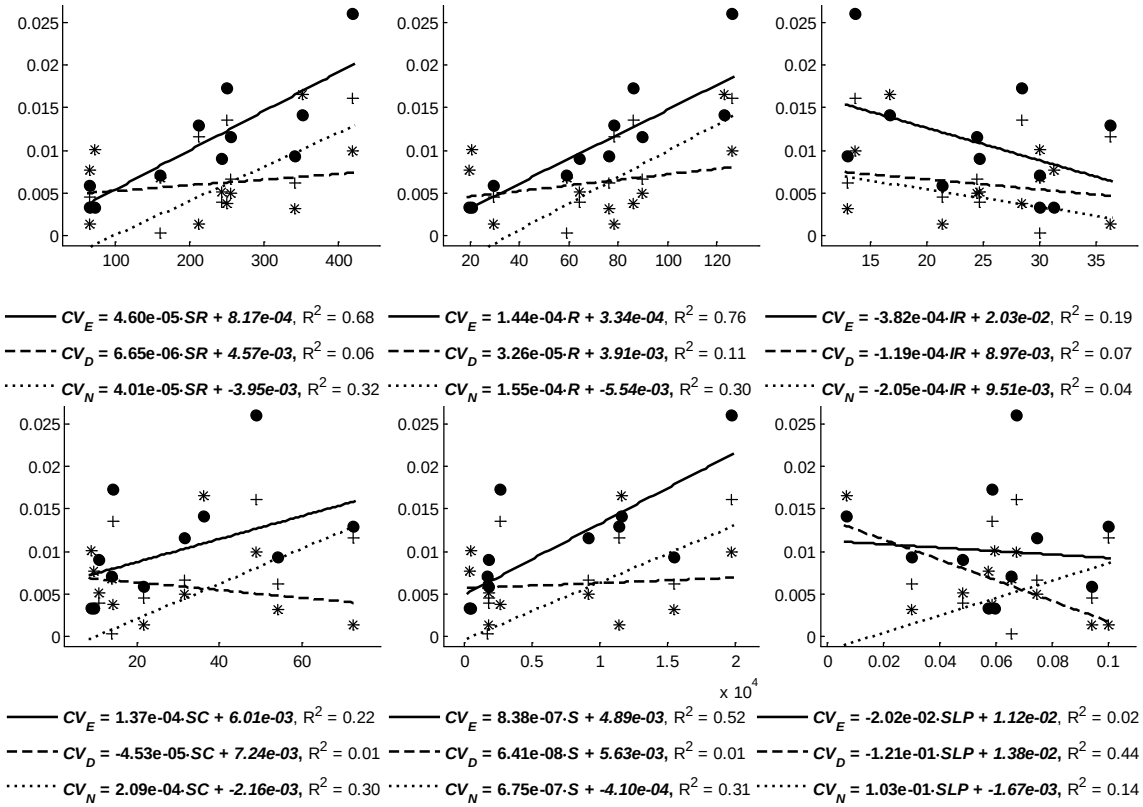

Figure 4 Concentrated flow processes as a function of hydrology, erosion and slope

Overall observations made for the plot-wide analysis are also valid here: (1) the incorporation of depth information in erosion volumes in channels improved correlation correlated with all variables (here again except for slope) with R^2 values for CV_E larger than those of CX_E (not shown in Figure 4), (2) runoff rate was a better predictor of eroded volume than cumulative runoff, (3) hydrology variables were better predictors of eroded volumes in channels than observed soil loss, (4) within channel deposition was primarily controlled by slope. Surface change metrics measured in channels were better correlated with hydrology, soil loss and slope variables than were plot-wide metrics indicated by an increase in R^2 in 21 of the 30 linear regressions on Figure 3 compared to Figure 4. However when TV_E and CV_E are plotted against precipitation P (Figure 5), one notices a slightly stronger correlation of P with TV_E. In other words, when relating surface change metrics to precipitation, R^2 increased with the inclusion of diffusive processes (sheet and splash erosion). This result is consistent with the current soil erosion theory which suggests a dependence of sheet and splash erosion processes on rainfall intensity. Likewise, when relating surface change metrics to runoff rate, R^2 was improved by excluding diffusive processes which is consistent with a dependence of concentrated flow processes (channel geometry) on runoff discharge.

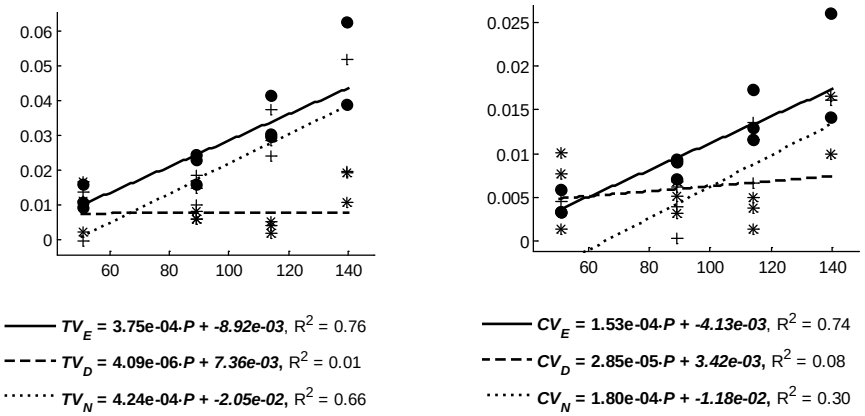

Figure 5 Plot-wide and channel erosion and deposition volumes as a function of precipitation

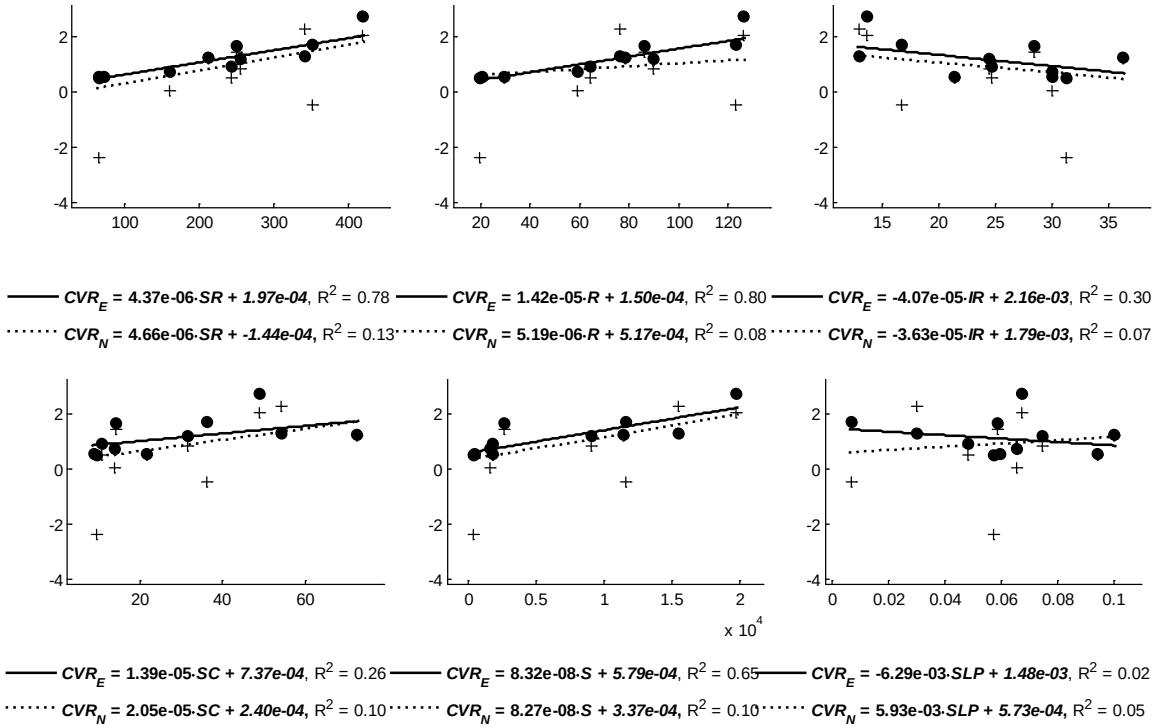

Figure 6 Area and volume-based ratios of flow concentration as a function hydrology, soil loss and slope

The ratios of flow concentration determined using volumes are shown in Figure 6. Overall the volume-based ratios showed again a stronger correlation with explanatory variables than the area-based ones. Also, an improvement in R^2 was observed with CVR_E compared to CV_E in Figure 4. This might be explained by the fact that CVR_E normalized channel erosion volumes to plot size and non-erodible contents (vegetation) which varied between plots due to practical field constraints. The R^2 values associated with CVR_N were, however, degraded compared to CV_N which is likely the result of confounding factors of deposition processes.

Figure 7 shows the relationship between α and α' (related to the energy spent on channel network expansion) as a function of hydrology and slope. A key finding that emerges from this analysis is that the hydrologic variable correlated better with α' than it did with α, suggesting that even though deposition volume might not be directly controlled by hydrologic parameters (Figure 3 and 4), its consideration is

essential in quantifying energy dissipated on channel widening. In other words, there might be a limit to sediment transport off-site for every incremental increase in runoff discharge (transport capacity concept).

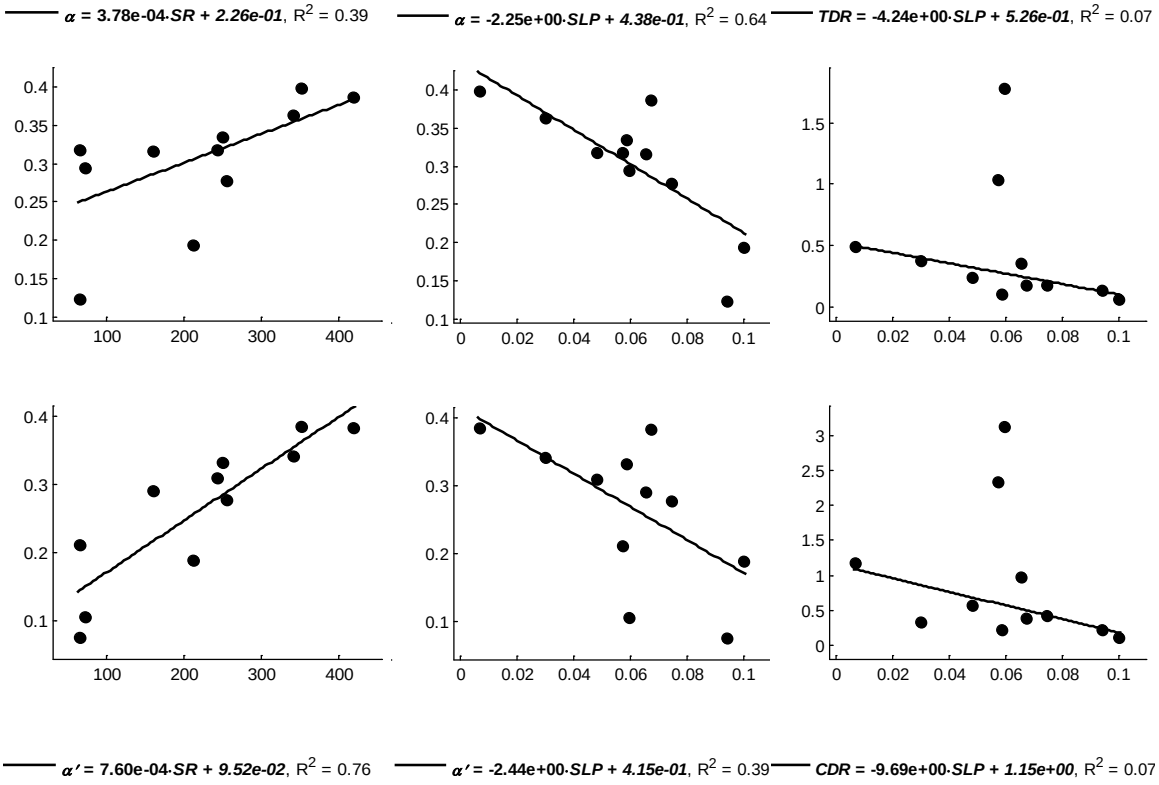

Figure 7 Volume-based channel expansion ratios (α = erosion volume based and α' = net volume based) as a function hydrology (*SR*) and slope. And plot-wide (*TDR*) and channel (*CDR*) deposition ratios as a function of slope

Another key finding in Figure 7 is the negative and relatively strong (R^2 = 0.64 for α and 0.39 for α') relationship between lateral energy expenditure and slope, consistent with the process of increase in downcutting relative to lateral expansion as slope increases. Also, Figure 7 shows that slope is negatively related to the proportion of re-deposited material (*TDR* and *CDR*), but the low number of observations adversely impacted the resulting R^2.

CONCLUSIONS

Rainfall simulations were conducted in saline rangeland communities of the Upper Colorado River Basin to quantify rainfall-driven salt transport from these environment to surface waters. Hydrology, erosion and high-resolution changes in surface microtopography measured during these simulations, were used in this study to answer many questions relevant to sediment transport processes in these saline rangelands and other sparsely vegetated rangelands.

Preliminary data show that analysis of the high resolution DEMs revealed that many interesting sediment transport processes that are traditionally difficult to quantify can now be examined with details and related to hydrologic inputs and landscape properties. Some of the key preliminary findings supported by our data include:

(1) the dependence of deposition on plot slope and its independence on hydrologic and soil loss variables,
(2) data supporting the process of increased downcutting as slope increased,
(3) significance of accounting deposition processes in overall runoff energy quantification,
(4) evidence of the existence of an equilibrium channel geometry with a given discharge that is marginally impacted by runoff duration.

This study will be valuable in developing semi-empirical equations for spatial extent and mass partitioning of soil loss between diffusive processes and concentrated flow erosion, as well as providing much needed insight into the processes of deposition and sediment storage.

TEMPERATURE SIMULATION OF A REACH OF THE METHOW RIVER NEAR WINTHROP, WASHINGTON

Jianchun Huang, Ph.D., P.E., Hydraulic Engineer, Bureau of Reclamation, Denver, CO, vhuang@usbr.gov; Jennifer Bountry, M.S., P.E., Hydraulic Engineer, Bureau of Reclamation, Denver, CO, jbountry@usbr.gov

Abstract: In this paper, a two-dimensional (2D) temperature model is tested within a reach of the Methow River near Winthrop, WA. The reach has a warm water tributary entering on river left and a cold water spring entering from river right. The 2D temperature model is spatially distributed in the lateral and longitudinal geographic extents, allowing for more accurate simulation of lateral changes in temperature across the channel than a 1D representation. The SRH-2D temperature model utilizes meteorological data as inputs (solar radiation, cloud cover, air temperature, dew point temperature, air pressure, and wind speed). Physical processes modeled include solar and atmospheric heating, effects of terrain and vegetation shading, heat exchange between water column and bed substrate, and losses due to evaporation, conduction, and back radiation. Two sets of data are used to test the model. Test one uses steady solution to simulate the lateral temperature mixing zone when warmer water from the Chewuch River enters from river left and colder water from Spring Creek enters from river right. Test two uses unsteady solution to simulate the continuous temperature change due to various water heat gains and losses.

INTRODUCTION

Lai and Mooney (2009) developed a two-dimensional (2D) temperature module for an existing 2D hydraulic and sediment transport model, SRH-2D. The 2D model incorporates data with both lateral and longitudinal geographic extents rather than lumping results into a point-to-point or uni-directional representation. The improved representation of spatial features allows more accurate simulation of lateral changes in temperature across the channel. The SRH-2D temperature model utilizes meteorological data as inputs (solar radiation, cloud cover, air temperature, dew point temperature, air pressure, and wind speed). Physical processes modeled include solar and atmospheric heating, effects of terrain and vegetation shading, heat exchange between water column and bed substrate, and losses due to evaporation, conduction, and back radiation.

In this research, the SRH-2D temperature model was verified in a reach of the Methow River near Winthrop, WA. The Methow River reach has a warmer water tributary entering on river left and a colder water spring entering from river right. Two sets of data were used to test the model. Test one involved using thermal infrared remote-sensing (TIR) imagery data that represents a grid of surface temperatures at a single river flow and a single point in time. This data was used to test how well the model can represent lateral changes in temperature across the channel. Surface water temperature can be different than depth-averaged temperature, which is computed by the 2D model. This difference may cause some variance in how well the 2D model results represent the TIR data, particularly in areas where the mixing rate of the river is slow or highly variable (due to stratification effects). However, the Methow is generally well mixed due to a steep slope and fairly shallow depths. Test two used three temperature loggers that provide continuous data over several months from spring to fall. The loggers provided a test of how well the model could represent temporal and longitudinal changes in temperature.

TEMPERATURE MODEL

Temperature Equation: The 2D depth-averaged flow equations are based on the assumptions that stream flows are shallow compared to width and the effect of vertical motion is negligible.
Conservation of thermal energy leads to the 2D depth-averaged temperature equation expressed as:

$$\frac{\partial hT}{\partial t}+\frac{\partial hUT}{\partial x}+\frac{\partial hVT}{\partial y}=\frac{\partial}{\partial x}\left[\frac{h\nu_t}{\sigma_t}\frac{\partial T}{\partial x}\right]+\frac{\partial}{\partial y}\left[\frac{h\nu_t}{\sigma_t}\frac{\partial T}{\partial y}\right]+\frac{\Phi_{net}}{c_w\rho_w}+\frac{q_{sp}}{A_{sp}}\left(T_{sp}-T\right) \quad (1)$$

In the above, T is depth averaged water temperature [C], x and y are horizontal Cartesian coordinates [m], t is time [s], h is water depth [m], U and V are depth-averaged velocity components [m/s] in x and y directions, respectively, ν_t is the turbulent viscosity and dispersion [m^2/s], σ_t is the turbulent Prandtl number, ρ_w is the water density [kg/m^3], $c_w$is the specific heat of water [J/kg/C], q_{sp} is the spring water flow rate [m^3/s] into the stream (zero if

spring flows out), A_{sp} is the area [m^2] of the spring water inflow, T_{sp} is the spring water temperature [C], and Φ_{net} is the net heat exchange [w/m^2] between water column and its surroundings (through water surface and streambed). The turbulent eddy viscosity (ν_t) is computed with a turbulence model (Rodi, 1993). The net heat flux, Φ_{net}, consists of six contributions as follows:

$$\Phi_{net} = \Phi_{ns} + \Phi_{na} + \Phi_{bed} - \Phi_{br} - \Phi_e - \Phi_c \tag{2}$$

where

Φ_{ns}= net solar radiation entering water surface;
Φ_{na}= net atmospheric radiation entering water surface;
Φ_{br}= heat loss by back radiation from stream (black body radiation);
Φ_e= evaporative heat loss at water surface;
Φ_c= conductive heat loss at water surface; and
Φ_{bed} = heat flux into stream at channel bed.

Solar Radiation: If measured solar radiation (Φ_{sm}) at water surface is available, the net solar radiation is computed as (Hauser and Schohl, 2003)

$$\Phi_{ns} = \Phi_{sm} R_s \tag{3}$$

where Φ_{sm} is measured solar radiation (shade free solar radiation at the water) and R_s is reflection and terrain and vegetation shading factor which is computed by the following equations (Hauser and Schohl, 2003):

$$R_s = \begin{cases} R_{sm} & \text{if } X_n \le B \text{ (shade free)} \\ 0.2 & \text{if } X_n > B+W \text{ (full shade)} \\ R_{sm}\frac{B+W-X_n}{W} + 0.2\frac{X_n-B}{W} & \text{if } B < X_n \le B+W \text{ (partial shade)} \end{cases} \tag{4}$$

In the above:

$R_{sm} = 1 - a(57.3\alpha)^{-b}$ = shade-free reflection factor (a and b see Table 1);
α = solar altitude in radians;
W = width of the stream cross section;
B = distance from trees to water edge;
$X_n = H_b \cos\beta / \tan\alpha$ = normal distance from trees to shadow edge;
H_b = tree and bank height from water surface;
$\beta = |\theta - 90/57.3|$ = angle between sun and stream axis normal in radian;
$\theta = \left|A_{zs} - \frac{A_{zr}}{57.3}\right|$ = angle between sun and stream axis in radian;
A_{zr}= river azimuth, clockwise from north to direction of flow in degree;
A_{zs} = sun azimuth in radian calculated by $\cos A_{zs} = -\frac{\sin\phi\sin\alpha - \sin\delta}{\cos\phi\cos\alpha}$.
ϕ = site latitude in radians; and
δ = is sun declination (between the sun and equator) in radians.

Table 1 Coefficients of solar radiation reflection.

Cloud Cover C	a	b
0-0.05	1.18	0.77
0.05 – 0.5	2.20	0.97
0.5 – 0.92	0.95	0.75
0.92 – 1.0	0.35	0.45

The solar altitude α is computed assuming spherical geometry, as follows (Huber and Harleman, 1968):

$$\sin\alpha = \sin\phi\sin\delta + \cos\phi\cos\delta\cos h \tag{5}$$

where ϕ is site latitude in radians, δ is sun declination in radians, and h is the sun hour angle in radians. If no measured solar radiation (Φ_{sm}) is available, the solar radiation that reaches the water surface can be estimated from (Martin and McCutcheon, 1999)

$$\Phi_{sm} = H_0 a_t C_a \tag{6}$$

where H_0 = the amount of radiation reaching the earth's outer atmosphere (Wm^{-2}); a_t= radiation scattering and absorption factor; C_a = the fraction of solar radiation not absorbed by clouds.
The fraction of solar radiation passing through the clouds is given by the cloud cover (C) as

$$C_a = 1 - 0.65C^2 \tag{7}$$

The flux of solar radiation that strikes the earth's outer atmosphere is estimated from

$$H_0 = \frac{H_{sc}}{r^2}[\sin\phi\sin\delta + \frac{12}{\pi}\cos\phi\cos\delta(\sin h_e - sinh_b)]\Gamma \tag{8}$$

H_{sc} = the solar constant (1390 Wm^{-2}); r = the relative distance (-) between the earth and sun; ϕ = the site latitude in radians; δ = sun declination (between the sun and equator) in radians; h_e and h_b = the solar hour angles at the end and the beginning of the time period over which H_0 is being calculated, respectively; and Γ = a correction factor for diurnal exposure to the radiation flux. The relative earth-sun distance can be estimated from

$$r = 1.0 + 0.017\cos\left[\frac{2\pi}{365}(186 - D_y\right] \tag{9}$$

where D_y = the Julian day of the year. The declination of the sun can be estimated from

$$\delta = \frac{23.45\pi}{180}\cos\left[\frac{2\pi}{365}(172 - D_y\right] \tag{10}$$

The hour angles (radians) at the beginning and ending of the period over which H_o is being calculated is computed from

$$h_b = \left\{\frac{\pi}{12}[(h_r - 1) - \Delta t_s + 12a_2]\right\} + b_2(2\pi) \tag{11}$$

$$h_e = \left\{\frac{\pi}{12}[h_r - \Delta t_s + 12a_2]\right\} + b_2(2\pi) \tag{12}$$

where h_r is the hour of the day from 1 to 24; the coefficient a_2 =1.0 for $h_r \leq 12$ and a_2 =-1.0 for $h_r > 12$. The coefficient b_2 varies with the magnitude of the quantity inside the curly brackets for both h_b and h_e in Eqs. (11) and (12). The coefficient b_2 = -1 for $\{\cdot\} > 2\pi$, b_2 = 1 for $\{\cdot\} < 0$, and b_2=0 otherwise.

The fraction of an hour between the standard meridian and the local meridian is Δt_s. In the United States, the standard meridians are at 75°, 90°, 105°, and 120° for eastern, central, mountain, and Pacific Time zones; respectively. The fraction can be calculated from

$$\Delta t_s = \frac{E_a}{15}(L_{sm} - L_{lm}) \tag{13}$$

where L_{sm} is the standard meridian, L_{lm} is the local meridian. $E_a = -1$ for west longitude and $E_a = 1$ for east longitude. For example, at Methow River at Winthrop, $L_{sm} = 120^o$ (Pacific Time zone), $L_{lm} = 120.167639^o$ (longitude of Winthrop), and $E_a = -1$ for west longitude.
The correction factor Γ in Eq.(8) is set to one at day time (between sunrise and sunset) and zero at night time. The standard time of sunset and sunrise can be estimated from

$$t_{ss} = \frac{12}{\pi}\cos^{-1}\left(-\frac{\sin\phi\sin\delta}{\cos\phi\cos\delta}\right) + \Delta t_s + 12 \tag{14}$$

$$t_{su} = -t_{ss} + 2\Delta t_s + 24 \tag{15}$$

The radiation scattering and absorption factor a_t in Eq.(6) can be estimated from

$$a_t = \frac{t + 0.5(1 - s - c_d)}{1 - 0.5R_g(1 - s - c_d)} \tag{16}$$

where c_d is a dust coefficient, which has a range of 0.0 to 0.13 and a typical value of 0.06; and R_g is the reflectivity of the water surface, which varies with the type of cloud cover as

$$R_g = a_3\left(\frac{180}{\pi}\alpha\right)^{b_3} \tag{17}$$

where α is the solar altitude in radians, calculated in Eq.(5) and a_3 and b_3 are coefficients (Table 2) depending on the cloud cover (C).

Table 2 Coefficients a_3 and b_3 describing the reflection of solar radiation at the water surface (source: Martin and McCutcheon, 1999; and Marciano and Harbeck, 1954).

Description	Fraction Cloud Cover (C)	a_3	b_3
Overcast	C> 0.9	0.33	-0.45
Broken	0.5 < C <0.9	0.95	-0.75
Scattered	0.1 <C <0.5	0.5	-0.97
Clear	C < 0.1	1.18	-0.77

The mean atmospheric transmission coefficient s and t in Eq. (16) is given by

$$s = \exp[-(0.465 + 0.134P_{wc})(0.129 + 0.171\exp(-0.88\theta_{am}))\theta_{am}] \tag{18}$$
$$t = \exp[-(0.465 + 0.134P_{wc})(0.179 + 0.421\exp(-0.721\theta_{am}))\theta_{am}] \tag{19}$$

where θ_{am} is the dimensionless optical mass, $P_{wc}$is the mean daily precipitable atmospheric water content, given by

$$P_{wc} = 0.85\exp(0.11 + 0.0614T_d) \tag{20}$$
$$\theta_{am} = \left(\frac{288 - 0.0065Z}{288}\right)^{5.256} / \left[\sin\alpha + 0.15\left(\frac{180\alpha}{\pi} + 3.855\right)^{-1.253}\right] \tag{21}$$

where T_d = the dew point temperature [C], Z = the site elevation (m) and α = the solar altitude in radians, calculated in Eq.(5).

Atmosphere Radiation: The net long-wave radiation (atmospheric radiation entering water surface) is computed as:

$$\Phi_{na} = 5.16432 \cdot 10^{-13}(1 + 0.17C^2)(T_a + 273.16)^6 \tag{22}$$

where C is cloud cover, fraction of the sky covered by clouds, and T_a is dry bulb air temperature [C].

Outgoing Black-Body Radiation: The outgoing black-body radiation emitted from the water surface is a function only of the water temperature, and it is given by (Huber and Harleman, 1968):

$$\Phi_{br} = \varepsilon_w\sigma(T_w + 273.16)^4 \tag{23}$$

where T_w is water-surface temperature [C], ε_w is emissivity (0.97 by Huber and Harleman (1968) and 0.98 by Tung et al. (2006), and σ is Stefan-Boltzman constant (5.672×10^{-8} w/m^2/K^4). In the current model, the depth averaged temperature T is used for T_w.

Evaporative Heat Loss: The evaporative heat loss is computed by:

$$\Phi_e = \rho_w L(a_1 + b_1 W_a)(e_s - e_a) \tag{24}$$

where:

$L = 4184(597 - 0.57T_w)$ =the latent heat [J/kg];
T_w = water surface temperature in Celsius;
W_a = wind speed (m/s);
a_1, b_1 = constants: a_1=0.0 to 4.0e-9; b_1=1.0e-9 to 3.0e-9;
$e_a = 2.171 \times 10^8 \exp\left[-\frac{4157}{T_d + 239.09}\right]$ = saturation vapor pressure [mb];
T_d = dew point temperature in Celsius; and
$e_s = \alpha_j + \beta_j T_w$ = saturation vapor pressure [mb] with coefficients in Table 3

Table 3 Coefficients to compute saturation vapor pressure.

T	j	αj	βj
0-5	1	6.05	0.522
5-10	2	5.10	0.710
10-15	3	2.65	0.954
15-20	4	-2.04	1.265
20-25	5	-9.94	1.659
25-30	6	-22.29	2.151
30-35	7	-40.63	2.761
35-40	8	-66.90	3.511

Conduction Heat Loss to Air: The conduction heat loss is:

$$\Phi_c = 0.61 \times 10^{-3} \rho_w L(a_1 + b_1 W_a) P(T_w - T_a) \tag{25}$$

where P is air barometric pressure [mb] and a_1 and b_1 are defined the same as in Eq.(24), T_w is water surface temperature [C], and T_a is dry bulb air temperature [C].

Heat Exchange with Stream Bed: Heat exchange between stream bed and stream water is significant for shallow streams and it consists of two contributions: conduction from bed to stream and net solar radiation entering bed. It is computed by the following expression:

$$\Phi_{bed} = \frac{k_b}{0.5\delta_b}(T_b - T_w) - (1 - A_b)(1 - \beta)\exp[-\eta(D - 0.6)]\,\Phi_{ns} \tag{26}$$

where k_b is the thermal conductivity of the streambed bed material, $\delta_b$is the effective bed thickness used for heat conduction computation, T_w is the water temperature, T_b is the effective stream bed temperature which is updated each time step by $T_b = T_b^{old} - \frac{\Phi_{\text{bed}}\Delta t}{\rho_b C_b \delta_b}$ with ρ_b and C_b the density and specific heat of the bed materials and Δt is the time step for simulation, A_b is albedo of bed material, β is fraction of solar radiation absorbed in the top 0.6m of surface water, η is extinction coefficient in water [1/m], and D is water depth [m].

RESULTS

Test Case with FLIR Data: Watershed Sciences (2009) provided TIR imagery for approximately 160 river miles in the Methow River Basin for the Yakama Tribe Fisheries. TIR images were collected with a temperature sensor mounted on the underside of a helicopter. Airborne TIR was used to map spatial temperature patterns in the Methow River. TIR images were recorded during a three-day flight from August 24 to August 26, 2009 over the

Methow, Twisp, and Chewuch Rivers. A four mile reach of the Methow River near Winthrop is used to simulate the two-dimensional temperature dynamics downstream of the Chewuch River Spring Creek confluences.

Simulated 2D water temperature is compared to measured surface temperature to test the ability of the model in predicting lateral thermal mixing. Surface water temperature (measured) may be different than depth-averaged temperature (computed) due to stratification. This difference may cause some variance in how well the 2D model results can represent the TIR data, particularly in areas where the mixing rate of the river is slow or highly variable. The Methow is, however, generally well-mixed due to a steep slope and fairly shallow depths. For this reason, the surface water temperature is used for the model upstream boundary condition.

Two river gage stations are located in the study reach: USGS 12448500 (Methow at Winthrop downstream of the confluence of the Methow and Chewuch) and USGS 12448000 (Chewuch at Winthrop upstream of the confluence). On August 26, 2009, the flow rate of Methow at Winthrop was 275 cfs and that of Chewuch at Winthrop was 89.1 cfs (Table 4). The combined flow in the Methow River and Spring Creek above the Chewuch is obtained from the difference between the two gages. Then, the incoming discharge for Spring Creek and the Methow River was solved by assuming the incoming temperature and discharge product for each tributary equals the temperature and discharge product in the downstream river at the gage. The flow rates at the Methow River above the Chewuch is set as 146.0 cfs and the combined flows from Spring Creek is set as 40.8 cfs., to reach a mixed temperature downstream of the Spring Creek 15.8 ^{o}C from the surveyed data. The calculation assumed that there is no heat sources and sinks within this short reach.

Table 4 Incoming flow rates and temperatures.

	Flow Rate (cfs)	Temperature (^{o}C)
Chewuch	89.1	17.3
Methow	146.0	15.4
Spring Creek	40.8	13.6

Figures 1 through 3 display measured water surface temperature and simulated water temperature results. Figure 1 shows measured water surface temperature in the vicinity of the Chewuch and Spring Creek confluences. The field data indicates the presence of temperature mixing zones downstream of the tributary confluences; the comparatively small inflow from Spring Creek produces a low temperature zone that is highly persistent in the streamwise direction, suggesting non-point source seepage along the bank. Figure 2 shows the SRH-2D simulated temperature using point-based model contributions from the Chewuch and Spring Creek. The simulation results qualitatively reproduce the zone of lateral temperature stratification downstream of the Chewuch River, however vastly under predict the extent to which the cold temperature zone persists along the bank downstream of Spring Creek.

Figure 3 shows the SRH-2D numerical temperature simulation with a non-point source of water seeping into the stream from Spring Creek. From the calibration process, it was determined that a combination of 20.7 cfs modeled as point source from Spring Creek and 20 cfs modeled as non-point source seeps produces qualitative agreement with the measurements (Figure 1), predicting mixing zones from both tributaries fairly well.

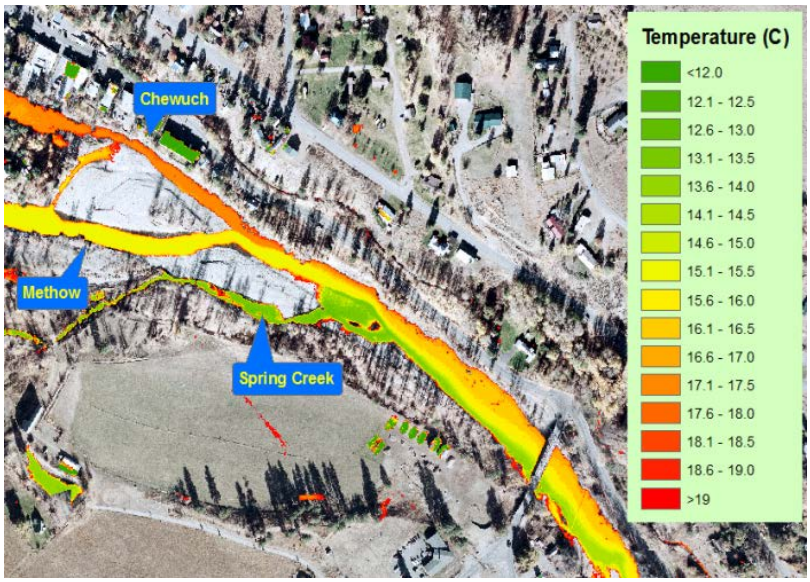

Figure 1 TIR imagery taken on August 26 2009 in the vicinity of the Chewuch River and Spring Creek. The color scale is mapped to measured water surface temperature. Warmer water from Chewuch River enters on the river left and colder water from the Spring Creek enters on the river right. Flow direction is from left to right.

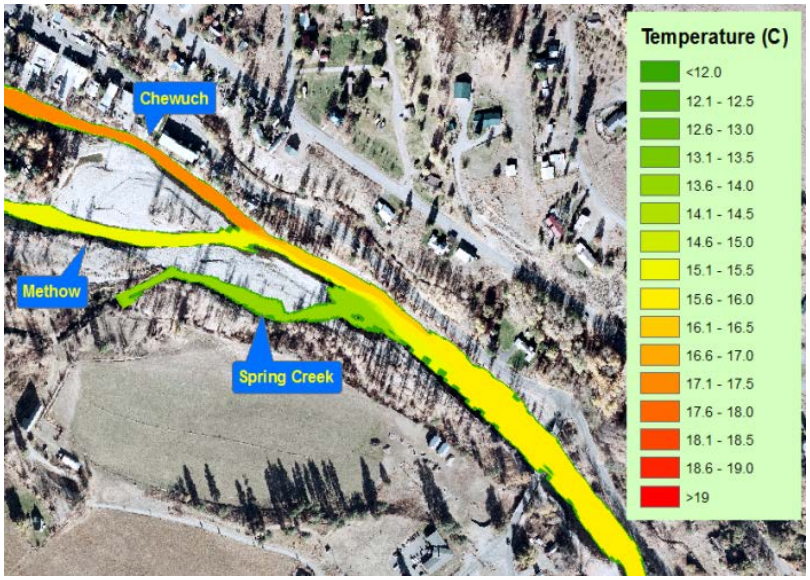

Figure 2 SRH-2D numerical simulation of water temperature at the confluences with the Chewuch River and the Spring Creek, with tributaries modeled as point sources. Color scale is mapped to predicted depth-averaged temperature. Flow direction is from left to right.

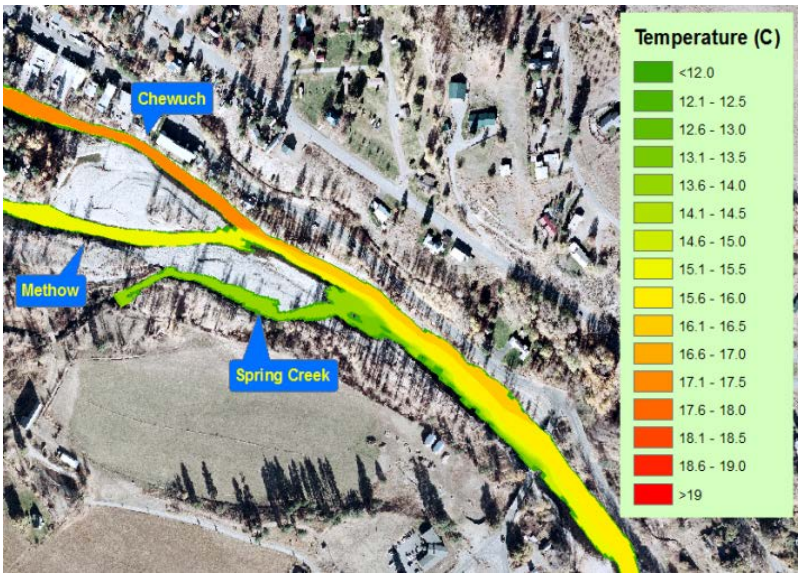

Figure 3 SRH-2D numerical simulation of water temperature at the confluences with the Chewuch River and the Spring Creek, with the Spring Creek contribution modeled as a combination of point-source and non-point source seeps from the right bank. Color scale is mapped to predicted depth-averaged temperature.

A sensitivity analysis was performed on the turbulent Prandtl number σ_t in Eq. (1). The turbulent Prandtl number is the ratio of momentum eddy diffusivity ν_t to thermal eddy diffusivity, and is typically on the order of one in natural turbulent flows. The results show that decreasing (increasing) the turbulent Prandtl number decreases (enlarges) the persistence of temperature gradients downstream of the tributary confluences.

Test Case with Log Data: In the second test case, SRH-2D is used to simulate unsteady flow and temperature over four months from June 1, 2012 to September 30, 2012. Several temperature loggers in the study reach provided continuous point temperature data that can be used to test model predictions of longitudinal changes in temperature. Three loggers provided continuous temperature measurements for upstream model boundary conditions at flow locations labeled Chewuch Mouth, Methow above Chewuch, and Spring Creek (Figure 4, Figure 5, and Table 5).

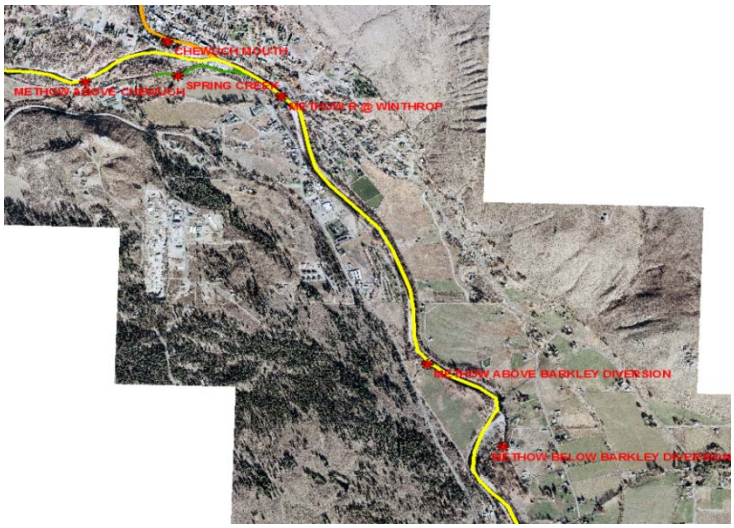

Figure 4 Temperature loggers located in the study reach.

Additional temperature logger data is needed to test model predictions along the channel. The logger location labeled Methow at Winthrop provided temperature downstream of the Chewuch and Spring Creek confluence at the US 20 bridge crossing in Winthrop. However, this location is in the temperature mixing zone; data was instead used from the logger located further downstream, labeled Methow above Barkley Diversion. Another logger, Methow below Barkley Diversion, located in the side channel which does not have a surface flow connection with the mainstem Methow River at the time of simulation and could not be used to test the model.

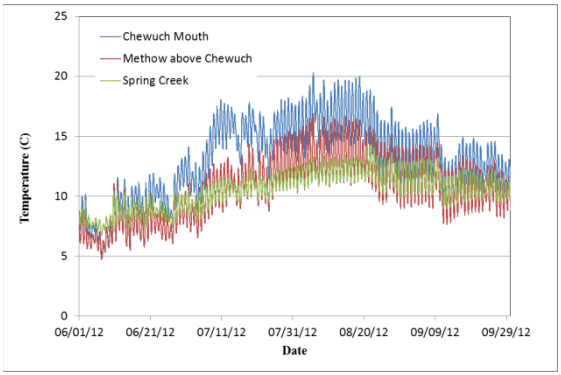

Figure 5 Methow, Chewuch, and Spring Creek inflow water temperatures used as upstream input boundary conditions for the model.

Table 5 Logger data available in the study reach.

Logger Location Label	Date Period
Chewuch Mouth	6/1/2005 to 9/18/2008, and 7/9/2010 to 10/11/2012
Methow Above Chewuch	6/30/2005 to 10/15/2009, and 7/16/2010 to 10/16/2012
Spring Creek	7/2/2005 to 10/15/2009, and 7/16/2010 to 10/16/2012
Methow at Winthrop	6/27/2005 to 10/13/2009
Methow above Barkley Diversion	11/26/2009 to 10/16/2012
Methow below Barkley Diversion	11/26/2009 to 10/16/2012

Two gage stations are located in the study reach (Figure 6): USGS 12448500 (Methow above Chewuch) and USGS 12448000 (Chewuch Mouth). There is no gage to measure flow in Spring Creek. The majority of the contribution from Spring Creek is due to ground seepage and the fish hatchery; further, there is no assumed correlation between the flow rates in the Methow and Spring Creek. For this reason, the same flow distribution used in the first test case was used in the second test case: 20.7 cfs from Spring Creek and 20 cfs from ground seepage on the right bank. Future field survey is recommended to measure the flow rate in the Spring Creek. The flow rate at the Methow above Chewuch is obtained by subtracting the flows at Chewuch and Spring Creek from the downstream gage at Methow at Winthrop.

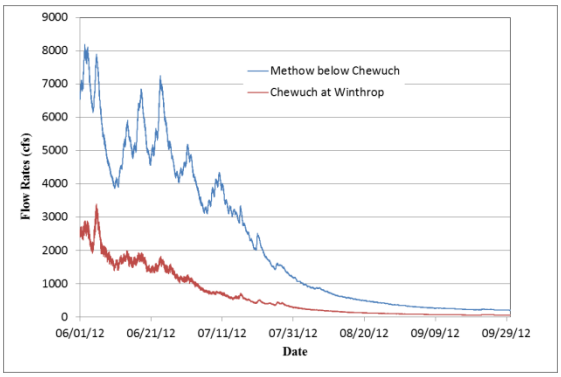

Figure 6 Methow and Chewuch River flow hydrographs used as upstream input boundary conditions.

The longitudinal temperature in the river is affected by the heat gain and loss at the water surface and channel bed. The dominant forms of heat gain are solar (short wave) radiation and atmospheric (long wave) radiation. The dominant forms of heat loss include back radiation from the stream, evaporative heat loss from the stream, and evaporative and conductive heat loss at the water surface. The heat flux to the channel bed is usually positive at day time and negative at night time. Solar radiation was not directly measured at the study reach, but was estimated from Eqs (6) to (21) given the cloud covering, elevation, and site latitude and longitude position.

Compared with logger data at the Methow above Barkley Diversion location, the model predicted the temperature fairly well Figure 7. The root mean square error is about 0.37°C. No temperature difference was observed in the channel transverse direction (well-mixed) at the Methow above Barkley Diversion location. The wind effect coefficients a_1 and b_1 as defined in Eq. (24) were set as 1.0×10^{-9} and 1.0×10^{-9}, respectively. The coefficients were set to their low ends in order to maintain a slightly increased temperature in the downstream direction. To better understand the effects of all source terms, a longer reach is recommended. In a small reach, the meteorological effects are small and the temperature is more driven by the upstream boundary conditions.

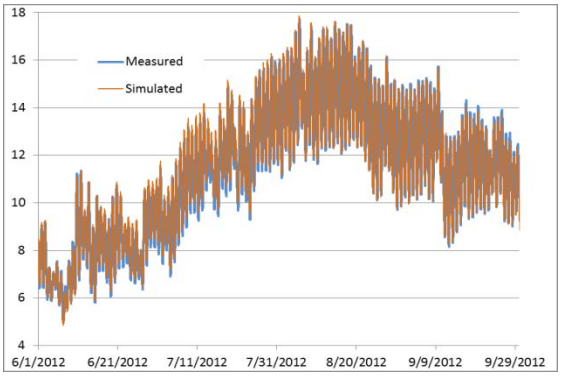

Figure 7 Measured and simulated water temperatures at the logger location labeled Methow above Barkley Diversion.

CONCLUSIONS

SRH-2D simulates the river temperature where water is well mixed in the vertical direction. First, the SRH-2D temperature module was tested using two sets of validation data from the Methow River near Winthrop, WA. Case one calculated a steady-state solution of the lateral temperature mixing zones downstream of the Chewuch (warmer water) and Spring Creek (colder water) confluences without any heat exchange with the air and channel bed. Case two calculated transient solutions of the temperature distribution driven by measured input hydrographs.
The model showed good accuracy in simulating the lateral temperature mixing zones downstream of tributary confluences when the model is well calibrated by adjusting the turbulent Prandtl number. In the Methow case, results show that the turbulent Prandtl number of one best reproduce the lateral temperature mixing. It was also shown that non-point source boundary conditions may be required to model spatially distributed contributions such as seepage of cold water from a spring.

The model was generally successful in reproducing the measured temporal variation in temperature measured at the Methow above Barkley Diversion location. In this four mile reach, the water temperature is mostly driven by incoming flow discharge and temperature, and not sensitive to weather/climate. For the Methow River, it is hypothesized from measured data that weather impacts to water temperature occur on the scale of multiple reaches, perhaps on the order of tens of river miles.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the Research and Development Office, Science and Technology Program of the Bureau of Reclamation for providing funding to this research. The authors would like to thank Raymond "Jason" Caldwell, former employee of Bureau of Reclamation, who performed the research on modeling of daily and sub-daily stream temperatures which was used as input data in this study. The authors thank co-workers Yong

Lai, Blair Greimann, Dan Dombroski, and Subhrendu Gangopadhyay for discussions and insight. Dan Dombroski's peer review is appreciated.

PHYSICALLY BASED METHOD FOR MEASURING SUSPENDED-SEDIMENT CONCENTRATION AND GRAIN SIZE USING MULTI-FREQUENCY ARRAYS OF SINGLE-FREQUENCY ACOUSTIC-DOPPLER PROFILERS

Abstract: As the result of a 12-year program of sediment-transport research and field testing on the Colorado River (6 stations in UT and AZ), Yampa River (2 stations in CO), Little Snake River (1 station in CO), Green River (1 station in CO and 2 stations in UT), and Rio Grande (2 stations in TX), we have developed a physically based method for measuring suspended-sediment concentration and grain size at 15-minute intervals using multi-frequency arrays of acoustic-Doppler profilers. This multi-frequency method is able to achieve much higher accuracies than single-frequency acoustic methods because it allows removal of the influence of changes in grain size on acoustic backscatter. The method proceeds as follows. (1) Acoustic attenuation at each frequency is related to the concentration of silt and clay with a known grain-size distribution in a river cross section using physical samples and theory. (2) The combination of acoustic backscatter and attenuation at each frequency is uniquely related to the concentration of sand (with a known reference grain-size distribution) and the concentration of silt and clay (with a known reference grain-size distribution) in a river cross section using physical samples and theory. (3) Comparison of the suspended-sand concentrations measured at each frequency using this approach then allows theory-based calculation of the median grain size of the suspended sand and final correction of the suspended-sand concentration to compensate for the influence of changing grain size on backscatter. Although this method of measuring suspended-sediment concentration is somewhat less accurate than using conventional samplers in either the EDI or EWI methods, it is much more accurate than estimating suspended-sediment concentrations using calibrated pump measurements or single-frequency acoustics. Though the EDI and EWI methods provide the most accurate measurements of suspended-sediment concentration, these measurements are labor-intensive, expensive, and may be impossible to collect at time intervals less than discharge-independent changes in suspended-sediment concentration can occur (< hours). Therefore, our physically based multi-frequency acoustic method shows promise as a cost-effective, valid approach for calculating suspended-sediment loads in river at a level of accuracy sufficient for many scientific and management purposes.

INTRODUCTION

Suspended-sediment concentration and discharge are poorly correlated in many rivers as a result of hysteresis in concentration and grain size produced by (1) changes in the upstream sediment supply and (2) hysteresis in bed roughness arising from lags between discharge and dune geometry during floods. Accurate sediment loads can be calculated in rivers exhibiting these types of hysteresis only if measurements of suspended-sediment concentration are made at time intervals more closely spaced than the timescales over which suspended-sediment concentration is observed to systematically vary independently of water discharge. Single-frequency acoustics have recently become popular for measuring suspended-sediment concentration at high temporal resolution. However, because acoustic attenuation and backscatter are both affected by changes in both the concentration and grain-size distribution of the suspended sediment, concentration biases exceeding a factor of two are common and concentration biases exceeding an order of magnitude are possible when only one acoustic frequency is used. Herein, we describe an unbiased physically based method for measuring suspended-silt-and-clay and suspended-sand concentration, and suspended-sand median grain size (D_{50}) using multi-frequency arrays of side-looking acoustic-Doppler profilers (ADPs), building on the work of Topping et al. (2004, 2006, 2007) and Wright et al. (2010). Data from and the locations of the study sites in this paper are available at: http://www.gcmrc.gov/discharge_qw_sediment/.

THEORETICAL FRAMEWORK

The initial theoretical development that ultimately led to the ability of using acoustics to measure suspended-sediment concentrations and grain-size distributions occurred during the early to mid 20th century, with much of this work occurring during World War II (Urick, 1975). Among the most important contributions of this early research

were the derivation and formalization of the sonar equations (National Defense Research Committee [NDRC], 1946; Urick, 1962). In our study, the following form of the active-sonar equation from Urick (1975) is used:

$$SL - 2TL + TS = RL + DT \tag{1}$$

where *SL* is the Source Level, 2*TL* is the 2-way Transmission Loss, *TS* is the Target Strength, *RL* is the Reverberation Level, and *DT* is the Detection Threshold. By standard convention, each of these terms is expressed as 10 times a base-10 logarithmic ratio of acoustic intensity, in units of decibels. Knowing the values of all of the terms in equation 1 is not required to approximately calibrate an ADP to measure suspended-sediment concentration. In many studies, only the values of 2*TL* and *RL* are used in combined, relative-backscatter form to develop such approximate calibrations (e.g., Thevenot et al., 1992; Gartner, 2004; Wall et al., 2006; Wright et al., 2010; Wood and Teasdale, 2013). These calibrations are referred to as approximate because they hold *TS* constant and therefore do not take into account how changes in the grain-size distribution of the suspended sediment affect *TS*. Depending on the instrument frequency and the grain-size distributions in suspension, neglecting the effects of changing grain size on *TS* can lead to substantial biases in ADP measurements of suspended-sediment concentration. Following the convention of Thevenot et al. [1992], the relative backscatter,

$$B = RL + 2TL \tag{2}$$

thus allowing equation 1 to be rewritten as:

$$SL - DT - B + TS = 0\ . \tag{3}$$

SL of the ADPs used in this study ranges from 191 to 196 dB; *DT* has been determined in this study to range from ~35 to 50 dB, and is the level associated with zero concentration of suspended sediment in the water. *B* is calculated for each cell along an acoustic beam where the amplitude of the acoustic signal strength, *A*, exceeds the effective noise floor. The effective noise floor is the sum of the ADP-measured noise floor and the noise-floor offset (determined by an iterative process that removes dependence of the measured acoustic attenuation and backscatter on cell number). In each cell,

$$RL = k_{SF}A \tag{4}$$

where *A* is the amplitude of the acoustic signal strength measured in counts, and k_{SF}=0.43 is a scale factor used to convert counts to decibels. By standard convention (Urick, 1975),

$$2TL = 20\log(r) + 2\alpha_W r + 2\alpha_S r \tag{5}$$

where *r* is the distance along the beam from the transducer to each cell in meters, 20log(*r*) is the spherical spreading loss term, α_W is the coefficient of absorption for acoustic energy in water in dB/m (depends only on temperature at the shallow-water and low-salinity conditions in rivers), and α_S is the sediment attenuation coefficient in dB/m. For convenience in solving for α_S, a new term is defined, the fluid-corrected backscatter (Wright et al., 2010),

$$B_F = RL + 20\log(r) + 2\alpha_W r \tag{6}$$

with α_S then being determined by **l**east-squares linear regression where the values of B_F are regressed on *r* (Topping et al., 2006, 2007b) while iteratively solving for the effective noise floor. In this regression, α_S is equal to -1/2 times the slope of the relation between *r* and B_F. Once α_S is known, *B* is then calculated in each cell where *A* exceeds the effective noise floor, finally allowing calculation of the beam-averaged backscatter, $\overline{B}$. $\overline{B}$ is *B* averaged first among all cells in a beam and them among all beams used on an ADP.

Attenuation: Acoustic attenuation caused by the presence of suspended sediment arises from two distinctly different physical processes that vary in importance largely as a function of instrument frequency, sediment grain size, and sediment density (Flammer, 1962). These processes are acoustic attenuation from: viscous losses arising from viscous drag between the water and sediment grains (Urick, 1948), and scattering losses arising from the

scattering of sound by the sediment grains in directions other than back toward the detector (Lamb, 1945; Urick, 1948; Morse, 1948). Viscous losses dominate when the suspended sediment is relatively fine whereas scattering losses dominate when the suspended sediment is relatively coarse. We use the conventions and methods of Urick (1948), Flammer (1962), Hay (1983), and Moore et al. (2013) to calculate a sediment attenuation coefficient (α_S) that includes the effects of both viscous- and scattering-losses as well as the effects of multiple grain sizes and wet densities of sediment. Following Urick (1948), α_S is the product of the unit sediment attenuation coefficient, α_{UNIT}, and the concentration of suspended sediment, C:

$$\alpha_S = \alpha_{UNIT} C \, . \tag{7}$$

In our study, the unit sediment attenuation coefficient is defined as the sediment attenuation coefficient at a suspended-sediment concentration of 1 mg/L, with α_S expressed in units of dB/m and C expressed in units of mg/L. α_{UNIT} is the combined ensemble-averaged viscous and scattering attenuation coefficients and is derived in this study using the equations of Moore et al. (2013), and making the appropriate conversions, such that it is expressed in units of decibel-liter per meter-milligram or dB-L/m-mg. Changes in the sorting and density of the suspended-sediment grain-size distribution and the frequency of the ADP all have a major influence on α_{UNIT} (Figure 1). From the example in Figure 1b, it is evident that there exists an optimal range of acoustic frequency, suspended-sand D_{50}, and suspended-silt-and-clay D_{50} where the sand contributes very little to α_{UNIT} and:

$$\alpha_S \approx \alpha_{UNIT} C_{SILT\text{-}CLAY} \tag{8}$$

where $C_{SILT\text{-}CLAY}$ is the suspended-silt-and-clay concentration. In many rivers the D_{50} of the suspended sand ranges from 0.0625 to ~0.25 mm (very fine to fine sand) and, in the absence of flocculation, the D_{50} of the suspended silt and clay ranges from ~0.0005 to ~0.01 mm (fine clay to fine silt). For the sorting of the grain-size distributions portrayed in Figure 1b, these median grain sizes result in a fair degree of separation between the value of α_{UNIT}

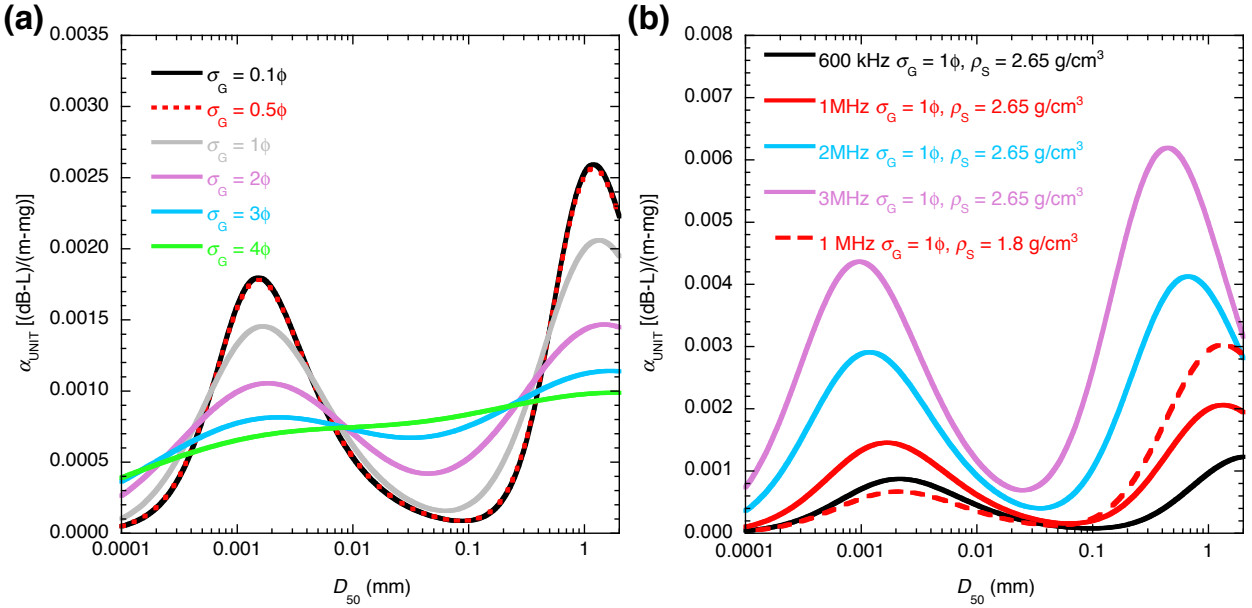

Figure 1 Effects of changes in (a) sediment sorting and (b) ADP frequency and sediment density (ρ_S) on α_{UNIT}. (a) Predicted values of α_{UNIT} at the 1-MHz frequency for the D_{50} of log-normal suspended-sediment grain-size distributions with geometric standard deviations (σ_G) of 0.1ϕ, 0.5ϕ, 1ϕ, 2ϕ, 3ϕ, and 4ϕ. ρ_S is held constant at 2.65 g/cm^3 (quartz density) in this example. (b) Predicted values of α_{UNIT} at acoustic frequencies of 600 kHz, 1 MHz, 2 MHz, and 3 MHz for the D_{50} of log-normal suspended-sediment grain size distributions with σ_G = 1ϕ and ρ_S = 2.65 g/cm^3, and α_{UNIT} at 1 MHz for the D_{50} of log-normal suspended-sediment grain size distributions with σ_G = 1ϕ and a montmorillonite wet ρ_S = 1.8 g/cm^3.

associated with the sand and the value of α_{UNIT} associated with the silt and clay, especially at lower acoustic frequencies. For these median grain sizes and acoustic frequencies, and so long as the suspended-sand concentration does not greatly exceed $C_{SILT\text{-}CLAY}$, $C_{SILT\text{-}CLAY}$ can therefore be reasonably accurately predicted by α_S. This result allowed Topping et al. (2006, 2007) and Wright et al. (2010) to develop their first-cut single-frequency approximate method of using acoustic attenuation to measure suspended-silt-and-clay concentration and acoustic backscatter to measure suspended-sand concentration.

Target strength and backscatter: Target strength, *TS*, is determined by the amount and nature of the sediment in suspension and by the dimensions of the ensonified volume (NDRC, 1946; Urick, 1975). Much research has been completed on the acoustic scattering effects of individual and, later, concentrations of particles in suspension (Rayleigh, 1896; NDRC, 1946; Urick, 1975; Sheng and Hay, 1988; Hay, 1991; Hay and Sheng, 1992; Thorne and Campbell, 1992; He and Hay, 1993; Thorne et al., 1993, 1995; Thorne and Hanes, 2002; Thorne and Buckingham, 2004; Thorne and Meral, 2008; Moore and Hay, 2009). Although the initial work in this field was conducted on regularly shaped particles, sufficient work using natural sand grains (in both single and mixtures of grain sizes) has allowed a sufficiently robust theory on how sound is backscattered by suspensions of sediment in water. The equation used to derive the relation for *TS* is the following version of the Thorne et al. (1993) equation:

$$P_{rms} = P_0 r_0 f \left[\frac{3Mtc}{8D\rho_S} \right]^{1/2} \frac{0.96}{ka_T \psi r} e^{(-2\alpha_N r)} \tag{9}$$

where P_{rms} is the reverberation-level pressure measured at the transducer (in Pascals), P_0 is the source-level pressure (in Pascals) at distance r_0 = 1 m from the transducer, r is the distance along the beam from the transducer (in meters), f is the nondimensional form function that describes the backscattering strength of sediment grains in water as a function of ka_S, $k = 2\pi/\lambda$ is the wave number (in 1/m), λ is the acoustic wavelength (in meters), a_S is the radius of the sediment grains (in meters), D is the diameter of the sediment grains (in meters), ρ_S is the density of sediment (in kg/m^3), M is the mass concentration of suspended sediment (in kg/m^3), t is the acoustic pulse duration (in seconds), c is the measured speed of sound (in m/s), a_T is the radius of the transducer (in meters), α_N is the attenuation coefficient (in nepers/m) resulting from the sum of α_W and α_S, and ψ is the non-dimensional near-field correction of Downing et al. (1995) that accounts for non-spherical spreading losses very near the transducer. We exclude this near-field correction because it is either negligible or, at higher frequencies, degrades the results by overcorrecting B_F in the first cell, thus resulting in negative biases in α_S that get larger with increasing $C_{SILT\text{-}CLAY}$.

The form function, f, used in this study is that of Thorne and Meral (2008), which takes into account both the effect of the non-spherical shape of natural sediment grains and the effect of multiple grain sizes. Relative to form functions evaluated for single-size spheres, these two effects combine to result in a substantial increase in f in the Rayleigh scattering regime ($ka_S < 1$), and a smaller decrease in the geometric scattering regime. Because this form function is used, M in equation 9 is the concentration of the grain-size distribution of suspended sediment with median grain size D_{50}. Hence, D in equation 9 is replaced with D_{50}. The fact that f and D_{50} are associated with a grain-size distribution and not just a single sediment grain size has major implications with respect to the derivation and physical interpretation of the target strength. The target strength derived below is therefore that for the entire grain-size distribution of sediment in suspension and not that for only sand. In cases where the amount of silt and clay greatly exceeds the amount of sand in suspension, the target strength will approach that for the suspended-silt-and-clay grain-size distribution and will be much different from the target strength for the suspended-sand grain-size distribution. One of the greatest source of error/bias in the methods used in previous studies that have related acoustic backscatter to the concentration of only suspended sand arises from these studies neglecting this important physical effect.

Because acoustic intensity is acoustic pressure squared and 1 neper = 8.686 dB, following the appropriate substitutions, simplifications, and rearrangement, equation 9 can be rewritten in the following decibel form:

$$RL = SL + \left[-20\log(r) - 2\log\alpha_W r - 2\log\alpha_S r \right] + 10\log\left[f^2 \frac{3Mtc}{8D_{50}\rho_S} \left(\frac{0.96}{ka_T} \right)^2 \right] \tag{10}$$

to be consistent with equation 1 and then further simplified to:

$$SL - B + 10\log\left[f^2 \frac{3Mtc}{8D_{50}\rho_S}\left(\frac{0.96}{ka_T}\right)^2 \right] = 0 . \quad (11)$$

Simple comparison of equation 3 and equation 11 suggests incorrectly that the right term of the three terms in equation 11 is essentially the target strength minus the detection threshold. Closer inspection of these two equations, however, indicates a problem arising from the conversion of equation 9 from pressure form to the logarithmic intensity form in equation 10 compatible with the sonar equations. When M goes to zero in equation 9, the reverberation-level pressure, P_{rms} also goes to zero. However, when M goes to zero in equation 11, RL goes to minus infinity, because the logarithm of zero is an infinitely large negative number. This problem can be corrected by limiting solution of equation 11 to only those cases where $M > 0$ and by adding a new term from equation 3, the detection threshold, DT. As used in this study, DT is slightly lower than the lowest measured RL in this study during conditions when the suspended-sand concentration was immeasurably small (<0.01 mg/L), conditions when RL is typically less than ~40 to 50 dB. Thus equation 11 can be written in final form as:

$$SL - DT - B = -TS = -10\log\left[f^2 \frac{3Mtc}{8D_{50}\rho_S}\left(\frac{0.96}{ka_T}\right)^2 \right] \quad (12)$$

and can be solved only when $M > 0$.

To finish the derivation of TS such that it is compatible with the backscatter – sediment-concentration relations derived from the sonar equations for constant grain size by Thevenot and others (1992), we: (1) convert M from SI units into the more conventional sediment-concentration units of mg/L and convert D_{50} from SI units into the more appropriate units of mm for sand and finer sediment (these two conversions cancel each other out), and (2) break TS in equation 12 into two parts, the Unit Target Strength, UTS, and, C, the concentration in mg/L of suspended sediment in a log-normal grain-size distribution with median grain size D_{50}. In this two-part form,

$$TS = UTS + 10\log C \quad (13)$$

where,

$$UTS = 10\log\left[f^2 \frac{3tc}{8D_{50}\rho_S}\left(\frac{0.96}{ka_T}\right)^2 \right] \quad (14)$$

and $UTS = TS$ when $C = 1$ mg/L. By virtue of equation 13 a tenfold change in C will result in a 10 dB change in TS when the grain-size distribution of the suspended sediment remains constant. Changes in the grain-size distribution affect both f and D_{50} in equation 13, resulting in a more complicated influence on TS than do changes in C.

The more complicated influence on TS of changes in the sand grain-size distribution under constant C is best illustrated through calculation of the Relative Unit Target Strength ($RUTS$), that is, the UTS relative to the UTS associated with a reference D_{50}, denoted as $D_{50\text{-REF}}$. $D_{50\text{-REF}}$ is the median grain size at a given location that best characterizes the D_{50} of the suspended sediment over the widest possible range in concentration. For convenience, the UTS associated with $D_{50\text{-REF}}$ is abbreviated as UTS_{REF}. $RUTS$ is calculated by simply subtracting UTS_{REF} from the UTS for all values of D_{50}. By virtue of the behavior of the $RUTS$, backscatter measurements made with higher-frequency ADPs are generally less sensitive to changes in suspended-sand D_{50} than are backscatter measurements made with lower-frequency ADPs. The $RUTS$ increases rapidly as a function of increasing D_{50} over most of the Rayleigh scattering regime, and only begins to plateau around ka_S ~0.5. The main implication of this result is that, when $ka_S < 0.5$, use of a single-frequency acoustic approach to measure suspended-sand concentration will be highly biased as a result of concentration-independent variation in D_{50}. Comparison between measured and theoretically determined values of the $RUTS$ are good (Figure 2). The behavior of the $RUTS$ as a function of frequency and D_{50} is

the physical process that allows accurate, that is, relatively unbiased, backscatter-based measurements of suspended-sand concentration and D_{50} to be possible when multiple acoustic frequencies are used.

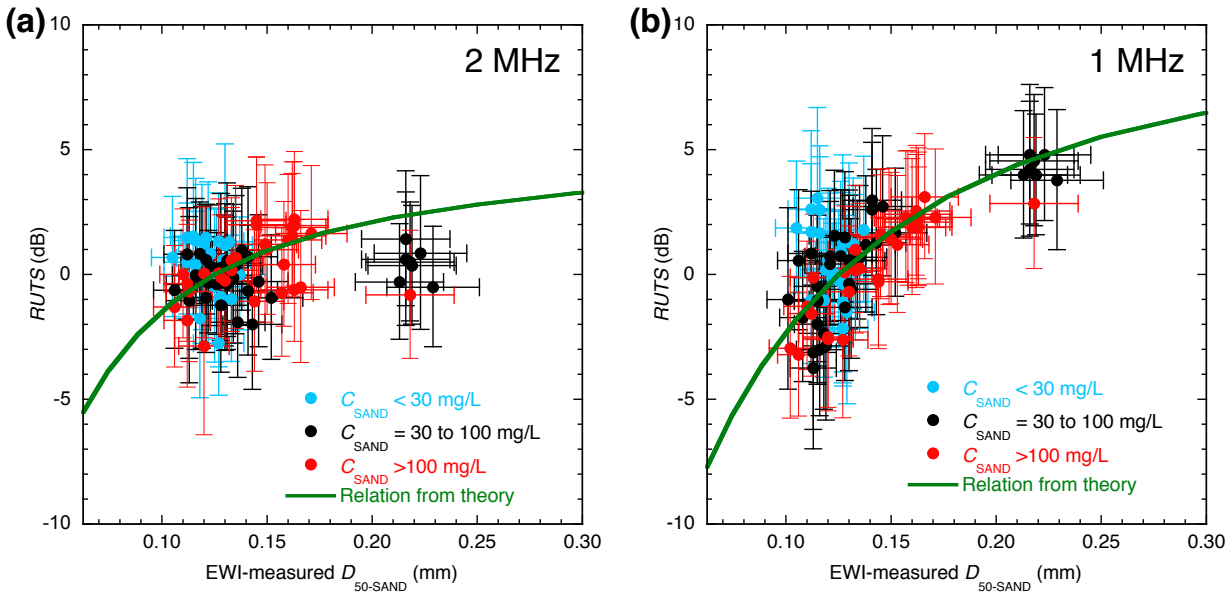

Figure 2 Comparisons of measured and theoretical values of *RUTS* at the Colorado River near river mile 30, 09383050, (CR30) study site, at (a) 2-MHz and (b) 1-MHz acoustic frequencies. Measured values of the *RUTS* are segregated into three different concentration ranges in these plots to allow evaluation of whether they depend on concentration; as indicated in these plots, there is no discernable dependence of the measured *RUTS* on concentration. $D_{50\text{-SAND}}$ error bars are 95%-confidence-level error bars that include both field and laboratory-processing errors in the EWI measurements of $D_{50\text{-SAND}}$; *RUTS* error bars are 95%-confidence-level error bars that include (1) both field and laboratory-processing errors in the EWI measurements of C_{SAND}, (2) a 2% estimated error in the ADP-calculated values of $\overline{B}$, and (3) the 95%-confidence-level error in the mean value of $\overline{B}$ time-averaged over the 1-hour interval centered on the temporal midpoint of the time of each EWI measurement.

Our derivation of the *UTS* and *RUTS* allows the Thevenot et al. (1992) simplification of the sonar equation to be re-derived in a convenient form for cases of varying grain size; a form that in this study uses backscatter measured at multiple frequencies to solve for both suspended-sediment concentration and D_{50}. In their simplification of the active sonar equation, Thevenot et al. (1992) showed that, when grain size is constant:

$$C = 10^{-0.1K+0.1B} \tag{15}$$

where C is sediment concentration in mg/L, B is relative backscatter (replaced in this study by $\overline{B}$ the beam-averaged backscatter), and K is a constant. Substituting equations 13 and 14 into equation 12 and rearranging equation 12 to be in the form of Thevenot et al. [1992] indicates that, when grain-size is allowed to vary, K is not truly constant, but is the sum of a constant part ($SL - DT$) and a varying part (*UTS*). The rearranged version of equation 12 after these substitutions is:

$$C = 10^{-0.1(SL-DT+UTS)+0.1\overline{B}}. \tag{16}$$

Thus, a generalized way to re-derive equation 15 such that grain size is free to vary is to define a new constant:

$$K_1 = SL - DT \tag{17}$$

and rewrite equation 16 as:

$$C = 10^{-0.1K_1 - 0.1UTS + 0.1\overline{B}} . \quad (18)$$

For the special case, where C is the concentration of suspended sediment with D_{50} equal to $D_{50\text{-REF}}$,

$$C = 10^{-0.1K_1 - 0.1UTS_{\text{REF}} + 0.1\overline{B}} . \quad (29)$$

Because

$$RUTS = UTS - UTS_{\text{REF}} \quad (20)$$

the general case where the median grain size of the sediment in suspension is allowed to vary can be written as:

$$C = 10^{-0.1K_1 - 0.1UTS_{\text{REF}} - 0.1RUTS + 0.1\overline{B}} . \quad (21)$$

Because UTS_{REF} is constant at a given study site, it is convenient to define another new constant:

$$K_2 = -\left(K_1 + UTS_{\text{REF}}\right) = -0.1\left(SL - DT + UTS_{\text{REF}}\right) \quad (22)$$

allowing the final more-general form of equation 15 for varying grain size:

$$C = 10^{K_2 + 0.1\left(\overline{B} - RUTS\right)} . \quad (23)$$

If only one frequency ADP is present, it is theoretically impossible to solve for both C and $RUTS$ for a given measured $\overline{B}$. However, if two or more frequencies are present, it is possible to iteratively solve for C and $RUTS$. This iterative approach is the basis for the method we use to calculate suspended-sand C and D_{50}.

As a grain-size distribution of suspended sediment broadens, the difference in the UTS between silt-and-clay- and sand-size sediment lessens as a result of the effect of decreased sorting on the form function. In cases where the geometric standard devation, σ_G, of a grain-size distribution is less than ~1.5ϕ, the UTS associated with silt grain-size distributions will be much less than the UTS associated with sand grain-size distributions. In these cases, the backscatter will be dominantly produced by sand-size sediment. Conversely, in cases where the σ_G of a grain-size distribution exceeds ~1.5ϕ, the UTS associated with silt grain-size distributions becomes a larger fraction of the UTS associated with sand grain-size distributions, and measurable backscatter will be produced by the silt-size sediment in addition to the backscatter produced by the sand-size sediment. Ultimately, in cases where the σ_G of a grain-size distribution exceeds ~3ϕ, the UTS associated with grain-size distributions of silt and clay will be nearly equal to the UTS associated with grain-size distributions of sand. Under these conditions, the backscatter produced by the suspended silt and clay is nearly as much as that produced by the suspended sand. Because the sorting of suspended silt and clay (σ_G = 2 to 3ϕ) is much broader than the sorting of suspended sand (σ_G = 0.63 to 0.65ϕ) at our study sites, a condition likely in most rivers, the backscatter produced by silt and clay must be accounted for under conditions when the concentration of the suspended silt and clay greatly exceeds that of the sand.

To allow accurate acoustic measurements of suspended-sand concentration to be made when even large concentrations of silt and clay are present (and most of $\overline{B}$ arises from the amount of silt and clay in suspension), a data-processing method was developed to allow separation of the part of $\overline{B}$ arising from sand-size sediment from the part of $\overline{B}$ arising from silt-and-clay-sized sediment. This method utilizes the differing theoretical behaviors of the UTS and α_S under different combinations of suspended silt and clay and suspended sand. An early empirical version of this method was described in Topping et al. (2007). The basis for the UTS part of this method is the development of a Base-Backscatter-Calibration (BBC) relation between $\overline{B}$ and the log-transformed EDI/EWI-measured suspended-sand concentration using equation 23 for conditions where the suspended sediment is

dominated by sand-size sediment with a median grain size within ¼ϕ of $D_{50\text{-REF}}$ and assumed constant sorting. Relations are then developed using both theory and empirical analysis to account and correct for the excess backscatter relative to this relation for conditions where the amount of silt and clay greatly exceeds the amount of sand in suspension. For accurate BBC relations to be developed, the average concentration of suspended sand along the beam must systematically relate to the EDI/EWI-measured velocity-weighted concentration of suspended sand in the cross section. Because of how the flow and suspended-sediment-concentration field interact with the local channel geometry at the locations of ADP deployments, there are typically differences between the average suspended-sand C and D_{50} in the part of the cross section ensonified by the ADP beams and the velocity-weighted suspended-sand C and D_{50} in entire EDI/EWI cross section. These differences lead to differences between the theoretically predicted (0.1 by equation 23) and empirically determined slopes and y-intercepts of the BBC relations. The BBC relation form of equation 23 allowing empirically determined slopes and y-intercepts is:

$$\log\left(C_{\text{SAND-REF}}\right) = K_2 + K_3\overline{B}_{\text{BASE}} \tag{24}$$

where $C_{\text{SAND-REF}}$ is the EDI/EWI-measured reference concentration in the river cross section of suspended sand with a median grain size equal to $D_{50\text{-REF}}$, and $\overline{B}_{\text{BASE}}$ is the base backscatter associated with $C_{\text{SAND-REF}}$.

The additional beam-averaged backscatter required to account for the amount of backscatter produced by the presence of suspended silt and clay at a given concentration of suspended sand is referred to as the excess backscatter, B'. Excess backscatter is calculated as:

$$B' = \overline{B} - \overline{B}_{\text{BASE}} . \tag{25}$$

Because

$$\overline{B} = TS + SL + DT \tag{26}$$

equation 25 can be rewritten as:

$$B' = \left(TS_{\text{SED}} + SL + DT\right) - \left(TS_{\text{SAND-REF}} + SL + DT\right) \tag{27}$$

and simplified to:

$$B' = TS_{\text{SED}} - TS_{\text{SAND-REF}} , \tag{28}$$

where TS_{SED} is the target strength of the suspended sand, silt, and clay mixture and $TS_{\text{SAND-REF}}$ is the target strength of $C_{\text{SAND-REF}}$. By definition, when all of the suspended sediment is composed of sand with $D_{50} = D_{50\text{-REF}}$, $B' = 0$. To derive the theoretically based value of B' at constant sand concentration and D_{50}, equation 13 can be rewritten as:

$$TS = 10\log\left[\frac{f^2}{D_{50}\rho_{\text{S}}}\right] + 10\log C + 10\log\left[\frac{3tc}{8}\left(\frac{0.96}{ka_{\text{T}}}\right)^2\right]. \tag{29}$$

After rearrangement and substitution of the quartz density of 2.65 g/cm^3 for the density of sand and replacement of the 0.1 theoretical slope of the BBC relation with the empirical slope K_3, equation 29 becomes:

$$B' = \left(\frac{1}{K_3}\right)\log\left[\left(\frac{f_{\text{SED}}}{f_{\text{REF}}}\right)^2\left(\frac{D_{50\text{-REF}}}{D_{50\text{-SED}}}\right)\left(\frac{2.65}{\rho_{\text{SED}}}\right)\left(1+\frac{C_{\text{SILT-CLAY}}}{C_{\text{SAND-REF}}}\right)\right] \tag{30}$$

where $C_{\text{SILT-CLAY}}$ is the concentration of silt and clay in mg/L, $D_{50\text{-SED}}$ is the median grain size of the sand, silt, and clay mixture in suspension, f_{SED} is the value of the Thorne and Meral (2008) form function calculated for the grain-size distribution of the sand, silt, and clay mixture, ρ_{SED} is the wet density of the sand, silt, and clay mixture, and f_{REF}

is the value of the Thorne and Meral (2008) form function associated with the $D_{50\text{-REF}}$ of the suspended sand. The theoretical behavior of B' predicted by equation 30 agrees well with the empirical behavior of B' (Figure 3).

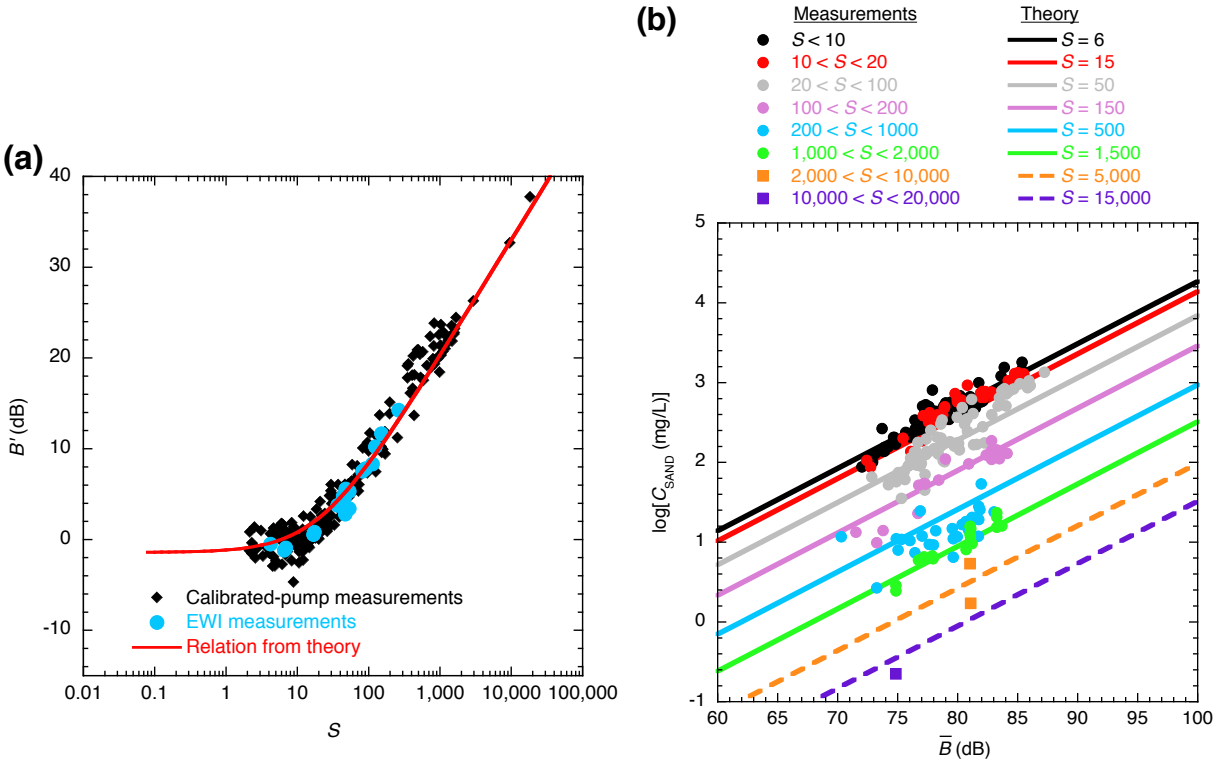

Figure 3 (a) B' plotted as a function of S for the 2-MHz ADP at the Rio Grande above Rio Grande Village, TX, 08375295, (RG-RGV) study site. The BBC relation used to calculate values of B' has a slope of 0.078. The theoretical relation for B' is derived using a sand grain-size distribution with $D_{50\text{-REF}}$ = 0.105 mm and σ_G = 0.65ϕ, and a silt and clay grain-size distribution with D_{50} = 0.002 mm, σ_G = 2.7ϕ, and a wet density of 2.65 g/cm^3. (b) Log(C_{SAND}) plotted as a function of $\overline{B}$ for 8 different ranges of S for the 2-MHz ADP at the RG-RGV study site. Measurements plotted are the same as in a. BBC relation fit to suspended-sediment measurements with $S \leq 10$ shown as solid black line; theoretical relations between $\overline{B}$ and log(C_{SAND}) at higher values of S calculated using the theoretical B' relation in a.

As a result of the theoretical behaviors of backscatter and attenuation under different suspended-sediment grain-size distributions, the backscatter produced by extremely high concentrations of suspended silt and clay can effectively mask the backscatter produced by sand when the ratio of suspended silt and clay to suspended sand, S, is high. As a result of backscatter masking by relatively high concentrations of suspended silt and clay, theoretically derived relations between $\overline{B}$ and log(C_{SAND}) at constant α_S become extremely steep (with almost no slope) at lower values of log(C_{SAND}), making it problematic to accurately solve for log(C_{SAND}). The steepness transition in these relations occurs at increasing values of S as the D_{50} of the silt and clay decreases. To calculate C_{SAND} using only the backscatter produced by the suspended sand, we subtract the silt-and-clay produced excess backscatter B' from measurements of $\overline{B}$ by using theoretically derived relations between $\overline{B}$, α_S, log(C_{SAND}), and S calculated on the basis of equations 8, 24, and 30 (Figure 4).

TWO-FREQUENCY *RUTS* METHOD

The two-frequency *RUTS* method for measuring C_{SAND} and D_{50} is an iterative process that uses as input (1) the single-frequency 1- and 2-MHz estimates of C_{SAND} calculated using the theory described in the previous section and (2) the theoretical relations between suspended-sand D_{50} and the *RUTS* at the 1- and 2-MHz frequencies. Because backscatter at higher frequencies is less affected by changes in the D_{50} of the suspended sand, the 2-MHz

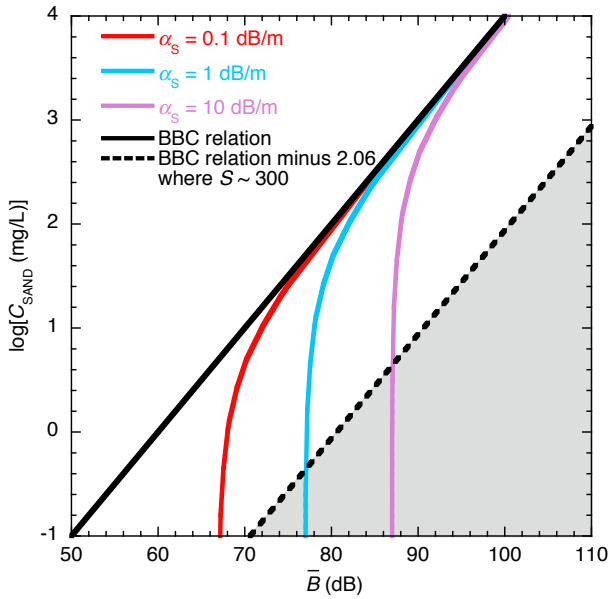

Figure 4 Behavior of theoretical relations between $\overline{B}$ and log(C_{SAND}) for different values of α_S at the 1-MHz frequency. The gray shaded regions indicate the regions of backscatter masking produced by relatively high concentrations of suspended silt and clay. Suspended-sand D_{50} = 0.125 mm, $\sigma_G = 0.63\phi$; suspended-silt-and-clay D_{50} = 0.001 mm, $\sigma_G = 3\phi$, ρ_S = 2.65 g/cm^3. BBC relation has a slope (K_3) of 0.1 and a y-intercept (K_2) of -6. Shown are the BBC relation and the relations between $\overline{B}$ and log(C_{SAND}) for the cases where α_S = 0.1, 1.0, and 10 dB/m. These relations between $\overline{B}$ and log(C_{SAND}) are near vertical when S exceeds ~300 in the gray shaded region.

estimate of C_{SAND} is chosen as the initial concentration estimate in this calculation. The difference in the values of $\overline{B}$ measured at the 1- and 2-MHz frequencies (corrected for B'), the theoretical *RUTS* relations, and the BBC relations for the 1- and 2-MHz ADPs are then used in an iterative fashion to calculate the D_{50} and concentration of the suspended sand that satisfies the constraint that the B'-corrected values of $\overline{B}$ measured at each frequency are associated with the same suspended-sand concentration. By this process, when the 1-MHz estimate of C_{SAND} exceeds the 2-MHz estimate, the suspended-sand D_{50} is calculated to be greater than $D_{50\text{-REF}}$ using the 1-MHz *RUTS* relation and the two-frequency value of C_{SAND} is calculated to be lower than the initial 2-MHz estimate of C_{SAND} using the 2-MHz *RUTS* relation and this new value of D_{50}. Conversely, when the 1-MHz estimate of C_{SAND} is lower than the 2-MHz estimate of C_{SAND}, the suspended-sand D_{50} is calculated to be less than $D_{50\text{-REF}}$ using the 1-MHz *RUTS* relation and the two-frequency value of C_{SAND} is calculated to be higher than the initial 2-MHz estimate of C_{SAND} using the 2-MHz *RUTS* relation and this new value of D_{50}. Compared to the initial single-frequency estimates of C_{SAND}, two-frequency measurements of C_{SAND} by this process are generally unbiased as a function of changing suspended-sand D_{50} (Figure 5). As expected on the basis of the theoretical behavior of the *RUTS* depicted in Figure 2, grain-size-driven biases in 1-MHz estimates of C_{SAND} are greater than in 2-MHz estimates of C_{SAND}.

RESULTS

Unless the range in suspended-sand D_{50} at a study site is smaller than about 1ϕ, two acoustic frequencies are required to produce measurements of suspended-sand concentration (C_{SAND}) that are unbiased by changes in the suspended-sand grain-size distribution. In cases where the range in suspended-sand D_{50} is smaller than about 0.75ϕ, reasonably unbiased results may be obtained by using only a single 2-MHz-frequency ADP, but only if the contribution of silt and clay to backscatter is accounted for. At our study sites, use of a single 1-MHz frequency ADP resulted in biased measurements of C_{SAND} regardless of the range in suspended-sand D_{50}. At almost all of our study sites, inclusion of B' resulted in a substantial reduction in the relative bias in the measurements of C_{SAND}. Furthermore, the inclusion of B' results in a much more substantial reduction in the maximum relative error. For

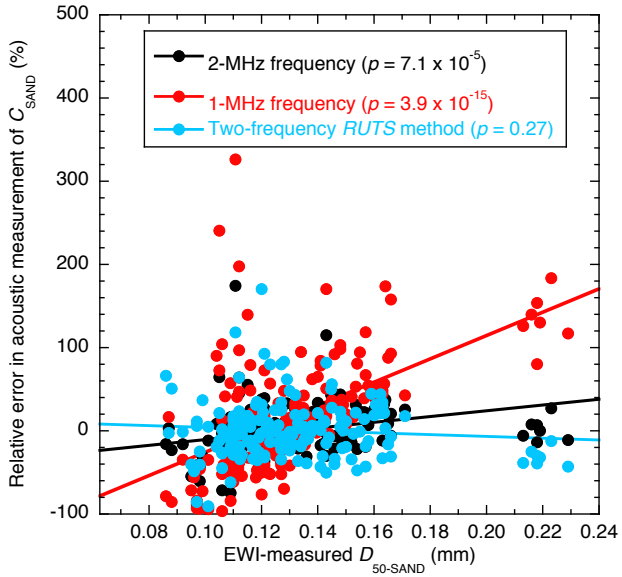

Figure 5 Relative errors in single-frequency and two-frequency acoustic measurements of C_{SAND} at the CR30 study site. F-tests conducted on the least-squares linear regressions fit to these relative errors indicate significant positive correlations (at the p = 0.05 critical level) between suspended-sand D_{50} and error for both the 1- and 2-MHz single-frequency measurements of C_{SAND}, but no significant correlation between suspended-sand D_{50} and error for the two-frequency measurements. The significant relation between suspended-sand D_{50} and error is much steeper at the 1-MHz frequency than at the 2-MHz frequency. These results indicate the presence of grain-size-driven bias in the single-frequency measurements of C_{SAND} that is larger at the lower frequency, as expected on the basis of the theoretical behavior of the *RUTS* depicted in Figure 2.

example, at the RG-RGV study site, the maximum relative error in the acoustic measurements of C_{SAND} when using the single-frequency method at 1 MHz neglecting B' is +95,900%; this enormous relative error decreases to +651% upon inclusion of the effects of B'. Furthermore, among the 173 paired acoustic and EWI measurements at the Colorado River near Grand Canyon, AZ, 09402500, study site, the maximum relative error in the acoustic measurements of C_{SAND} when using the single-frequency method at 2 MHz neglecting B' is +1,410%; this extremely large relative error decreases to +65.6% upon inclusion of the effects of B'.

The two-frequency acoustic measurements compare well with the physical measurements of the velocity-weighted suspended-silt-and-clay, suspended-sand concentrations, and suspended-sand median grain sizes in the river cross sections at the study sites on the Colorado River and Rio Grande (Figure 6). Wilcoxon-Mann-Whitney tests conducted on in- and out-of-sample data from the Colorado River study sites indicate that the in-sample and out-of-sample errors in the acoustic measurements of silt and clay concentration and sand concentration are not significantly different at the 0.05 critical level. In Figure 6a, the acoustic and physical measurements of suspended-silt-and-clay concentration are in good agreement over the range from ~100 mg/L to ~20,000 mg/L; in figure 6b, the acoustic and physical measurements of suspended-sand concentration are in good agreement over the range from ~2 mg/L to ~5,000 mg/L. Though not shown in figure 6a because the physical measurements are calibrated-pump measurements, acoustic and calibrated-pump measurements of suspended-silt-and-clay concentration have been found to agree well at concentrations as high as ~30,000 mg/L on both the Colorado River and Rio Grande. In Figure 6c, the acoustic and physical measurements of suspended-sand D_{50} are in reasonable agreement over the range from ~0.08 to 0.25 mm. Although the variance about the line of perfect agreement in Figure 6c appears larger than in Figures 6a-b, this is a visual artifact of the differences in scale between the figure panels; five orders of magnitude are plotted in Figures 6a-b, whereas less than one order of magnitude is plotted in Figure 6c. In reality, the variance about the line of perfect agreement in Figure 6c is smaller than in Figures 6a-b.

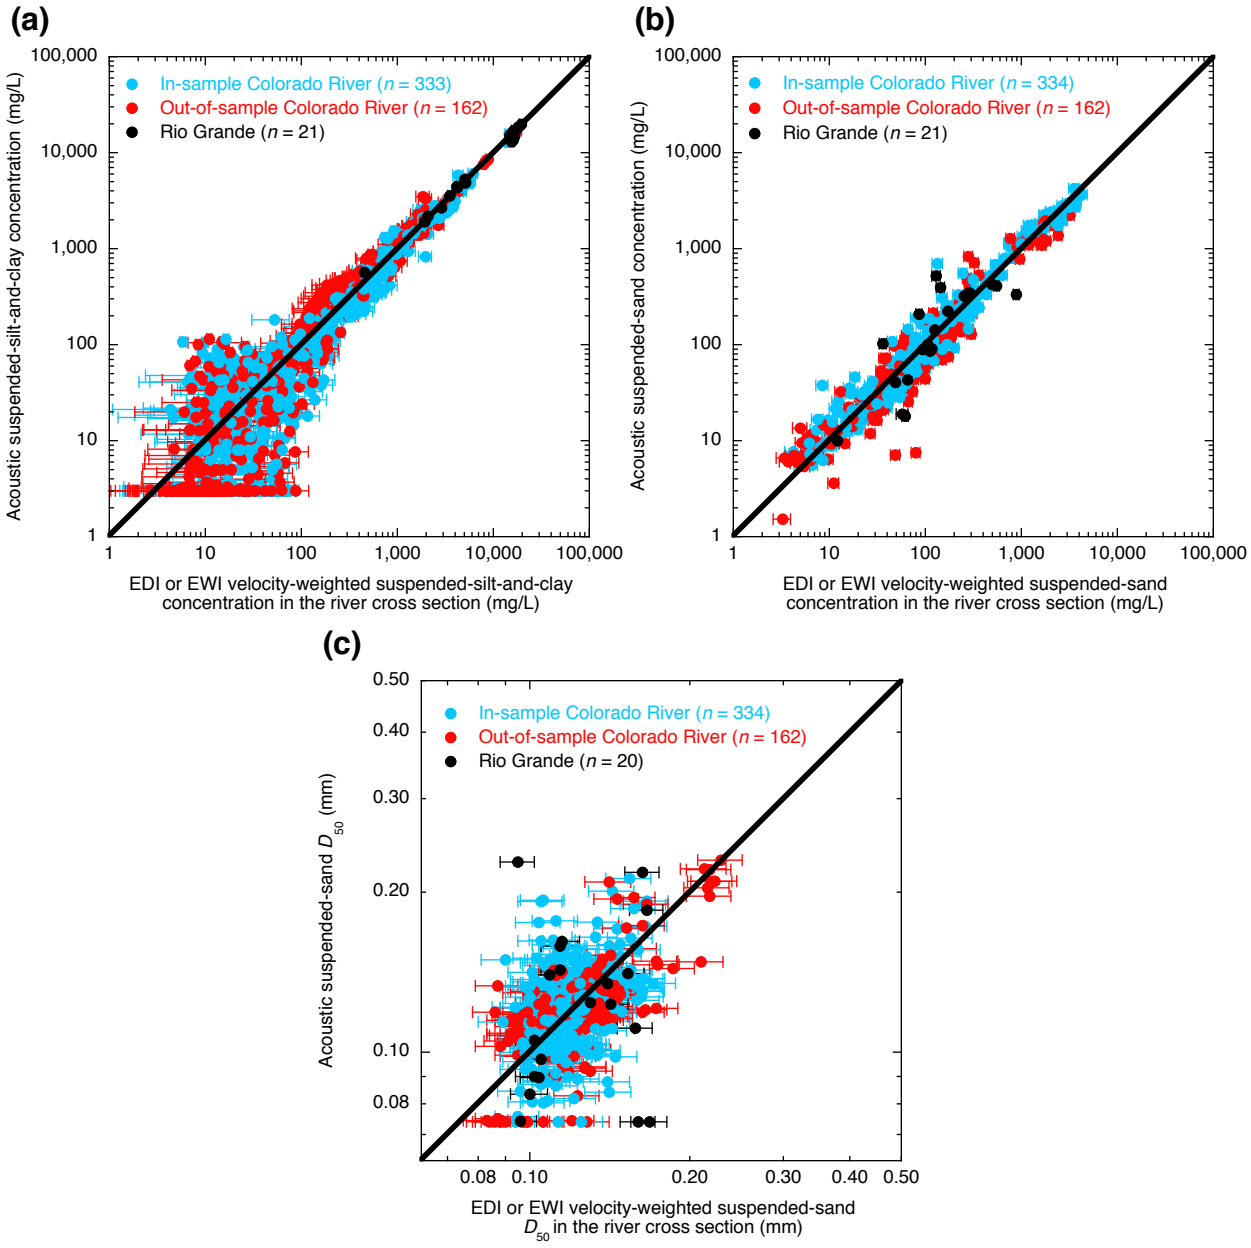

Figure 6 Two-frequency acoustic measurements of the velocity-weighted (a) suspended-silt-and-clay concentration, (b) suspended-sand concentration, and (c) suspended-sand D_{50} in the river cross section plotted as a function of the EDI or EWI-measured values of these parameters at the five Colorado River and Rio Grande study sites where the EDI/EWI measurement cross section is located within 200 m of the ADP arrays. Black solid lines are the lines of perfect agreement between the EDI/EWI measurements at the acoustic measurements. In-sample data are those used in the calibration of either of the two ADPs at a study site; out-of-sample data are not used in any calibration. Horizontal error bars indicate the 95%-confidence-level combined field and laboratory errors in the EDI/EWI measurements calculated using the methods in Topping et al. (2010, 2011).

For all three of the parameters plotted in Figure 6, the the log-transformed variance is approximately symmetric about the lines of perfect agreement, indicating the presence of little bias in the method; a result supported by F-tests conducted on the relative errors associated with each acoustic measurement. Only in the case of the acoustic

measurements of the suspended-sand D_{50} do the F-tests indicate the presence of bias; there is a tendency for a small positive bias in the acoustic measurements of suspended-sand D_{50} when $D_{50} < D_{50\text{-REF}}$ and for a small negative bias in these measurements when $D_{50} > D_{50\text{-REF}}$. Although the two-frequency acoustic measurements are generally unbiased, the presence of reasonably large variance about the lines of perfect agreement indicates that these measurements are subject to relatively large random error. For both suspended silt and clay and suspended sand, the log-transformed variance about the lines of perfect agreement decreases significantly with increasing concentration. In the case of sand, this decrease in variance is gradual, whereas in the case of silt and clay, this decrease in variance is rapid between concentrations of 1 and 100 mg/L and more gradual between concentrations of 100 and 20,000 mg/L. These negative correlations between concentration and the log-transformed variance about the lines of perfect agreement indicate that the relative errors in the acoustic measurements of suspended-silt-and-clay concentration and suspended-sand concentration both decrease with increasing concentration. For suspended-sand D_{50}, the log-transformed variance about the line of perfect agreement, and therefore the relative error in the acoustic measurements of suspended-sand D_{50}, is approximately constant across the measured 0.09 to 0.25-mm range.

Abstract: The use of acoustic and other parameters as surrogates for suspended-sediment concentrations (SSC) in rivers has been successful in multiple applications across the Nation. Critical to advancing the operational use of surrogates are tools to process and evaluate the data along with the subsequent development of regression models from which real-time sediment concentrations can be made available to the public. Recent developments in both areas are having an immediate impact on surrogate research, and on surrogate monitoring sites currently in operation.

The Surrogate Analysis and Index Developer (SAID) standalone tool, under development by the U.S. Geological Survey (USGS), assists in the creation of regression models that relate response and explanatory variables by providing visual and quantitative diagnostics to the user. SAID also processes acoustic parameters to be used as explanatory variables for suspended-sediment concentrations. The sediment acoustic method utilizes acoustic parameters from fixed-mount stationary equipment. The background theory and method used by the tool have been described in recent publications, and the tool also serves to support sediment-acoustic-index methods being drafted by the multi-agency Sediment Acoustic Leadership Team (SALT), and other surrogate guidelines like USGS Techniques and Methods 3-C4 for turbidity and SSC.

The regression models in SAID can be used in utilities that have been developed to work with the USGS National Water Information System (NWIS) and for the USGS National Real-Time Water Quality (NRTWQ) Web site. The real-time dissemination of predicted SSC and prediction intervals for each time step has substantial potential to improve understanding of sediment-related water-quality and associated engineering and ecological management decisions.

INTRODUCTION

Streamflow, sediment, and water-quality data are needed to establish baseline information for water-resource managers to evaluate historical and current conditions and plan management alternatives. Real-time, continuous SSC data can be useful for monitoring river response downstream of areas affected by recent wildfires, construction or remediation activities, levee failures, or changing land uses. Additionally, real-time data can provide an early warning for operators of municipal water supply and hydroelectric facilities concerned with avoiding damage to infrastructure from sediment. Surrogates are becoming widely used to better understand physical and chemical processes in natural systems (Rasmussen and others, 2009). Acoustic technology is becoming increasingly used for velocity measurements and is also being used as a surrogate for sediment concentrations.

The Surrogate Analysis and Index Developer (SAID) tool is a standalone tool to assist in the development of ordinary least squares (OLS) regression models that relate response and predictor variables (Helsel and Hirsch, 2002) by providing visual and quantitative diagnostics to the user (figure 1). The tool is written in the Matlab® programming language. There is no limit on the number of explanatory variables to be used in the linear model and no requirement of which explanatory variables to use. SAID is under beta development and is not yet formally released as a USGS software product.

SAID has applications for relating surrogate-technology parameters such as turbidity, acoustics, and others. SAID can be used for processing acoustic parameters to be used as predictor variables for suspended-sediment concentrations (SSC).The sediment-acoustic method, which assumes a constant spatial suspended-sediment concentration and grain size distribution with respect to range along the acoustic axis of the beam, utilizes acoustic data from fixed-mount stationary acoustic Doppler velocity meters (ADVM). Some of the earliest USGS applications and research were done by Topping and others (2004, 2006, 2007), Wright and others (2010), Landers

(2012), and Wood and Teasdale (2013). The sediment-acoustic method, as described in these references, is used in SAID to compute the sediment attenuation coefficient and sediment corrected backscatter from ADVM acoustic parameters. SAID allows for quick adjustment of complex ADVM data-processing options, changes in the variables used in the regression, and evaluation of the created model. The tool also enables the user to transform loaded variables, build linear regression models, view linear model diagnostic statistics and plots, export the model information, and generate a predicted time series.

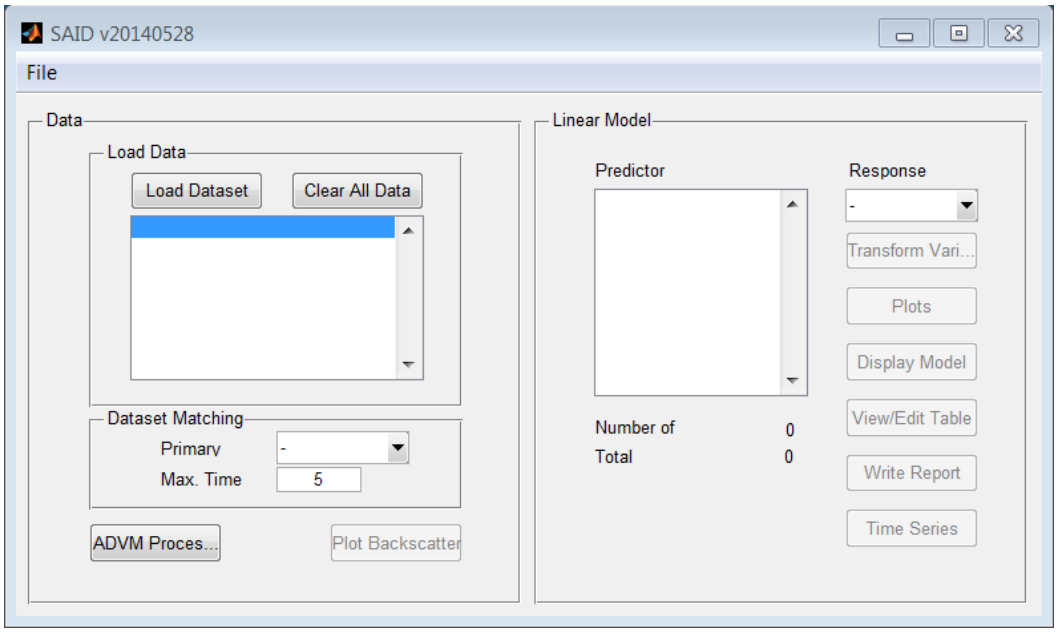

Figure 1 Main SAID window for beta version 20140528

This paper provides an overview on processing and loading data into SAID for developing regression models among surrogate data and measured constituents. In addition, this paper discusses the ADVM configuration parameters that are used in the calculation of acoustic surrogate parameters. Lastly, the paper gives an overview of how the regression models developed in SAID can be used in utilities that have been developed to disseminate predicted SSC in real-time.

SURROGATE ANALYSIS AND INDEX DEVELOPMENT

In the development of linear regression models, explanatory and response variables must be selected. These variables are contained in time series dataset files stored on disk. Because surrogate observations are continuous, and constituent observations occur at irregular time intervals, it is typical to store surrogate and constituent time series in separate dataset files. In order to choose observation sets of variables to develop a linear regression model, observations from the surrogate and constituent time series must be matched. Once a linear regression model is created from a set of matched observations, it must be evaluated for validity and appropriateness. SAID provides the ability to load and match datasets, select the response and predictor variables, and evaluate the created linear regression model. An overview of the dataset workflow is briefly described below and the following sections describe the process to develop regression models in more detail.

- ***Loading datasets***
  - Data that are stored on disk in ASCII files are loaded into memory by SAID.
- ***Choose primary datasets***
  - A dataset is selected that serves as the primary time series to synchronize observations. The selected dataset is known as the primary dataset and other loaded datasets become secondary datasets.
  - Adjusting the maximum time difference value (Max. Time) changes the upper limit of the time difference to which observations are synchronized.

- ***Choose linear model variables***
  - Available variables will be displayed in the Predictor Variables list box and the Response Variable drop-down list. SAID creates a linear model after a valid set of predictor and response variables are selected.
- ***Evaluate linear model***
  - SAID provides several diagnostic plots to determine if the created linear model created fits the assumptions of the OLS method.

Datasets: SAID is capable of loading two types of data. The term "loaded datasets" refers to datasets that have been loaded from disk. The data can be stored as tab delimited ASCII files or a collection of Argonaut ASCII files. Loaded datasets are not necessarily stored in separate files because of a constituent/surrogate relationship. Having dissimilar time steps is a typical reason for storing and loading datasets separately.

Variables with names that match the patterns CellXXAmpY and CellXXSNRY (where XX is the cell number, from 00 to 99, and Y the beam number, either 1 or 2) are dedicated variables for backscatter counts (Amp) and signal-to-noise ratio (SNR) and are used in the computation of the sediment attenuation coefficient and mean sediment corrected backscatter. These variables are not available for use in the creation of a linear model but are necessary in the computation of the ADVM acoustic surrogate metrics.

Variables named ADVMTemp and Vbeam also are dedicated variables used for the temperature and water depth. The temperature must be in units of degrees Celsius and is directly used in computing the ADVM parameters and is therefore necessary. The water depth is used to determine if the cell is out of water when the vertical orientation is selected in the ADVM Processing dialog box. A minimum Vbeam value also is set by the user in order to exclude samples taken when the water is below a certain depth.

During the time a dataset is being loaded, the program checks for variable names that are already loaded. If a variable that is in the dataset that is to be loaded exists in an already loaded dataset, then the selected dataset will not be loaded. Once the datasets are loaded, the data are then available for matching.

Matching Time-Series Observations: In order to build a linear model, it is necessary that a dataset with observations of predictor (surrogate) and response (water-quality) variables exist. Matching occurs in order to synchronize observations from the loaded datasets. The result of matching is the creation of a single dataset containing the matched data, which is then used to develop the linear model.

The primary dataset is the loaded dataset that contains the observations whose date and time of observation form the basis for matching in the secondary datasets. In a typical application for SAID, the primary dataset is the dataset that contains the constituent observations. The primary dataset is chosen by selecting it from the Primary Dataset drop-down list (figure 1). A linear model will not be created until a primary dataset is selected.

Secondary datasets are loaded datasets that contain observations that are matched to primary dataset observations. The term secondary dataset refers to all of the datasets that are not the primary dataset. Observations from the secondary datasets are only copied to the synchronized dataset if they have a date-time that matches a primary dataset observation within the user specified time interval allowance (Max. Time).

Selecting a primary dataset initiates the matching algorithm. For each observation in the primary dataset, SAID calculates the minimum absolute time difference between the observation date and time variables and the date and time variables of the secondary dataset being compared. If the minimum absolute time difference is less than or equal to the user specified value for the maximum time difference, the observations from the secondary dataset being compared are matched with the observations of the primary dataset and the values are copied to the matched dataset. If the minimum absolute time difference is greater than the user specified maximum time difference (Max. Time), then the corresponding variables in the observation in the matched dataset are set to an invalid value. In other words, the observation in the primary dataset will not be matched to an observation in the dataset being compared.

After a primary dataset is selected, the program will indicate that it is matching datasets and will remain unresponsive until the matching is complete. The time it takes for the program to create a matched dataset depends on the number of loaded datasets and the number of observations in each dataset. When the program has completed the matching algorithm, the variables available for use in the linear model are shown in the Predictor Variables and Response Variable lists.

Processing and Viewing Acoustic Backscatter Data (optional in SAID): The following ADVM-related parameters are required by SAID before the acoustic backscatter data are processed and acoustic surrogate parameters are computed:

- ADVM Configuration - Frequency, Effective Transducer Diameter, Slant Angle, Blanking Distance, Cell Size, Number of Cells
- ADVM Processing - Intensity Scale Factor (if Amp is selected for Backscatter Values), Minimum Mid-Point Cell Distance, Maximum Mid-Point Cell Distance, Minimum Vbeam

The configuration parameters are taken from a configuration record file that is saved by the ADVM with each ADVM data file. Once the required parameters in the ADVM Processing window have valid values, the ADVM parameters with at least one valid observation will be available in the Predictor Variables list. By clicking on the ADVM Processing button (figure 1), the ADVM configuration and processing options used in the calculation of the ADVM parameters can be changed (figure 2). ADVM configurations needed for input to SAID can be found in the setup parameters section of the ADVM software.

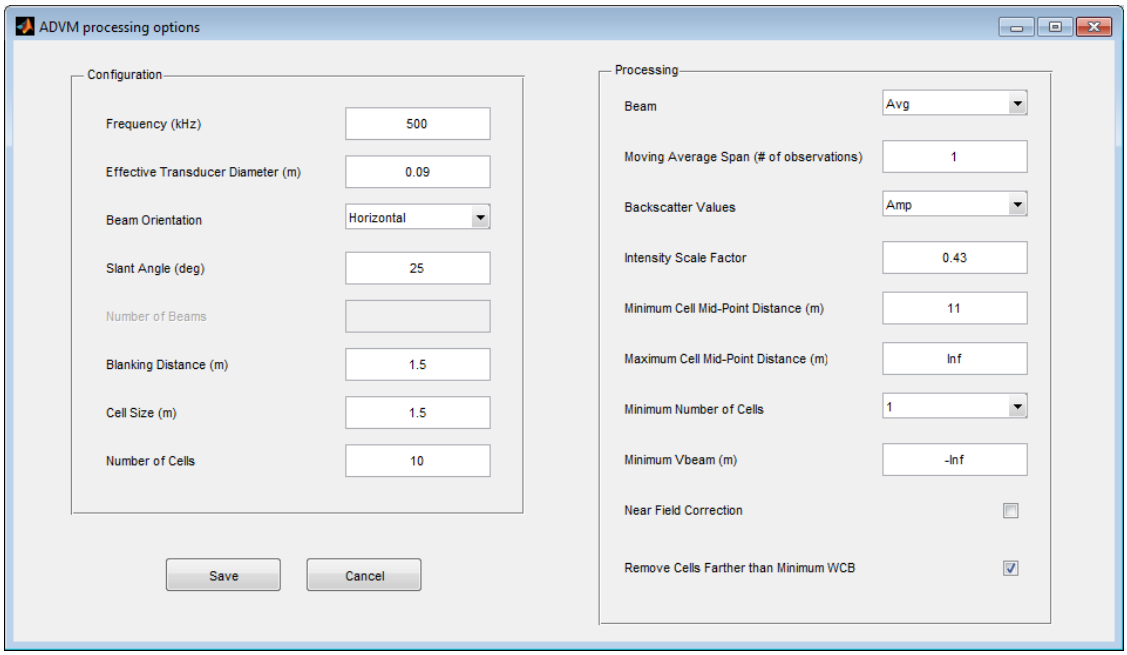

Figure 2 ADVM deployment configuration and acoustic parameter options window

Configuration Parameters: The following parameters indicate the ADVM type and setup and are necessary to compute the acoustic surrogate parameters (figure 2).

- ***Frequency*** – The frequency of the ADVM acoustic signal.
- ***Effective Transducer Diameter*** – The effective diameter in meters of the ADVM transducer. The effective transducer diameter is only used when the Near Field Correction option is selected in the Processing section.
- ***Beam Orientation*** – The orientation of the acoustic beams of the ADVM. If 'Vertical' is selected for this field, then the Vbeam for each observation is compared to the cell edges, and each cell that is out of water is marked as invalid.
- ***Slant Angle*** – The angle of the acoustic beam with respect to the vector that represents the cell distance from the instrument. This angle, along with the blanking distance, cell size, and number of cells, is used to find the mid-point distance of each cell along the acoustic beam.

- ***Number of Beams*** – The number of acoustic beams on the instrument. This value is not used. SAID assumes that the instrument has two beams.
- ***Blanking Distance*** – The distance in meters from the instrument to the beginning of the first cell. This value is used in the computation of the mid-point distance of each cell along the acoustic beam.
- ***Cell Size*** – The length of each cell in meters. This value is used in the computation of the mid-point distance along the acoustic beam of each cell.
- ***Number of Cells*** – The number of cells in the configuration of the ADVM under analysis. The number of cells directly affects the values displayed in the Minimum Number of Cells drop down list.

Processing Parameters: The following parameters control how ADVM backscatter data are screened and processed (figure 2).

- ***Beam*** – The beam number from which the backscatter values are taken. When 'Avg' is selected for this field, the average cell backscatter values are used.
- ***Moving Average Span*** – The span, in number of observations, used in a centered moving averaging of the backscatter time series. The span must be an odd positive integer.
- ***Backscatter Values*** – The backscatter values used in the computation of the ADVM parameters. When 'Amp' is selected, the backscatter values are multiplied by the value in the Intensity Scale Factor field. The Intensity Scale Factor field is made available only when 'Amp' is selected. (Caution: the model developed will be specifically for SNR or Amp units and cannot be switched without building a new model. All empirical testing for best model using SNR or Amp should be evaluated.)
- ***Intensity Scale Factor*** – The scaling factor to convert backscatter counts to decibels. This field is only available when 'Amp' is selected in the Backscatter Values drop-down list. The factor defaults to 0.43 (typical for SonTek® instruments); but should be taken from manufacturer literature for specific ADVMs.
- ***Minimum Cell Mid-Point Distance*** – The minimum distance in meters from the transducer that the mid-point of a cell has to be in order for it to be used in the computation of the ADVM parameters.
- ***Maximum Cell Mid-Point Distance*** – The maximum distance in meters from the transducer that the mid-point of a cell can be in order for it to be used in the computation of the ADVM parameters.
- ***Minimum Number of Cells*** – The required minimum number of valid cells that an ADVM sample has to have in order for its computed parameter to be included as an observation in the linear model.
- ***Minimum Vbeam*** – The minimum value for Vbeam that a sample must have in order for it to be used as an observation. Vbeam is the water height in meters that the ADVM reports.
- ***Near Field Correction*** – When the box is checked, a near field correction to the backscatter values is made (Downing and others, 1995). When the box is not checked, no near field correction is applied. In general, data from the near field should be avoided by setting the blanking distance and/or Minimum Cell Point distance greater than the near field for a given instrument.
- ***Water Corrected Backscatter (WCB) Profile Adjustment*** – When this box is checked, the range of cells that include and are beyond the cell with the minimum water corrected backscatter (minWCB) are not included in the calculation, unless the cell with the minWCB is the last or first cell in the range considered.
    - If the cell with the minWCB is the last cell, the value is retained and all cells are used to calculate the sediment corrected backscatter and attenuation coefficient.
    - If the cell with the minWCB is the first cell, all other cells are not considered, and the water corrected backscatter value in the first cell is used as the sediment corrected backscatter value for the observation, and no attenuation coefficient is calculated.

Viewing acoustic backscatter profiles: When a valid response variable is matched with valid predictor variables, the Plot Backscatter button will be made available. When this button is clicked, a window with three sets of axes is displayed. From the top, the axes show Sediment Corrected Backscatter (SCB), Water Corrected Backscatter (WCB), and Measured Backscatter (MB), all in decibels, versus the cell mid-point distance along the acoustic beam (figure 3). Also shown in the window is a list of observation numbers and times from the model. The observation times are taken from the primary dataset. Only the backscatter samples that correspond to observations in the linear model are shown. Selecting sample times in the list displays the plots of the backscatter values on the axes. Multiple observations can be selected and plotted.

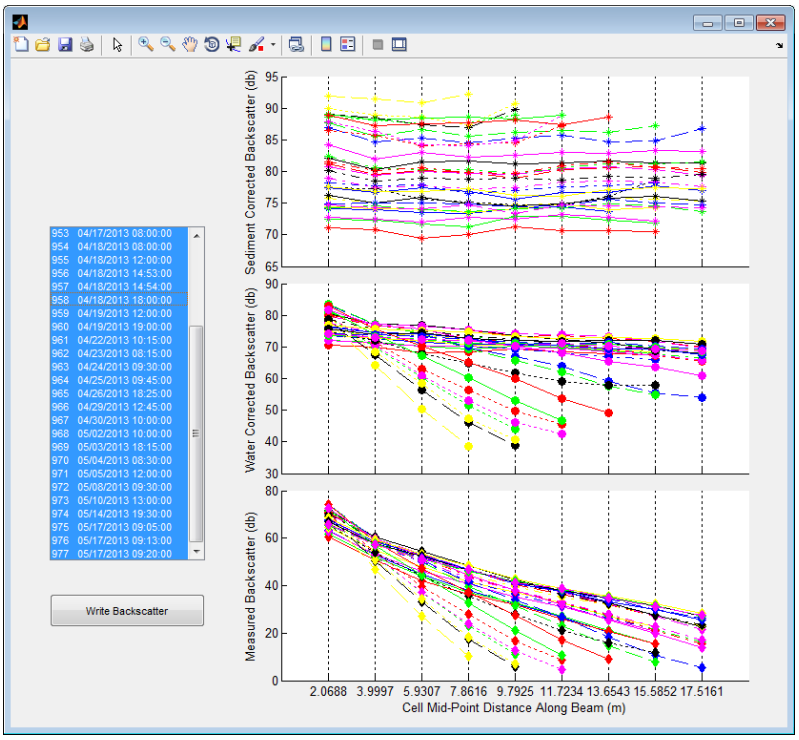

Figure 3 Backscatter profile plotting window

Development of Linear Regression Models: The available variables for use in the development of linear regression models in SAID appear in the Predictor Variable list and Response Variable in the Linear Model screen (Figure 4). There is no limit on the number of variables used in the creation of an Ordinary Least Squares (OLS) linear regression model, and there are no restrictions regarding which variables must be used. The Transform Variable button provides the option to transform a loaded variable using a transform function. When transformed, the variable will be available as a selection in the Predictor Variable list and the Response Variable drop down list.

As datasets are loaded, and if the Match Variable is a valid selection, the variables that are available for use in developing the linear model are shown in the Predictor Variables list and the Response Variable drop-down list. Selecting a variable in the Predictor Variables list, then one from the Response Variable drop-down list, will result in the generation of a model. Selecting the variable that is used for the Response Variable in the Predictor Variables list deselects the predictor variables and resets the response variable selection to the first in the list.

After a model is successfully created by selecting variables, a user can begin to evaluate the model results. This program includes tools to assist in model evaluation, available using the Plot Backscatter, View/Edit Table, Display Model, Write Report, Plots, and Time Series buttons. The number of observations used in the model is shown next to the Number of Observations label.

If a valid linear model exists within the program, the Number of Observations field will show the number of samples used in the development of the linear model. This corresponds to the number of valid observation values for the selected variables within the primary dataset. The Total Samples field shows the total number of samples in the loaded dataset. This number corresponds to the number of samples in the dataset that is selected in the Match Variable drop-down list.

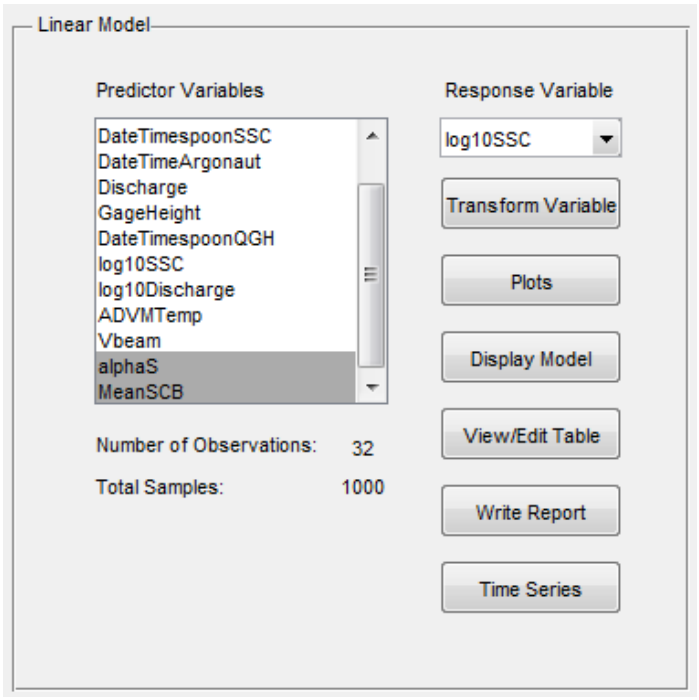

Figure 4 Linear Model options on the main SAID window

Evaluation of Regression Models: SAID provides several ways to graphically evaluate the linear model. Clicking on the Plots button within the main SAID window will display another window that provides several plotting options. In any plot figure, if Data Cursor Mode is enabled, any observation data point can be selected and the corresponding observation number will be shown along with the values plotted. The Model button will show different figures depending on if the linear model is a simple linear regression (SLR) or a multiple linear regression (MLR) or if the response variable is transformed. If the existing linear model is an SLR model, then a figure with the response observations plotted against the explanatory observed values will be shown (figure 5). When the existing model is an MLR, a partial residual plot for each variable in the model will be shown. If the response variable is transformed, then a linear-space plot will be shown with a smeared estimate fit line and confidence bounds.

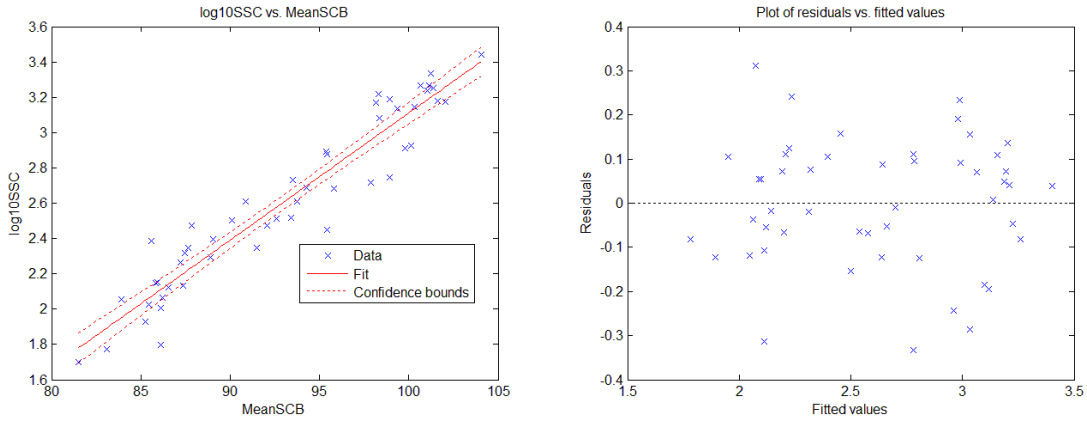

Figure 5 Linear model scatter plot and residual plot for a SLR model

Predicted versus observed plots can be selected to display the predicted response variable with the observed response variable. Also plotted is a one-to-one data line for comparison. If the response variable is transformed, then an additional figure will show the predicted versus observed values in linear space. Additionally the following residual plots can be selected:

- ***Raw Vs. Fitted***—Illustrates a plot of the raw residuals against the fitted response values.
- ***Probability***—Normal probability plot of raw residuals.
- ***Stan. Ser. Corr.***—Standard serial correlation plot of the residuals shown with a LOWESS fit line to detect autocorrelation. If the LOWESS fit line shows a trend that deviates far from 0, serial correlation may be present.
- ***Vs. Time***—Raw residuals plotted against time to see if a time dependent trend exists with the residuals.

The Display Model button will provide a window that displays the model results and statistics (figure 6). The information includes the linear equation, coefficient estimates, estimated confidence intervals, R^2 values for the model, and root mean squared error. This information also is written to a report with the Write Report button on the main SAID window.

Figure 6 Linear model regression model statistics window

Clicking on the View/Edit Table button will display a window that contains the observation information used in the model. The information shown is the observation number, the corresponding primary date and time variable, the response variable, and the predictor variables. Also shown are diagnostic statistics for each observation for outlier detection (Helsel and Hirsch, 2002). Calculated indicator values that exceed the corresponding critical values for the model are highlighted in red.

Observations can be removed by checking the boxes in the far left column and clicking the Remove Observation button. This action flags the date and time within the program and sets the variables that correspond to the date and time to an invalid value. Once a date and time is flagged as removed, any future variables that are used in the model will have the corresponding values set as invalid. This will continue until the Restore All Observations button is clicked, which clears the date and times flagged.

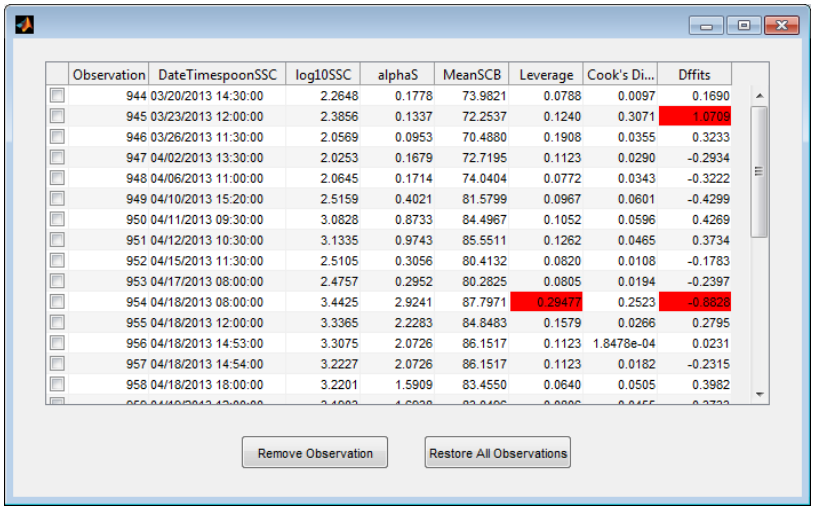

Figure 7 Observation table window used to view and remove observations from the model dataset

Generation of Report Output: To write a full summary report for the linear model, click on the Write Report button within the main SAID window. The user will be prompted for a location and name of a comma separated value file to write the report to. Selecting and entering a valid location and file name will write the report. The contents of the report include:

- ADVM configuration and processing options
- Dataset file names and locations
- Linear model summary and statistics
- Critical outlier indicator values
- The dataset observations that were used in the creation of the model along with Observation number, fitted response variable values, raw residuals, an estimate of the non-transformed variable with bias correction applied (if the response variable is transformed), and calculated outlier indicator values
- The observations that were removed from the model dataset

REAL-TIME DATA DISSEMINATION UTILITIES

After a surrogate regression model is developed and approved, the model can be used to generate continuous, real-time SSC estimates. The USGS has two utilities that make use of the computational algorithms in SAID to continuously estimate and display real-time sediment data:

- Real-time Acoustic Sediment Surrogate DAta Transfer (RASSDAT) program
- National Real-Time Water Quality (NRTWQ) program

RASSDAT is a Visual Basic Graphical User Interface (GUI) wrapped around a Python™ script that runs on a Windows® computer (figure 8), interfaces with the USGS National Water Information System (NWIS), and displays computed SSC on the NWIS Web Interface (http://waterdata.usgs.gov/nwis). NRTWQ is run from a centralized server and displays computed SSC on the NRTWQ Web site (http://nrtwq.usgs.gov/; figure 9). RASSDAT is under beta development and is not yet formally released as a USGS software product. Questions about RASSDAT development can be directed to the authors.

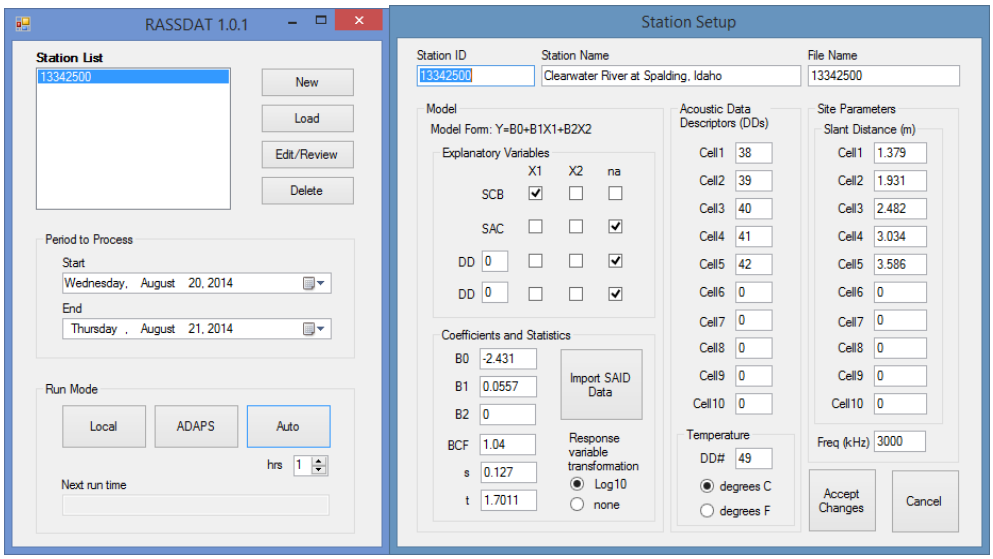

Figure 8 Screen captures of main processing (left) and station setup (right) windows from the USGS RASSDAT program, beta test version 1.0.1.

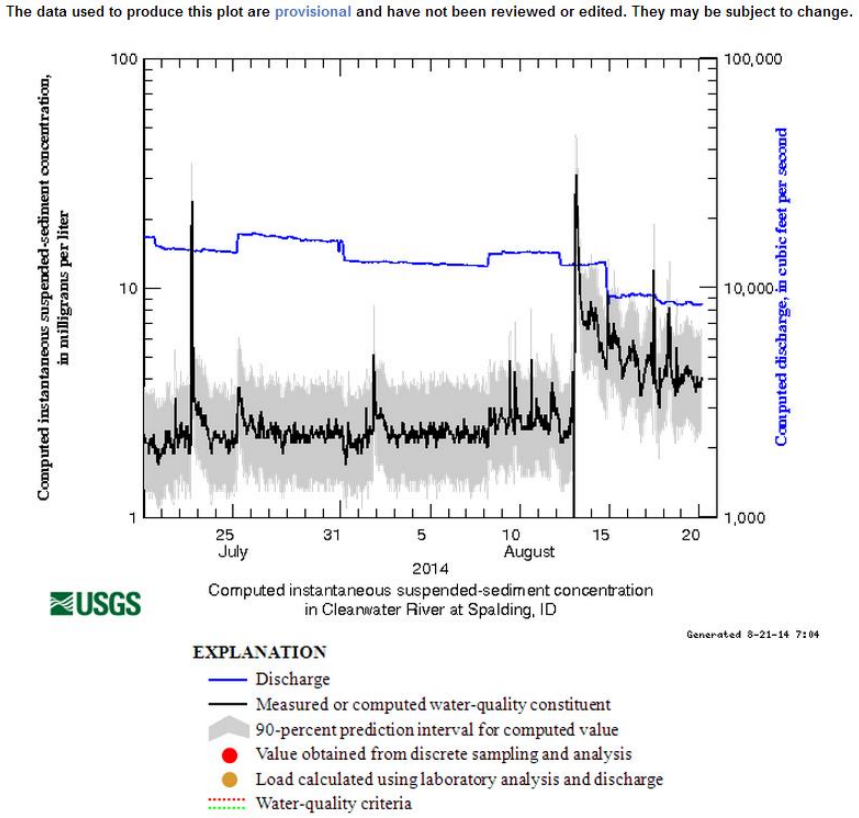

Figure 9 Screen capture from NRTWQ Web site showing example of SSC and SSC prediction intervals computed by using a sediment acoustic surrogate model developed for the Clearwater River at Spalding, Idaho (USGS Identification number 13342500).

SUMMARY

The use of continuous parameters as surrogates for water quality constituents has been successful in multiple applications across the Nation. Critical to advancing the operational use of surrogates are tools to process and evaluate the data along with the subsequent development of regression models from which real-time sediment concentrations can be made available to the public. Recent developments of these tools are having an immediate impact on surrogate research, and on surrogate technologies for monitoring, assessment, rapid decision making, and adaptive management. The Surrogate Analysis and Index Developer (SAID) standalone tool processes complex datasets and creates regression models that related surrogate to constituent data by providing visual and quantitative diagnostics to the user. SAID is currently under development and beta testing at the U.S. Geological Survey.

SAID can be used to create regression models between surrogate data and constituent measurements. Additionally, SAID is a standalone tool to assist in the development of ordinary least squares (OLS) regression models with any response and predictor variables by providing visual and quantitative diagnostics to the user. There is no limit on the number of variables that can be used in the linear model, and there are no restrictions regarding which variables must be used. The sediment acoustic method utilizes acoustic parameters from fixed-mount stationary equipment with the assumption that the sediment concentration along the acoustic beam path is constant for a given time period. Within SAID, the user can set ADVM configuration and processing options, transform a loaded variable, build linear regression models, view linear model diagnostic statistics and plots, export the model information, and generate a predicted time series.

After a surrogate regression model has been developed and approved, the model can be used to generate continuous, real-time SSC estimates. Results from SAID provide direct inputs to two USGS utilities: the Real-time Acoustic Sediment Surrogate DAta Transfer (RASSDAT) program and the National Real-Time Water Quality (NRTWQ) program. The output from these utilities are displayed on USGS Web sites as real-time continuously computed sediment data. RASSDAT, currently under development and in beta testing at USGS, is a Visual Basic Graphical User Interface (GUI) wrapped around a Python™ script that runs on a Windows® computer, interfaces with the USGS National Water Information System (NWIS), and displays computed SSC on the NWIS Web Interface (http://waterdata.usgs.gov/nwis). NRTWQ is run from a centralized server and displays computed SSC on the NRTWQ Web site. The real-time dissemination of predicted SSC and prediction intervals for each time step has substantial potential to improve understanding of sediment-related water-quality and associated engineering and ecological management decisions.

ACKNOWLEDGEMENTS

The USGS Midwest Region and the Federal Interagency Sediment Project supported the development of these utilities. The Midwest Region support was through the River Sediment and Nutrient Investigations Initiative. We thank the many beta testers for their thorough testing and comments. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Geological Survey.

EFFECTIVE PARTICLE SIZES OF COHESIVE SEDIMENT IN NORTH MISSISSIPPI STREAMS

Roger Kuhnle, Research Hydraulic Engineer, National Sedimentation Laboratory, USDA-Agricultural Research Service, Oxford, MS, roger.kuhnle@ars.usda.gov;

Daniel Wren, Research Hydraulic Engineer, National Sedimentation Laboratory, USDA-Agricultural Research Service, Oxford, MS, daniel.wren@ars.usda.gov .

Abstract Knowledge of the size of cohesive sediment particles transported in streams is important information for predicting how the sediment and contaminants the sediment may be carrying will be transported by the flow. Cohesive sediments (less than 0.062 mm in diameter) generally are not transported in their primary dispersed particle sizes, but commonly assume larger sizes as aggregates and/or as flocs. Due to a lack of models for predicting effective particle sizes of fine sediments in streams, it is common for researchers and practitioners to assume that the sediment transported in a stream assumes the primary size of the sediment. Information on the effective sizes of fine sediment in streams is available for only a small number of streams. More data on the effective size of cohesive particles in streams is needed to allow more accurate modeling of their transport. In this investigation, measurements of the effective particle size were made using a portable laser particle size analyzer which was deployed in three streams during runoff events. The primary particle sizes were determined from samples of the suspended sediment which were collected in close proximity to and at the same time as the effective particle sizes were measured. The effective particle sizes were found to be coarser than the primary sizes and did not vary in a predictable manner with the stage of the streams during the runoff events. Ratios of the effective mean sediment size to the primary mean sediment size ranged from 6 to 21 for the three streams considered.

INTRODUCTION

Accurate determinations of the sizes of sediments are necessary for the study of sediment transport by flowing water. The grain size along with other physical properties of the sediment, including the composition, density, and shape are needed for determining how the sediment will be transported and how it will interact with materials in the water column such as chemicals and aquatic biota. The most widely accepted method for measuring particles greater than 62 microns in diameter is the use of sequentially sized sieves. For particles finer than 62 microns, pipettes and calculated fall velocities are typically used. Other techniques, based on automated fall-velocity determinations and laser-based measurements are also in use, but have not been standardized and tested and adopted by sedimentationists to the extent that sieve and pipette methods have been.

Measurements of the diameters of sand-sized sediments (62-2000 microns) and coarse silt-sized sediments (30-62 microns) that are transported in a channel have become routine and are repeatable if proper sediment collection and preparation methods are used (Rigby and Wren, 2013); however, the determination of the effective sizes of finer sediments in transport is problematic. As the size of the sediment decreases, properties such as cohesion and interactions with aquatic biota become important (Droppo, 2001) and measurement of size becomes more difficult. The effective particle size distribution (EPSD) of fine (< 62 microns in diameter) suspended sediment in fluvial transport is generally regarded to develop in balance with local conditions (Kranck, 1979), such that samples that are withdrawn from the channel, stored, and resuspended will have a particle size distribution that is not representative of the one present while the particles were in fluvial transport (Phillips and Walling, 1995). Measurements of fine sediment particles in fluvial transport must therefore be measured in situ.

Traditionally, studies of sediment transport by streams have made the assumption that the dispersed sizes of the inorganic material of the fine sediment fraction contain the information that is important for discerning how that sediment will be transported. However, because fine sediments in fluvial transport often consist of composite particles (Droppo, 2001; Walling and Woodward, 2000; Woodward and Walling, 2007) which may be composed of aggregates inherited from when the sediment was eroded (Meyer et al., 1980), or which formed by flocculation in the channel of the stream (Droppo, 2001), dispersed sediment size will not yield useful information on how fine sediment is transported or what it is carrying. Large differences in EPSD of fine sediments have been measured over separate sub-catchments of one basin (Woodward and Walling, 2007). Effective mean particle sizes have been found to be just slightly larger than the primary particle sizes (Williams et al., 2007) to more than two orders of magnitude larger than their constituent mineral grains (Woodward and Walling, 2007). Measurements from a wider variety of physical conditions and stream types are needed to determine the range of EPSD expected for different conditions. Measurements of EPSD and primary size distributions of fine sediments in fluvial transport from three streams northern Mississippi are presented and compared.

FIELD SITES

Samples of the fine suspended sediment in transport during runoff events were collected from three locations, Goodwin Creek, Yocona River, and Little Tallahatchie River, all located in the northern part of the state of Mississippi (Figure 1). The drainage areas upstream from the sample collection points were as follows: 18 km^2 for station 2 of Goodwin Creek, 679 km^2 for the bridge crossing of Mississippi State Highway 7 at the Yocona River, and approximately 3000 km^2 for the bridge crossing of Mississippi State Highway 7 at the Little Tallahatchie River. The samples from Goodwin Creek were collected 65 m upstream of the station 2 gauging station. The Yocona River samples were collected 10 m downstream of the bridge crossing of Mississippi State Highway 7 and south of Oxford. The samples from the Little Tallahatchie River were collected 300 m downstream of the bridge crossing of Mississippi State Highway 7 north of Oxford. Land use was 39 and 60 percent agriculture for the Yocona (Mississippi Department of Environmental Quality, 2003) and Little Tallahatchie Watersheds (Free Flow

Power, 2013), respectively. Recent surveys of land use at Goodwin Creek Watershed indicated that 8 percent of the land was cultivated (Kuhnle et al., 2008).

Figure 1. Map of the three sample locations: 1 – Little Tallahatchie River, 2 – Yocona River, 3 – Goodwin Creek.

Sample Collection

The collection of samples was undertaken as soon as practical after rainfall caused runoff events. Physical samples of sediment and water were collected while wading in water up to 1 m in depth. The samples were collected near the surface using 20 L buckets to ensure that sufficient quantities of sediment were collected to measure dispersed or primary sediment size distributions. After being transported to the laboratory and total weights had been measured, the samples were allowed to settle and the clear water was decanted. The sediment was collected and organic material was removed by treating with hydrogen peroxide. Samples were agitated overnight after the addition of sodium hexametaphosphate. Primary particle size distributions (PPSD) were determined in the laboratory following standard techniques using the pipette method (Brakensiek et al., 1979).

Measurement of Effective Particle Size Distributions

A self-contained portable laser particle size analyzer was used to collect measurements of EPSD of the fine sediments that were concomitant in time with the collection of physical samples. This instrument measures particle diameter using 32 logarithmically spaced size classes from 2.5 to 500 µm (LISST-100X, Type C from Sequoia Scientific). The size distribution of the particles is measured by volume with no assumptions made concerning density or mass. While the previous version of the instrument software only had the option of calculating the equivalent spheres size distribution, version 5.0 of the instrument software has the option to convert the diffraction data to particle diameters using algorithms which were developed using the light scattering properties of natural, random shaped particles (Agrawal et al., 2008). As fine sediment grains generally are not spherical, our experience with the new routines is that they yield more accurate size distributions than previous versions that used the spherical shape assumption. In some of the deployments the turbidity of the water was of a sufficient magnitude that the laser beam could not be pass through the measurement volume of the LISST. In these cases a 90 percent path reduction module was used to allow data to be collected.

The LISST was deployed in a vertical position with the measurement area perpendicular to the direction of the flow. The instrument was positioned near the bank in water depths of 0.6 to 0.9 m on the Yocona and Little Tallahatchie Rivers, and either near the bank or in the center of the channel mounted on a moored floating platform (Figure 2) on Goodwin Creek. The end of the instrument was mounted between 0.15 to 0.3 m below the surface of the flow.

Figure 2. Deployment of the LISST on tethered floating platform in Goodwin Creek during 06/10/2014 runoff event.

Effective size data was collected from five runoff events on Goodwin Creek, one runoff event on the Yocona River and one event on the Little Tallahatchie River (Table 1). Most of the samples were collected during relatively low stages in the channels after the peak flow had passed. Primary particle size data was measured for three of the events on Goodwin Creek and the events from the Yocona and Little Tallahatchie Rivers (Table 1).

Table 1. Dates and locations of sample collection.

date	location	Mean stage during sampling (m)	Relation to peak stage	Range in effective sizes (mm)	Range in primary sizes (mm)	Mean ratio effective to primary size
04/11/2013	Goodwin Creek, upstream of station 2	1.14	during	0.025 – 0.029	--	--
04/19/2013	Goodwin Creek, upstream of station 2	0.25	11 hours past	0.015 – 0.031	--	--
04/04/2014	Goodwin Creek, upstream of station 2	0.31	2.6 hours past	0.012 - 0.017	0.0029 - 0.0034	4.6

RESULTS

Particle Sizes

The effective particle sizes with time for the sampled runoff events are presented in Figures 3 and 4. Changes in effective mean grain sizes over the periods measured (0.8 – 1.2 hr) on Goodwin Creek were nearly constant or changed gradually for three of the events, while the mean effective sizes during the 04/19/13 and 06/10/14 events increased by factors of 2.1 and 4.4, respectively. Changes in the trends of effective size were also small for the events sampled on the Yocona and Little Tallahatchie Rivers (Figure 4). Mean sizes of primary particles ranged from 0.0024 to 0.0084 mm with ratios of effective to primary sizes ranging from 4.6 to 16.9 (Table 1).

To investigate more fully the observed changes in effective sediment size during the 04/19/14 and the 06/10/14 runoff events on Goodwin Creek, the D_{16} and D_{84} particle sizes (sizes in which 16 and 84 percent of the distribution are finer) were plotted in Figure 3B and 3F. It is apparent for both of these runoff events that the D_{84} of the effective size distribution increased more rapidly than the D_{16} size. This was particularly true in the beginning part of the measured flows. Apparently the initial changes in mean size occurred mostly in the coarser part of the size distribution. This may be related to how flocs are created and destroyed during a runoff event.

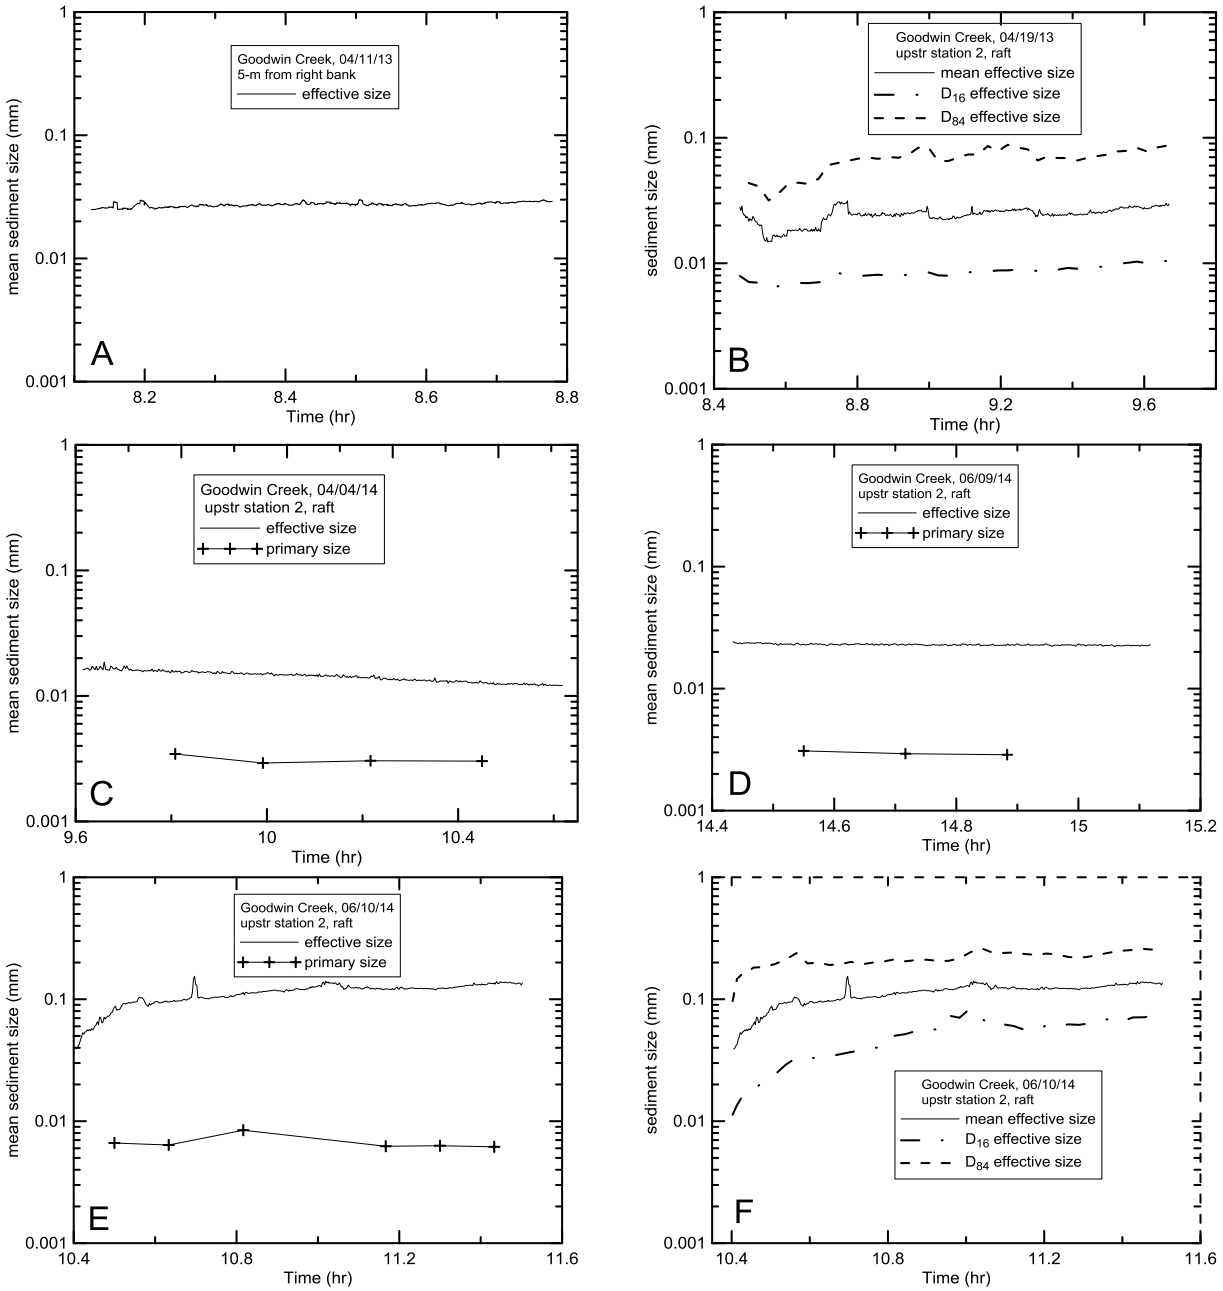

Figure 3. Effective and primary particle sizes measured in the main channel of Goodwin Creek 65 m upstream of gauging station 2.

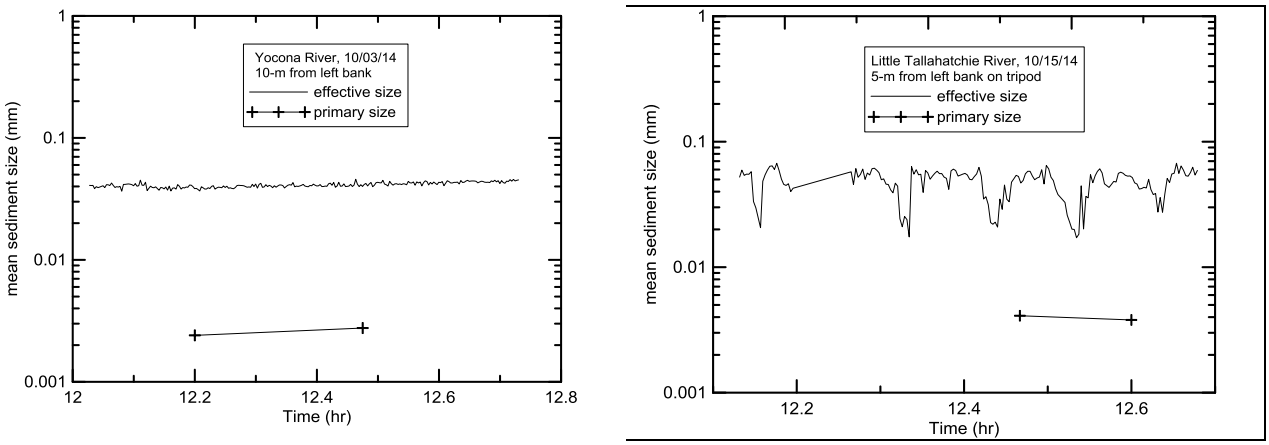

Figure 4. Effective and primary particle sizes measured at the Yocona River and Little Tallahatchie Rivers.

Discussion and Conclusions

The particle size data from this study indicates that the fine sediments of Goodwin Creek, Yocona River, and Little Tallahatchie River are transported as aggregated or flocculated collections of primary particles that range in size from about 5 to 20 times the mean diameter of the dispersed primary particles. Particle size data collected from multiple runoff events on Goodwin Creek have demonstrated that effective sizes may vary by more than an order of magnitude from different runoff events collected at the same site, while the mean sizes of primary particles varied only by about a factor of two. It has also been observed that effective sizes may vary by at least a factor for four over relatively short periods of time with nearly steady conditions of flow in the channel. The reasons for this range in effective sizes are possibly related to changes in the sources of sediment to the channel and how they were eroded and transported. It is clear that the effective particle sizes on the three watersheds were similar even though the drainage areas of the watersheds range over more than two orders of magnitude and channel lengths of the main channel upstream of the measurement sites were 10, 35, and 100 km for the Goodwin Creek, Yocona River, and Little Tallahatchie Rivers, respectively.

Past studies on the provenence of fine sediment conducted at Goodwin Creek have revealed that the dominant sources of sediment changed from surface to bank dominated during the course of a runoff event (Wilson et al., 2008, 2014) and may also vary with season and the characteristics of the rainfall and runoff. The different processes of erosion associated with different sediment source types would likely lead to different effective sediment size signatures in the channel of a stream. Aggregates of fine sediment, for example, may be more plentiful in sediment that was derived from bank erosion than from sediment that originated from upland sources. The intensity of the rainfall event and shape of the hydrograph also would likely affect the size of eroded particles and the evolution of particles as they are transported through the channels of a watershed. The season of the year may also be an important piece of information affecting effective sediment sizes particularly in watersheds with significant percentages of the land surface involved in agriculture activities such as tillage, planting, and cultivation. It has been shown from previous studies that the type and extent of agricultural practices have a direct effect

on the nature of runoff and the production of fine sediment from plots and watersheds (McGregor et al., 1969; Dendy et al., 1979; Kuhnle et al., 1996). This may also be true when biological activity affects particle flocculation (Droppo, 2001).

A related study conducted on the River Exe watershed in southern England (Williams et al., 2007), in which effective sizes were measured with a LISST-100, found that median of the EPSD ranged from about 70 to 200 microns over four runoff events. Two of the events were in the spring of the year and two were in the fall of the year and the durations of the measurements were 2.5 to 16 hours. These median values were about three to four times larger than the values measured in this study. It is not clear to what extent the differences in measured EPSD from the Exe watershed and the ones from this study were due to physical differences of the watersheds or to the effect of sampling differences. Measurements collected over larger portions of several runoff events from different seasons would yield a better picture of the variations present in EPSD on watersheds such as Goodwin Creek.

Abstract

Excessive sediment transport in rivers causes problems for flood control, soil conservation, irrigation, aquatic health, and navigation, as well as transporting harmful contaminants like organic chemicals and eutrophication-causing nutrients. In Minnesota, more than 5,800 miles of streams are identified as impaired by the Minnesota Pollution Control Agency (MPCA) due to elevated levels of suspended sediment.

The U.S. Geological Survey, in cooperation with the MPCA, established a sediment monitoring network in 2007 and began systematic sampling of suspended-sediment concentration (SSC), total suspended solids (TSS), and turbidity in rivers across Minnesota to improve the understanding of fluvial sediment transport relations. Suspended-sediment samples were collected from 14 sites from 2007 through 2011. Analyses of these data indicated that the Zumbro River at Kellogg in southeast Minnesota had the highest mean SSC of 226 milligrams per liter (mg/L) followed by the Minnesota River at Mankato with a mean SSC of 193 mg/L. The single highest SSC of 1,250 mg/L was measured at the Zumbro River during the 2011 spring runoff. The lowest mean SSC of 21 mg/L was measured at Rice Creek in the northern Minneapolis-St. Paul metropolitan area.

Total suspended solids (TSS) have been used as a measure of fluvial sediment by the MPCA since the early 1970s; however, TSS concentrations have been known to underrepresent the amount of suspended sediment. For this study, comparisons between concurrently sampled SSC and TSS indicated significant differences at every site, with SSC on average two times larger than TSS concentrations.

Regression analysis indicated that 7 out of 14 sites had poor or no relation between SSC and streamflow. Only two sites, the Knife River and the Wild Rice River at Twin Valley, had strong correlations between SSC and streamflow, with coefficient of determination (R^2) values of 0.82 and 0.80, respectively. In contrast, turbidity had moderate to strong relations with SSC at 10 of 14 sites and was superior to streamflow for estimating SSC at all sites. Suspended-sediment basin yields indicated that the Minnesota River had the largest mean annual sediment basin yield of 120 tons of sediment per year per square mile.

INTRODUCTION

Excessive sediment transported in rivers causes problems for flood control, soil conservation, irrigation, aquatic health, and navigation. Fluvial sediment becomes entrained in a stream by way of erosion from land surfaces, or from channel bed and bank erosion. Streams transport sediment by maintaining the finer particles in suspension with turbulent currents (suspended-sediment load) and by intermittent entrainment and movement of coarser particles along the streambed (bedload). Fine-grained sediment can serve to transport harmful contaminants such as organic chemicals, heavy metals, and eutrophication-causing nutrients (Baker, 1980).

The most recent U.S. Environmental Protection Agency compilation of States' water-quality reports under Section 305(b) of the Clean Water Act identifies sediment as one of the leading causes of impairment in the Nation's rivers and streams (U.S. Environmental Protection Agency, 2009, 2012). In Minnesota, more than 5,800 miles of streams are identified as impaired due to elevated levels of suspended sediments (Minnesota Pollution Control Agency, 2009a).

The Minnesota Pollution Control Agency (MPCA) incorporated a grab sampling procedure and laboratory analysis of total suspended solids (TSS) for measurement of fluvial sediment in the early 1970s. The grab sampling procedure and TSS measure were adopted by the MPCA for various reasons, including the assumption that the TSS method would provide an adequate representation of suspended sediment and the procedures for the collection and laboratory analysis of samples for suspended-sediment concentration were cost prohibitive. Marked differences between TSS and SSC field sampling procedures and subsequent laboratory analysis largely contribute to the significant differences between concentrations of TSS and SSC (Gray et. al, 2000). For field sampling, TSS samples

are collected at the center of the stream cross section (Minnesota Pollution Control Agency, 2011), whereas SSC samples are collected using federally approved (through the Federal Interagency Sedimentation Project) isokinetic samplers (Davis, 2005) and width- and depth-integrated procedures as described by Edwards and Glyssen (1999). The primary difference in laboratory procedures is that the TSS analytical method uses a pipette to extract a predetermined volume (subsample) from the original water sample to determine the amount of suspended material, whereas the SSC analytical method measures all of the sediment and the mass of the entire water-sediment mixture (American Public Health Association, American Water Works Association, and Water Pollution Control Federation, 1998). Gray et. al (2000) reported that the use of a pipette to obtain subsamples subjects the analyses to substantial biases compared to the SSC method.

The continued need to measure fluvial sediment and recent technological advances has led to the use of turbidity as a surrogate for suspended sediment, particularly in locations where streamflow alone is not a good estimator of SSC (Lewis, 1996; Rasmussen et. al, 2009). Optical turbidity sensors measure the amount of emitted light that is reflected by suspended particles in the water column, and have been used successfully to predict SSC, assuming the relation between the turbidity signal and SSC can be calibrated from physical samples (Lewis, 1996; Christensen et. al, 2000; Uhrich and Bragg, 2003; Rasmussen et. al, 2009). For this study, a portable desktop turbidity meter was used to measure turbidity concurrently with SSC sampling to investigate what relation may exist between turbidity and SSC for streams in Minnesota.

The purpose of the study presented here was to document findings based on sediment data collected by the U.S. Geological Survey (USGS), in cooperation with the MPCA, on selected rivers in Minnesota from 2007 through 2011. Specifically, the study examines suspended-sediment data to (1) describe suspended-sediment concentrations (SSC), total suspended solids (TSS), turbidity, and particle-size fractions for selected rivers across Minnesota's major watersheds; (2) quantify the difference between SSC and TSS; (3) develop relations among streamflow, SSC, TSS, turbidity, and suspended-sediment loads; and (4) estimate suspended-sediment loads and basin yields. This paper presents a condensation of the study by Ellison et. al (2014) and associated results.

DESCRIPTION OF THE STUDY AREA

A map of the State showing the locations of the sites in this study relative to the major watersheds and major streams in Minnesota is shown in Figure 1.

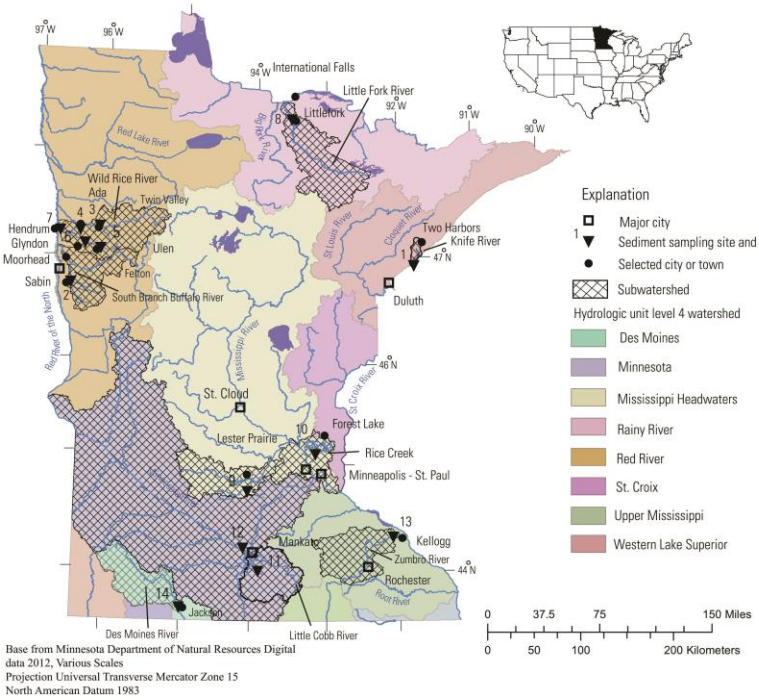

Figure 1 Major watersheds and locations of sediment sampling sites in Minnesota.

The 10 watersheds selected for this study represent a cross section of watershed characteristics present in Minnesota. Minnesota's geologic history of advancing and retreating glaciers affected most of the State and contributed to the development of the general soil types and topographic relief (Sims and Morey, 1972). Most of the northeastern part of the State is forested, but has some open pasture and sparse cultivated crops (Tornes, 1986). The far western and southern regions of Minnesota are intensively cultivated. Between these regions lies a transition area with a mixture of cultivated crops, pasture, and forests. Urban (developed) areas are scattered throughout the State, but the largest is the Minneapolis-St. Paul metropolitan area.

METHODS OF DATA COLLECTION AND ANALYSIS

Data were collected from February 2007 through November 2011. Fourteen sites were sampled 5–14 times per year during the open-water season (Table 1). Few samples were collected during the winter months because historically, less than 4 percent of annual loads were transported during the winter months (Tornes, 1986). Water samples were collected at all sites for analysis of SSC and particle-size fractions less than 0.0625 millimeters (mm) (fines). For this study, particles in suspension greater than 0.0625 mm are categorized as sands.

14	05476000	Des Moines River at Jackson, Minn.	43° 37' 06"	94° 59' 05"	1,250	25

Streamflow data were obtained from existing USGS or MPCA/Minnesota Department of Natural Resources (MDNR) streamgages. Of the 14 sampling sites, 13 were colocated at the corresponding streamgage; the exception was the South Branch Wild Rice River near Ulen (site 5) where no streamgage was available. For the South Branch Wild Rice River near Ulen (site 5), streamflow was estimated by extending streamflow from a nearby USGS streamgage [South Branch Wild Rice River near Felton (site 6)] using the MOVE-1 (Maintenance of Variance Extension, Type 1) statistical program (Hirsch, 1982).

DATA COLLECTION

Suspended-sediment samples were collected at all 14 sites using isokinetic samplers and equal width and depth-integrating techniques following procedures by Edwards and Glysson (1999). Most samples were collected using a D–74 rigid bottle sampler suspended from a bridge during nonwadeable flows and a DH–48 hand-held sampler during wadeable flows. Following collection, samples were transported to the USGS sediment laboratory in Iowa City, Iowa, where they were composited into a single sample and analyzed for suspended-sediment concentration and fines particle-size fraction.

Grab samples for laboratory TSS analysis were collected in 1-liter (L) plastic containers near the centroid of the stream cross section following MPCA sampling protocols (Minnesota Pollution Control Agency, 2011). The TSS samples were collected at seven sites and were refrigerated and delivered to the Minnesota Department of Health laboratory in St. Paul, within seven days of the collection date.

Grab samples for field measurements of turbidity were collected at 13 of 14 sites (Minnesota River at Mankato were only collected periodically) from the centroid of the stream cross section in a 1-L plastic container. A subsample of the contents was transferred into a glass vial, which was then placed into the instrument cell compartment of a portable Hach model 2100P (Hach Company, Loveland, Colorado) turbidimeter to obtain the measurement.

Daily mean streamflow data were obtained from existing USGS or MPCA/MDNR streamgages to develop sediment transport relations and to calculate sediment loads. Streamflow data for 10 of the sites were from the USGS (*http://waterdata.usgs.gov/mn/nwis/sw/*), and streamflow data for 3 sites (sites 4, 9, and 13; Table 1) were from the MPCA (*http://www.dnr.state.mn.us/waters/csg/index.html*). The USGS and MPCA/MDNR determine streamflow at streamgages by use of the rating-curve method (the relation between streamgage height and streamflow) for each station following Rantz et. al (1982).

DATA ANALYSIS

Sediment concentration data and measures of daily mean streamflow were analyzed to obtain summary statistics and perform nonparametric match-pair tests, simple linear regression (SLR), and load estimation using S-Plus statistical analysis software (TIBCO Software Inc., 2010). The Wilcoxon signed-rank test (Helsel and Hirsch, 2002) was conducted to determine if significant differences could be detected between matched pairs of SSC and TSS.

For model development, SLR was used to calculate SSC based on daily mean streamflow, TSS, and turbidity. For SLR models, *p*-values were used to evaluate the model's null hypothesis for statistical significance [*p*-values less than (<) 0.05 indicated statistical significance], whereas the coefficient of determination (R^2) was used to assess the linear association between the response and explanatory variable and to assess how well the model was able to accurately predict outcomes of the response variable.

The SLR can be used to estimate unknown values of a response variable from a known quantity of an explanatory variable if a statistically significant correlation between the variables exists. For SLR to produce a useable model, assumptions are that the two variables are related linearly, that the variance of the residuals is constant (homoscedastic), and that the residuals are distributed normally (Helsel and Hirsch, 2002). These assumptions commonly are violated by measured water data, so the data are transformed to logarithmic values to satisfy these assumptions. Logarithmic base-10 (log10) transformation has been determined to be effective in normalizing residuals for many water-quality measures and streamflow (Helsel and Hirsch, 2002). There exists a consequence of transformation of the response variable, in this case SSC, which must be accounted for when computing SSC values. When the regression estimates are retransformed to the original units, bias is introduced (usually negative) in the

computed SSC values (Miller, 1951; Koch and Smillie, 1986). To correct for this retransformation bias, Duan (1983) introduced a nonparametric bias-correction factor (BCF) called the "smearing" estimator. The equation to compute the smearing BCF for base-10 logarithmic transformation follows (Duan, 1983):

$$BCF = (\sum_{i=1}^{n} 10^{e_i})/n \quad (1)$$

where

n is the number of samples, and

e_i is the difference between each measured and estimated concentration, in log units.

Regression-computed SSC values are corrected for bias by multiplying the retransformed SSC value by the BCF.

Sediment loads were estimated using S-LOADEST, which is an interface-driven, S-PLUS version of LOADEST, which is a FORTRAN program for estimating constituent loads in streams and rivers (Runkel et. al, 2004). The S-LOADEST program is based on a rating-curve method (Cohn et. al, 1989, 1992; Crawford, 1991) that uses regression to estimate constituent loads in relation to several explanatory variables, which most commonly are streamflow and time (seasonal component). The regression is developed using daily loads calculated from the sample concentration and daily flow for that sample.

SUSPENDED-SEDIMENT CONCENTRATIONS, TOTAL SUSPENDED SOLIDS, TURBIDITY, AND PARTICLE-SIZE FRACTIONS

Sediment samples were collected during a wide variety of streamflow conditions. The Zumbro River at Kellogg (site 13) had the highest mean SSC [226 milligrams per liter (mg/L)] among all sites. High SSC in the Zumbro River is attributed in part to the combined effects of climate, high topographic relief, and erodible soils. Steep terrain in the lower part of the watershed increases the erosion potential. The Minnesota River at Mankato (site 12) also had high mean SSC (193 mg/L). Although the Minnesota River Valley has low relief in the valley, the edges of the river valley are lined with steep bluffs and ravines (Minnesota Pollution Control Agency, 2009b). The Zumbro River at Kellogg produced the single highest SSC of 1,250 mg/L at a streamflow of 1,800 cubic feet per second (ft^3/s) during the 2011 spring snowmelt runoff. The Wild Rice River near Ada (site 4) had a mean SSC of 185 mg/L, similar in magnitude to the Minnesota River. Elevated SSC values on the main stem of the Wild Rice River have been linked to cultivated agriculture (Brigham et. al, 2001) and artificial channelization of the main stem from flood-control projects. One of the lowest mean SSC values of 37 mg/L occurred within the same watershed at the South Branch Wild Rice River near Ulen (site 5). The lowest mean SSC of 21 mg/L occurred at Rice Creek below Old Highway 8 in Mounds View (site 10) in the northern Minneapolis-St. Paul metropolitan area. The lowest SSC values of 2 mg/L were measured at the Little Cobb River near Beauford (site 11) on December 28, 2010, at a streamflow of 108 ft^3/s; at Rice Creek on September 15, 2010, at a streamflow of 31 ft^3/s; and at the Knife River near Two Harbors (site 1) on September 10, 2008, at a streamflow of 5 ft^3/s.

The TSS samples were collected concurrently with SSC samples at seven sites, and TSS concentrations followed similar spatial patterns as SSC. For example, similar to the SSC data, the largest mean TSS concentration of 182 mg/L was measured at the Zumbro River, whereas the smallest mean TSS of 25 mg/L was measured at the Little Fork River at Littlefork (site 8).

Variability in turbidity measurements was relatively smaller than SSC variability and followed spatial patterns similar to those of SSC and TSS. The Zumbro River and Wild Rice River near Ada had the largest mean turbidity values of 101 and 89 nephelometric turbidity ratio units (NTRUs), respectively. Rice Creek had the smallest single turbidity value along with a very narrow range of values (1 to 9 NTRUs). The narrow range of values observed at Rice Creek is attributed to the combined effect of low SSC and high percentage of sand-sized particles. Laboratory trials indicate that turbidity sensors are less sensitive to sand-sized particles than to fine-sized particles (Conner and De Visser, 1992; Hatcher et. al, 2000).

For particle sizes, suspended fines (sediment sizes less than 0.0625 mm) were documented in markedly higher percentages than suspended sands at all sites, with the exception of Rice Creek. The largest mean percentage of fines was at the Wild Rice River at Hendrum (site 7), where 92 percent of the material in suspension consisted of fines. Other large mean percentages of fines were at the South Branch Buffalo River at Sabin (site 2), Wild Rice River at

Twin Valley (site 3), and the Little Fork River with 88, 83, and 84 percent, respectively. Suspended fines were noticeably lower at Rice Creek when compared to other sites. Although fine-sized particles composed most of the total suspended sediment, the percentage of suspended sands was appreciable for many samples at many sites. The largest mean percentage of sand particles in suspension was observed at Rice Creek, where a mean of 45 percent of the material in suspension was sand-sized. Other substantial mean percentages of sands were measured at the Zumbro River, South Branch Wild Rice River near Felton (site 6), and the Minnesota River with 35, 33, and 28 percent, respectively.

COMPARISON BETWEEN SUSPENDED-SEDIMENT CONCENTRATIONS AND TOTAL SUSPENDED SOLIDS

For this analysis, the Wilcoxon signed-rank test (Helsel and Hirsch, 2002) was used to test if concurrently sampled pairs of SSC and TSS were different within sites. Box plots illustrate the variation in SSC and TSS at all sites (Figure 2) and are consistent with the Wilcoxon signed-rank test results, which indicated median values of SSC were larger than median values of TSS at each of the seven sites where TSS samples were collected concurrently with SSC. When comparing SSC to TSS median concentrations, the overall mean percent difference indicated that SSC was about 100 percent larger than TSS. The largest percent difference between median values of SSC and TSS was at the South Branch Buffalo River site and the smallest difference was at the Des Moines River.

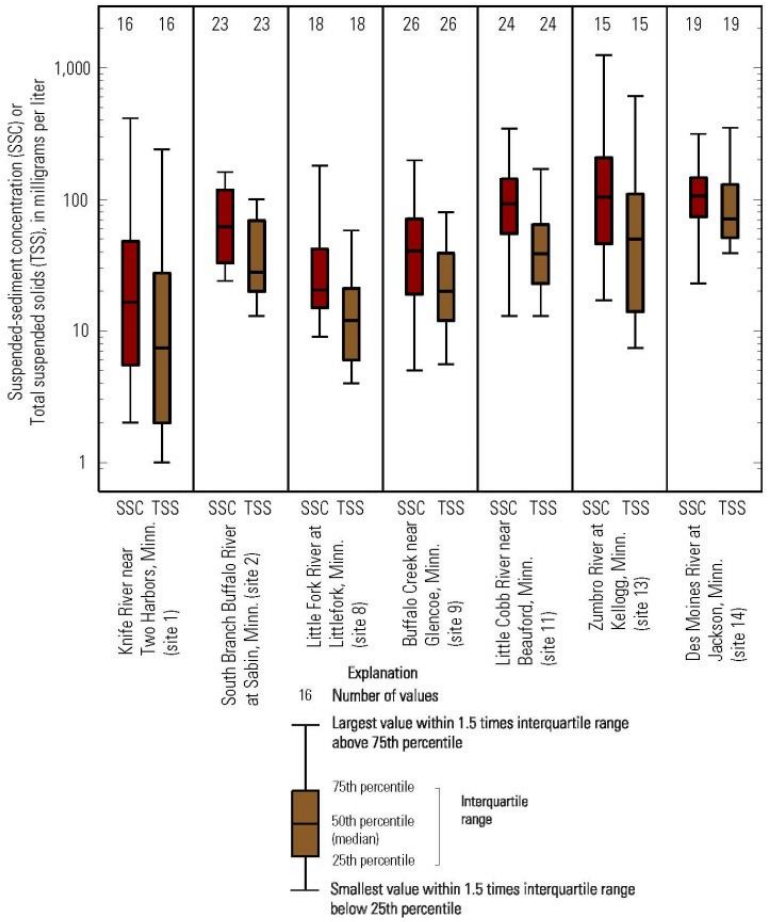

Figure 2 Boxplots of suspended-sediment concentrations (SSC) and total suspended solids (TSS) for selected sites in Minnesota, 2007 through 2011.

RELATIONS AMONG STREAMFLOW, SUSPENDED-SEDIMENT CONCENTRATIONS, TOTAL SUSPENDED SOLIDS, AND TURBIDITY

Variations in streamflow provide important information related to the timing and changes in sediment concentrations and has widely been used to develop SSC prediction models. The relation between SSC and streamflow for each site is presented in Table 2 and illustrated in Figure 3. Best-fit regression lines represent the relation between SSC and streamflow, and can be used to evaluate how SSC responds to changes in streamflow within and among sites. The gradient of the lines provides an indication of how quickly SSC changes with changes in streamflow. The strength of the relation can be seen in how closely the observed data fall along the regression line. Lines with steep positive gradients from left to right indicate SSC increases quickly as streamflow increases. In this study, the sites with the steepest gradients were the Knife River, Wild Rice River near Twin Valley, Wild Rice River near Ada, Little Fork River, Rice Creek, Minnesota River, and Zumbro River (Figure 3). Moderate gradients were observed at the South Branch Wild Rice River near Felton and the Des Moines River. Low or level gradients, which indicate that SSC changes little as streamflow increases, were observed at the South Branch Wild Rice River near Ulen, Buffalo Creek, and the Little Cobb River. The negative relation, indicated by a negative gradient, for the South Branch Buffalo River, is unusual. Negative gradients indicate that the amount of suspended sediment in streams may be diluted during periods of increased streamflow due to limited supply of sediment.

Table 2 Summary of simple linear regression models to evaluate suspended-sediment concentrations using streamflow as the explanatory variable for selected sites in Minnesota, 2007 through 2011.
[mg/L, milligrams per liter; R^2, coefficient of determination; BCF, Duan's bias correction factor; SSC, suspended-sediment concentration; Q, daily mean streamflow; <, less than]

Site number (Figure 1)	Station name	Number of samples used for regression	Regression model (mg/L)	R^2	Standard error residual (mg/L)	p-value	BCF
1	Knife River near Two Harbors, Minn.	27	$SSC = 0.9276 \times Q^{0.7175}$	0.82	12.7	<0.01	1.227
2	South Branch Buffalo River at Sabin, Minn.	40	$SSC = 280.7 \times Q^{-0.2213}$	0.22	10.7	<0.01	1.270
3	Wild Rice River at Twin Valley, Minn.	29	$SSC = 0.2691 \times Q^{0.9241}$	0.80	25.8	<0.01	1.212
4	Wild Rice River near Ada, Minn.	29	$SSC = 0.5526 \times Q^{0.8579}$	0.67	34.0	<0.01	1.417
5	South Branch Wild Rice River near Ulen, Minn.	25	$SSC = 26.1 \times Q^{0.0987}$	0.00	6.2	0.34	1.423
6	South Branch Wild Rice River near Felton, Minn.	27	$SSC = 20.93 \times Q^{0.3085}$	0.14	26.1	0.03	1.643
7	Wild Rice River at Hendrum, Minn.	27	$SSC = 24.84 \times Q^{0.2163}$	0.16	17.0	0.02	1.284
8	Little Fork River at Littlefork, Minn.	32	$SSC = 1.360 \times Q^{0.4563}$	0.65	3.8	<0.01	1.119
9	Buffalo Creek near Glencoe, Minn.	42	$SSC = 43.2 \times Q^{0.0897}$	0.02	10.2	0.19	1.581
10	Rice Creek below Old Hwy. 8 in Mounds View, Minn.	21	$SSC = 0.2842 \times Q^{0.9223}$	0.44	3.1	<0.01	1.263
11	Little Cobb River near Beauford, Minn.	68	$SSC = 102 \times Q^{0.0003}$	0.02	8.2	0.99	1.310
12	Minnesota River at Mankato, Minn.	32	$SSC = 9.738 \times Q^{0.3286}$	0.41	20.0	<0.01	1.173
13	Zumbro River at Kellogg, Minn.	18	$SSC = 0.0348 \times Q^{1.2314}$	0.54	61.5	<0.01	1.399
14	Des Moines River at Jackson, Minn.	25	$SSC = 23.07 \times Q^{0.2419}$	0.17	15.6	0.02	1.313

Results of the SLR analysis between SSC and streamflow presented in Table 2 provide a quantitative description of the plots shown in Figure 3. The relation between SSC and streamflow was significant statistically (p-value <0.05)

at 11 of the 14 sites (Table 2). The strongest correlations between SSC and streamflow were determined for the Knife River (R^2=0.82) and the Wild Rice River at Twin Valley (R^2=0.80). The Wild Rice River near Ada, Little Fork River, and Zumbro River had moderate R^2 values of 0.67, 0.65, and 0.54, respectively. Rice Creek and the Minnesota River had modest R^2 values of 0.44 and 0.41. The remainder of the sites (7 out of 14 sites) had poor relations between SSC and streamflow. The three sites that did not have a significant relation (p-values≥0.05) were the South Branch Wild Rice River near Ulen, Buffalo Creek, and Little Cobb River.

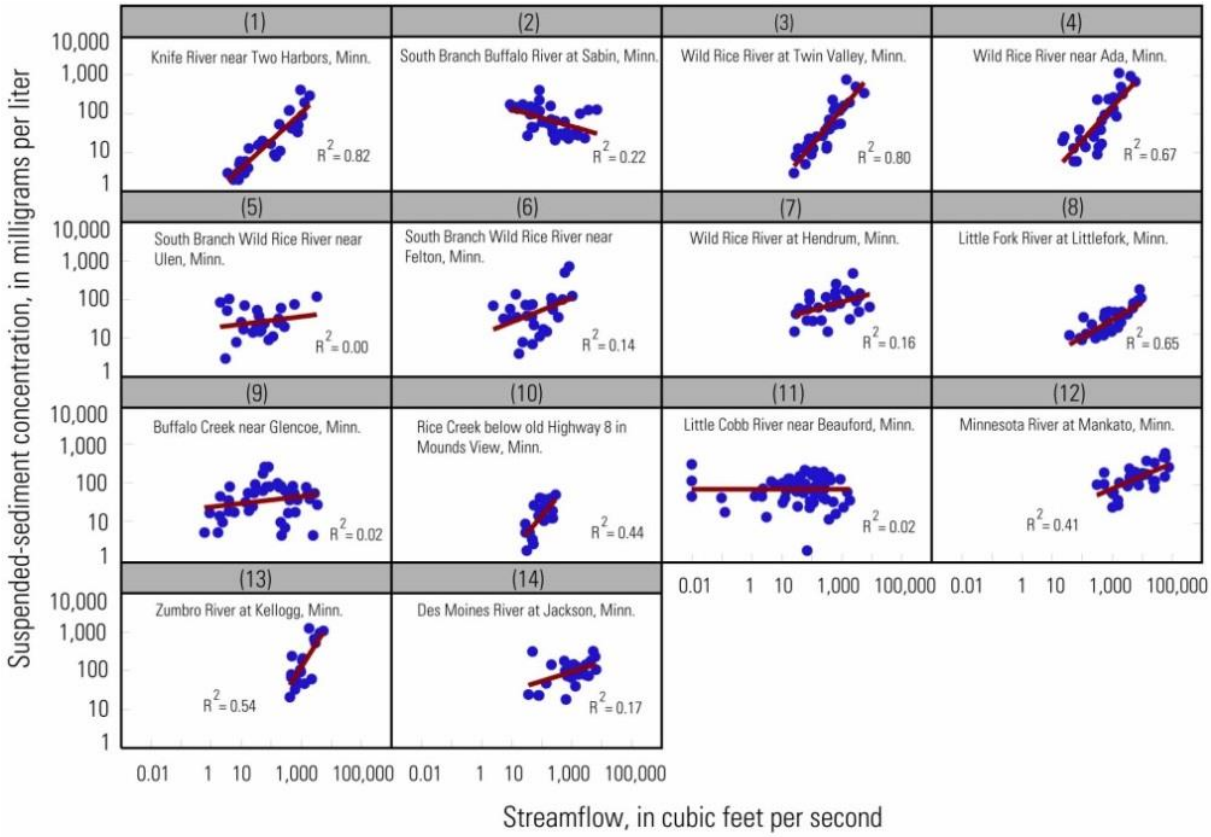

Figure 3 Relation between suspended-sediment concentrations and streamflow for selected sites in Minnesota, 2007 through 2011.

The overall relation between SSC and turbidity is shown in Figure 4, and regression models for the SSC-turbidity relation are presented in Table 3. The R^2 values for the SSC-streamflow models and SSC-turbidity models indicated that turbidity was correlated more strongly to SSC than was streamflow at all sampling sites (Tables 2 and 3). Among the largest increases in R^2 was at the Wild Rice River at Hendrum, which increased from 0.16 to 0.86 between the SSC-streamflow model and SSC-turbidity model. Two sites, the Knife River and the Wild Rice River at Twin Valley, had modest increases in R^2 values from 0.82 to 0.87 and from 0.80 to 0.82, respectively. The Wild Rice River near Ada, the Little Fork River, and the Zumbro River, had notable increases in R^2 values from 0.67 to 0.85, 0.65 to 0.82, and 0.54 to 0.63, respectively. For this study, there was not enough turbidity values available at the Minnesota River at Mankato (site 12) to develop the relation between SSC and turbidity.

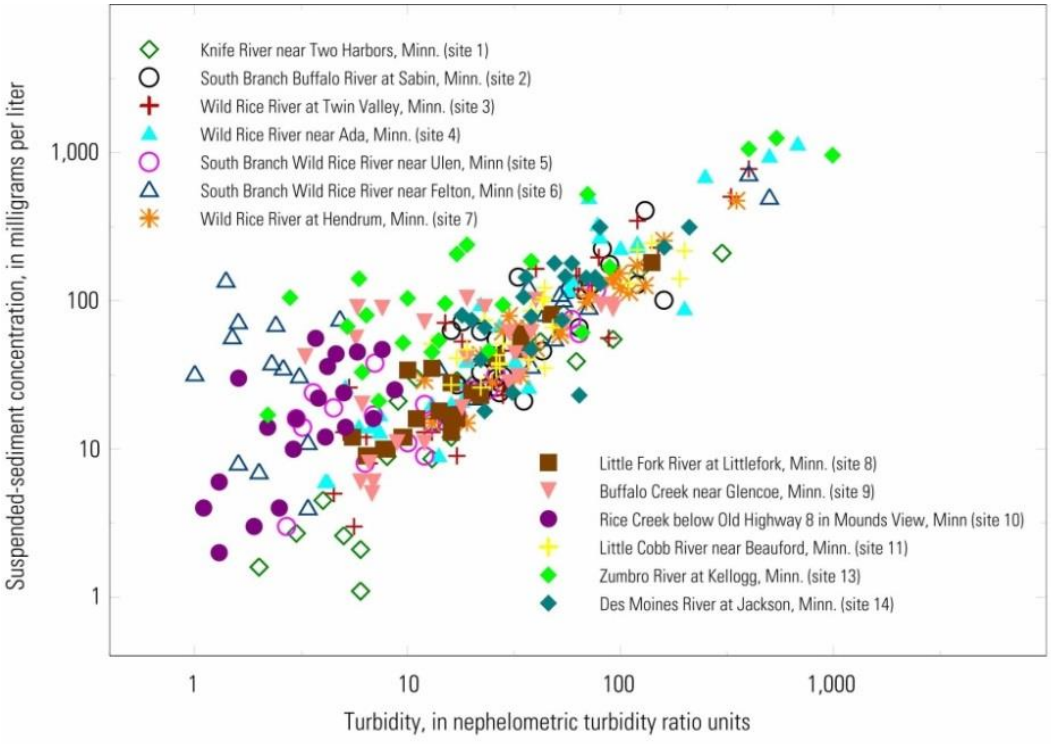

Figure 4 Relation between suspended-sediment concentration and turbidity for selected sites in Minnesota, 2007 through 2011.

Five sites with poor or no relation between SSC and streamflow had significant correlations and large increases in R^2 when using turbidity as the explanatory variable. For example, R^2 values for the Wild Rice River near Ulen and the Little Cobb River increased from 0.00 to 0.57 and from 0.02 to 0.70, respectively. For the South Branch Buffalo River, South Branch Wild Rice River near Felton, and Buffalo Creek, R^2 values increased from 0.22 to 0.54, from 0.14 to 0.50, and from 0.02 to 0.25, respectively. The smallest change was for Rice Creek, where only a 1-percent increase in R^2 was determined. These results indicate that turbidity was superior to streamflow in estimating SSC, and that turbidity may be beneficial as a surrogate for SSC in many of Minnesota's rivers.

Table 3. Summary of regression models to evaluate suspended-sediment concentrations using turbidity as the explanatory variable for selected sites in Minnesota, 2007 through 2011.
[mg/L, milligrams per liter; R^2, coefficient of determination; BCF, Duan's bias correction factor; SSC, suspended-sediment concentration; *Turb*, turbidity; <, less than]

SUSPENDED-SEDIMENT BASIN YIELDS

Suspended-sediment loads were calculated to estimate basin yields using the S-LOADEST program. The S-LOADEST program incorporates time-series data for streamflow, a dataset of constituent concentrations, and a time component to estimate annual and seasonal loads for the constituent of interest. The form of the regression equation used in the S-LOADEST model is described in Ellison et. al (2014). Mean annual basin yields for suspended sediment, suspended sands, and suspended fines are shown in Figure 5. Comparing annual sediment yields among sites across Hydrologic Unit Code Level 4 watersheds provides insight on erosion rates and describes the relative measure of degradation occurring on the landscape.

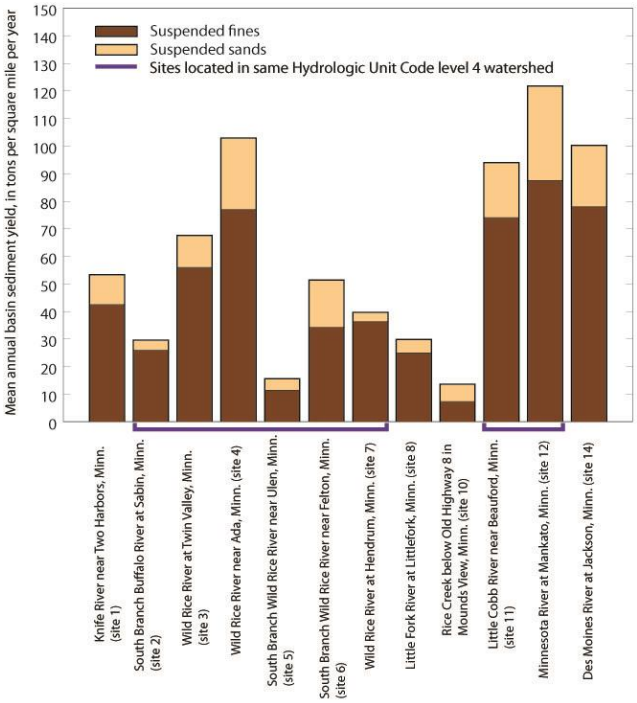

Figure 5 Mean annual basin yields of suspended sediment for selected sites in Minnesota, 2007 through 2011.

ACKNOWLEDGMENTS

This report presents a compilation of information supplied by many agencies and individuals. The authors would like to thank the Minnesota Pollution Control Agency, Wild Rice Watershed District, and the Rice Creek Watershed District for their assistance with this study. Dave Lorenz, Kristen Kieta, Joel Groten, Domenic Murino, Lance Ostiguy, Mark Brigham, and Christiana Czuba of the U.S. Geological Survey are acknowledged for assistance with office and field aspects of the study. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

COARSE PARTICULATE ORGANIC MATTER TRANSPORT IN TWO ROCKY MOUNTAIN STREAMS

Cenderelli, Fluvial Geomorphologist/Hydrologist, USDA Forest Service, National Stream and Aquatic Ecology Center, 2150 Centre Ave., Fort Collins, CO 80526, dcenderelli@fs.fed.us.

Abstract Samples of coarse particulate organic matter (CPOM) were collected over one-month snowmelt highflow seasons in two high-elevation, subalpine, streams in the Rocky Mountains. Bedload traps developed for sampling gravel bedload were found to be suitable samplers for CPOM transport. When flow overtopped bedload traps, CPOM transport rates were adjusted to estimate and add the unsampled CPOM portion traveling higher in the water column; when nets overfilled, CPOM transport rate were adjusted for the reduction in captured transport. CPOM transport rates were well related to flow in consecutive samples but showed pronounced hysteresis over the diurnal fluctuations of flow, between consecutive days, and over the rising and falling limbs of the high-flow season. Hysteresis effects require intensive sampling and establishing separate rating curves for all rising and falling limbs in order to compute annual CPOM load. Annual CPOM export for the two streams was 2.7 and 4 kg/ha/year, but both streams exported 6.5 and 6.6 kg/ha/year in the forested portion of the watershed.

INTRODUCTION

Coarse particulate organic matter (CPOM) is comprised of particles 1-100 mm, and those particles play an important role as a food source for benthic organisms (e.g., Fisher and Likens, 1973). Furthermore, fluvial transport of CPOM is one of the forms in which carbon is exported from a basin. CPOM typically contributes about 2.5-10% of total carbon export (Wallace et al., 1995, 1997; Richardson et al., 2005), and knowledge of CPOM export is needed when establishing watershed carbon budgets that account for input, consumption, retention, and export. Dry CPOM supplied to a stream (e.g., as litter fall) tends to be transported on the surface over relatively short distances (up to several 100 m, Jones and Smock, 1991; Webster et al., 1994; Wallace et al., 1995) before becoming trapped around obstacles where particles become waterlogged, sink, and accumulate on the stream bottom. Submerged CPOM experiences carbon leaching, microbial colonization (conditioning), shredding by invertebrates, and physical abrasion (Foucreau et al., 2013). In snowmelt regimes, when CPOM deposits are re-entrained at the beginning of high-flow season, fully waterlogged CPOM from the channel bed, together with some dry CPOM that had been stranded along the banks, is transported through the watershed and exported. Studies of annual CPOM export are rare from high elevation Rocky Mountain streams where large tracts of forested land are located in the US (Webster and Meyer 1997; Turowski and Hilton, 2013). This study makes a start towards filling this gap.

Because CPOM is lightweight (compared to inorganic bedload) and easily entrainable by flow, one may postulate that transport rates of waterlogged CPOM are influenced by the interplay between (local) flow hydraulics and the dynamics of storage and release from local retention within the streambed and along the banks; hence transport is variable over time and with discharge. Several publications have suggested that CPOM transport rates respond very quickly to increased flow rates (Beschta, 1981; 1983a; Perry and Rose, 1984; Estep and Beschta, 1985; Wallace et al., 1995; Kiffney et al., 2000; Johnson et al., 2006; Beschta and Jackson, 2008; Turowski et al., 2013; Turowski and Hilton, 2013), whereas Angradi (1991) found no such relation. However, despite the relative importance of CPOM in the carbon budget and concerted efforts (Webster and Meyer, 1997; Richardson, 1992; Richardson et al., 2005, 2009), temporal dynamics of CPOM transport over the annual highflow season have not been adequately described.

Difficulties in measuring the downstream conveyance of CPOM have posed the biggest problem to advancing insights into its transport dynamics. CPOM export from a basin can be quantified by excavating and analyzing the annually accumulated material in debris basins (Bilby, 1981), but that practice reveals no insights into transport dynamics. The collection of all mobile CPOM in a screened sampling box under an overfall and emptying the box episodically, biweekly or daily during high flows (Wallace et al., 1995; Johnson et al., 2006), is a workable practice

reserved to small streams draining catchments of a few ha in size with discharges of a few liters/second. In larger streams, only portions of the CPOM transport can be sampled. Placing drift nets into the water column for minutes or hours at a time, episodically throughout the year (e.g., Newbern et al., 1981; Perry and Rose, 1984; Angradi, 1991; Jones and Smock, 1991; Kiffney et al., 2000) is limited to tranquil flows. Beschta (1981, 1983a) and Beschta and Jackson (2008) collected CPOM during stormflow events as by-catch in bedload samples in a 7.6 by 7.6 cm opening Hel-ley-Smith sampler with a 0.2 mm mesh-width net. However, those measurements are limited to the lower 7.6 cm of the water column and miss organic matter carried higher up. Turowski et al. (2013) collected CPOM transport in a high-energy mountain torrent, sampling the entire water column using bedload traps 0.2 m high (Bunte et al. 2007, 2008, 2010). They present the only transport relation known so far. In this study we: 1) demonstrate use of bedload traps for sampling CPOM transport in high-energy but wadeable streams during a high-flow season, 2) document CPOM transport and its variable relations to water flow (hysteresis) over a snowmelt high-flow season, and 3) provide estimates of annual CPOM export in two high elevation Rocky Mountain streams.

STUDY SITES

Study sites CPOM samples were collected in conjunction with gravel bedload sampling in two cobble-bed streams in the Rocky Mountains. The studies were conducted in 2001 and 2002 (Bunte, 2001; Bunte and Swingle, 2003), about 10 years before the widespread onset of pine beetle kill in the central Rocky Mountains. Both study streams have snowmelt runoff regimes and daily fluctuations of flow. See Table 1 for site and basin characteristics.

Little Granite Creek The Little Granite Creek study site (Figure 1a) in NW Wyoming is located 3.3 km above the confluence with Granite Creek. Downstream of Pleistocene glaciated headwater areas, the valley is typically confined by forested hillslopes (Lodgepole Pine (*Pinus contorta*), Engelmann Spruce (*Picea engelmannii*), Douglas Fir (*Pseudotsuga menziesii*)), but opens to a 45-50 m wide meadow 135 m upstream from the sampling site. The stream is incised about 1.1 m into the valley fill, keeping most high flows confined to the channel. The sampling site was located within a 25-m long straight run. Flow stage elevation was digitally recorded in 15-minute increments. Flow velocity was measured almost daily at about 20 verticals across the channel with an electromagnetic current meter at 0.6 of the flow depth to compute discharge and establish a hydrograph. Bankfull flow (Q_{bkf}) was estimated from field evidence and from the long-term flow record of a near-by stream adjusted by drainage area of the study stream.

East St. Louis Creek East St. Louis Creek is a steep, cobble-bed mountain stream (Figure 1b) in the Fraser Experimental Forest (http://www.fs.usda.gov/main/fraser/about/site-description) in central Colorado. The drainage basin is covered by glacial till, and near-stream valley slopes are typically gentle. Most of the basin is located in subalpine forest (Engleman spruce, Subalpine fir (*Abies lasiocarpa*), Lodgepole pine); there are a few quaking aspen (*Populus tremuloides*), alder (*Alnus incana*), and willows (*Salix* species). The streambed is typically incised by about 1 m

which prevents extensive overbank flooding. The sampling site was located in a short and locally wide plane-bed section a few meter upstream of a weir pond where discharge is recorded continuously at a crested weir. Bankfull flow was taken as the 1.5-year recurrence interval flow of a long-term flow record.

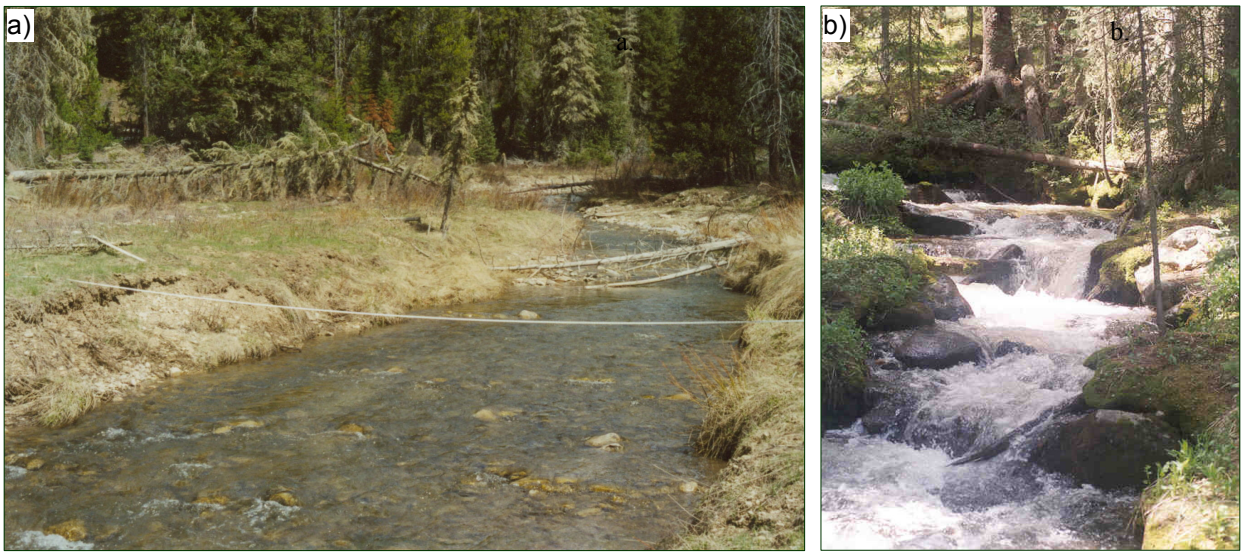

Figure 1: Upstream view of the Little Granite Creek (a) and East St. Louis Creek (b) study sites.

METHODS AND ANALYSES

Sampling with bedload traps and the sampling scheme Bedload traps (Bunte et al., 2004, 2007, 2008, 2010) that were used for sampling CPOM transport together with gravel bedload in this study (Bunte, 2001; Bunte and Swingle, 2003) have the shape of a shoebox without a bottom placed on its long side. The aluminum frame is 0.2 m high, 0.3 m wide, and 0.1 m deep; a net 1 to 1.6 m long with a 3.6 mm mesh width is attached to the frame (Figure 2a). The frame is placed onto a 0.41 by 0.35 m aluminum ground plate that is installed flush with the average height of the bed and anchored to the stream bottom with two metal stakes that are pounded into the bed. Adjustable straps attached to the frame are tied around the metal stakes and hold the sampler in place. This set-up allows bedload traps to be deployed for sampling times ranging from minutes to hours depending on transport rates and fill level of the net. For emptying, the string that closes the net at its downstream end is untied, the contents are shaken into a large bucket, and the string is re-tied for another round of sampling. Samples can thus be taken back-to-back during a field day, while the sampler frames remain fastened on the ground plates (Figure 2b). Four traps were installed about 1 m apart across the stream at the two study sites. Sampling covered an 8-10 hour period between the daily falling limbs of flow in the late morning and the daily rising limbs up to or just past daily peak flow in the evening. Bedload traps were removed from the stream bed overnight to avoid overfilling them.

Figure 2: Bedload traps installed at E. St. Louis Cr. (a); Retying the net after emptying the contents into buckets (b).

At Little Granite Cr., the 2002 snowmelt hydrograph had two distinct peaks, one on May 21 (85% Q_{bkf}) and one on June 1 (110% Q_{bkf}) (Figure 3a). CPOM sampling started at 21% Q_{bkf} on the first rising limb with 1-hour samples and continued daily until the end of the first discharge peak two weeks later. Over the second discharge peak, samples were collected alternately over intervals of 10 and 60 minutes. Sampling extended over another two-week period until flow had decreased to 40% Q_{bkf} on the second falling limb. Five to eight samples were collected each day, totaling 92 samples over the four-week high-flow season. At East St. Louis Cr., all CPOM samples were collected over 1-hour periods, starting at 44% of Q_{bkf} a week into the high-flow season, covering peak flow that was 70% of Q_{bkf}, and ending 17 days later at 36% of Q_{bkf} (Fig. 3b). Two to seven samples were collected per day on most days, totaling 73 samples.

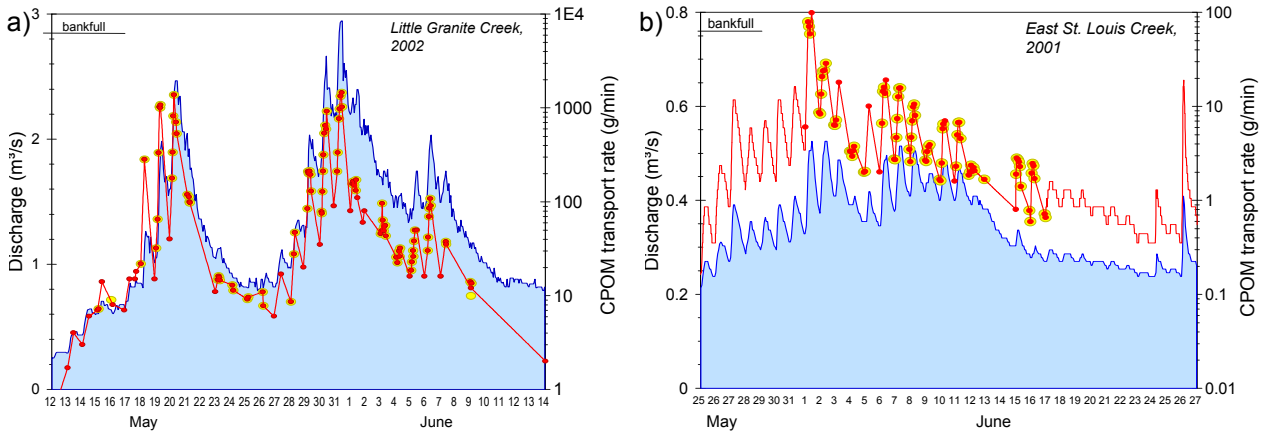

Figure 3: Peakflow portion of the annual hydrograph (blue line) with measured CPOM transport rates (yellow dots), those extrapolated for times of daily peak and low flow (red dots), and the interpolated continuous record of CPOM transport rates (red line) at Little Granite Creek (left) and East St. Louis Creek (right). Note different scales of plots.

CPOM composition Most of the CPOM collected in the bedload traps consisted of small cones from coniferous trees, cone scales, coniferous needles, small twigs and sticks (typically 1-3 cm in diameter, 10-30 cm long), leaves (mainly willow), small, spongy pieces of wood, and occasional hard pieces of bark. CPOM was dark brown in color and appeared as thoroughly soaked mulch from the forest floor. Dry needles were more frequent early in the high-flow season; at higher flows, sticks joined the CPOM mixture. Later in the high-flow season, rain, sleet, and hail washed, dislodged, and tore off dry needles and the green tips of coniferous trees that were included in the CPOM mix together with parts of fresh herbaceous plants. The CPOM composition in the study streams is similar to the CPOM the authors have collected during bedload measurements in several other Rocky Mountain streams.

The density of waterlogged CPOM is slightly higher than that of water. When water flow was still clear during moderate high flows, the authors observed CPOM to travel as bedload, rolling, sliding, and bouncing along the bed surface, especially the plump conifer cones and soaked wood pieces. At larger flows, CPOM moved in larger hops and in near-bed suspension; small organic particles moved as suspended load within the water column, while dry sticks floated. As flow approached bankfull flow conditions, the water was turbid, and the channel bed was not visible.

Field processing The combined sample volumes of wet CPOM and gravel bedload reached up to 20 liters. Early in the highflow season, sample volumes were comprised mostly of CPOM, but the CPOM portion decreased to less than half the volume later in the high-flow season. Samples collected near peak flow in the two study streams are shown in Figure 4. CPOM and gravel bedload were typically separated in the field to keep bagged sample volumes manageable and to minimize the number of bags with rotting CPOM to be dealt with later. Samples smaller than 1 liter were poured into a metal bowl and stirred with water to allow gravel bedload particles to sink; CPOM was then removed from the top by carefully decanting the wet organics into a bucket and helping the process along with a rubber spatula (Figure 5a). The action of stirring with water and decanting was repeated several times until all CPOM was removed. Large CPOM and gravel bedload samples were handled either in small batches as described above or pre-processed in a 20-liter bucket: after stirring with plenty of water and settling of the gravel particles, CPOM was removed from the top using a large wire-mesh spoon (Figure 5b). After repeating the process several

times, the remainder of the sample—bedload containing some CPOM—was separated in a bowl as described above. The volume of wet CPOM samples was determined in a clear 500 ml measuring cup or in a graded 10-liter bucket.

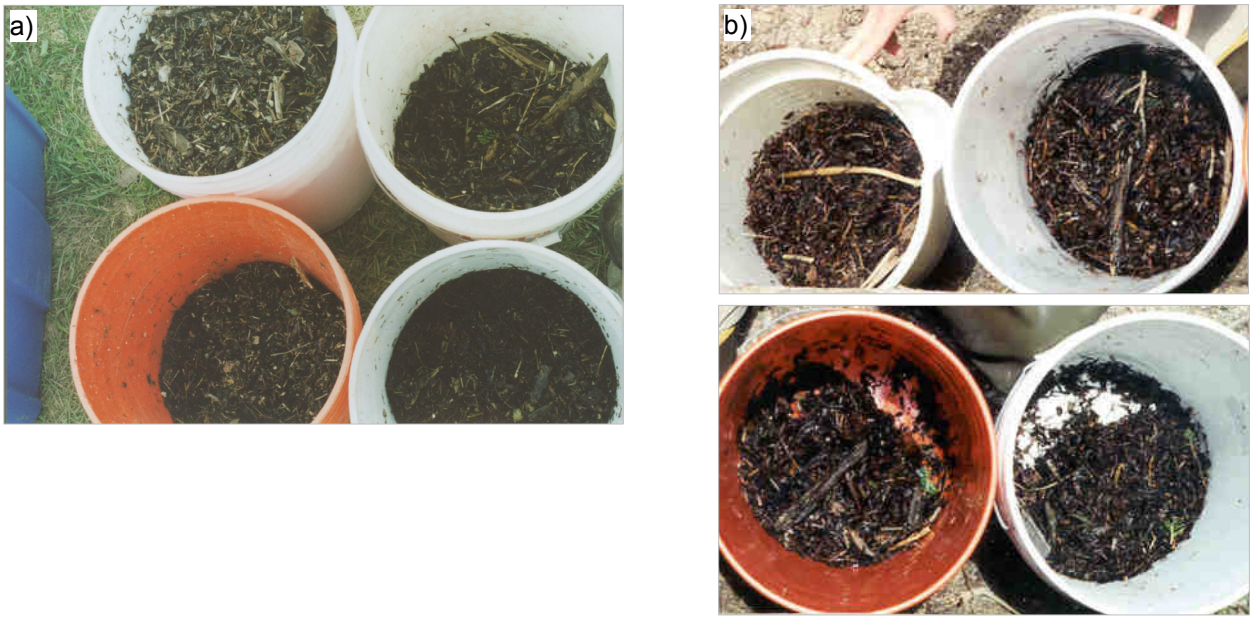

Figure 4: CPOM samples collected at high flow in the four traps at Little Granite (a) and East St. Louis Creek (b).

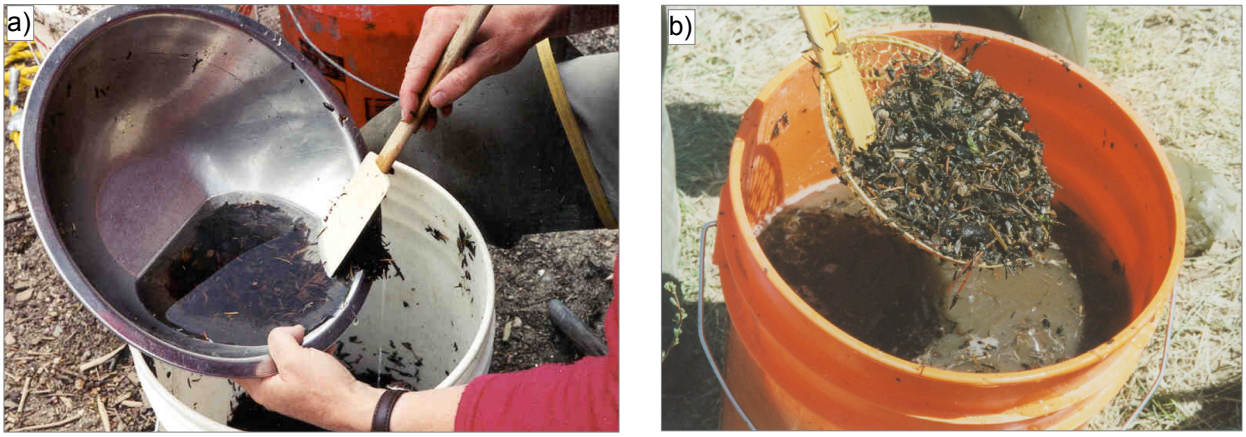

Figure 5: Field separation of CPOM from inorganic bedload in small (a) and large samples (b).

Computation of wet volumetric and dry mass CPOM transport rates Wet volumetric CPOM transport rates ($Q_{CPOM\ vol}$; l/hour) were computed individually for each stream width segment (w_1 *to* w_4) represented by one of the traps because trap spacing and sampling time differed slightly between traps. The cross-sectional wet volumetric CPOM transport rate is obtained from the sum over all width segments:

$$Q_{CPOM\ vol} = \frac{V_1 \cdot w_1}{w_s \cdot t_{s1}} + \frac{V_2 \cdot w_2}{w_s \cdot t_{s2}} + \frac{V_3 \cdot w_3}{w_s \cdot t_{s3}} + \frac{V_4 \cdot w_4}{w_s \cdot t_{s4}} \quad (1)$$

V is the CPOM volume per trap, w_s is the trap width, and t_s is the sampling duration. The summed stream sections equal the active stream width. A dozen CPOM samples from the two streams were dried to constant weight in a low temperature oven. The dry mass transport rate Q_{CPOM} (g/hr) is obtained from multiplying the wet volumetric transport rate by the mean dry weight of 112 g/l at E. St. Louis Cr. (std. dev. of 11.2 g) and 93.3 g/l at Little Granite Cr.

Adjustment for unsampled CPOM passing over the traps Flow sometimes overtopped the bedload traps—that extend 0.2 m above the bed—leaving near-surface CPOM transport unsampled. At Little Granite Cr., the two central

traps became overtopped at 20% Q_{bkf} and the two lateral ones at 30% Q_{bf}. The maximum overflow height reached 0.22 m during the brief periods of peak flow. To estimate the unsampled CPOM portion, a vertical concentration profile of CPOM needs to be assumed. If the concentration of waterlogged CPOM particles (C_{CPOM} [g/m^3]) is highest near the stream bottom, and given a near logarithmic velocity profile with the fastest flow (v [m/s]) near the water surface, CPOM transport rates per stream section (Q_{CPOM} [g/m^2·s] = $C_{CPOM} \cdot v$) are approximately even throughout the water column (Figure 6a). If, by contrast, C_{CPOM} is roughly even vertically through the water column, Q_{CPOM} is highest near the water surface (Figure 6b). If large amounts of CPOM (e.g., many dry sticks) float near the water surface, while waterlogged CPOM transport is concentrated near the bottom, a much larger portion of CPOM transport is missed by not sampling the top of the water column (Figure 6c).

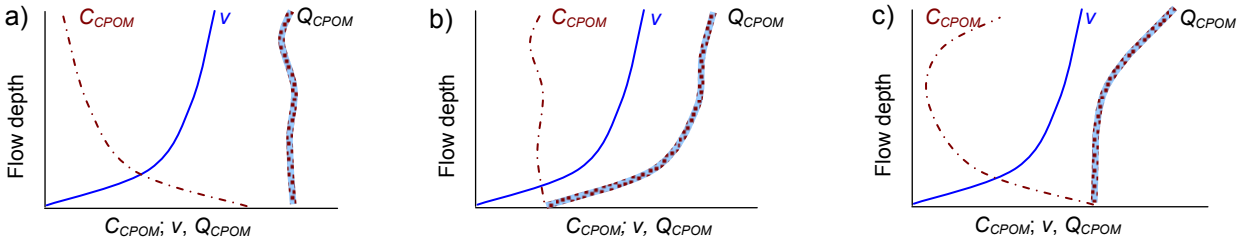

Figure 6: Interplay between C_{CPOM}, v, and Q_{CPOM}. Downward increasing trend of C_{CPOM} causes a vertically approx. even Q_{CPOM} profile (a). Vertically even C_{CPOM} causes highest Q_{CPOM} near the stream surface (b). Downward increasing C_{CPOM} together with high near-surface concentration also cause the highest Q_{CPOM} near the surface.

Based on visual field observation of where within the water column CPOM is transported, this study assumed a downward increasing trend for C_{CPOM} with a vertically even distribution Q_{CPOM} (Figure 6a) in which case the unsampled portion of CPOM transport is directly proportional to the height of flow overtopping the traps h_{top}. Overtopping heights were recorded at various flows Q for all traps, and h_{top} was described as a logarithmic function of Q where x and m are regression coefficients.

$$H_{top} = x\,(\log Q) + m \tag{2}$$

Once Q started overtopping one of the traps, overtop-adjusted transport rates $Q_{CPOM\ adj}$ were computed from measured transport rate $Q_{CPOM\ meas}$ as

$$Q_{CPOM\ adj} = \left(h_{trap} + \frac{h_{top}}{h_{trap}}\right) \cdot Q_{CPOM\ meas} \tag{3}$$

where the trap height h_{trap} which included the frame and the net thickness is 218 mm. During the brief peak flow periods, the overtop-adjusted cross-sectional $Q_{CPOM\ adj}$ rates at Little Granite Creek were up to twice the sampled values. At East St. Louis Creek, flows did not exceed 70% Q_{bkf}, and the sampling site was also considerably wider than the average stream width. Only one of the four traps became overtopped at 35% Q_{bkf}, and the maximal h_{top} was 6 cm at the highest measured flow. The overtopping adjustment increased cross-sectional CPOM transport rates by less than 6% for those flows.

Adjustment of 1-hour samples at Little Granite Creek During the first rising limb in 2002, almost all samples at Little Granite Cr. were collected over 1-hour sampling times, but 1-hour and 10-minute samples were collected alternately during the first falling limb and the second rising and falling limbs. CPOM transport rates computed from 10-minute samples ($Q_{CPOM\ 10}$) were generally larger than those computed from 1-hour samples ($Q_{CPOM\ 60}$) at similar flow (Figure 6a and b), indicating that 1-hour samples had a reduced sampling efficiency. This would occur when the nets overfilled or clogged which reduced through flow and capture rates. Differences in capture rates between sampling times were negligible early in the high-flow season, but $Q_{CPOM\ 10}$ exceeded $Q_{CPOM\ 60}$ by a factor of up to two at the highest transport rates near peak flow (Figure 6a). In order to use all samples collected over the highflow season in the analyses of annual CPOM export, the reduced sampling efficiency of the 1-hour samples was accounted for by adjusting 1-hour transport rates to those that might have been obtained by 10-minute sampling. The 1-hour and 10-minute CPOM samples were collected at alternate times, and because discharge changed quickly between samples, transport rates for the two sampling times cannot be directly related to each other. Instead, CPOM

transport rates for both sampling times were predicted for eight flow values evenly spaced between Q_{min} and Q_{max} from the second rising and falling limb CPOM rating curves (Figure 7a). To account for the inherent bias in predictions from a power function with data scatter, each predicted $Q_{CPOM\ 10}$ and $Q_{CPOM\ 60}$ was multiplied by a bias correction factor *CF*. From the several correction functions available (see discussion by Hirsch et al. 1993), the one proposed by Ferguson (1986, 1987) was selected for ease of computation ($CF = \exp(2.651\ SE_y^2)$ where SE_y is the standard error of the y-estimate.

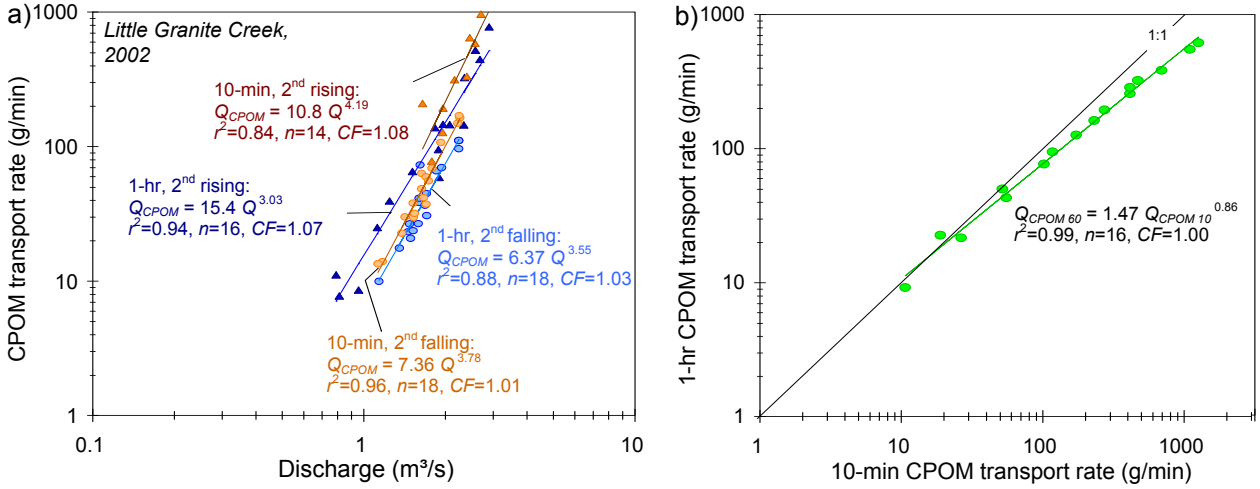

Figure 7: Relations of overtop-adjusted CPOM transport rates from 1-hour and 10-minute sampling with discharge during the second rising and falling limbs of flow at Little Granite Creek, 2002 (a). Relation between 1-hour and 10-minute Q_{CPOM} predicted from CPOM transport relations in panel (a) (b).

The relationship between predicted 1-hour and 10-minute Q_{CPOM} transport rates $Q_{CPOM\ 60}$ and $Q_{CPOM\ 10}$ was well defined with an r^2=0.99 (Figure 7b). Assuming that this relation established from data collected during the second discharge peak likewise applied to the first discharge peak, the inverse of the regression function in Figure 7b ($Q_{CPOM\ 60adj} = 0.666\ Q_{CPOM\ 10}^{1.155}$) was used to adjust all 1-hour CPOM transport rates >10 g/min for their reduced sampling efficiency; no adjustment was needed for small samples for which sampling time had no effect on sampling efficiency. After adjustments, there were 91 individual CPOM transport rates available over the high-flow season for computations of annual CPOM export at Little Granite Cr. Peak flow (70% Q_{bf}) and maximum Q_{CPOM} (81 g/min) were much lower at East St. Louis Cr., so a reduction in sampling efficiency of 1-hour samples was unlikely, and all 73 collected 1-hour samples were used without time adjustment to compute CPOM transport relations.

CPOM transport rates and relation to discharge The range of measured CPOM transport rates extended over more than two orders of magnitude in both study streams (Figure 8a and b). Due to pronounced hysteresis, Q_{CPOM} scattered over one order of magnitude in both streams for a given flow, and this resulted in a comparatively poor fit of the power function transport relationships $Q_{CPOM} = a \cdot Q^b$ fitted to all CPOM data (r^2 of 0.60 and 0.73) where *a* is the coefficient and *b* the exponent. By contrast, power function relations fitted to measured CPOM transport rates and flows for the individual rising and falling limbs were well defined in both study streams (r^2 between 0.85 and 0.96; see transport equations in Figure 8a and b), but differ notably among each other and from the relation for all data. The pronounced differences of transport relations between rising and falling limbs of flow makes clear that separate CPOM rating curves needed to be used to compute CPOM load over the high-flow season.

At East St. Louis Cr., the exponent *b* fitted to the relation $Q_{CPOM} = a \cdot Q^b$ for all data is 4.5, while exponents for individual rising and falling rating curves range between 6.6 and 7.1. At Little Granite Cr., Q_{CPOM} increases less strongly with flow, yielding an exponent of 3.5 for all samples, while exponents for individual limbs of flow are within 3.0 and 4.1. The Q_{CPOM} transport relations reported here are of similar steepness as the relation established by Turowski et al. (2013) for the Swiss Erlenbach torrent with an exponent $b = 4.42$, likewise sampled with bedload traps.

Computation of seasonal CPOM loads using a rating curve and a summation approach Both a rating curve and a summation approach were employed to compute seasonal and annual CPOM loads. For the rating curve

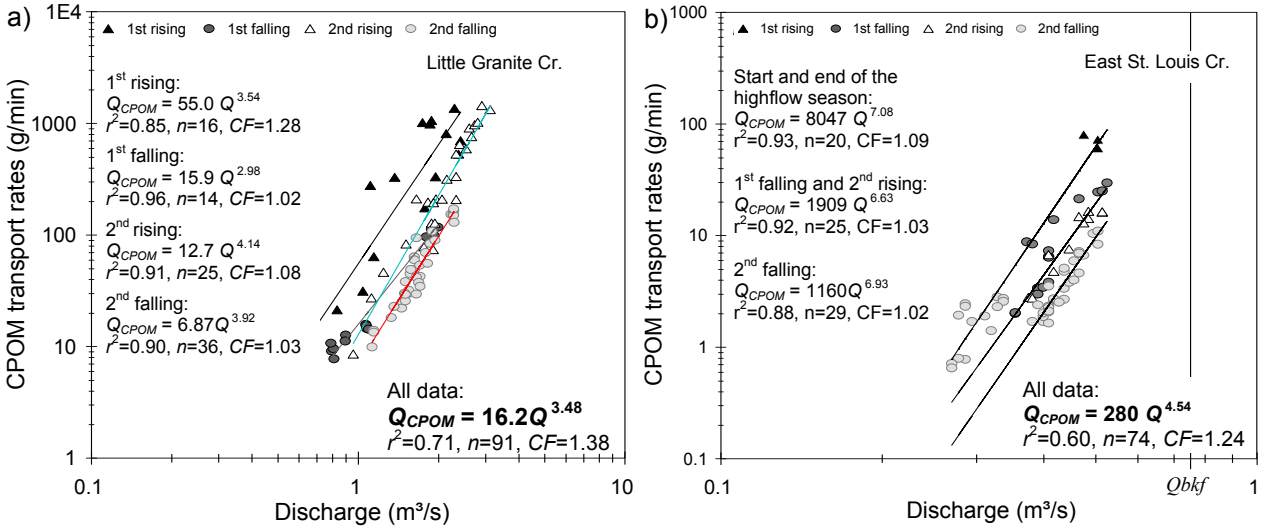

Figure 8: Relations of CPOM transport rates vs. discharge for seasonal rising and falling limbs of flow at Little Granite Creek (a) and East St, Louis Creek (b). All *p*-values are < 0.0001. Note different plot scales for a) and b).

approach, each flow value of the 15-minute hydrograph was multiplied by the CPOM transport rate (g/min) predicted for that flow from the respective power function $Q_{CPOM} = a \cdot Q^{b}$ rating curve (Figure 8a and b), multiplied by the Ferguson (1986, 1987) bias correction factor *CF*, multiplied by 15 to integrate over each 15-minute time increment, and summed over the rising and falling limbs of the high-flow season. Seasonal CPOM loads during the unmeasured flows prior to the high-flow season, the post high-flow falling limb, and late summer low flows were computed from a rating curve approach. Zero CPOM transport was assumed for both streams between fall and spring when flows are very low (5-10% of bankfull), and a snow cover shields most of the stream surface from CPOM input.

Summation approach The sequence of CPOM fluxes computed from samples collected over the daily rising limbs of flow (and adjusted for sampler overtopping and overfilling where needed) generally followed the diurnal fluctuations of flow. The lowest and highest daily transport rates fell onto the daily minima and maxima of flow at both streams. This correspondence can be used to extend the observed daily trends to peak- and low-flow times at which CPOM was not measured and to estimate daily maximum and minimum Q_{CPOM} when needed. CPOM transport rates were then interpolated geometrically (due to power-function relations of Q_{CPOM} with Q) between daily low-flows and peak flows to obtain a value for each 15-minute increment. This created a continuous 15-minute estimate of CPOM transport rates over the high-flow season (Figure 3a and b). Multiplication of Q_{CPOM} by the time of each 15-minute increment and summing over the sampled time period of the high-flow season yielded the CPOM load for the sampled portion of the highflow season. A rating curve approach was used to compute CPOM loads for the unsampled pre- and post high-flow seasons, extending trends from the CPOM rating curves for the first rising limb and the second falling limb, respectively, to lower flows. At Little Granite Cr., no hydrograph was available for the 80-day remainder of the seasonal falling limb between July 12 and Sept. 30, and a constant value of Q_{CPOM} = 0.05 g/min was assumed.

Simulating a hydrograph with bankfull flow at East St. Louis Creek Because CPOM transport rates increase with water discharge and hence with the highflow volume, a comparison of annual CPOM export between basins should be referenced to "normal" flow years, defined as years in which flows reach or slightly exceed the bankfull level for a few days. Flows at Little Granite Cr. peaked briefly at bankfull, approaching a normal year. For East St. Louis Cr. that had peaked at only 70% of bankfull flow, the study simulated a hydrograph that peaks at bankfull. To this end, measured peak flow was increased by 0.244 m^3/s to reach a bankfull flow of 0.764 m^3/s, and a smooth hydrograph was created by tapering off the mathematical flow addition towards the rising and falling limbs. CPOM transport rates were estimated by extrapolating the rating curves established for rising and falling limbs of flow in 2001 (Figure 8b). The predicted transport rates were then applied to each 15-minute time increment and summed over the new hydrograph. The stream's CPOM supply was considered sufficient to permit extension of the measured East St. Louis Cr. CPOM rating curves to bankfull flow because measured CPOM transport rates during a small flow peak on the falling limb of the hydrograph at the end of the high-flow season were higher than those

predicted from the falling limb rating curves that were based on measurements early on the falling limb. This suggested sufficient CPOM supply to allow CPOM transport rates to increase with increasing flow up to bankfull flow.

RESULTS

Annual CPOM export Annual CPOM export at Little Granite Cr. in 2002 computed from the summation approach was 3.6 metric tonnes (t) which represents a yield of 2.7 kg/ha/year. The vast majority (97%) of the annual export occurred during the 1-month high-flow season (Table 2), while only 0.4, 2.8, and 0.2% of the annual CPOM export occurred prior to high flow, after high flow, and later during summer low flows, respectively.

Table 2: CPOM transport rates and loads computed for hydrograph portions at Little Granite Cr. in 2002.

Time period	Hydrograph portion	Flow range (m^3/s)	No. of days	Range of transport rates (g/min)	Seasonal load (t)	% of annual export
April 18 - May 12	prior to high flow	0.08-0.34	24	0.001 – 1.5 *[1)]	0.013	0.4
May 12 - June 14	high flow	0.25-3.26	33	0.8 – 1458 [3)]	3.45	96.6
June 14 - July 11	falling limb	0.29-1.17	27	0.06 – 13 *[2)]	0.101	2.8
July 12 - Sept 30	late summer low *Q*	0.15-0.29 est.	80	0.05 *[2)]	0.006	0.2
Oct 1 – April 17	base flow	0.09-0.15 est.	201	0	0	0
2002 annual export (t)	entire year		365		3.57	100
Basin yield (kg/ha/yr)	entire year				2.73	

* estimated by extrapolation from rating curve for [1)] first rising limb; [2)] second falling limb; [3)] based on intensive sampling that facilitated using a summation approach.

Annual CPOM export at East St. Louis Cr. was 169 kg during the 2001 low-flow year, with a basin yield of 0.211 kg/ha/year—more than an order of magnitude less than exported from Little Granite Cr. Most of the CPOM export occurred within the high-flow period (82%), although notable amounts (11%) were still supplied during the falling limb (see 2001 in Table 3). Annual CPOM export at East St. Louis Cr. for a simulated bankfull hydrograph (see bf-year in Table 3) reached 3.2 metric tonnes, 19 times more than computed for the low-flow year. While this estimate might have some uncertainty because trends measured in the low-flow rating curves were extrapolated to higher flows (when perhaps supply exhaustion may set in), it shows the important role that runoff plays in annual CPOM export from a basin. Other studies have shown that differences in the CPOM export of more than an order of magnitude between years are not unusual (Bilby, 1981; Wallace et al., 1995).

Table 3: CPOM transport rates, loads, and yields for various hydrograph parts at East St. Louis Cr. in 2001 and for a year with a simulated a hydrograph reaching the bankfull level

Time period	Hydrograph part	Days	Flow range (m^3/s)		Range of transport rates (g/min)		Loads and yields		% of annual export

[1)] Based on rating curve for 1st rising limb; [2)] based on summation approach and intensive sampling; [3)] based on rating curve for all data.

Comparison of CPOM export and yield CPOM export was slightly higher at Little Granite Cr. (3.6 t) compared that at East St. Louis Cr. (3.2 t) for the simulated bankfull hydrograph. Per basin area, though, East St. Louis Cr. yielded more CPOM (4.0 t) than Little Granite Cr. (2.7 t). For the forested portion of the basin area, both streams had similar CPOM exports of 6.6 and 6.5 kg/ha/year, a low estimate given that flows just briefly reached bankfull.

While little information exists for coniferous forests (Richardson et al. 2005), mean annual CPOM exports of about 0.4 to 10 kg/ha are reported for deciduous watersheds (Table 4). Per forested watershed area, CPOM export of 6.5 and 6.6 kg/ha/year from the two subalpine Rocky Mountain watersheds is comparable to export from deciduous forests such as in the Atlantic NE Hubbard Brook (e.g., Bilby 1981) and the Brazilian Mato Grosso (Johnson et al., 2006).

Table 4: Comparison of CPOM export reported for various streams with forested watersheds.

[1] est. for a year with bankfull flow; [2] based on 11 and 12 years prior to removal of debris dams; [3] based on a reported 3.5% portion of CPOC on total carbon export; [4] assuming basin areas are fully forested; [5] 21% basin area are fully forested; of the partially forested area (41%), half is counted to the fully forested area (=21% + 20.5% = 41.5% forested); 38% is above treeline or otherwise unforested; [5] 62% basin area are fully forested; 33% above treeline and 5% otherwise sparely forested.

DISCUSSION AND SUMMARY

Bedload traps with a 4-mm mesh were found suitable for sampling the CPOM-gravel bedload mix. Traps that extend through the entire water column over all flows would be desirable for a more complete capture of CPOM transport. However, during high flows, taller traps may not be able to withstand the greater force of flow near the top of the water column, possibly causing the traps to bend backwards and become dislocated from the ground plates. To estimate CPOM transport passing above the bedload traps, measuring profiles of the vertical CPOM concentration at increments through the water column at various flows might be useful. Care should be taken not to overfill the nets which may require a reduction in sampling times when loads are high. CPOM transport rates presented here may constitute a conservative estimate because the 4-mm mesh might not representatively sample the 1-4 mm portion of CPOM. However, based on the large amounts of captured conifer needles and needle fragments, elongated particles probably roll over the bed or tumble in the flow rather than go straight like an arrow that might pass straight through the mesh. Sampler nets with 1-mm mesh were also found to be less suitable for collecting CPOM because CPOM easily clogs those nets, causing a reduction in hydraulic and sampling efficiency (Bunte et al. 2015, *session 5C*). Since gravel bedload and CPOM are jointly transported and jointly captured in the sampler, it makes sense to combine field projects of bedload and CPOM sampling.

CPOM transport rates showed seasonal hysteresis that was more pronounced than what has been measured for gravel bedload transport at the study streams. The extremely supply driven (and limited) transport dynamics cause CPOM transport relations to differ drastically between individual rising and falling limbs of the high-flow hydrograph, as well as between the pre-and post runoff seasons (Bilby and Likens, 1980; Wallace et al., 1995). At Little Granite Cr., the season's first rising limb Q_{CPOM} was 4-5 times higher than Q_{CPOM} on the first falling limb, 3-4 times higher than on the second rising limb and about 6 times higher than on the second falling limb (Figure 8a). At East St. Louis Cr., Q_{CPOM} during the first rising limb was about 3 times higher than on the shared transport relation for the first falling and second rising limb (Figure 8b) and also about 6 times higher than on the second falling limb. During small rainfall peaks towards the end of the highflow season at East St. Louis Cr., Q_{CPOM} approached the relationship of the first rising limb, suggesting that CPOM was still available for transport on the falling limb in this in low-flow year.

The quick response of Q_{CPOM} to increasing flow in both streams indicates that CPOM is easily entrained and transported, i.e., transport is hydraulically controlled. However, the hysteresis relations, and transport rates that decrease over time, show that the response of CPOM flux to flow is also governed by the availability of CPOM supply which changes over the course of the high-flow season.

As Q_{CPOM} is strongly related to flow, 95% of the annual CPOM export was concentrated in the central one-month period of the snowmelt high-flow season in both study streams. Strong hysteresis effects during that period require that CPOM transport be intensively sampled and that separate CPOM rating curves are established for each portion of the typically multi-peaked snowmelt hydrograph. For example, had CPOM at Little Granite Cr. been sampled over only a few consecutive days (i.e., been limited to one of the rising or falling limbs of flow), and only one rating curve (together with bias correction factor CF) been used to compute the highflow CPOM load, computed loads might have varied between 1.7 tonnes (if field sampling was limited to the second falling limb) and 9.7 tonnes (if field sampling was limited to the 1st rising limb) depending on whether the field visit occurred early or late in the high-flow season. By contrast, using the appropriate rating curve for each limb resulted in a CPOM load of 3.5 tonnes which is very close to the annual load of 3.6 tonnes computed from the summation approach.

CPOM yields in the two high-elevation Rocky Mountain study streams with subalpine coniferous forests was 2.7 and 4.0 kg/ha/yr for bankfull flow events, but both streams yielded similar amounts (6.6 and 6.5 kg/ha/yr) per forested portion of the basin area. Those Rocky Mountain CPOM yields are similar to export reported for North Eastern deciduous forests (7-15 kg/ha/yr), and the Brazilian Mato Grosso. Due to high inter-annual variability, CPOM export is ideally based on the average of long-term observations. Failing that, it might be advisable to compute CPOM for normal flow years in which bankfull flow is reached or slightly exceeded for a few days.

Acknowledgement We thank Sandra Ryan and Mark Dixon for the 2002 flow data from Little Granite Creek and L. Porth, K. Elder, and B. Starr (all USDA Forest Service, Rocky Mountain Research Station, Fort Collins, CO) for the 2001 East St. Louis Creek flow data. Field work and part of the data analysis was funded by the USDA Forest Service Stream Systems Technology Center, Fort Collins, CO. Further analyses and part of the manuscript were prepared while K.B. received support from the Swiss Federal Research Institute (WSL) in Birmensdorf, CH. Sandra Ryan and Ellen Wohl (CSU) provided friendly reviews of the manuscript. We thank John Potyondy (USFS ret.) for vision, insight, and long-term support of our field studies.

SEDIMENT BUDGETS, TRANSPORT, AND DEPOSITIONAL TRENDS IN A LARGE TIDAL DELTA

Tara L. Morgan-King, hydrologist, U.S. Geological Survey Sacramento, California, tamorgan@usgs.gov; Scott A. Wright, research hydrologist, U.S. Geological Survey Sacramento, California, sawright@usgs.gov

INTRODUCTION

The Sacramento-San Joaquin Delta is the largest delta on the west coast of the United States. It is formed where the confluence of California's two largest rivers (the Sacramento and San Joaquin) meet the ocean tides and has a significant physical gradient from fluvial to tidal. It is a semi-diurnal system (two high and two low tides per day). Today, the Delta is one of the most manipulated in the United States. Once composed of many shallow, meandering and braided dendritic channels and dead-end sloughs and wetlands, it is now a network of leveed canals moving clear water around subsided islands. It historically has supported a biologically diverse tidal wetland complex, of which only 3% remains today (Whipple et al., 2012). It has also witnessed a collapse in the native fish populations. The Delta provides critical habitat for native species, however the hydrology and water quality are complicated by manipulations and diversions to satisfy multiple statewide objectives. Today water managers face co-equal goals of water supply to Californians and maintenance of ecosystem health and function. The Delta is a hub for both a multi-hundred-million dollar agricultural industry and a massive north-to-south water delivery system, supplying the primary source of freshwater to Central Valley farmers and drinking water for two-thirds of California's population. Large pump facilities support the water demand and draw water from the Delta, further altering circulation patterns and redirecting the net flow toward the export facilities (Monsen et al., 2007).

Fluvial sedimentation, along with organic accumulation, creates and sustains the Delta landscape. Hydraulic mining for gold in the watershed during the late 1800s delivered an especially large sediment pulse to the Delta. More recently, from 1955 to the present, a significant sediment decline has been observed that is thought to have been caused mostly by the construction of water storage reservoirs that trap the upstream sediment supply (Wright and Schoellhamer, 2004). Today, one concern is whether the volume of sediment supplied from the upper watershed is sufficient to support ecological function and sustain the Delta landscape and ecosystem in the face of climate change, sea level rise, and proposed restoration associated with the Bay Delta Conservation Plan (http://baydeltaconservationplan.com). Ecosystem health is a management focus and 150,000 acres of restoration is currently proposed, therefore it is of increasingly important to understand the quantity of sediment available for marsh and wetland restoration throughout the Bay Delta Estuary. It is also important to understand the pathways for sediment transport and the sediment budget into each of three Delta regions (figure 1) to guide restoration planning, modeling, and management.

In this paper, we present our preliminary findings while revisiting previous sediment flux research (Wright and Schoellhamer, 2005). Our current understanding of the hydrology of the Delta has been improved by a larger network of monitoring sites and new, higher quality

instrumentation to monitor turbidity, which we use as a surrogate for suspended sediment. The central Delta, specifically, is an extremely complicated and dynamic mixing zone hydrologically influenced by changes with river discharge, tides, seasons, diversions, and flow path modifications. Sacramento River flow into the central Delta is reduced by gates on the Delta Cross Channel (DCC figure 1) that are periodically closed, directing flows to the west Delta and San Francisco Bay. One critical issue is the migration of native fish through the Delta and the physical entrainment with the current into the south Delta. This often leads to mortality at the California and Federal pumping facilities and compromises population resilience (Kimmerer, 2008; Grimaldo et al., 2009). The annual spawning migration of delta smelt from Suisun Bay and the western Delta into the central and south Delta where they can potentially be entrained is believed to be triggered by the increase of Delta turbidity. The increased turbidity is caused by the influx of suspended sediment from the Sacramento River into the central Delta during the first major storm of the year (also known as the "first flush").

Our objectives for this paper are to 1) quantify annual sediment budgets for the Delta during water years 2011, 2012, and 2013, 2) to describe the primary pathways for sediment into each Delta region shown in figure 1, and 3) to explain the timing and magnitude of sources of sediment into the Delta. We evaluated the primary sediment peak of winter storms with a focus on the significance of the Georgiana Slough pathway (from GEO to MOK on figure 1) into the central Delta channels. One specific question we wanted to address is how much sediment moves into the central Delta during the peaks of the storm-related-sediment pulses during the initial prespawning migration of delta smelt compared to the total annual sediment load for a given water year (figure 2). The sediment information has been a missing link to migration and entrainment analysis. We know that the first significant rise in turbidity in winter, initiated by a big storm, is thought to initiate migration (Bennet et al., 2014; Grimaldo et al., 2009) and the majority of salvage (ie. captured and "saved" from entrainment) occurs during net negative flows (Kimmerer, 2009; Grimaldo et al., 2009). We hope, therefore, to help managers understand the effects of sediment and turbidity on fish migration in terms of the quantity and pathway of sediment that is transported to the pump facilities because salvage often leads to mortality.

METHODS

Turbidity, a surrogate measurement for calculating suspended-sediment concentrations (SSC) and load, is a water quality parameter that describes the cloudiness or opacity of the water due to suspended solids (Gray and Gartner, 2008). Turbidity as a surrogate has been successfully used for sediment analysis and demonstrated by Rasmussen and others (2005), Urich and Bragg (2003), Lietz and Debiak (2005), Wood and Teasdale (2013), Buchanan and Morgan (2010). Turbidity data from our network of sites described in figure 1 were corrected for calibration drift and fouling errors as described in Wagner et al. (2006).

Discharge data came from the California Department of Water Resources (DWR) and U.S. Geological Survey (USGS). Channel discharge was calculated from measurements using acoustic Doppler current profiler (ADCP) data and the index velocity method for tidal channels (Ruhl and Simpson, 2005). These data were accessed through the Water Information System (NWIS) http://waterdata.usgs.gov/ca/nwis, with exception to Mallard Island discharge data

which came from the DWR DAYFLOW website and was accessed from http://www.water.ca.gov/dayflow.

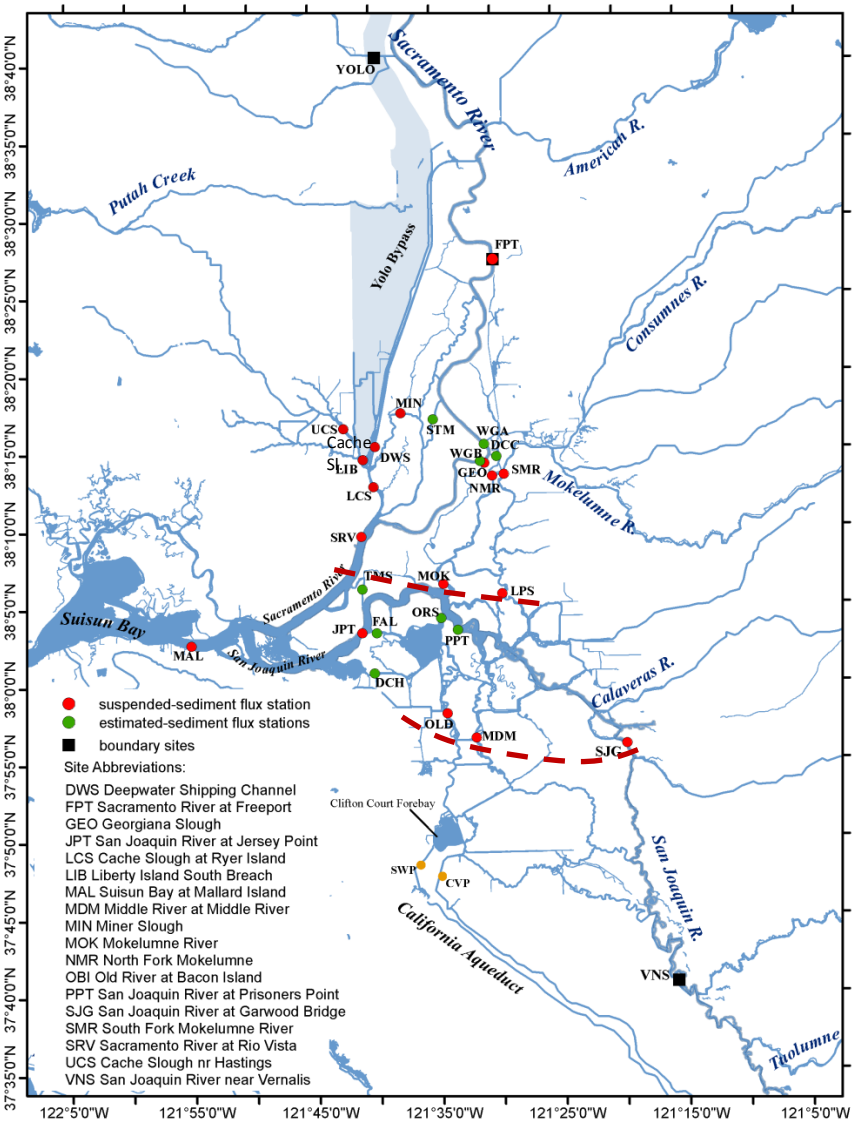

Figure 1. The north, central, and south regions of the Delta suspended-sediment-monitoring network are demarcated by the red dashed lines. We show 17 sediment-flux-monitoring stations, eight stations where sediment fluxes were estimated, and three boundary stations (FPT, YOLO, and VNS) which measure the primary sediment inputs from the Sacramento and San Joaquin Rivers. Measurements of tidal flow using acoustic Doppler current profilers were available at all stations so that fluxes could be estimated. The Georgiana Slough pathway is the channel between GEO and MOK.

The in-stream optical turbidity sensors and water samples were used to monitor suspended-sediment concentrations at seventeen sites (figure 1) strategically chosen from the larger network to allow for regional estimates of sediment loads and deposition. Suspended-sediment concentration data were collected across a number of Delta sites by the USGS during water years

2011-2013 (October 1, 2010–September 30, 2013). At all sites discussed herein, turbidity data was collected from optical sensors that are co-located with ADCPs to measure flow. Discharge weighted suspended-sediment concentrations (SSC_{xs}) were derived from depth-integrated water samples collected across the cross-section using the equal discharge increment technique and standard samplers (Edwards and Glysson, 1999). The output of the optical turbidity sensors were calibrated to the cross-sectional-average SSC so that a record of SSC, suspended-sediment flux (SSF), and loads could be computed. Yolo Bypass carries flow and sediment from the Sacramento River during floods and sediment loads were estimated using the methods in Wright and Schoellhamer (2005). Total sediment loads entering the Delta were determined by summing loads from the YOLO, FPT, UCS, NMR, SMR, and VNS stations (see figure 1). Sediment loads at Mallard Island were estimated using the approach discussed in McKee et al. (2013). The sediment entering the Delta, but not transported out at MAL, is considered to have been deposited in the Delta.

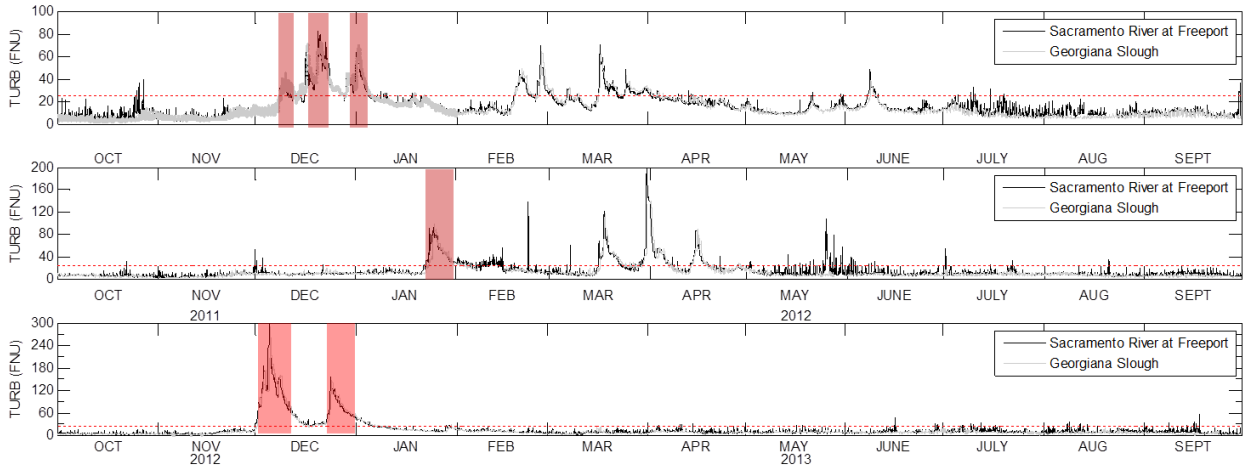

Figure 2. FTP and GEO turbidity time series, with the time periods isolated out for analysis in each of 2011 (top), 2012 (middle), and 2013 (bottom). These time periods isolated in red are thought to be the critical times associated with the initial migration of prespawning delta smelt. The red dashed line depicts the turbidity threshold of 25 FNU at FPT that was used to depict the storm pulse. Events identified as yielding the first flush span 22 days in 2011, 12 days in 2012, and 26 days in 2013. Note the differing y-axis for each graph.

RESULTS

DELTA SEDIMENT BUDGET AND DEPOSITION ZONES

The Sacramento River and San Joaquin Rivers are dominated by fluvial advection of sediment into the Delta, however the Sacramento River is the dominant source of flow and sediment (Wright and Schoellhamer, 2005). In general, the distributary channels throughout the Delta are also dominated by seaward advection, however, tidal dispersion and sediment settling also occurs. The average deposition/sediment budget for each of the three regions (north, central, and south) during the three-year time period discussed herein, is shown in figure 3 (left panel). The total sediment load into each Delta region for each year is shown in figure 3 (right panel). The largest sediment load to the Delta is from the north and decreases southward. On average,

roughly two-thirds of sediment supplied to the Delta is deposited, (Wright and Schoellhamer, 2005) however the proportion of sediment deposited varies from year to year as is to be expected. For 2011, around 69% of the total sediment load was deposited. In 2012, 45% of the total sediment was deposited, and in 2013, roughly 32% of the sediment was deposited.

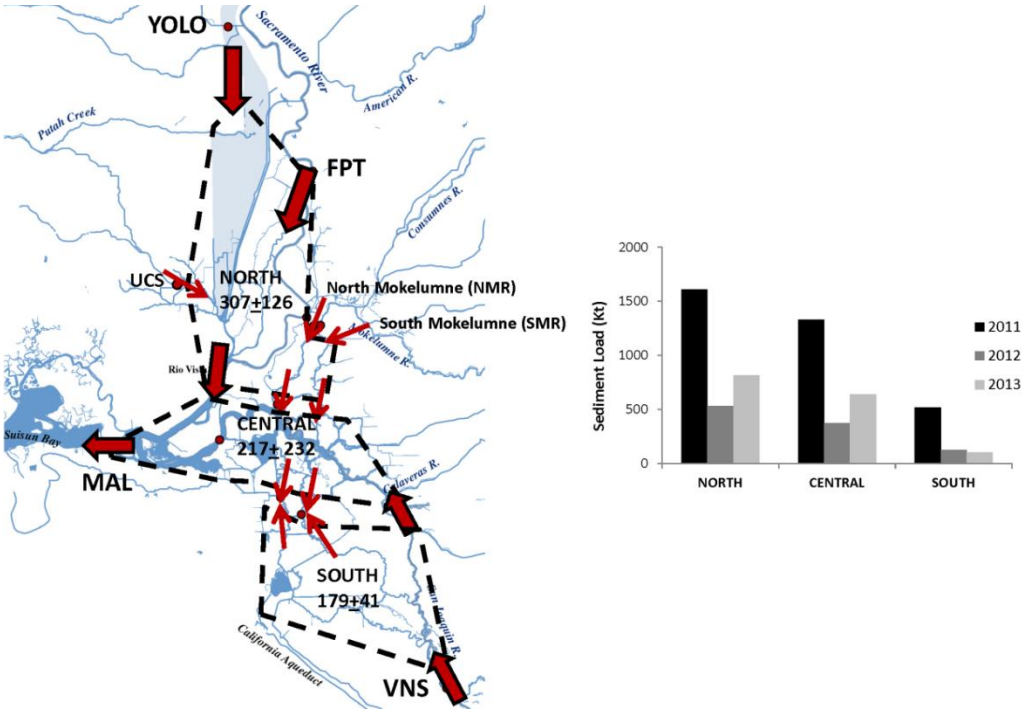

Figure 3. Map showing the Delta regions (left) defined by the black dashed line for north, central, and south Delta, and shows the average mass of deposition with the standard error. The bar graph (right) shows the annual sediment load in thousand metric tons to each region for each of 2011, 2012, and 2013. The sediment load from Rio Vista is considered part of the Central Delta. Bold arrows represent the primary paths for the Sacramento and San Joaquin Rivers. Additional pathways within the Delta are represented by red arrows. Note the opposing arrows for Old and Middle Rivers as sediment flux changes seasonally and with flow conditions.

PRIMARY PATHWAYS OF SEDIMENT

The primary pathways for fluvial sediment entering the Delta and it's regions, are shown in figure 3 (left panel) and figure 4 with bold arrows. The Sacramento and San Joaquin Rivers are the primary pathways of sediment from the watersheds to the north and south Delta respectively, however the maximum annual sediment flux was from the Sacramento River (1085 Kt at FPT in 2011) as shown in figure 4A, during an above average flow year. It carried three times as much sediment into the Delta than the San Joaquin River. In 2013 (a below average flow year), the volume of sediment supplied by the Sacramento River to the Delta was seven times that of the San Joaquin (roughly 80% of the total load into the Delta). Most of the sediment within the main-stem Sacramento River remains in suspension and is transported past Rio Vista and then seaward towards Suisun Bay. A portion of the sediment in the Sacramento River is also advected into various distributaries such as Miner Slough, Streamboat Slough, and Georgiana Slough (figure 4).

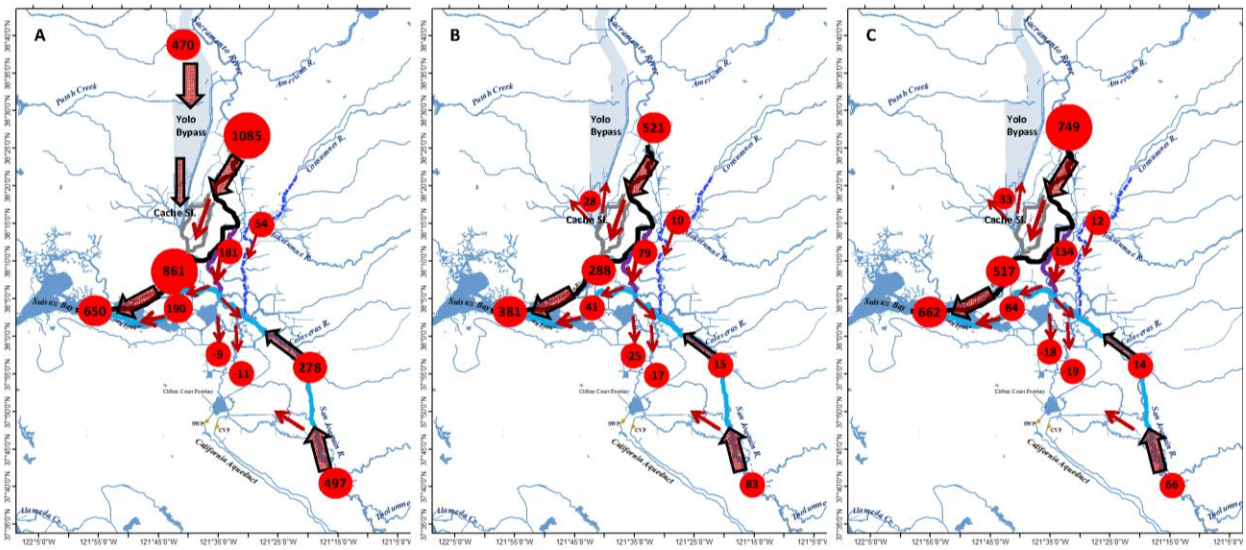

Figure 4. Primary pathways of sediment transport for 2011 (A), 2012 (B), and 2013 (C). The major riverine sediment pathways have red polygon arrows and the smaller distributary pathways are shown with red line arrows. The Sacramento River is represented by a black line and the San Joaquin River is represented by an aqua blue line. The east side Consumnes and Mokelumne River pathway to Little Potato Slough is represented by a blue-dashed line. Miner and Steamboat Slough distributaries are in gray, and Georgiana Slough is shown in purple. The sediment loads in thousand metric tons for various sites are shown with red circles proportionally sized.

The sediment from the Sacramento River is advected into distributaries and further transported either into the north Delta/Cache Slough region (north of LCS in figure 1 and figure 4) via 1) Sutter Slough (not shown) to Miner, or 2) Steamboat Slough, or 3) into the central Delta via Georgiana Slough (figures 1 and 4). Georgiana Slough and the Mokelumne River are influenced by the fluvial characteristics of the Sacramento River and sediment in these channels is advected to the central Delta. Most of the suspended sediment observed at site MOK (70% on average) comes from the Sacramento River via Georgiana Slough during the wet season and not directly from the tributaries of the Mokelumne. The Georgiana Slough pathway supplied a larger volume of sediment to the central Delta than the San Joaquin River during both 2012 and 2013 (figure 4B and 4C). In 2013, the annual sediment flux into the central Delta from the San Joaquin River at SJG, was 15% of the flux at MOK. Sediment originating from the Sacramento River can then make its way into the south Delta. In 2012, specifically, the sediment flux seaward from the central Delta was nearly equivalent to the sediment flux advected southward down Old and Middle Rivers (figure 4B).

DISCUSSION

DEPOSITIONAL PATTERNS

Proportional to sediment supply, on average, the north Delta had the least amount of deposition (30% on average) and the south Delta had the most (figures 3 and 4). This is because of the difference in the magnitude of flow in the Sacramento River compared to the San Joaquin River. Sacramento River sediment transport is dominated by advective processes; sediment remains in

suspension and is carried seaward past Rio Vista (SRV) to Suisun Bay (MAL). In contrast, a large portion of sediment advected down the San Joaquin River settles out of suspension and is deposited in the south Delta region especially during below average flows such as those occurring during 2012 and 2013. Based on a three year average, roughly 70% of the sediment advected down the San Joaquin River past Vernalis (VNS) is deposited in the south Delta Region.

The central Delta had approximately 50% deposition (and the most of any region) in 2011, but had little deposition in both 2012 and 2013. In these two years, the central Delta had the least sediment deposition of all three regions (23%). The Sacramento River alone supplied nearly 85% of sediment to the Delta proper and can account for roughly 70% of the sediment into the central Delta. Furthermore, our data suggest that for 2012 and 2013 (below average flows with little flow and sediment coming from the San Joaquin River watershed), a portion of the sediment entering the central Delta which is not advected seaward, moves further into the south Delta.

South Delta sediment is supplied from the north and the south direction and there is significant deposition. In 2011, when there was above average flow, sediment transport was predominantly seaward down the San Joaquin River. However, in 2012, 82% of the sediment load from the San Joaquin River observed at Vernalis (VNS) stayed in the south Delta. In addition, during 2012 and 2013, the quantity of deposition in the south Delta was greater than the mass of sediment advected down the San Joaquin River past VNS. Sediment is additionally advected into the south Delta from the central Delta because of the net negative flow that the large water pumps facilitate (figure 5). The sediment flux is in the landward direction into the south Delta via Old and Middle Rivers.

CENTRAL DELTA SEDIMENT

In this section, we address sediment transport pathways in the context of delta smelt migration. Specifically, we wanted to know the sediment transport pathways that lead to pumping curtailments either through increased turbidities in the south Delta or smelt salvage at the export facilities. To do this, we computed the sediment load from the first flush storm for each year of 2011, 2012, and 2013 to 1) determine the major contributions to the sediment load and thus increased turbidity in the central Delta and 2) to determine the sediment load of a first flush storm compared to the annual sediment load, to address the potential for making the Delta clearer in the summer if the first flush loads were reduced. Figure 2 shows the time periods which were isolated to compare the first flush sediment loads vs. the annual loads. Though these may not be the largest sediment loads of the year, the turbidity from a first flush event is correlated to fish migration (Sommer et al., 2011) and fish entrainment (Grimaldo et al., 2007) so we consider the first flush turbidity peaks to be the most critical time periods for delta smelt migration (Sommer et al., 2011, Bennett and Burau, 2014). We used a turbidity threshold of 25 FNU to define the first flush peaks at FPT (figure 2).

Sediment from Georgiana Slough is advected to the Mokelumne River and to the San Joaquin River. During low flow conditions, it is the main source of sediment to the central Delta. Compared to the total annual sediment load, the quantity of sediment which moves down Georgiana Slough during the first flush events shown in figures 2 and 6 varies from year to year and depends on flow conditions. In 2011, 21% of the annual sediment load down Georgiana

occurred within 22 days between December 8 and January 4, and 28% of the annual load occurred during the period of December 7 to January 9 (figure 6). Another 48% of the annual load was transported during mid-March to mid-April when approximately 50% of the total annual deposition into the central Delta occurred (figure 7 period 4). In 2012, only 12% of the

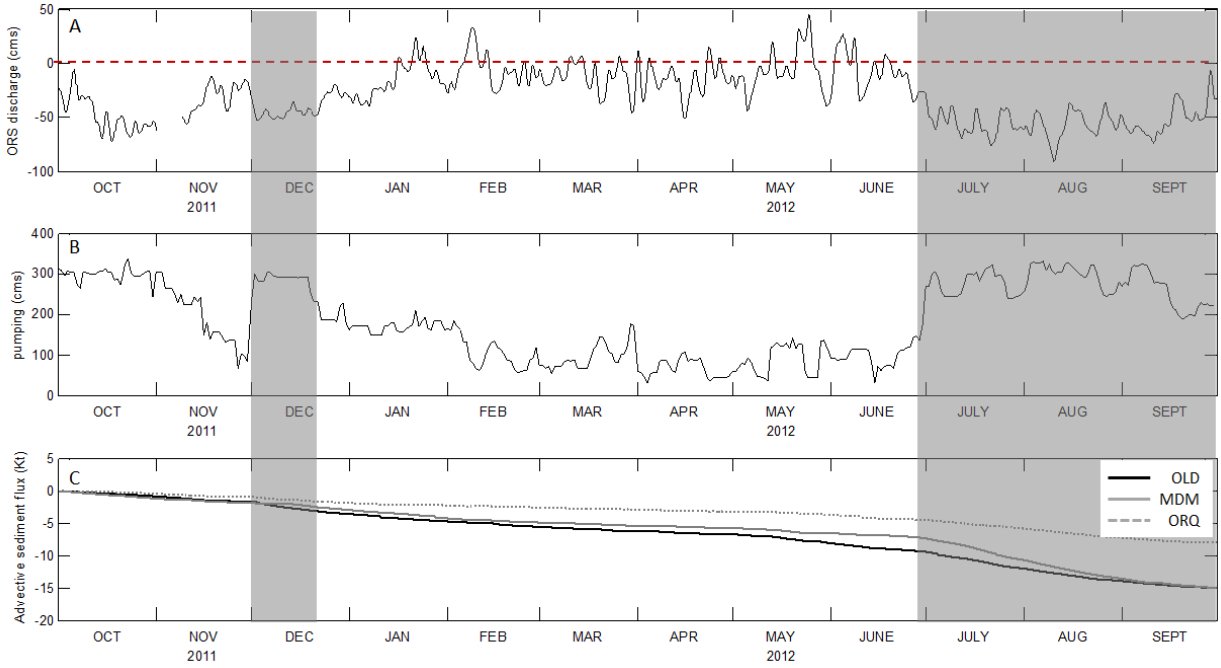

Figure 5. The highlighted gray areas in December and July-September represent more negative flow at ORS in 2012 (A) with increased pumping volumes (B), and a steeper negative advective sediment flux slope (C). Positive is ebb flow to the north and seaward; negative is towards the south Delta. Note that the daily pumping volume shown is for the combination of both State and Federal facilities.

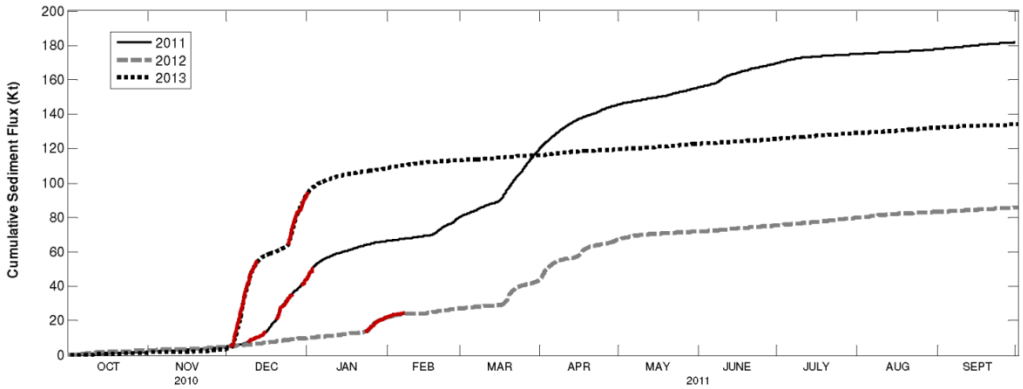

Figure 6. Georgiana Slough cumulative sediment load in thousand metric tons (Kt) for 2011, 2012, and 2013 showing the first flush sediment flux for the time periods outlined by the red lines here and coinciding with figure 2.

annual sediment load in Georgiana moved downstream towards MOK during the first flush compared to 2013, when 67% of the annual sediment load was advected downstream during the first flush time period. The largest first flush sediment load from the Sacramento River to the Delta occurred during 2013. Figure 8 shows the sediment supplied to the central Delta by each channel during the 2013 first flush. Eliminating this sediment supply to the Delta would significantly affect the quantity available for subsequent tidal and wind-wave resuspension. Sediment resuspension elevates turbidity and enhances habitat quality.

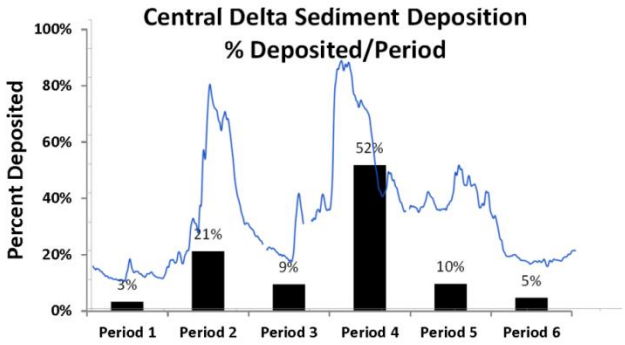

Figure 7. Approximate proportion of sediment deposition during 2011 within the central Delta from 6 different time periods. The blue line represents the tidally filtered FPT hydrograph image superimposed (unscaled) on the graph to show the flow patterns compared to the deposition patterns.

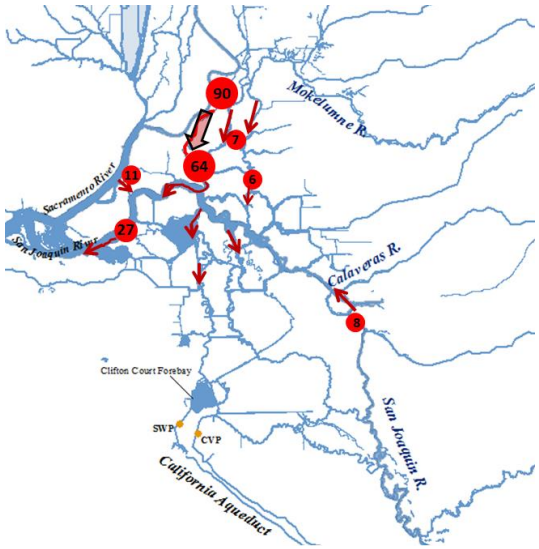

Figure 8. Total estimated sediment loads in thousand metric tons to the central Delta from each channel during 2013 for the time periods described in figure 2. Sizes of circles are intended to represent magnitude of sediment load and arrows represent direction of transport. The Georgiana Slough pathway to the Mokelumne is shown in red underneath the black arrow. The North and South Mokelumne tributaries are represented by one total (seven thousand metric tons).

CONCLUSIONS

The average sediment load during 2011-2013 to each of three Delta regions decreased from north to south. The north Delta has the largest sediment load, but proportionally, the smallest percentage of deposition because the Sacramento River is dominated by advective seaward sediment transport. Sediment supplied by the Sacramento River is additionally advected down various distributaries such as Sutter Slough, Miner Slough, Steamboat Slough, and Georgiana Slough.

Sediment from Georgiana Slough and the Delta Cross Channel is advected towards the Mokelumne River and into the central Delta; a major contribution to the total sediment supply into the central Delta is from the Georgiana Slough pathway. Sediment from Georgiana Slough is advected into the Mokelumne River and, during the 2013 first flush as described in figure 2, was nearly 70% of the load to the central Delta (south of the MOK and east of JPT). Less than 10% of the total sediment supply to this area was from the San Joaquin River during 2013. The 2013 annual sediment supply to the central Delta was dominated by one month of flow from the Sacramento River. If this supply was eliminated during the winter time period via upstream diversions along the Sacramento River, as proposed by the Bay Delta Conservation Plan, or some other means, the sediment supply to the central Delta in the 2013 example would be reduced by 70%.

Net flow (and advective sediment flux) is directed from the central Delta to the south Delta toward the export facilities and has been referred to by others as a hydrodynamic "pull" (Arthur et al. 1996, Monsen et al. 2007, Grimaldo et al. 2007). During low flow conditions both tidal dispersion and the effect of the pump facilities limit seaward transport where there is a predominantly net negative advective sediment flux from the south/central Delta into the south Delta.

THE STUDY OF MOST PROBABLE MEAN DAILY BANKFULL RUNOFF VOLUMES IN SMALL WATERSHEDS DOMINATED BY CONVECTIVE/FRONTAL CHANNEL FORMING EVENTS AND THE CO-INCIDENT INNER BERM CHANNELS – PART I.

Thomas J. Garday, Hydraulic/Civil/Mechanical Engineer
Little Rock AR 72202
meanderingriverman@gmail.com

Abstract

Small watersheds influenced pre-dominantly by rainfall of short-duration (<24 hours), exhibit an inner berm channel that resides below the floodplain. For modelling and calibration; the inner berm and floodplain are two distinct geomorphic stages of hydraulic and hydrologic significance. Bankfull discharge ($Q_{Bankfull}$) and stage represents the incipient floodplain level, the recurrence of $Q_{Bankfull}$ is derived from the annual flood-frequency distribution. Whereas the most probable one-day bankfull runoff volume ($Q_{Daily\ Bankfull}$) and stage coincides with the top of the inner berm sediment deposits (Q_{IB}) and calibrated to a flow duration. Both features can be surveyed and verified using hydraulic & hydrologic analyses and regional bankfull curves (discharge vs. drainage area). Part I presents an empirical procedure to develop ratios of most probable runoff volume to peak ($Q_{Daily\ Bankfull}$ to $Q_{Bankfull}$). Ratios are derived for 34 stream gages stratified by physiographic sections. Thirty three gages have 36 $Q_{Bankfull}$ published in 6 regional curve studies that span the Interior Plains Central Lowland Dissected Till Plains, Appalachian Highlands Piedmont province Piedmont Upland section, and the Atlantic Plain Coastal Plain (western) Embayed section. $Q_{Daily\ Bankfull}$ are derived from published $Q_{Bankfull}$ and calculated ratios, average annual durations are mapped on flow duration curves. Regional $Q_{Daily\ Bankfull}$ curves express Inner Berm growth by power relationships of drainage area. A handful of observations are noted in which published $Q_{Bankfull}$ plots on the $Q_{Daily\ Bankfull}$ regional curve, indicating co-incidence of $Q_{Daily\ Bankfull}$ to a geomorphic surface at Q_{IB}.

INTRODUCTION

A watersheds 'natural bankfull discharge' $Q_{Bankfull}$ is within a range of channel-forming discharges Q_{CF}, where Q_{Peak} is usually in the ~1 to 2-year return interval range ($Q_1 - Q_2$), Leopold, Wolman & Miller (1964). They recognize "*the channel is formed and re-formed during a range of flows lying between the lower limit of competence and an upper limit at which the flow is no longer confined within the channel.*" Wolman & Miller (1960) use 'geomorphic effectiveness' to describe a range of Q_{CF} exceeding threshold forces, that move the most material and perform the most work in modification of surface form. They all agree, $Q_{Effective}$ can often be approximated by $Q_{Bankfull}$, which in many rivers, is ~$Q_{1.5}$. They studied large watersheds whose hydrology was pre-dominantly snowmelt, groundwater or thunderstorm driven. They recognize maximum sediment flux is frequently transported by summer thunderstorms. Ideally, $Q_{Bankfull}$ fills the natural channel to the point of incipient flooding. Discharges above $Q_{Bankfull}$ would spill out onto the adjacent floodplains; suspended sediments and floating debris would transfer away from the channel to act upon the floodplain surfaces. The majority of $Q_{Daily\ Bankfull}$ is contained within the channel to act upon bed and banks dependent on material sizes and critical thresholds attained. $Q_{Daily\ Bankfull}$ is similar to Blench's (1951) dominant discharge *"a steady discharge that would produce the same result as the actual varying discharge."*

Klein (1976) stated one must understand the watershed's hydrologic regime before applying sediment transport equations. He used 'basin peakedness factors" to note hydrologic distinctions in basin characteristics. "Bankfull events" generated in small watersheds by thunderstorms are limited in energy, magnitude, runoff volume and duration; $Q_{Bankfull}$ is usually much larger than $Q_{Daily\ Bankfull}$, such that $Q_{1.5}$ does not produce 24 hours of Q_{CF}. Both Klein and Hewlett & Hibbert (1965) recognize that most of the transportation activity occurs within a short time of the hydrograph peak and recommended to separate 'quick flow' from total flow. Biedenharn & Copeland (2000) propose *for large watersheds* to use a steady mean daily discharge integrated from a flow duration curve with a proper bed-material-load rating curve to determine the flow class interval that moves the largest load fraction. They acknowledge "*mean daily values can under-represent the occurrence of short-duration, high magnitude flow events that occur within the averaging period. On large rivers such as the Mississippi River, the use of the mean daily values is acceptable because the difference between the mean and peak daily discharges is negligible. On smaller streams, flood events may last only a few hours, so that the peak discharge is much greater than the corresponding mean daily discharge."* The inner berm capacity, (Q_{IB}) is shaped over time by various runoff volumes. Melton (1936) recognized the geomorphic significance of the low-flow channel regime: "*those that nearly fill the channel but do not over-top its banks*". Q_{IB} often forms into a non-continuous bench of fine sediments, often vegetated and

alternating banks. Q_{IB} resides at the top of the sediment slope (e.g. point bars), where water slope tends to even out between pools and riffles.

PURPOSE AND SCOPE

In small watersheds where the majority of channel forming events are generated by convective/frontal precipitation (non-snowmelt); the Inner Berm capacity (Q_{IB}) is significant to the sediment regime. Q_{IB} typically convey 99 to 99.4% of all yearly Q_{Daily} at or below the sediment bench stage. In designing stream restoration, bank stabilization, fish passage, and road culvert/bridge crossings, it is important to recognize and match the inner-formation of Q_{IB} to drainage area. Part I outlines a mathematical procedure derived from continuous recording stream gages to estimate the most probable minimum one-day runoff volume ($Q_{Daily\ Bankfull}$), formed by $Q_{Bankfull}$. $Q_{Daily\ Bankfull}$ is the area under a 24-hour bankfull hydrograph; runoff volume and shape sets the duration (T_{CF}) of most effective Q_{CF}. $Q_{Daily\ Bankfull}$ also neatly approximates Q_{IB}. Part II: A study of $Q_{Daily\ Bankfull}$ in the Ninnescah River Watershed, Kansas, compares regionalized $Q_{Daily\ Bankfull}$ curves to surveyed Q_{IB} at fifteen watershed sites, 6 sites include USGS gage stations.

STUDY AREAS

The mathematical procedure is applied on 34 USGS stream gage stations across 4 hydro-physiographic provinces and 7 states. Eight principal authors identified and published 36 $Q_{Bankfull}$ at 33 gage stations: Emmert & Hase (2001) determined $Q_{Bankfull}$ for 8 gages on the Central Lowland Dissected Till Plains (Figure 1). Six gages on the main stem of Soldier Creek (Nemaha & Jackson Counties) allow study of typical growth of Q_{IB} in the downstream direction.

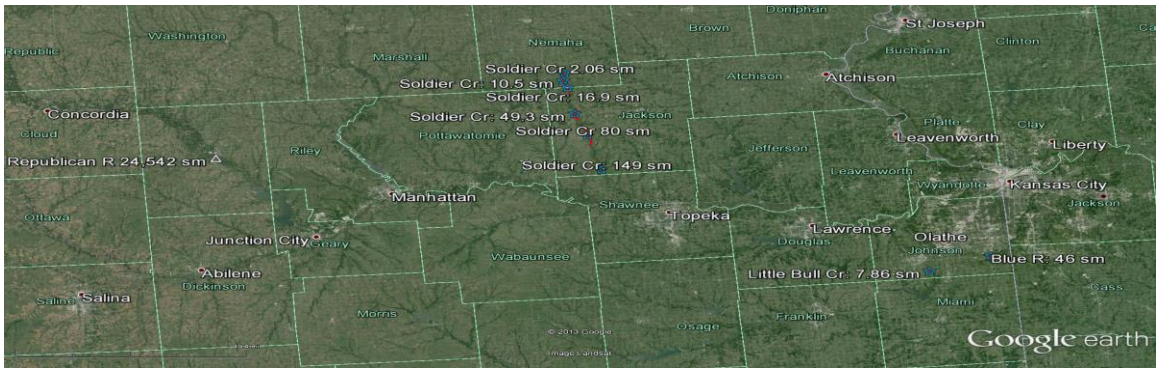

Figure 1 Eight gage locations on the Central Lowland Dissected Till Plains of Kansas

Leopold et al. (1964), White (2001), Cinotto (2003), McCandless et al. (2002), Harman et al. (1999) determined $Q_{Bankfull}$ for 20 gages on the Piedmont Upland section (Figure 2) across Pennsylvania, Maryland, and North Carolina.

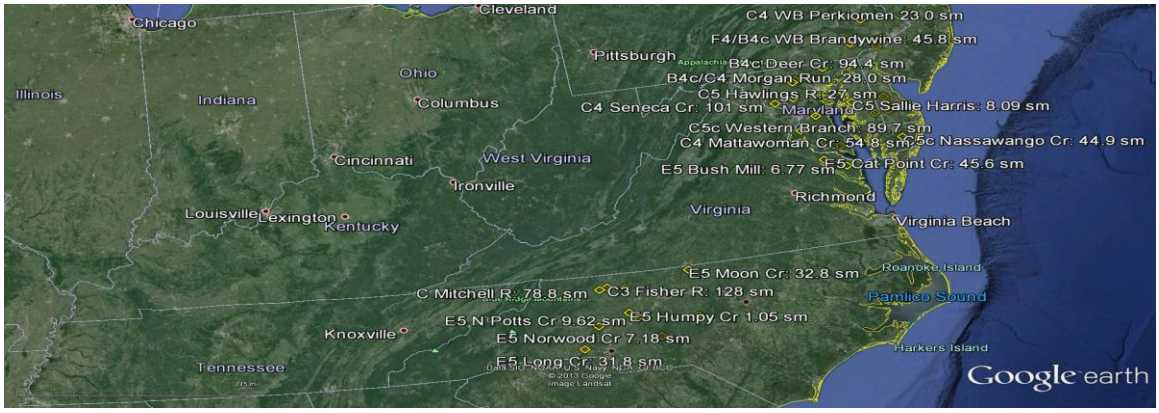

Figure 2 Twenty gage locations on the Piedmont Upland section (PA, MD & NC)

McCandless (2003) and Krstolic et al. (2007) determined $Q_{Bankfull}$ for 5 gages on the Atlantic Coastal Plain, western embayed section (Figure 3) spanning Delaware, Maryland and Virginia.

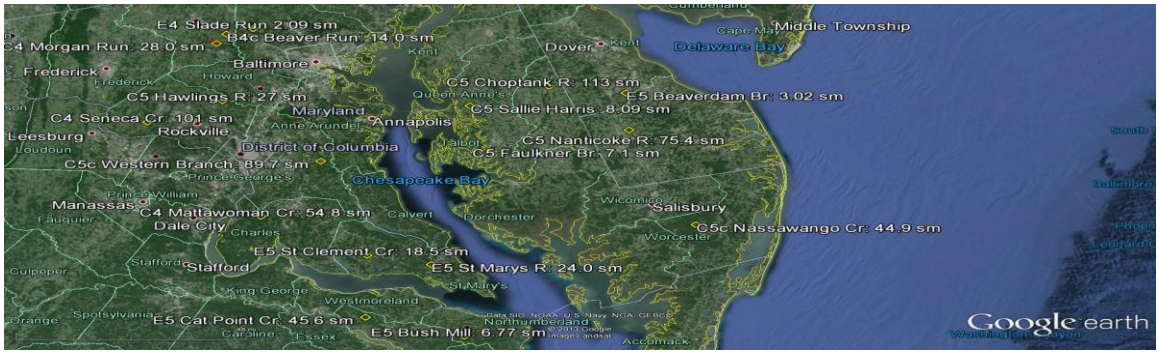

Figure 3 Gages located on the Atlantic Coastal Plain embayed section (DE, MD & VA)

METHODS

Determination of $Q_{Bankfull}$ Return Interval (RI)

The Log Pearson Type III distribution (LPIII) and the 1st order least squares curve-fit of the Weibull distribution are averaged to determine the recurrence intervals of $Q_{Bankfull}$. Outliers (annual Q_{Peak} too high or low) identified in the LPIII process were also removed from the Weibull plotting positions. Figure 4 shows the two flood frequency distributions for Seneca Creek at Dawsonville, Maryland USGS 01645000.

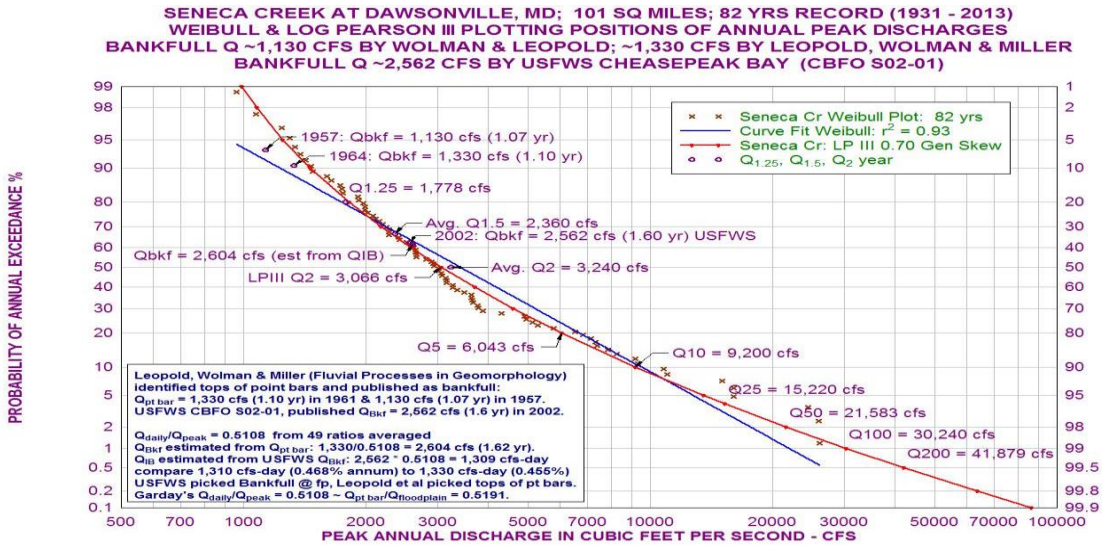

Figure 4 Log Pearson Type III and Weibull Distributions for Seneca Creek, Maryland

Approximation of Most Probable Duration (T_{CF}) for Q > $Q_{Daily\ Bankfull}$

For small watersheds, the bankfull event is modelled as a one-day hydrograph, the area under the hydrograph is $24*Q_{Daily\ Bankfull}$. Assumed hydrograph shape is trapezoidal below $Q_{Daily\ Bankfull}$, and triangular above with $Q_{Bankfull}$ at the apex. The trapezoidal base is 24-hour; it may start and end with or without base flow. The duration (T_{CF}) for which Q exceeds $Q_{Daily\ Bankfull}$ must equal the upper trapezoidal time base at $Q_{Daily\ Bankfull}$. Figure 5 shows the bankfull hydrograph based on these requirements for a gage on Soldier Creek in Kansas. Note the cross-shaded areas below $Q_{Daily\ Bankfull}$ must equal the cross-shaded area above $Q_{Daily\ Bankfull}$.

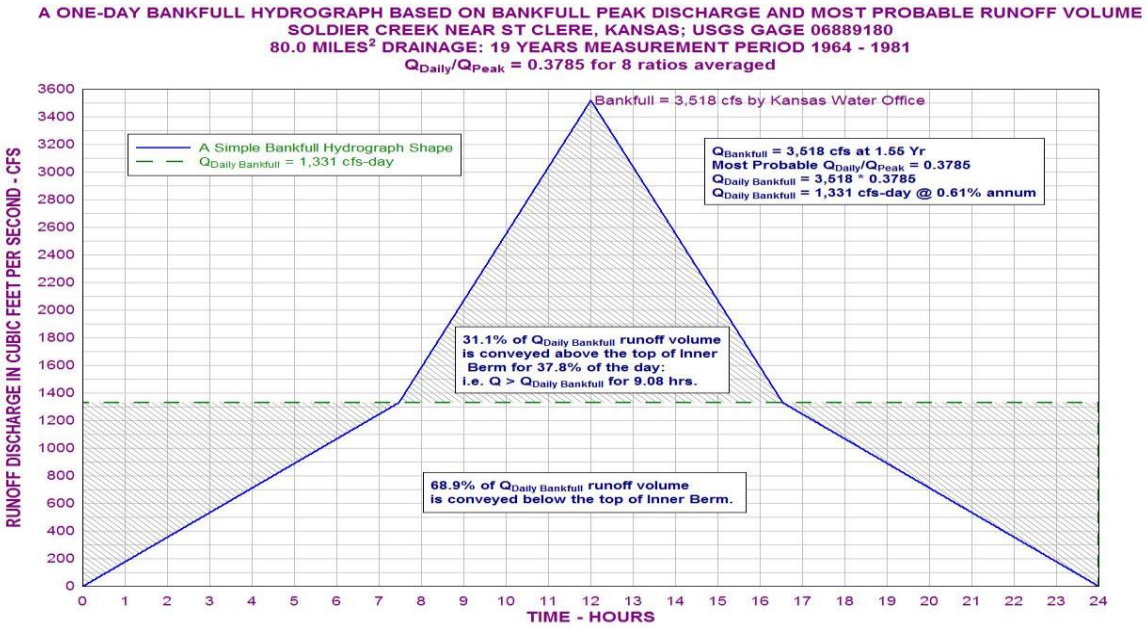

Figure 5 Assumed 1-day bankfull hydrograph shape based on peak and most probable runoff volume.

The duration (hours) of T_{CF}, represents strongest flow (Q exceeds $Q_{Daily\ Bankfull}$) in a minimal bankfull event, it can be solved by setting the sum of the trapezoidal and the triangular areas equal to the runoff volume in cfs-hours.

$$½ * (24 + T_{CF}) * Q_{Daily\ Bankfull} + ½ * T_{CF} * (Q_{Bankfull} - Q_{Daily\ Bankfull}) = 24 * Q_{Daily\ Bankfull} \quad (1)$$

$$T_{CF} = 24 * Q_{Daily\ Bankfull}/Q_{Bankfull}\ (\text{hours})\ \text{for which}\ Q > Q_{Daily\ Bankfull} \quad (2)$$

Computation of the Most Probable $Q_{Daily\ Bankfull}/Q_{Bankfull}$ Ratio

It is further assumed the long-term most probable $Q_{Daily\ Bankfull}/Q_{Bankfull}$ hydrologic ratio can be approximated using sufficient gage data: the average of Q_{Daily}/Q_{Peak} ratios for which Q_{Peak} is in the channel-forming range (Q_{CF}). Q_{CF} in all this work is generally between $Q_{1.25}$ and the mean annual flood (Q_{MA}). In calculating the return intervals of Q_{MA}, high outliers were removed from the flood averages. The return interval of Q_{MA} generally varies from 2.3 to 3.1 years it is somewhat sensitive to number of years of record relative to the magnitudes of floods in the period of record. Q_{MA} being a flood discharge is plotted on the LPIII curve and is not averaged with the Weibull distribution.

$Q_{Daily\ Bankfull}$ is computed as the product of $Q_{Bankfull}$ and the most probable Q_{Daily}/Q_{Peak} ratio.

$$Q_{Daily\ Bankfull} = Q_{Bankfull} * Q_{Daily}/Q_{Peak} \quad (3)$$

Computation is demonstrated using USGS gage 01645000 Seneca Creek at Dawsonville, MD. Seneca Creek $Q_{Bankfull}$ is documented by Leopold et al. (1964) and McCandless et al. (2002). For 82 years of annual maximums, 49 Q_{Peak} qualify as 1-day channel-forming events, 49 Q_{Daily}/Q_{Peak} ratios are averaged: 40 ratios involve Q_{Peak} between ~$Q_{1.25}$ and ~Q_2 and 9 ratios between ~Q_2 and ~Q_{MA}. Single event Q_{Daily}/Q_{Peak} ratios range from 0.12 to 0.75, but cumulatively, the running average or most probable Q_{Daily}/Q_{Peak} ratio converges to 0.51 and remains unchanged (to 2 decimal places) for the largest 15 Q_{Peak} at or below Q_{MA}.

Table 1 lists annual maximum discharges Q_{Peak} (column 3) in ascending order, the *largest* Q_{Daily} of the three days surrounding Q_{Peak} (1-day prior, on, or 1-day after) is chosen, (column 2) and single event Q_{Daily}/Q_{Peak} ratios (column 6). The most probable Q_{Daily}/Q_{Peak} ratio (0.5109) is the mean of all ratios (last value in column 7).

Table 1 Computations of Seneca Creek's most probable Q_{Daily}/Q_{Peak} Ratio

Durations of $Q_{Daily\ Bankfull}$ Annual Exceedance

Each gage is/was a continuous recording gage, (CRG) which produce Q_{Daily} for the respective period of record. Flow duration curves (FDC) were assembled using EXCEL spreadsheets that sorts and counts Q_{Daily} records by water year. Q_{Daily} from all water years are combined into 39 flow class intervals determined by the flow values closest to 100%, 99.99, 95, 90, 85, 80, 75, 70, 65, 60, 55, 50, 45, 40, 35, 30, 25, 20, 15, 10, 9, 8, 7, 6, 5, 4, 3, 2, 1, 0.9, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3, 0.2, 0.1, and 0.05% annual exceedances. One percent annual exceedance (1% annum) is 3.6525 days/year or ~87.66 hours/year. The USGS rounds Q_{Daily} to the nearest integer above 10 cfs-day and to the nearest 10 cfs-day above 1,000 cfs-day. As percent annums are often developed from irrational fractions, it is not always possible to derive an integral flow on the specified exceedance class interval. For Seneca Creek, Q_{Daily} of 29 cfs-day is at 90.5% annum which is the closest integral flow to the desired 90.0% interval.

Leopold, Wolman & Miller (1964) identified bankfull durations of 0.40-0.60% annum common for the Maryland/Pennsylvania Piedmont Upland section (hydrologic records up to 1963). Nixon (1959), who studied rivers in the United Kingdom, concluded bankfull stage is co-incident with flows equaled or exceeded 0.6% annum on the FDC. Figure 6 shows three FDC's with similarities in shape but variations in annual duration of $Q_{Daily\ Bankfull}$. Seneca Creek at Dawsonville is plotted with Hawlings River near Sandy Spring, MD, both Upland section streams with similar $Q_{Daily\ Bankfull}$ durations. Whereas the $Q_{Daily\ Bankfull}$ duration of Beaverdam Branch at Houston, DE on the Coastal Plain (western) embayed section, downslope to the Piedmont Upland section, is ~twice as long.

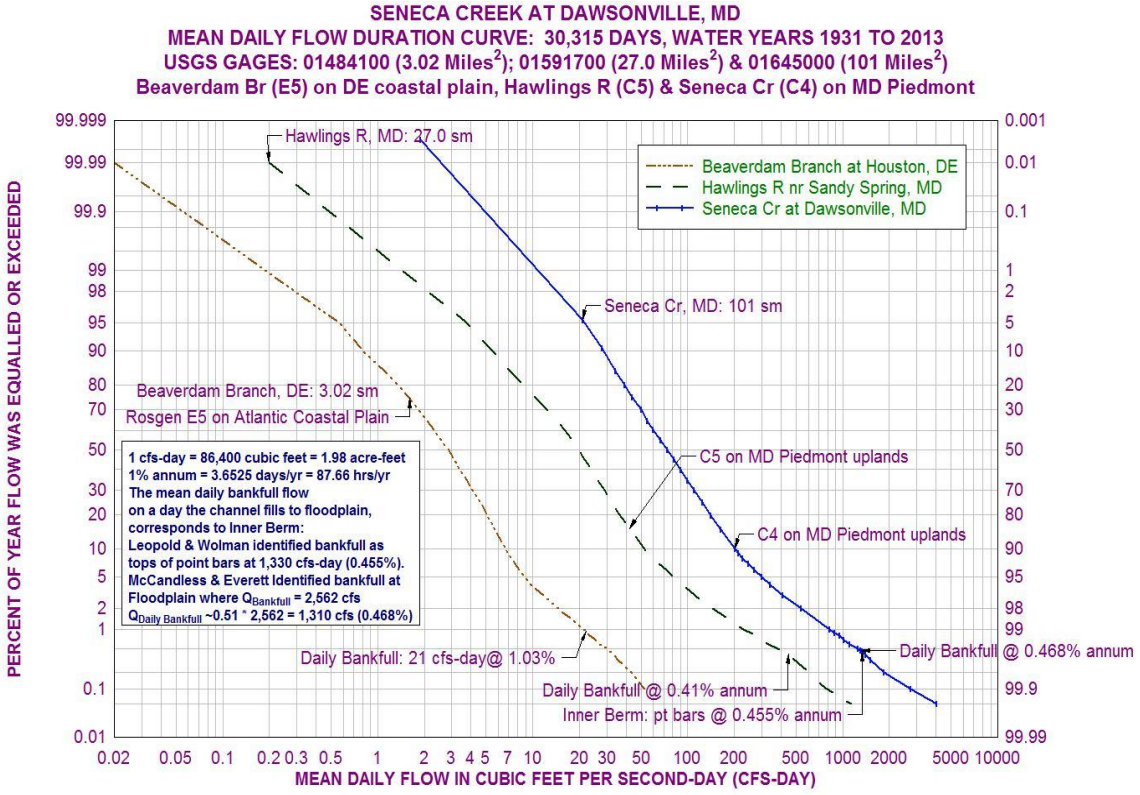

Figure 6 Flow Duration Curves of 3 Rosgen stream types in MD & DE across 2 physiographic regions

RESULTS

The gages (and results) are stratified by physiographic province according to Fenneman (1946). Results are presented in Tables (summarizing published $Q_{Bankfull}$, calculated Q_{Daily}/Q_{Peak} ratios, most probable $Q_{Daily\ Bankfull}$ and associated % annum durations), Figures (plots of Regional $Q_{Daily\ Bankfull}$ vs. DA & $Q_{Bankfull}$ vs. DA Curves), & Equations (first-order curve fits of Regional Curves using the DPLOT plotting program). The two derived power equations are substituted into equation 2 to express most probable duration T_{CF} that flow is above $Q_{Daily\ Bankfull}$.

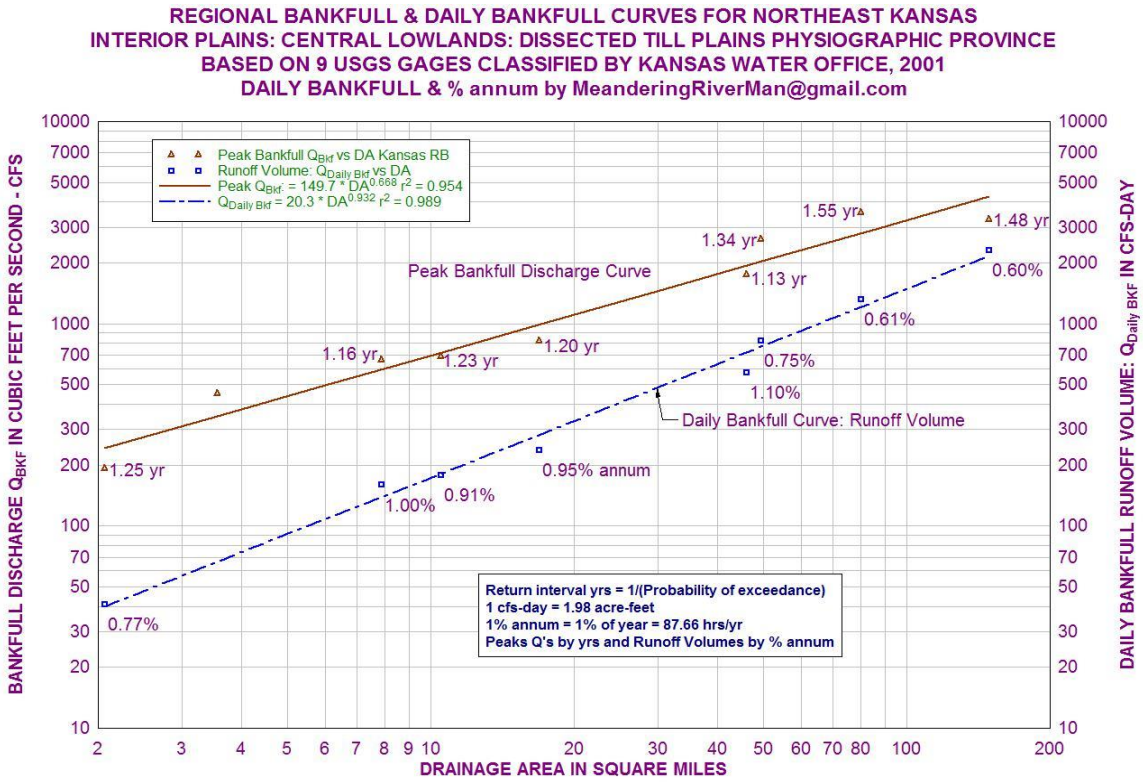

Figure 7 Regional $Q_{Bankfull}$ and $Q_{Daily\ Bankfull}$ Curves for Northeast Kansas

Equations 4, 5 & 6 apply to small watersheds in northeast KS for drainage areas 2.06 miles^2 to 149 miles^2.

$$Q_{Bankfull} = 149.7 * DA^{0.668} \quad \text{(cfs)} \quad r^2 = 0.954 \quad (4)$$

$$Q_{Daily\ Bankfull} = 20.31 * DA^{0.932} \quad \text{(cfs-day)} \quad r^2 = 0.989 \quad (5)$$

$$T_{CF} = 3.256 * DA^{0.264} \quad \text{(hours)} \quad (6)$$

Appalachian Highlands Piedmont province Piedmont Upland section

Generally, the North Carolina watersheds have ~25.3% less annual runoff, ~25% less channel-forming time, but ~22.5% more inner berm capacity than in similar watersheds of Maryland and Pennsylvania. The 20 gage set was stratified further by runoff criteria resulting in two sets of regional curves & power equations. Equations 7, 8 & 9 apply to small watersheds in NC Piedmont uplands for drainage areas 1.05 miles^2 to 128 miles^2.

Equations 13 - 15 apply to small watersheds in DE, MD and VA coastal plain drainage areas 3.02 to 54.8 miles^2.

$$Q_{Bankfull} = 9.516 * DA^{1.195} \quad \text{(cfs)} \quad r^2 = 0.992 \quad (13)$$

$$Q_{Daily\ Bankfull} = 5.497 * DA^{1.179} \quad \text{(cfs-day)} \quad r^2 = 0.996 \quad (14)$$

$$T_{CF} = 13.864 * DA^{-0.016} \quad \text{(hours)} \quad (15)$$

DISCUSSION

The intention in developing $Q_{Bankfull}$ power equations and Regional Curves is not to supersede the work of the original authors, but to demonstrate the r^2 coefficients of the $Q_{Daily\ Bankfull}$ curves are generally better than for $Q_{Bankfull}$.

Co-Incidence of Regional $Q_{Daily\ Bankfull}$ Curves and Inner Berm (Q_{IB})

Seneca Creek: Leopold, Wolman & Miller (1964) published $Q_{Bankfull}$ at 1,330 cfs (1.1 year RI) at tops of point bars, 1,330 cfs-day corresponds to 0.46% annum flow duration. In 2002, McCandless and Everett, published $Q_{Bankfull}$ at 2,562 cfs (1.6 year RI). Using McCandless and Everett bankfull pick and Q_{Daily}/Q_{Peak} = 0.51, (derived from Table 1). Predicted $Q_{Daily\ Bankfull}$ = 2,562 cfs * 0.51 = 1,310 cfs-day at 0.47% annum on FDC, (Figure 6), a 1.6% difference.

$$Q_{Point\ Bar}/Q_{Floodplain} = 1{,}330/2{,}562 = 0.5191 \quad (16)$$

$$Q_{Daily\ Bankfull}/Q_{Bankfull} \sim Q_{Daily}/Q_{Peak} = 0.5109 \quad (17)$$

$$Q_{Daily}/Q_{Peak} \sim Q_{Daily\ Bankfull}/Q_{Bankfull} \sim Q_{Inner\ Berm}/Q_{Floodplain} \quad (18)$$

In Table 4 and Figure 10, $Q_{Bankfull}$ for Bush Mill Stream (01661800) and for Mattawoman Creek (01658000) are plotted to demonstrate that the USGS and USFWS identified geomorphic surfaces at 50 cfs (1.06 year) & 540 cfs (1.18 year) respectively, both plot close to the calculated Q_{IB} curve. On respective FDC's; 50 cfs-day plots at 1.01% annum, 540 cfs-day plots at 1.05% annum, both strongly agree with other $Q_{Daily\ Bankfull}$ durations of gages in the Atlantic Coastal Plain western embayed section.

Table 2, Figures 7 & 11 demonstrate changes in the Q_{Daily}/Q_{Peak} ratios (& $Q_{Daily\ Bankfull}$) of six gages on the main stem of Soldier Creek, (same valley type) are consistent in the *downstream direction.* As drainage area increases the inner berm stage (top of sediment bars) approaches bankfull (floodplain) stage. Simultaneously $Q_{Daily\ Bankfull}$ approaches $Q_{Bankfull}$ and the surrogate Q_{Daily}/Q_{Peak} ratio approaches unity. The two curves are asymptotic, but intersection of two linear curves would define "large watersheds", where Biedenharn & Copeland's (2000) assumptions hold true. Figure 11 is courtesy of Paul D. Miller, P.E. C.F.M., with GBA in Lenexa, KS. Mr. Miller surveyed & analyzed $Q_{Bankfull}$ for gages (red triangles) around the Kansas City area, then super-imposed his set with equations 4 (Central Kansas (Garday) and 5 (Q_{IB} (Garday)). His independent analyses, demonstrates *physical geomorphic features coincident with predicted* $Q_{Daily\ Bankfull}$.

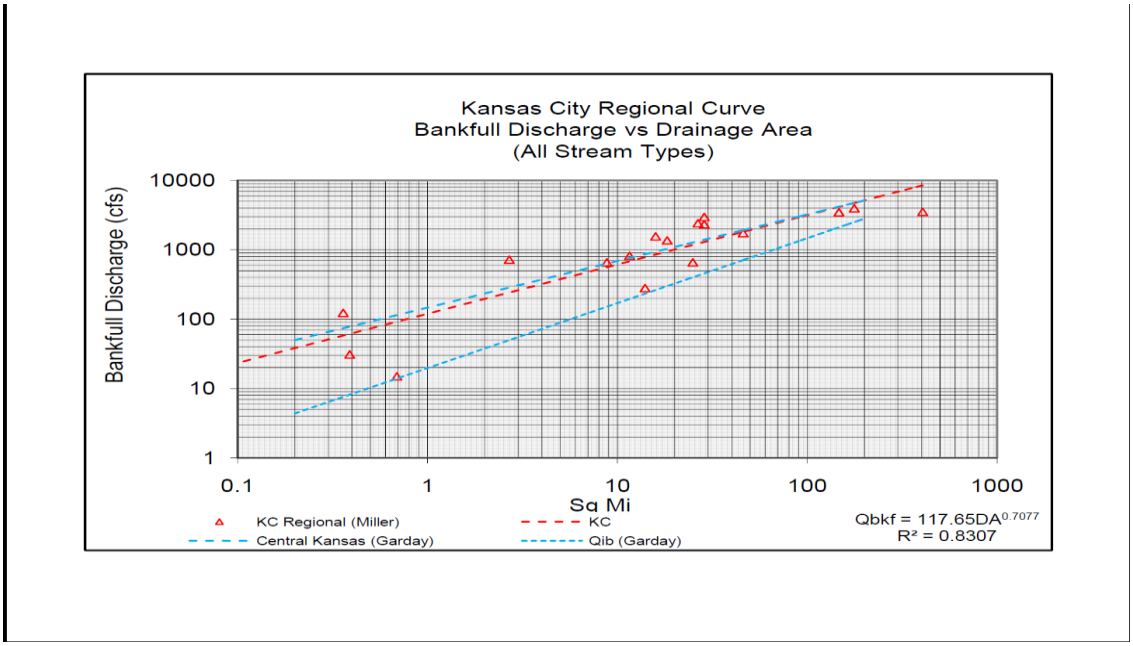

Figure 11 Kansas City Regional Bankfull Discharge Curves, Courtesy Paul D. Miller.

Most Probable Q_{Daily}/Q_{Peak} Ratios

Other methods to determine most probable Q_{Daily}/Q_{Peak} were evaluated: 15-minute instantaneous discharges were analyzed to use the largest 24-hour runoff volume under Q_{CF}. Surveys and analyses of 5 riffle cross-sections on the Sinsinawa River near Menominee; Illinois gage 05414820 at 39.6 miles^2 in the Wisconsin Driftless section: The Q_{Daily}/Q_{Peak} (**0.2243**) from averaging twenty (15-minute interval) storm hydrographs (1989-2004; $Q_{1.27} < Q_{Peak} < Q_{3.11}$) compared to Q_{Daily}/Q_{Peak} (**0.2338**) from averaging twenty three annual maximums (1967-2012; $Q_{1.25} < Q_{Peak} < Q_{2.99}$). Results of geomorphic surveys: $Q_{Bankfull}$ = 1,534 cfs and Q_{IB} = 364 cfs-day at 0.45% annum on FDC. Estimated $Q_{Daily\ Bankfull}$ = 359 cfs-day at 0.46% annum on FDC, actual $Q_{Inner\ Berm}/Q_{Bankfull}$ ~**0.2373**.

ACKNOWLEDGEMENTS

I must credit my survey team members who have shared their professional views and knowledge of riparian riverine systems over the years: Aaron Pugh, USGS geologist/hydrologist; Ron Redman, biologist/surveyor/WQ specialist, Arkansas Natural Resource Commission; Danny Goodwin, geographer/groundwater specialist, USDA NRCS; Christopher Haring, USACE geologist, Rock Island District. I would also like to thank Paul Miller, for sharing his Kansas City Regional Curves and all organizations - local, state, and federal, who have contributed funding to the USGS stream gage network, **Thank You**.

Abstract: The evolution of gravel-bed rivers has major implications for the management and restoration of these streams and their associated aquatic habitat. This is particularly true in braided rivers, where abundant sediment supply and rapid fluctuations in streamflow lead to a high degree of dynamism. Because channel evolution frequently results from decadal to centennial scale forcings such as shifts in water or sediment supply, these timescales of change often preclude field-based measurement of channel morphodynamics. One potential alternative to field-based observation is numerical modeling. However, no morphodynamic model for gravel-bed rivers exists that can predict channel evolution at relevant spatiotemporal scales (e.g. decadal to centennial timescales at bar-scale resolution). Here we present a new event-based morphodynamic model that couples hydraulics driven by computational fluid dynamics with a simplified sediment routing algorithm based on sediment travel distances derived from field and laboratory data. This model efficiently quantifies morphodynamics at spatiotemporal scales coincident with those of channel change. Sediment travel distances, or path lengths, are estimated using morphologic unit spacing in modeled channels. We validate this model using high-resolution laboratory flume and field data collected annually on braided rivers. This morphodynamic model closes a longstanding knowledge gap in our ability to predict channel response at meaningful spatiotemporal scales. When used as a scenario-based exploration tool for predicting channel response to altered hydrologic or sediment regimes, it may provide valuable guidance for the management and restoration of gravel-bed rivers.

INTRODUCTION

Some of the most commonly studied processes in riverine environments occur over time and space scales that render traditional field-based observation impractical or impossible [Gurnell et al., 2009]. These fluvial dynamics include channel migration [Hooke, 1995; Black et al., 2010], shifts in channel form [Landon et al., 1998; Kondolf et al., 2002], and alterations in hydrology and/or sediment delivery [Kondolf, 1997; Montgomery and Buffington, 1998; Grams and Schmidt, 2005]. All of these dynamics occur frequently on timescales ranging from decades to centuries, and channel response to hydrologic and sediment regime shifts may manifest across a variety of spatial scales ranging from individual channel units (e.g. meters) to reaches spanning several kilometers. In such instances where the spatiotemporal scale of channel response renders field-based methods of observation intractable, representation of the fluvial environment using numerical models is invaluable both in terms of disentangling the relative efficacy of competing processes acting to shape channels and predicting future channel response to geomorphic forcings [Nicholas, 2005; Gurnell et al., 2012].

Despite the immense value of numerical models in the explanation and prediction of fluvial processes, the timescales at which channel evolution occurs render most available morphodynamic models (those which predict changes in channel form over time) impractical. Historically, one way of dealing with this problem has been to simplify the physics involved in modeling, giving rise to the so-called ‘reduced complexity’ or 'cellular automata' models [RC/CA; Murray and Paola, 1994; Coulthard et al., 2002; Thomas and Nicholas, 2002]. These models simplify the transport of water and sediment across a cellular network representing the riverscape using a rule set governing each process involved. Because these rule sets are simplified representations of the physics involved in hydrodynamics and sediment transport, RC

models achieve a great deal of computational efficiency, allowing calculations over large spatiotemporal extents (e.g. kilometer-scale, decadal-to-centennial timescales; Nicholas and Quine, 2007; Thomas et al., 2007). Yet this computational efficiency comes at the expense of field realism; because of the simplified nature of the physical processes, particularly the inability to conserve hydraulic momentum leading to inaccurate representation of pool dynamics and meander migration [Nicholas and Quine, 2007], reduced complexity models often fail to reproduce observed channel behavior at the spatial scales of change.

On the other hand, the subset of morphodynamic models driven by computational fluid dynamics (CFD; Bates et al., 2005) involve hydrodynamic components that approximate the solution of the Navier-Stokes Equations and subsequently drive sediment transport. To ensure computational stability, morphodynamics are typically computed by solving a form of the Exner equation (1) of sediment continuity (Paola and Voller, 2005) at fine time steps (seconds-minutes). The Exner equation predicts bed elevation change over time ($\partial z/\partial t$) as a function of sediment porosity (γ_p) and the spatio-temporal divergence of sediment flux (∇Qs). This reliance on rapid calculation of morphodynamic evolution comes at the cost of vastly increased computational overhead, making CFD-driven morphodynamic models suitable only over fine spatiotemporal scales for most users (e.g. hours-months at meter-scale resolution; Ferguson, 2007; Coulthard and Van de Wiel, 2012).

$$\frac{\partial z}{\partial t} = \frac{1}{1-\gamma_p}\left(\frac{\partial V_s}{\partial t} + \nabla \cdot Q_s\right) \quad (1)$$

We hypothesize that the fusion of CFD and RC-based morphodynamic modeling may present a novel way forward, in that the high spatial fidelity afforded by CFD-driven models may be coupled with a simplified, empirically-derived rule set for sediment transport and morphodynamic channel evolution (cf. Nicholas and Quine, 2007). As such, this paper presents a new, hybrid morphodynamic model termed the *Model of Riverine PHyiscal form and Ecohydromorphic Dynamics (MoRPHED.)*

THE MODEL

As with previously-developed morphodynamic models, MoRPHED contains routines for simulating hydrodynamics and uses these calculations to drive sediment transport. This section details the methods used in in each of these components, along with ancillary routines such as the parameterization of model boundaries, sediment grain size, and bank erosion. A flowchart of model operation along with required/optional inputs and outputs are shown in Figure 1, and these components are discussed throughout this section. The salient components of the model that directly impact our validation results are discussed here.

Hydraulic Model: The hydraulic component of MoRPHED is driven using the freely-available, open-source Delft3D software (Version 4.00.01, Deltares, Delft, Netherlands). Delft3D solves the shallow-water form of the Navier-Stokes equations, and herein we employed the model in two-dimensional (depth-averaged) form, as this provided an ideal compromise between computational efficiency and the ability to resolve hydraulics at the scale of our DEMs [Lane et al., 1999]. For all modeling, we employed Cartesian orthogonal grids generated using the RGFGRID module of the Delft3D suite and kept constant throughout a modeled event series, and adjusted the model time step to satisfy the Courant-Friedrichs-Levy condition. Models were run at a steady upstream discharge and were allowed to run to steady state (no observed change in depth, velocity, or inundation extent in QUICKPLOT model postprocessor).

For all simulations, discharge was specified at the upstream boundary and a corresponding water surface elevation was set at the downstream boundary. Delft3D requires an input DEM, along with simulated water discharge and boundary conditions. The downstream water surface elevation for each modeled

discharge was used to parameterize the hydraulic model boundary, and was calculated by determining reach-scale conveyance associated with reach-average slope and roughness [cf. USACE, 2010]. Although numerous hydraulic variables can be computed and exported from Delft3D, here we used (a) water depth, (b) flow velocity resolved into streamwise and lateral components, and (c) bed shear stress.

MoRPHED is an event-scale model, predicting channel evolution at the scale of individual floods. We do this for two reasons, (a) because the calculation of morphodynamics at coarser intervals allows for greatly reduced computational overhead associated with the model, and (b) because we argue that modeling at finer intervals, while allowing the ability to capture rapid transient events such as prograding bedload sheets and bank retreat during the course of a single flood, is difficult if not impossible to validate since the most common data geomorphologists have describe channel form only before and after a single event [Bertoldi et al., 2010; Williams et al., 2013; Mueller et al., 2014] along with sediment transport resulting from that event [Pyrce and Ashmore, 2003a, 2003b; Snyder et al., 2009; Kasprak et al., 2015].

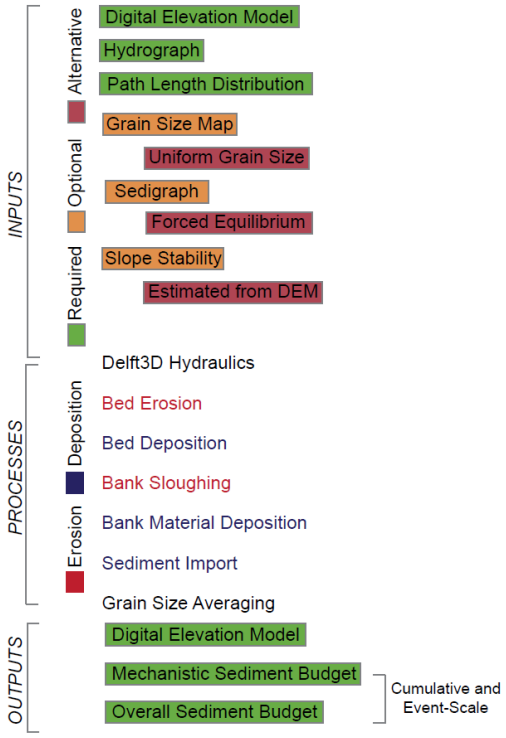

Figure 1 Flowchart of modules included in MoRPHED and their operation

Sediment Entrainment: MoRPHED employs a critical nondimensional value of the bed shear stress (Shields stress) to determine whether sediment can be entrained at a particular location. As our model is developed and used on gravel-bed rivers, the theory and threshold values of Shields stress for entrainment have been well studied in these settings. Incipient motion for gravel occurs when the Shields stress (τ^*) exceeds 0.03-0.07 [Buffington and Montgomery, 1997; Snyder et al., 2009]:

$$\tau^* = \frac{\tau_B}{(\rho_s - \rho)gD} \tag{2}$$

where ρ_s is sediment density (2650 kg/m^3), g is acceleration due to gravity, and D is the median particle size (see Section 2.4). The bed shear stress (τ_B) was computed using the output from Delft3D.

[Montgomery et al., 1996] proposed an event-scale model to predict sediment scour depth (D_s):

$$D_s = \frac{Q_b}{u_b \rho_s (1-\gamma)} \tag{3}$$

where Q_b is the average bedload transport rate during the event, u_b is the bedload velocity, and γ is the bed sediment porosity. Estimating Q_b, while straightforward, is often inaccurate as it is a strongly nonlinear process; however, most transport relations take a power-law form (e.g. Meyer-Peter Müeller equation):

$$Q_b = (\tau_b - \tau_{bC})^{1.5} \tag{4}$$

where the critical bed shear stress is given for a particular grain size by rearrangement of Equation 2. Bedload velocity is calculated via an equation of the form:

$$U_b = a(u_* - u_{*C}) \tag{5}$$

where u_*, the shear velocity, is computed as

$$u_* = \sqrt{\frac{\tau}{\rho}} \tag{6}$$

Which can be estimated directly from the bed shear stress obtained from Delft3D. The constant a in Equation 6 has been studied by many researchers [Garcia, 2008], and is generally around 9.

Sediment Transport and Deposition: Once entrained, sediment is mobilized downstream along flowlines which are delineated using velocity components from Delft3D to calculate velocity vectors.

At each cell along the flowpath, the volume of sediment to be deposited is given by a path length distribution (Figure 2). In the simplest sense, this distribution details the proportion of all eroded sediment which is deposited at a particular distance downstream. These distributions have been studied by numerous researchers and found to take several forms in braided rivers. Exponential decay, or heavy-tailed distributions (Figure 2A) are marked by a large number of particles that are mobilized short distances downstream, and may result from floods that do not generate sufficient shear stress for particle transport across the braidplain [Pyrce and Ashmore, 2003a, 2003b]. During floods which are competent across large areas of the braidplain, typical path length distributions exhibit peaks which correspond to the location of likely depositional sites downstream (Figures 2B, 2C). Kasprak et al. [2015] and Pyrce and Ashmore [2003a, 2003b] both noted that these depositional sites were most frequently the location of bar heads (e.g. flow diffluences; those places where one anabranch splits into multiple channels). As such particle path length distributions could be readily constructed using morphometric indices which described the characteristic diffluence spacing in braided channels. MoRPHED deposits sediment in cells along delineated flowpaths in a volume given by the path length distribution, which is specified by the user and can take a variety of forms in the model with chosen moment statistics (Gaussian, Exponential Decay, or any user-defined shape input using a text file).

Sediment Import and Export: For each simulated event, MoRPHED tracks the volume of sediment passing the downstream or lateral reach boundaries. In effect, export of sediment occurs when the user-specified path length distribution is longer than the flowpath delineated from a particular erosion cell. When this occurs, the remaining volume of sediment is recorded by MoRPHED as having been exported from the reach. Sediment import is user-specified and can be (a) set equal to the volume of sediment export during the preceding event (e.g. sediment equilibrium; Grams and Schmidt, 2005; Mueller et al.,

2014), (b) specified as a percent of sediment export during the preceding event, or (c) specified via a text file detailing volumetric sediment import during each event (e.g. sedigraph timeseries). Algorithmically, MoRPHED computes flowpaths from each wetted cell at the upstream reach boundary and distributes the total volume of imported sediment to each cell of each flowpath as specified in the user-input path length distribution.

MODELING SITE

The wandering gravel bedded River Feshie (Figure 3) is a tributary of the River Spey and drains 231 km^2 of mountainous, postglacial terrain. Underlain by metamorphic and igneous rocks, the basin ranges from around 230 m to 1260 m in elevation. The mean flow near the river's outlet was reported by Ferguson and Werritty [1983] as 8 m^3/s with Q_5 = 80 m3 sec^{-1}. Topographic data for the 1 km study reach of the Feshie consist of nine years of resurveys (2000, 2002-2008, 2013) comprising more than a decade of channel change using RTK-GPS (2000-2006) along with TLS and RTK-GPS fusion scans performed for three years (2007-8, 2013). Additionally, the Feshie dataset contains continuous hydrograph data (~55 years) and aerial photo records (~60 years), along with UK Ordnance Survey channel planform maps dating to 1869. The Feshie has been the site of a great deal of previous research ranging from bar morphodynamics [Ferguson and Werritty, 1983; Wheaton et al., 2013], development of riverine survey and DEM-differencing/change detection methodologies [Brasington et al., 2000; Hodge et al., 2009; Wheaton et al., 2009, 2013] and ongoing morphodynamic modeling efforts [Raj Baral et al., In Prep.]. The combination of annual resurveys capturing over a decade of channel change in combination with mapping and aerial photographs dating back over a century make the Feshie an ideal candidate with which to examine the performance of MoRPHED at annual and decadal scales.

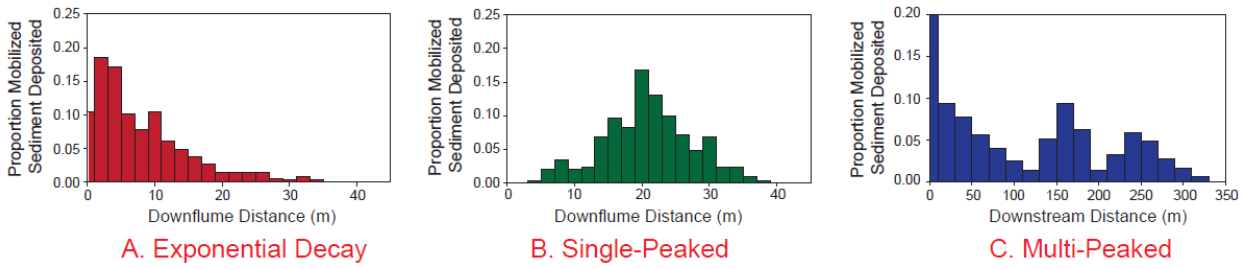

Figure 2 Example path length distributions

RESULTS AND ANALYSIS

Hydraulic Modeling and Validation: The use of Delft3D to model two-dimensional hydraulics in braided, gravel-bed rivers is discussed extensively by Williams et al., [2013], who specifically applied the model to the braided River Rees in new Zealand. As with Williams et al. [2013], the inundation extent outputs of Delft3D on the Feshie were compared with field-surveyed values and used to calibrate the model parameters (Colebrook-White roughness and horizontal eddy viscosity) until good agreement was reached.

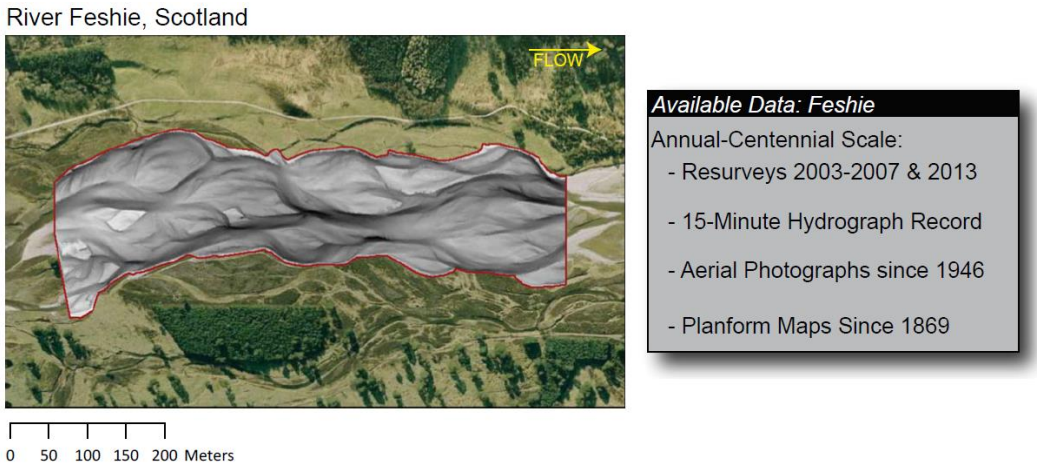

Figure 3 River Feshie modeling reach; base is a 2014 aerial photo with 1 m hillshade overlay

We leveraged existing surveys of wetted areas from 2003-2007 in concert with surveyed water depth in those years to examine the performance of Delft3D with regard to inundation extent and flow depth at randomly selected points across the braidplain. Because field surveys were conducted at low flows to facilitate rapid measurement of braidplain topography, here we are only able to validate the results of Delft3D at these low flows. However, Delft3D has been employed and validated on gravel-bed braided rivers at flood stage [Javernick, 2014], demonstrating that the model can accurately reproduce flood-stage hydraulic features and can be used to drive morphodynamic evolution at the event-scale. For modeling on the Feshie, we estimated discharge by downscaling the average observed flow for the relevant survey period at the nearest gauging station (SEPA # 8013, Feshie at Feshiebridge) located approximately 11 km downstream, using a coefficient of 0.71 [Wheaton et al., 2013]. We estimated the downstream water surface elevation using surveyed inundation extent in combination with the DEM for each year modeled. Downstream water surface elevations estimated from the spatial data were cross-checked using a reach-scale conveyance calculation [Williams et al., 2013].

Results of our validation of Delft3D on the Feshie at low flow are shown in Figure 4. Here we report (a) the mean of depth differences between modeled and observed values (D_{diff}), along with (b) the congruence of the modeled and measured inundation extents (F_c; cf. Bates and Roo, 2000) as described by the ratio of intersection and union areal extents. These two metrics are described by equations 12 and 13, respectively.

$$D_{diff} = \frac{\sum_i^n x_{mod} - x_{obs}}{n} \tag{7}$$

$$F_c = \frac{IA_{obs} \cap IA_{mod}}{IA_{obs} \cup IA_{mod}} * 100 \tag{8}$$

The validation metrics indicate that at low flow, Delft3D accurately predicted both depth and inundation extent across the Feshie study reach. Both D_{diff} and Fc are consistent with validation work performed by Williams et al., [2013], and are indicative of good agreement between hydraulic model and field-observed flow characteristics.

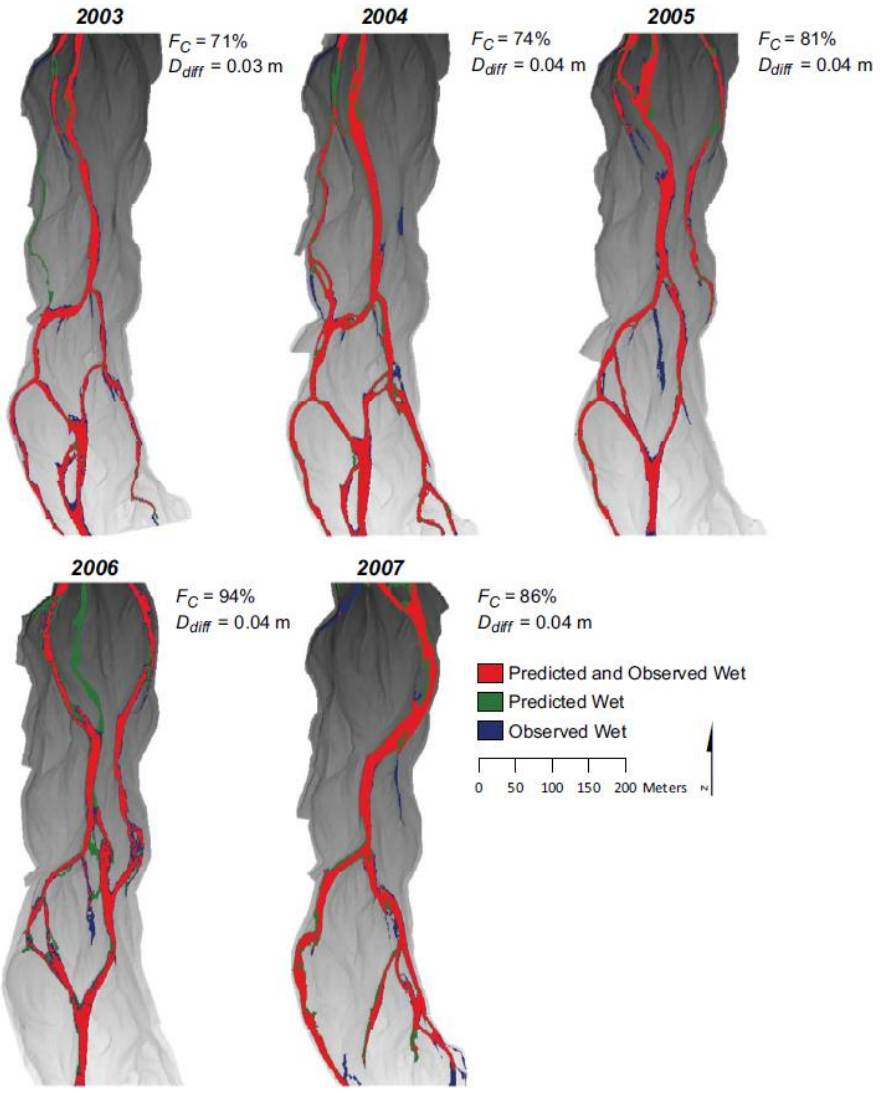

Figure 4 Hydraulic model validation on River Feshie. Mean depth of difference (D_{diff}; Equation 7) and congruence of fit (C_f; Equation 8) are shown for five years of survey data.

Morphodynamic Model Outputs: We modeled two one-year periods using MoRPHED, (a) the period between 2003 and 2004 and (b) the period between 2006 and 2007. We modeled the peak discharge of each flood over 42 m^3/s (high bankfull discharge; Wheaton et al., 2013), for a total of 5 floods in 2003-2004 and 16 floods in 2006-2007. For the hydrologic record and flood peaks over 42 m^3/s, see Wheaton et al., [2013]. We set sediment import equal to sediment export for each model run (reach-scale equilibrium; Figure 1). Though variable grain size is available in MoRPHED, a constant grain size of 0.1 m (representative D_{50} for the Feshie reach; Hodge et al., 2009) was used in these simulations. Bank erosion was not included, as refinement of process representations for lateral channel migration is ongoing. Modeled floods and resultant DEMs-of-Difference (DoDs) from the 2003-2004 and 2006-2007 model periods are shown in Figure 5 and compared with field-surveyed DoDs from the same period.

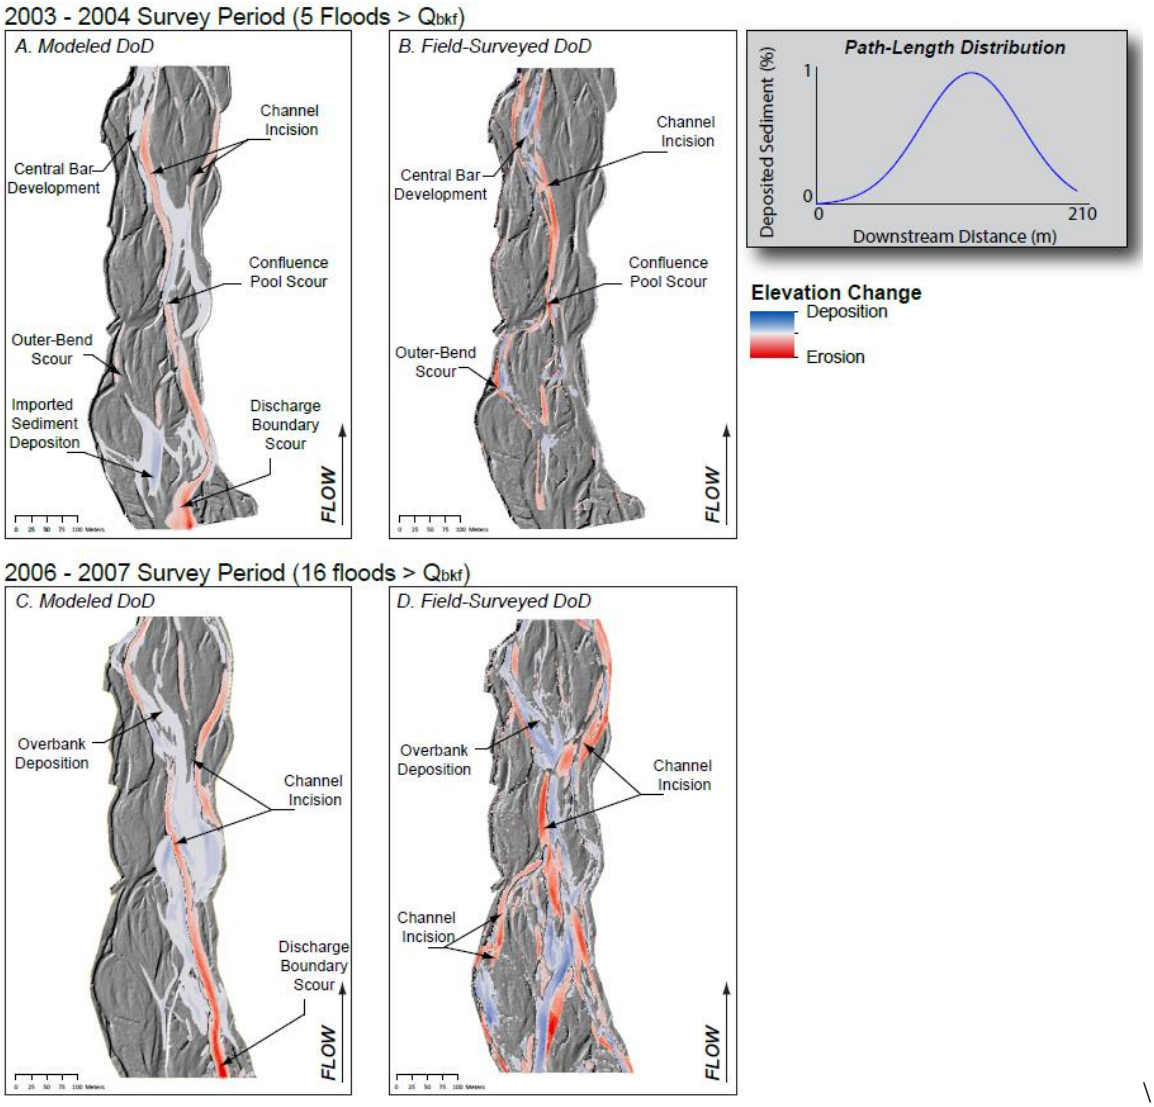

Figure 5 Modeled (A, C) and field-surveyed (B, D) geomorphic change on the River Feshie for 2003-2004 and 2005-2006 periods. DoDs are thresholded to only display geomorphic change greater than 0.1 m in magnitude.

For the 2003-2004 simulation, results of MoRPHED modeling agree reasonably well with geomorphic change observed in field surveys (Figure 6A, 6B). Continuous channel incision along the main anabranch is reproduced, along with bar edge trimming and associated deposition at the downstream end of the study reach. High-magnitude confluence pool scour is observed in both model and field surveys. However, while sediment scoured at the confluence is deposited immediately downstream in the MoRPHED simulation, this sediment appears to have been transferred further downstream (or out of the reach entirely) when examining the results of field surveys (Figure 5B).

In the 2006-2007 simulation, MoRPHED does not reproduce field-surveyed changes as well (Figure 6C, 6D). While certain areas of change are seen in both field and modeled data (e.g. channel incision and overbank deposition near the downstream end of the reach), the model does not appear to reproduce the dynamics of the numerous anabranches that underwent geomorphic change across the braidplain. We believe the simplified planform produced by MoRPHED is largely the result of not explicitly including

bank erosion in the model. As such, focused erosion leads to a largely single-thread channel planform, rather than lateral channel migration forcing avulsions and a dynamic braided channel planform [Ferguson, 2007]. Implementation of a bank erosion algorithm is an ongoing component of MoRPHED model development.

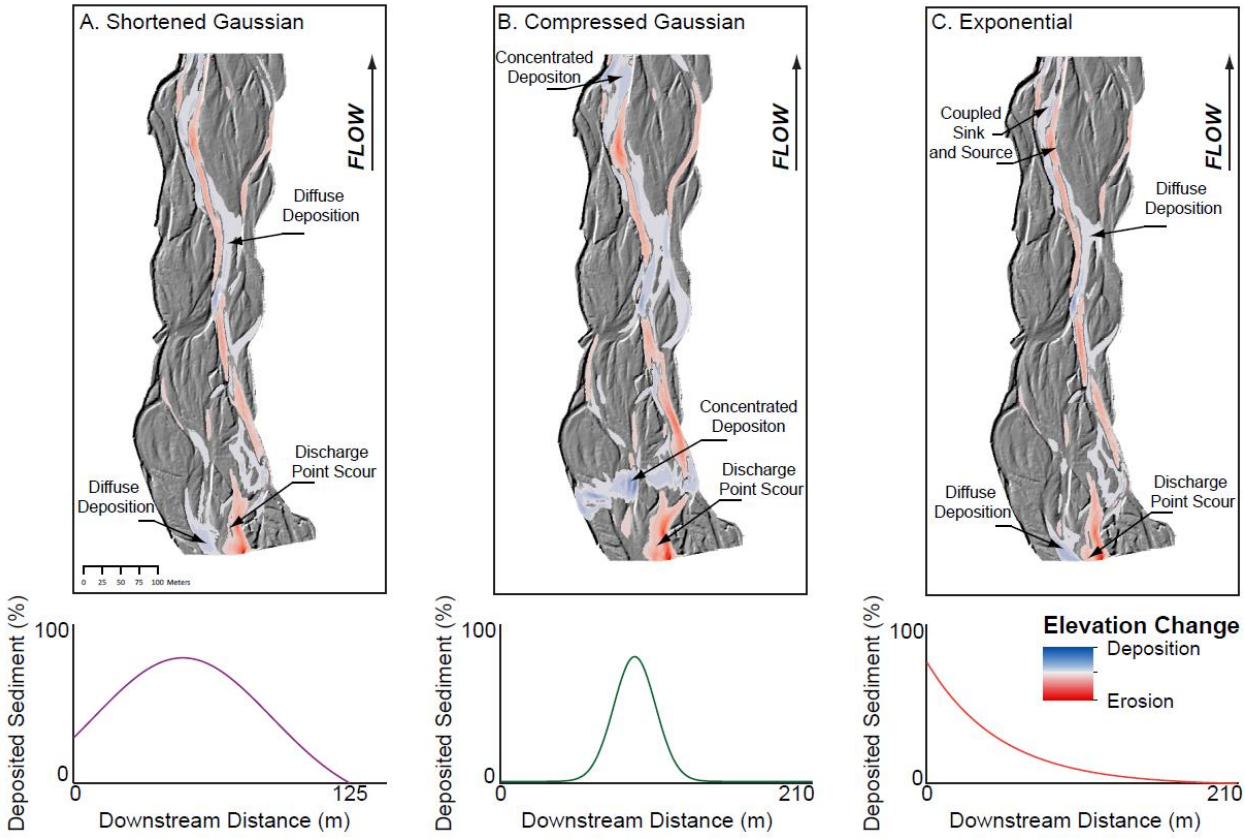

Figure 6 Results of modeling 2003-2004 period using three different path length distributions. DoDs are thresholded to only display geomorphic change greater than 0.1 m in magnitude.

In each model run, inaccuracies due to boundary effects can be observed, with high-magnitude scour at the upstream end of the reach due to channel bed erosion at water discharge points used in the Delft3D model. This scoured sediment (along with imported sediment) creates areas of deposition that were either (a) not observed in field surveys (Figure 6A, 6B), or were observed in a different anabranch than predicted by the model (Figure 6C, 6D).

Morphodynamic Process Representations: Whether or not certain processes are included in any morphodynamic model, along with the algorithms by which those processes are represented, has major implications for the computation efficiency and field-realism of the output solution. To this end, MoRPHED is not only a working morphodynamic model, but perhaps more importantly, provides an interchangeable framework by which users can explore the morphodynamic results of altering process representations. To illustrate this, we conducted three additional simulations using the 2003-2004 discharge record, each of which employs a modified path length distribution (Table 1). The results of these simulations are shown in Figure 6.

Table 1 Path length distribution parameters used in process representation modeling

Name	**Length (m)**	**Coefficient 1**	**Coefficient 2**
Default	210	$\sigma = 40$	$\mu = 125$
Shortened Gaussian	125	$\sigma = 40$	$\mu = 50$
Compressed Gaussian	210	$\sigma = 10$	$\mu = 125$
Exponential	210	$a = 0.1$	$b = 0.2$

While the shortened Gaussian and exponential distributions produced relatively similar model outputs, the compressed Gaussian distribution produced morphologies that reflected the high degree of coupling between erosion and deposition sites. This is particularly visible when observing the high-magnitude deposition resulting from sediment import or the concentrated deposition resulting from central bar trimming in Figure 6B. In Figures 6A and 6C, the deposition resulting from this bar scour is more longitudinally diverse, reflecting that deposition is spread over larger areas in the shortened Gaussian and exponential distributions. The focused nature of deposition in the compressed Gaussian distribution also has implications for erosion, with more high-magnitude erosional areas visible in Figure 6B; these erosional areas were likely not counter-balanced by the extensive depositional sheets seen in Figure 6A and 6C, and occur as more longitudinally-continuous, low-magnitude areas of scour.

CONCLUSIONS

This research seeks to develop a morphodynamic model that combines aspects of computational fluid dynamics with simplified morphologic-sediment transport relations to minimize computational overhead and allow increased simulation time at high spatial resolution. The MoRPHED model developed here has been run over two annual periods along a wandering, gravel bed river. During the 2003-2004 period, which was marked by a small number of peaks over the bankfull discharge (n = 5), the model reproduced field-surveyed geomorphic change reasonably well, although differences in the location of deposited sediment were observed, along with inaccuracies resulting from discharge point locations used in the hydraulic component of MoRPHED. In the 2006-2007 simulation, which was marked by a greater number of flows exceeding bankfull discharge (n = 16), the absence of a bank erosion algorithm in MoRPHED was notable, as the channel tended towards a single-thread planform in model simulations. Ongoing development of MoRPHED seeks to implement bank erosion dynamics and refine model boundary parameterization. MoRPHED is open-source software which is freely available at http://morphed.joewheaton.org, along with user manuals, tutorials, and example datasets.

ACKNOWLEDGEMENTS

Development of MoRPHED is supported by the National Science Foundation (Award #7086465). Extensive development assistance is provided by Philip Bailey (North Arrow Research), Matt Nahorniak (South Fork Research), James Brasington (Queen Mary University of London), and James Hensleigh, Sara Bangen, and Eric Wall (all of Utah State University and EcoLogical Research).

Ball, Hydraulic Engineer, PE, CFM, USACE Seattle District, Seattle, WA travis.d.ball@usace.army.mil; Matthew J. Hubbard, Engineer 1, Brown and Caldwell, Tacoma, WA, mhubbard@brwncald.com

Abstract: This paper presents a simple, robust, and relatively efficient workflow to create and "burn in" high resolution synthetic river bathymetry data into existing LiDAR datasets. The Synthetic Bathymetry (SB) method uses widely available GIS and hydraulic modeling techniques to create physically-based synthetic bed elevation data without introducing significant error in computed water surface elevations and average channel velocities, under conditions where discharge at time of DEM data acquisition is known. The SB method was applied and validated on a small, steep, braided cobble bed river, large and small cobble bed wandering rivers with wide floodplains, and a small, entrenched, low gradient river with tidal influence all in Washington State – as well as a very large, flat gradient reservoir reach in Montana. As a test of the validity of the approach the results of models based on SB data were compared against models based on traditional survey methods, and against models based on LiDAR alone. For low (base) flows, bankfull (2-year) and 100-year flood flows the differences in computed water surface elevations, inundation area, and velocity were small (MAE in water surface elevation of less than 1 foot for all 5 study reaches under low flow, and less than 1 foot for all but the reservoir reach under 2 year and 100-year flood flows). At lesser flood flows to bankfull flows, the MAE in stage is modestly higher, as compared with the baseline models. For the reservoir reach, the model results were generally poor during 100-year flood flows as compared with the other rivers, however the error reduction in water surface elevation (from use of an unadjusted DEM alone) was nearly 30 feet. The good to excellent agreement of the SB models to the baseline in four of the five study reaches is attributed to the ability of the SB method to create the flow area needed to convey flood flows at comparable stages and velocities as survey based models. The SB method holds promise for speeding up and reducing the cost of 1-D and 2-D hydraulic modeling efforts where multiple decimal place accuracy is not required. The SB method can significantly reduce error in cases where only a DEM is available, and reduce the need for tedious, subjective terrain data manipulation commonly associated with interpolation between widely spaced cross sections. The SB method could improve the quality of models in cases where site conditions (unstable channel, remoteness, turbidity, safety) prevent bathymetric data collection but otherwise allow for above-water aerial survey techniques (photogrammetry, satellite, LiDAR, Structure from Motion). Other potential uses include estimation of bed elevations to track sediment movement under rapidly changing conditions, such as below a dam removal.

INTRODUCTION

This paper presents a relatively simple technique for creating physically based riverine bathymetric data from digital elevation models (DEMs) and discharge data using GIS and the US Army Corps of Engineers software HEC-RAS (USACE 2014). For the purposes of this paper DEM pertains to topographic datasets derived from photogrammetry or Light Detection And Ranging (LiDAR) techniques. The method described in this paper results in a “burned in” or “eroded” (synthetic) river bottom within a digital terrain model that otherwise lacks bathymetric data. In shallow rivers the method has shown promise at preserving riffle crest elevations, side channels, and large in-channel roughness elements. The technique can be used for any case where flow is nominally unidirectional, confined within banks, and is either known or can be estimated at time of topographic survey. Virtually any 1-D or 2-D modeling package that allows for computation of inundation maps can use this method.

The method, termed herein as the synthetic bathymetry (SB) method, has several potential applications in the fields of hydrology, hydraulics and fluvial geomorphology and is best suited for determining reasonably accurate water surface elevations in situations where data is scarce and/or where projects do not require stringent accuracy. The method also allows for filling in gaps between surveyed cross sections without interpolation, which helps preserve the near bank, and mid channel topography (large roughness elements) that may be important for 2-dimensional model studies. It also allows for a physically based estimate of riverbed elevations below the water surface which can be valuable for estimating long term geomorphic change over large areas.

This paper investigates the relative accuracy of one dimensional hydraulic models constructed from surveyed cross sections, from DEM data alone, and from DEM data blended with SB data. Published flood insurance study data or recently calibrated survey-grade hydraulic models are used as benchmarks to test the validity of the results using SB data.

BACKGROUND

LiDAR data sets are becoming widespread and have quickly become some of the most valuable data for hydrologic, hydraulic and geomorphic studies. The LiDAR data is usually extracted and processed for inclusion in a numerical model of hydrologic processes. Due to technical limitations many LiDAR datasets lack elevation information below the water surface (bathymetry), requiring collection of channel data with other methods. Alternately, models are used without this data due to cost constraints, reducing the quality of the results. As survey and post processing technologies improve, terrestrial floodplain topography can be acquired for large study areas in the time it takes to fly along the river in a helicopter or airplane. Despite their high resolution, most available LiDAR data sets used to create DEMs do not include bathymetric LiDAR data (now possible with certain sensors and shallow, clear water conditions – see River Bathymetry Tool Kit (McKean et al, 2009)). Other recent innovative methods to remotely survey the channel bottom, which also require clear water conditions, include correlation of aerial imagery based DEMs to physical measurements of depth (Javernick et al, 2014). Currently, several technologies are available to acquire high resolution topographic and bathymetric data to support floodplain studies (Bangen et al, 2014). Many of these technologies are complex and costly to use. Considerable effort and skill are necessary to check, verify, and blend available data to create a seamless riverine terrain model. Also, due to the high equipment costs associated with some technologies and large data sets created by modern equipment, considerable effort and expense are necessary to acquire, maintain, and post-process these data. But as two dimensional modeling moves to the forefront of hydraulic engineering practice, the demands for bathymetric data will continue to increase.

Thus, the current state of the practice is one where engineers and scientists have a plethora of terrestrial data sets to choose from, from which any number of cross sections can be created. Below-water bathymetric data, however, remain sparse and difficult to acquire in many settings. Use of interpolated or "best guess" bathymetry in hydraulic models introduces unknown errors that add uncertainty and risk to project findings and decisions resulting from the modeling. Fortunately, many of the issues resulting from missing bathymetry can be partly overcome by applying first principles and combining off-the-shelf GIS and hydraulic modeling software. This paper presents and validates one such method, termed the Synthetic Bathymetry (SB) method that allows for automatic manipulation of terrain data to "burn in" SB data under the LiDAR water surface to address circumstances where underwater survey data is lacking but improved model accuracy is desired.

SYNTHETIC BATHYMETRY METHODOLOGY

Commonly used open channel flow numerical models allow for computation of fluid depth based on first principles of open channel flow (conservation of energy, continuity of flow, conservation of momentum). If a numerical backwater model is used, such as HEC-RAS (USACE 2014), to perform a standard step backwater calculation, the energy losses due to cumulative expansion, contraction, and roughness losses can be accounted for in estimating the local variation in hydraulic conditions, such as velocity, depth, and stage. As with most open channel flow models, the quality of the hydraulic output depends on the quality of the input, namely survey data and how well the modeler captures the characteristics of the terrain.

For purposes of floodplain modeling and mapping, the goal is typically to first compute the losses in energy (expressed as fluid head) using standard step backwater computations, then to map the resulting water surface elevations across the terrain data used to construct the model. All major changes in cross section, planform, slope, and roughness need to be represented in the model to yield good estimates of local and cumulative energy losses. If a river model is constructed accounting for local changes in slope, width and roughness, then the depths and velocities can still be computed even if the bed elevations are not known with high accuracy. In this situation the accuracy of the results will be biased by the initial error in the bed elevations. Recognizing that LiDAR provides an extensive and detailed record of the water elevation at time of survey (calibration data), we can write the following equation for the LiDAR surveyed water surface elevation (WSE_{Survey}) resulting from a hydraulic simulation of the flow elevation at time of the LiDAR flight:

$$\mathbf{WSE}_{\mathbf{Survey}} = \mathbf{WSE}_{\mathbf{initial}} - \mathbf{E}_{\mathbf{initial}} \quad (1)$$

Where E represents error, the difference between the computed elevation ($WSE_{initial}$).and the "true" elevation and If the water level in the LiDAR is treated as terra firma in the model cross sections (as a false river bottom), all flow will then occur above the "correct" elevation. Thus the depth of flow above the initial "false bed" is the error in equation 1.

$$\mathbf{E}_{\mathbf{initial}} = \mathbf{WSE}_{\mathbf{initial}} - \mathbf{Z}_{\mathbf{false\ bed}} = \mathbf{Y}_{\mathbf{initial}} \quad (2)$$

Where:

$\mathbf{Z}_{\mathbf{false\ bed}}$ = **Bare earth LiDAR elev** = $\mathbf{WSE}_{\mathbf{Survey}}$

$\mathbf{Y}_{\mathbf{initial}}$ = **initially computed flow depth (above raw DEM)**

Expressed spatially, across a raster grid, at all locations within a raster cell,

$$\mathbf{E}_{\mathbf{initial\ (ij)}} = \mathbf{Y}_{\mathbf{initial\ (ij)}} \quad (3)$$

Where i and j denotes the spatial location of a given raster cell of a given dimension. It is then proposed that,

$$\mathbf{Z}_{\mathbf{SB\ (ij)}} = \mathbf{Z}_{\mathbf{false\ bed\ (ij)}} - \mathbf{Y}_{\mathbf{initial\ (ij)}} \quad (4)$$

Where $Z_{SB\ (ij)}$ represents a synthetic river bottom elevation at a given raster cell. By subtracting the initially computed flow depth ($Y_{initial\ (ij)}$) from the false bed ($Z_{false\ bed\ (ij)}$) at every raster cell, the synthetic river bottom is "burned" or "eroded" into the DEM, creating the SB data set ($Z_{SB\ (ij)}$). Note that the error is specific to each location in the modeled space, and that modern versions of both open channel flow and GIS software are needed to perform the above calculations. In this paper, Arc GIS version 10.1 and HEC-RAS version 5.0 were used. This version of HEC-RAS allows for simulation of 1- or 2-dimensional flows and rapid computation of inundation depth rasters (Geotiff format) at all points in the model domain. SB data creation requires low flow inundation depth rasters to be created at the same resolution as the underlying terrain raster (Figure 1).

Figure 1 below illustrates a short a portion of two Dungeness River low flow hydraulic models created to test the effects of the different bathymetric data sources on model accuracy (see low flow calibration and high flow calibration sections of this paper for more discussion). Figure 1 shows how the raw, LiDAR Only (LO) DEM compares with a SB based DEM, and how the approach uses GIS raster math to calculate the elevation of the SB raster data at the grid cell scale. Note the greater area of inundation present in the LO low flow model results – which is due to the effects of the artificially high false bed in the DEM. Also note the planar contours of the channel bed present in the LO DEM as compared with the SB DEM.

Once the "burned" or "eroded" DEM is created the quality of the resulting data needs to be checked by running the low flow hydraulic model extracted from the SB data. The low flow model should include reasonable flow resistance parameters and the best estimate for discharge available throughout the model domain. Using the water surface profile plot options and comparing the initial DEM-based plan to the SB-based plan in HEC-RAS allows for verification that the results are reasonable (Figure 2). Our experience is that minimal tuning of n-values is necessary to provide good fit between the computed and surveyed low flow water surface elevations. Figure 2 is representative of the quality of fit that results when low flow data is known with confidence and high quality LiDAR is used.

In application of the SB workflow (described during talk) we found that there are common difficulties when calibrating to low flow surveyed water elevations extracted from the DEM. These typically occur at the downstream end of the model (if the starting water surface is assumed to equal the surveyed water surface). Our initial experiences suggest that starting the model at normal depth will overcome most downstream boundary problems. Increasing n values locally can be used to force the river to deeper depths where pools are known to be present. If calibration difficulties are encountered throughout the model, this is most likely an indication of poor discharge estimates in the model. Even if available survey data is outdated, it should be used as a check of the SB DEM. If the SB data is suspect, it should be replaced with traditional survey data.

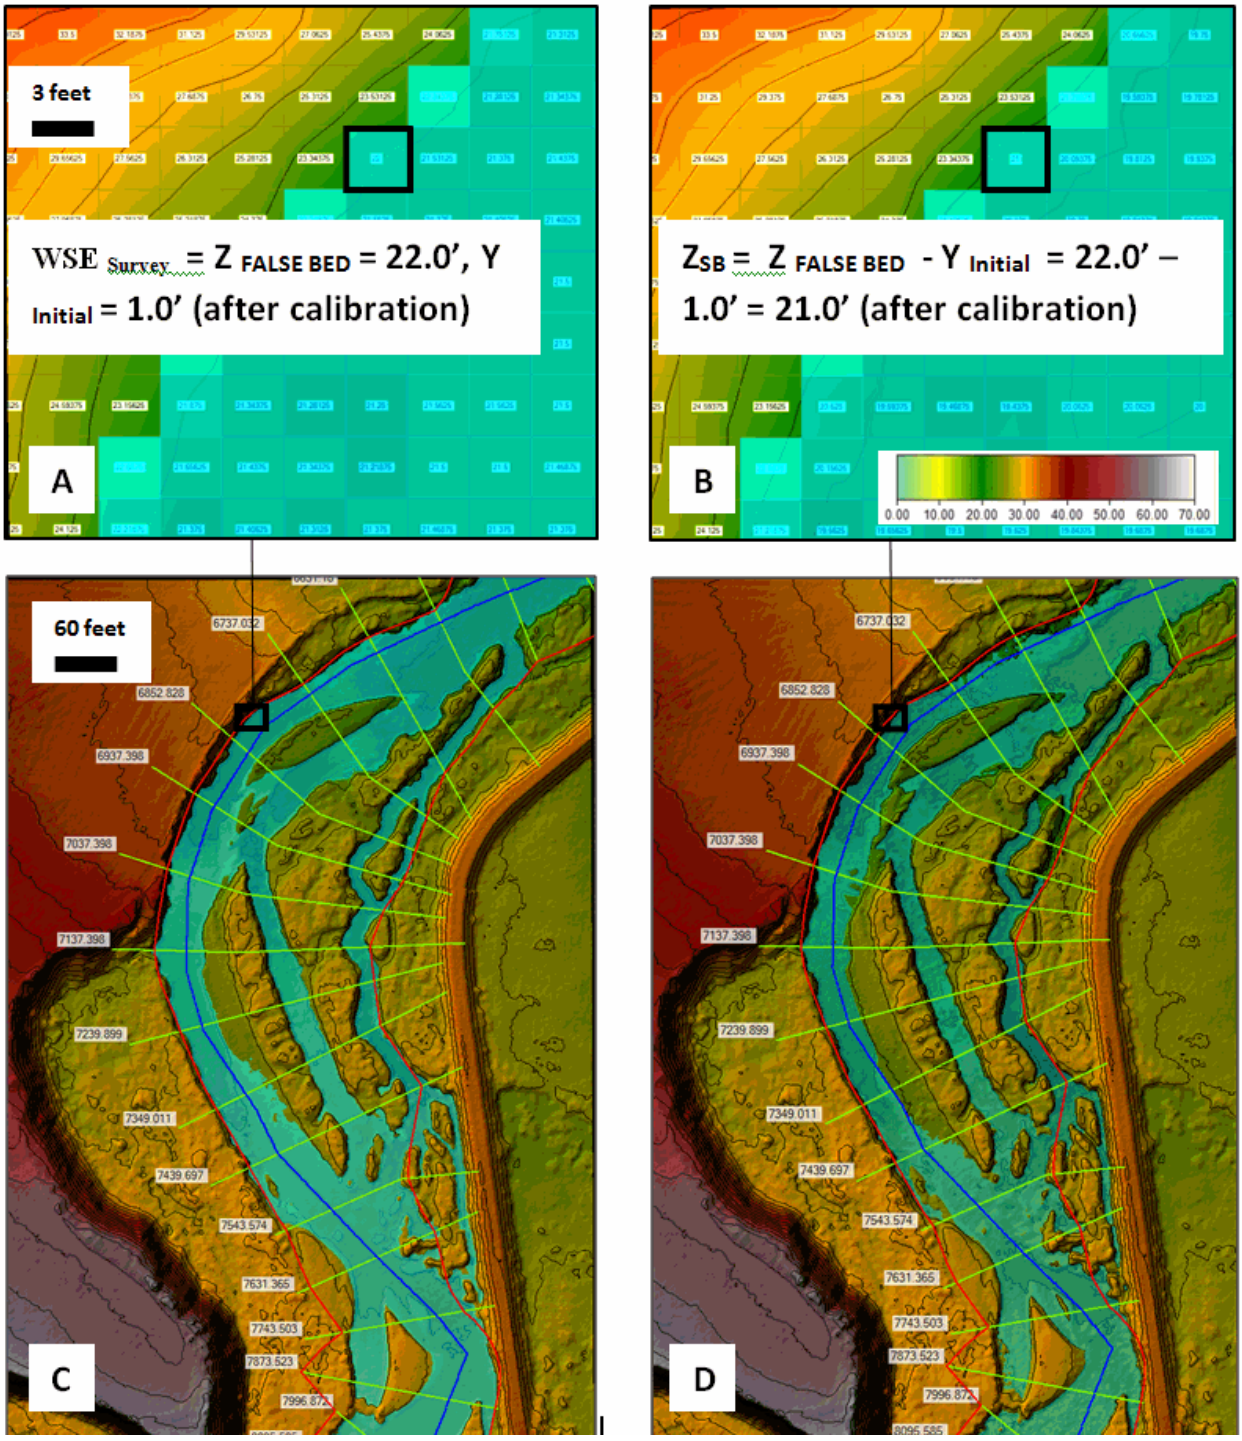

Figure 1: Dungeness River, WA (RM 1.3 to RM 1.6). (A) Close up showing initial LiDAR terrain grid cell center elevations ($Z_{FALSE\ BED}$). Each grid cell is 3 feet x 3 feet. Blue shaded numbers are cells that are wetted. Discharge at time of survey is 340 cfs. (B) Close up showing SB terrain computed grid cell center elevations (Z_{SB}), and how Z_{SB} is computed. (C) LiDAR terrain data overlaid with low flow hydraulic model cross sections, river centerline, banks, and resulting initial estimate of inundation area for flow at time of the LiDAR flight. Contour interval is 2 feet. Flow direction is south to north. (D) Synthetic bathymetry terrain data overlaid with low flow hydraulic model and computed inundation area. Note that all major geomorphic landforms with exception of deep pools are captured.

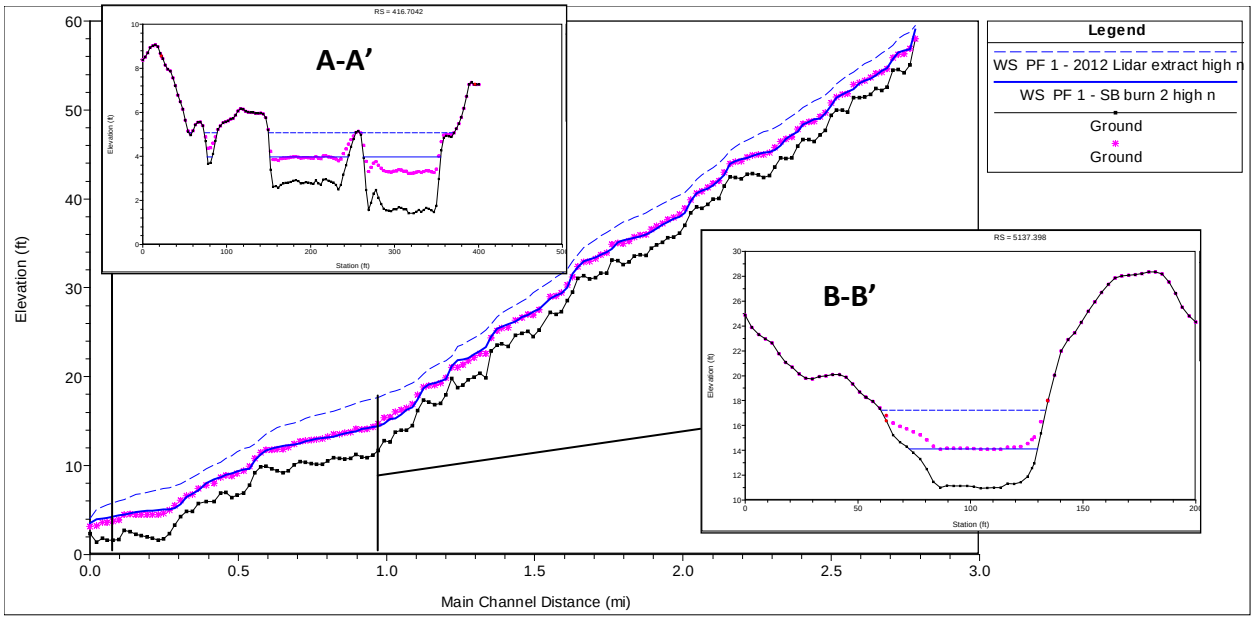

Figure 2 –Dungeness River, WA. Low flow hydraulic model verification against LiDAR surveyed water surface. In the water surface profile and cross sections the dashed blue line is initial estimate of water surface profile using LiDAR false bed elevation. Blue solid line is water surface computed after burning the initial depths into the LiDAR to create synthetic bathymetry (SB) data. Pink * is initial LiDAR surveyed water surface elevation (assumed to equal lowest point on cross section extracted from bare earth LiDAR) used to validate SB low flow model. Cross section A-A' shows how the method is able to burn side channels and main channels simultaneously while preserving large scale geomorphic features. The error in the depth is partly attributable to uncertainties about how much flow was in the main channel vs. the side channel. If the side channel was assumed dry, the main channel would have been stamped to a deeper elevation, which may have resulted in a better match. These errors are unavoidable without aerial photos to aid decisions on where to set limits of the channel in the model. Cross section B-B' is representative of how the method works in an ideal setting. The water surface matches the LiDAR survey, with minimal alteration of the cross section shape.

Note that the SB DEM is created after one or more calibration attempts to match low flow water elevations. This ensures that the low flow model and DEM have adequate conveyance to match low flow water surface elevations. In real rivers, as well as in numerical models, it is widely known that riffles are a primary control on flood elevations and that at high flows water surface elevations tend to follow a smoother longitudinal profile that drowns out bed elevation undulations more prominent at low flows. A fundamental assumption embedded in this approach is that as long as the SB DEM is the result of a well calibrated numerical model that captures riffle elevations (as shown in Figure 2 above), error in thalweg elevations between riffles will not significantly impact estimates of flood elevations. A primary goal of the high flow validation section of this paper is to test the validity of this assumption.

STUDY REACH DATA

Hydraulic models developed by others were acquired to establish baseline conditions for investigating the effects on the results of hydraulic models derived from ground survey based methods, from LiDAR alone, and from LiDAR blended with SB data. All baseline models used for validation purposes were developed by others. The Green River models were acquired from King County, prepared as part of a Preliminary Revised Flood Insurance Study (2007). The Skykomish River model was obtained from Snohomish County and was developed as part of a Revised Flood Insurance Study (2010). The Dungeness River model was developed by USACE Seattle District as part of a Feasibility Study (2014). The Clark Fork model was developed by USACE Northwest Division as part of the Columbia River Treaty Flood Risk Assessment (2012). All baseline models were used as-is, reflect real-world conditions and are based on modern modeling and mapping standards.

The Dungeness, Skykomish, and Green River in western Washington State, and the Clark Fork River, a tributary to the Columbia in Idaho and Montana were used for this study (Figure 3). For ease of comparison the Green River model was subdivided into the Middle and Lower Green Rivers based on a geologic reach break near river mile (RM) 32. All study reaches in Washington State are glacially modified alluvial floodplains, draining heavily forested mountains that have hydrology typical of the Puget Sound lowlands (high intensity fall and winter rains, spring snowmelt runoff). A flood control dam on the Green River caps flood flows at the pre-dam 2-year recurrence interval discharge, while the Skykomish and Dungeness are free flowing. In contrast, the Clark Fork River study reach is wholly contained by a bedrock gorge and is heavily influenced by hydroelectric dams located at both ends of the study reach, which causes the river to behave like a reservoir under all but the highest discharges.

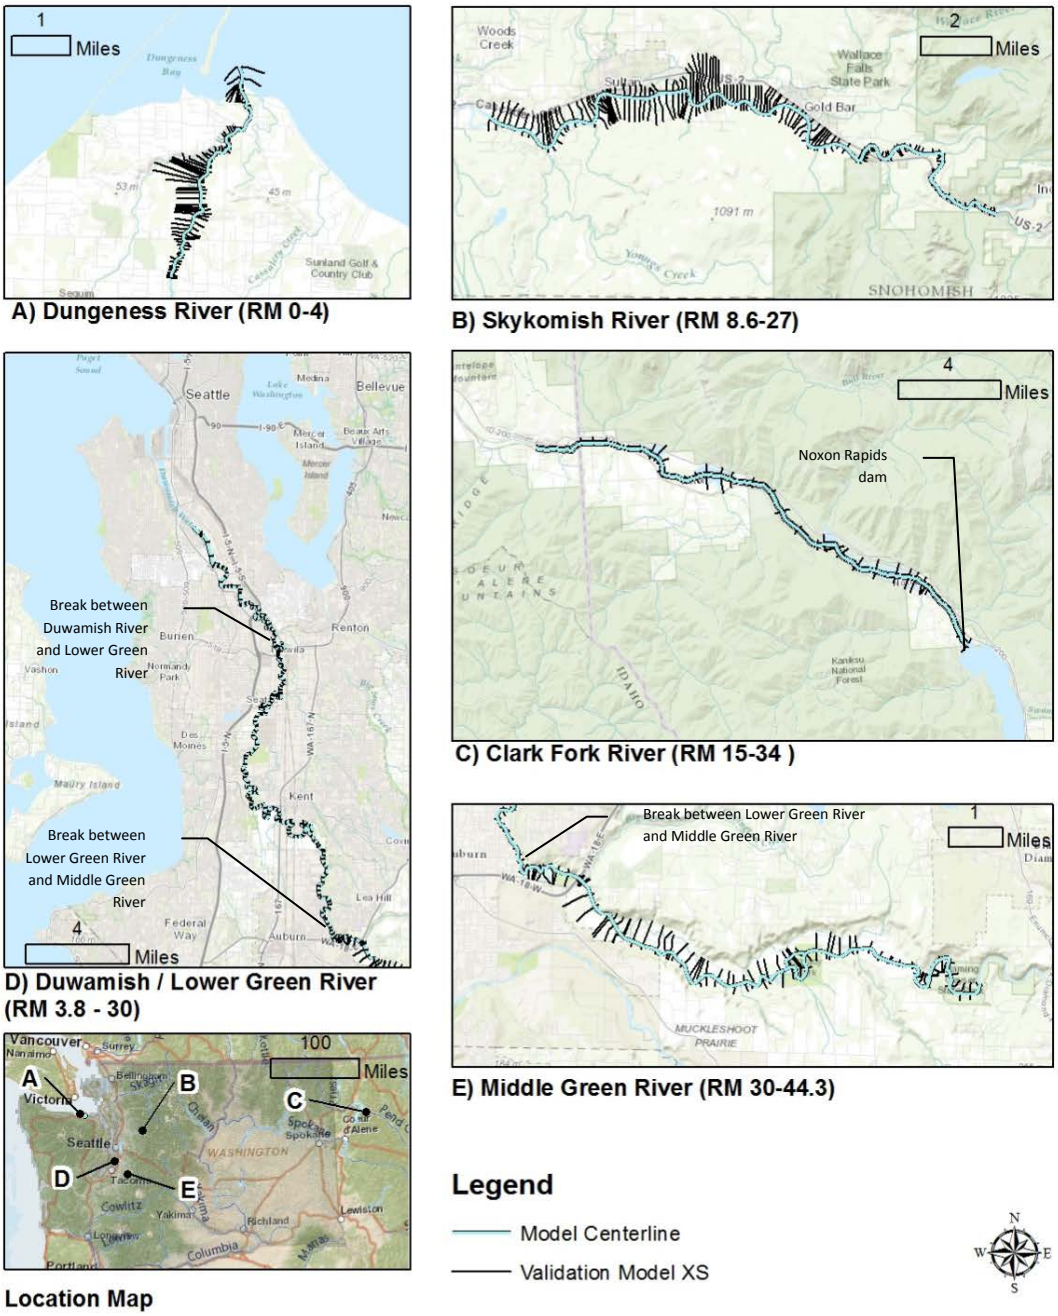

Figure 3: Location and vicinity maps of SB low flow and validation model reaches

The Dungeness River is the shortest and steepest of the study reaches, with the lowest 100-year discharge, while the Lower Green River is the longest and narrowest of the study reaches (Table 1). The flattest and most confined reach is the Clark Fork River – however the flat gradient is the result of a downstream dam. The natural valley gradient is much steeper given the canyon setting. The Dungeness, Skykomish, and Middle Green River are gravel/cobble bedded with boulders in places. The Skykomish River is the largest of the alluvial rivers studied, with large amplitude migrating meanders and wide floodplain All alluvial rivers studied are artificially confined by road embankments, revetments and levees near developed areas, the lower half of the Dungeness River and Lower Green River being the most confined. Hydrologic data available is of relatively high quality, with more than 80% of the study reaches gauged for all but the lower half of the Skykomish River. Flows at time of survey were about 10% of the 2 year discharge for the Dungeness and Green River, about 4% for the Skykomish, and about 22% for the Clark Fork, indicating that the discharge at time of survey was well below bankfull conditions.

Table 1: Study Reach Low Flow and Baseline Model Data

				Reach Average (Std Dev)		Discharge Estimates (cfs)

SB LOW FLOW MODEL CALIBRATION

The key issues affecting the quality of the results of the SB method are determining the extent of low flow model cross sections, estimating the amount of flow present within the model at time of survey, and deciding how much to refine the model to achieve good match to the surveyed water surface elevations.

Table 2 below summarizes the error in the SB and LiDAR Only (LO) computed water surface elevations – in low flow conditions – for the five study reaches with respect to surveyed water surface elevations at each transect location in the model, after one or two calibration attempts. Calibration consisted of adjusting Manning's n values in the channel for the low flow model to better match the LiDAR surveyed water surface. In cases where significant amounts of flow was diverted at different elevations into side channels we either isolated all the flow into the dominant channel by limiting the cross section width, or constructed a connected side channel reach. The results were compared with the surveyed water elevations, which are extracted from the low point on each model cross section. Alternatively one could have used a 2-D model to estimate water elevations in the main and side channels at low flow.

The results for all five study reaches provide excellent-to-good matches of the surveyed water elevations during low flow conditions (average difference in computed low flow elevation is less than 0.1 to 0.5 feet from surveyed

elevation). In contrast the average error using only the LiDAR data ranges from 1.8 to 5.6 feet (and more than 25 feet in the Clark Fork reservoir reach). Note that in all cases additional refinements of the SB data to better match surveyed elevations were possible, however we viewed the low flow results as favorable enough to proceed to high flow validation.

Table 2: Low flow SB derived hydraulic model results after calibration vs. LO hydraulic model results as compared with low-flow surveyed water surface elevations

Reach length (mi)	2.8		20.1		18.9		26.1		14.3	

The excellent results on the 26-mile long Lower Green River reach were surprising given the tidal influence, however the survey at low tide and trapezoidal channel shape helped ensure that much of the channel conveyance area was captured in the initial terrain data. The higher-than-average errors in the Skykomish model are attributed to large uncertainties in flow at time of survey, effects of split flows around gravel bars, and errors and artifacts in the older vintage LiDAR data (trees, etc.). The excellent results for the Dungeness are partly attributed to the modern techniques used to acquire and post process the LiDAR data and the presence of a stream gage within the reach. The Clark Fork River reach – which is a backwatered canyon upstream of a dam – actually fairs better in the low flow than high flow model run (discussed in next section) because the known water surface at the downstream pool drives the water surface profile throughout the reach.

The good to excellent results over a wide range of channel sizes, slopes, and geomorphic types suggests that the SB method is capable of creating low flow hydraulic models that closely match surveyed water elevations, while preserving major geomorphic features of the channel (Figure 1D, Figure 2). Additionally, use of LiDAR data without adjustment may result in errors (under low flows) that exceed tolerances for most types of engineering studies. The effects of using unadjusted bare earth LiDAR data or SB terrain data without further parameter adjustment for flood conditions are presented in the next section.

SB HIGH FLOW MODEL VALIDATION

To validate the SB (and LO) DEMs, baseline hydraulic models developed by others to estimate floodplain depths and elevations were modified by re-cutting all cross sections from the original LO DEM and from the SB DEM. The steady flow step backwater models were then run with the new cross section data but without any further parameter or boundary condition adjustments to determine how the errors in the underlying terrain data affected the model results for the “bankfull” 2-year (50% annual exceedance probability) and “base” 100-year (1% annual exceedance probability) flood events.

Table 3 below summarizes the error in computed water surface elevation, flow area, average channel velocity, and average channel shear stress for the five study reaches from SB-based model and LO-based model with respect to results computed from the baseline models. The error statistics shown in Table 4 represent reach averages of the cross sectional difference between the results for the SB model or LO model and the baseline model. The percent change in error in Table 3 represents the reduction in error resulting from use of the SB model vs. the LiDAR only model.

Table 3: Study Reach Average Absolute Error Residuals in Computed WSE, flow area, velocity, and shear stress for SB and LiDAR Models with respect to Baseline Model

Note 1 – Study average % change is the difference in the LO reach average error statistic and SB reach average error statistic divided by the reach average LO error statistic, then averaged for all reaches (excluding Clark Fork).
Note 2 – Study average % change includes Clark Fork.

From Table 3 we can see that the study reach median error in SB model computed water surface elevation (WSE) ranged from -0.4 feet (Lower Green River) to 0.7 feet (Clark Fork) for the 2-year event, and ranged from -0.3 feet to 4.9 feet for the 100-year event (same reaches). The Dungeness and Middle Green models have the best overall match of the baseline WSEs, with 0.2 feet or less error on average for both the 2 year and 100-year events. Figure 5 provides a representative comparison of computed water surface profiles for all study reaches. The improvement in results from use of the SB method is most pronounced for the Lower Green, Clark Fork and Dungeness, which are all highly channelized or confined. The unconfined Middle Green and Skykomish have overbank floodplains that convey much of the flood flow, causing the results to be less sensitive to use of SB data.

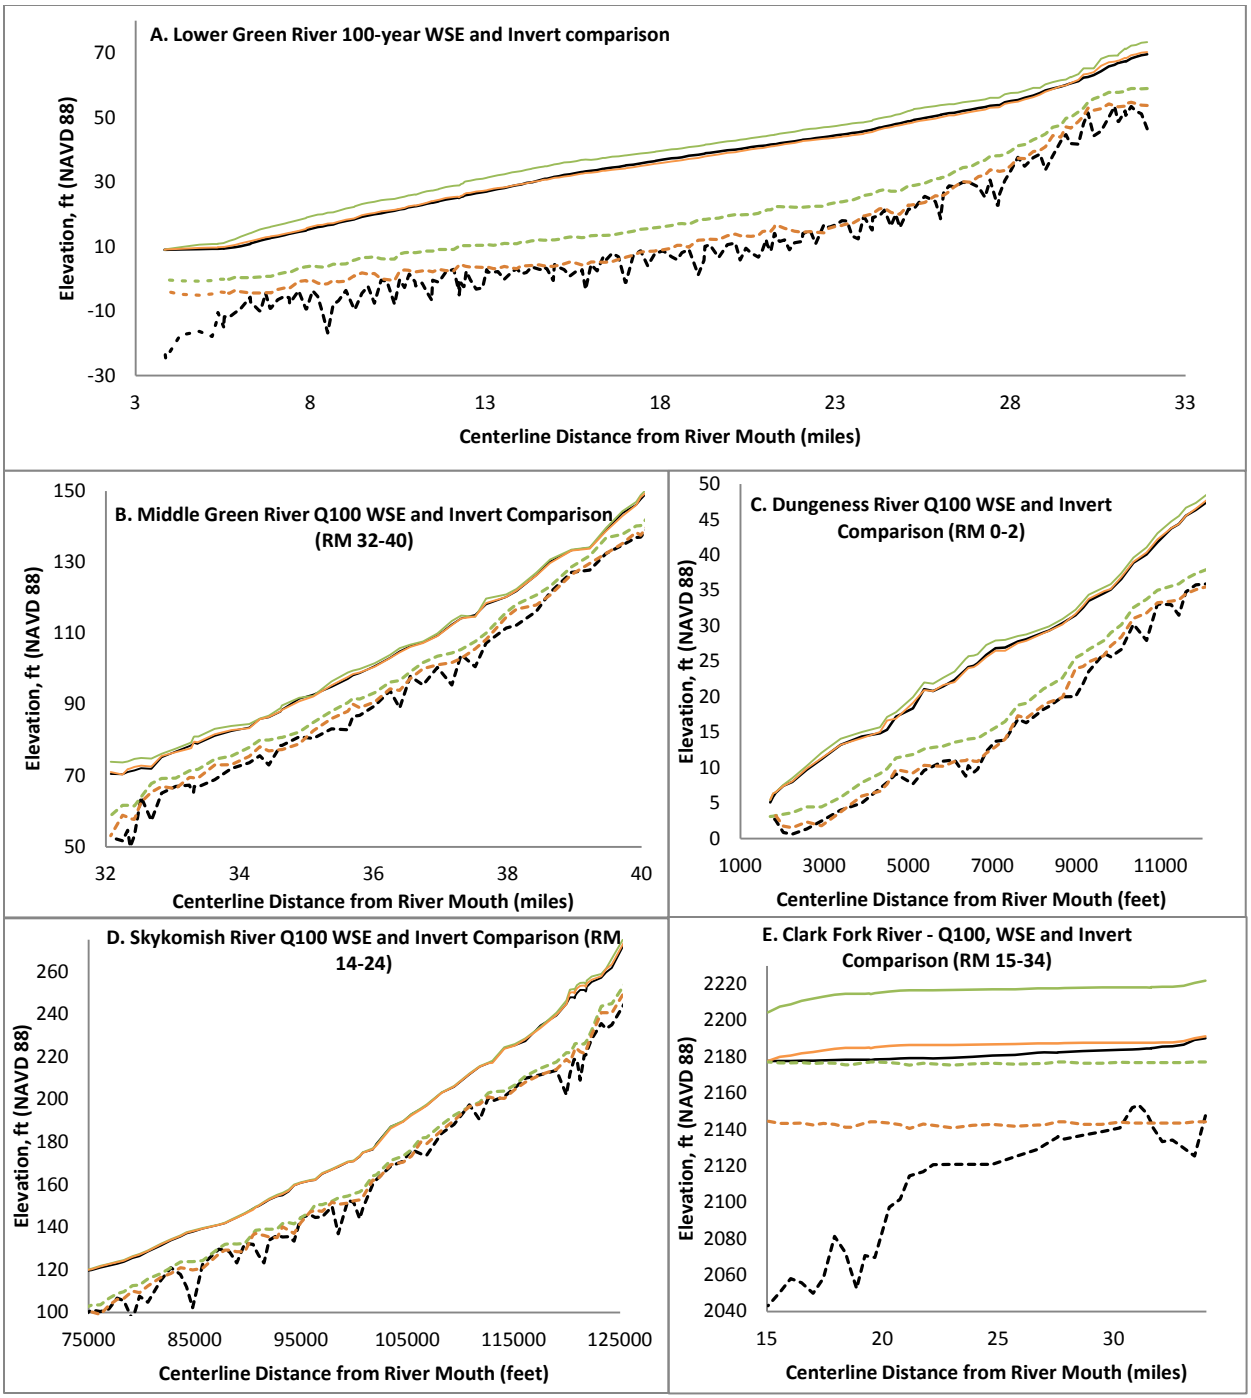

Figure 5. Computed 100-year flood water surface profiles and invert elevations for A) Lower Green (RM 3-32), B) Middle Green (RM 32-40), C) Dungeness (RM 0-2), D) Skykomish (RM 14-24), E) Clark Fork (RM 15-34). Green lines reflect initial bed elevation and computed WSE from original LO data, orange lines reflect SB bed elevation and computed WSE from SB data, black lines reflect surveyed bed elevation and computed WSE from baseline RAS model. Solid lines are computed WSEs, dashed lines are invert elevations.

The limitations and benefits of the SB method are seen from inspection of the Clark Fork results. Clearly the method cannot reproduce the river invert elevations submerged under the dam backwater, however the model still reduces average error in stage by more than 25 feet if one had used the LiDAR alone. For all but the Clark Fork the SB channel invert tracks the elevation of existing riffles quite closely, and results in hydraulic models that closely match

those of the baseline model in terms of WSE, flow area, velocity, and shear stress. Compared with models based on use of LiDAR alone, results are significantly improved for all study reaches.

The slight upward bias in flood stage resulting from the SB approach (under normal conditions) and more pronounced upward bias from use of LiDAR data without adjustment is when comparing total inundation area. Inundation area error is 0-5% in all reaches using the SB method, compared to 2-50% using the LO model. The error for the 2-year event is higher than that of the 100-year event for all but the channelized (trapezoidal) Lower Green. At higher stages the other reaches use more floodplain conveyance – which is not affected by the bathymetric data collection method.

SUMMARY

The SB method allows for creation of reasonable synthetic channel bathymetry data from LiDAR data, flow information, and widely available GIS and hydraulic software. The quality of the results can be easily demonstrated by comparing computed water elevations and velocities to the DEM water surface elevation at time of survey and to baseline model results or to high water marks. For this study the SB method results (comparison of computed flood stage to baseline) were excellent for a short steep sediment laden river with recent LiDAR and a gage within the reach, and poor for a reach upstream of a dam where true channel depths were many times that estimated using the SB approach. For a low gradient tidal river and medium gradient gravel bed river the results were very good. On a medium gradient wandering gravel bedded river with older LiDAR and higher uncertainty over low flow discharge the data were generally good to poor in isolated areas near bridges.

For all five study reaches the SB method significantly reduces the errors resulting from use of cross sectional data derived from LiDAR alone but does not eliminate the errors. This trend of reduced error is observed for all the flows analyzed and all the hydraulic parameters analyzed, other than depth. The median and average error when compared to baseline hydraulic models was typically less than 1 foot at bankfull stages, and under ideal conditions was less than 0.5 ft at 100-year flood stages. A river reach that is significantly affected by downstream backwater caused by a dam was used to check the quality of the method under non-ideal conditions. While the stage errors at low flow were less than 1 foot, the SB method was not able to create enough conveyance to pass 100-year flood flows with less than 4.7 feet of error (reach average). While this result at first glance is poor compared with the other reaches studied, the relative reduction in error compared with using a DEM without bathymetry is about six-fold. The location within a bedrock canyon suggests the error may not be significant with respect to adjacent development.

DISCUSSION

Under low and 2-year flood conditions we observed good to excellent matches of baseline and SB water surface elevations for all five study reaches, with the MAE of less than 1 foot for all but the Clark Fork reservoir reach. (Note that the results presented in this paper are not being compared to observed conditions at high flows which means that while the SB model results may provide a good match to the baseline model, the quality of the SB model with respect to real world conditions has only been evaluated for low flows and not under flood conditions). For nearly all flows and reaches, the results of the validation effort were surprisingly good (for the parameters that are typically meaningful for analysis and design, with the exception of maximum depth) considering that the SB based models lacked below-water survey data. This suggests that in similar conditions we would expect to have similar results, provided the quality of datasets and approach used to derive the SB data are similar.

To understand why the SB data results in a model that agrees well with the baseline, consider the significant error in maximum depth associated with models that still provided good to excellent estimates of flood stages (Figure 5) and inundation area. Concurrently, the good results of flow area, velocity, and stage shown in Table 3 (resulting from a 1-D step backwater model) suggest only reasonable estimates of cross sectional area, slope, and roughness are required. Because we are simulating physics of flow in one dimension, using open channel flow equations, all flow is assumed to be down valley, contained within banks, steady and uniform. During low flows, when LiDAR is typically acquired, these conditions are satisfied more often than not. We are simply using physical equations in the SB method (hydraulic model) to tell us how much space (area or volume) flow “takes up” at a given location. Then we are using GIS to create that space below the surface of a DEM for the river so it can pass the surveyed flow at the surveyed elevation. These results appear to confirm our primary assumption that as long as riffles are captured in the SB DEM that errors in flood stage will be small.

The quality of the results in this study are likely related to the setting and quality of the underlying data used to create the SB data. Reaches where the river was confined (Dungeness, Lower Green) with a trapezoidal cross section had the best agreement with the baseline models. The effort to create and apply SB data is significantly less than that needed to perform channel surveys. In less than one day we were able to use the technique to create a 40 mile long model that matched the baseline model computed 100-year flood elevations by less than 0.5 ft on average. While reach average hydraulic conditions computed from 1-D SB based models tracked closely with the baseline models, errors were higher at bankfull stages than at flood flows when the floodplain is active. Other difficulties were encountered where significant backwater was present, at hydraulic constrictions, and abrupt changes in grade or bed elevation. While no effort was made to calibrate the SB models to historical high water marks, we are confident that the close agreement with the baseline model results (with the exception of the Clark Fork) would allow for good calibration with reasonable parameters.

While the SB method will typically result in a DEM that includes a wider and shallower river than exists, it avoids the creation of artifacts common with using educated guesses or automated techniques to "burn" channels into DEMs from sparse survey data. For example all features above the water surface are preserved rather than "averaged out" as occurs when topography is created from widely spaced cross sections. This preserves side channels and bars that may be important for capturing flow paths or effects of macro roughness elements, however it will not capture deep pools or submerged features that may be important for habitat studies. This implies that a potential benefit of the SB approach is to improve the accuracy of a DEM (and model) between surveyed sections.

THE NEED FOR DUE DILLEGENCE AND REFINEMENT

This paper presents the promising results of a validation study of a method to create synthetic bathymetry for five rivers in the Pacific Northwest of varying size and geomorphic character. Until such time that the method has been validated for a wider range of channel types and rivers by other practitioners, we must recommend against applying it in cases where higher resolution survey grade data is warranted (i.e. life safety is of concern). In cases where flow data at time of DEM survey is lacking or uncertain, the SB approach will not provide reliable results, and could result in under-estimation of flood risk. Field data (discharge-elevation rating curves) may be needed to ensure the results are reasonable or to improve results. The potential cost savings of this method, while attractive, implore practitioners to collect detailed calibration and verification datasets to demonstrate the quality of the underlying SB data and model results. Models developed with this approach should be flagged as such, and a calibration and verification write-up should be included with model documentation. Before applying the SB method to a reach lacking a baseline model it is strongly recommended that one first independently validate the approach on a reach with a survey grade calibrated model to ensure that the approach is providing reasonable results. Further validation studies of the SB method with 1-D and 2-D unsteady state models are also recommended.

AKNOWLEDGMENTS

The authors appreciate the support of Seattle District staff and management and Clallam County, King County, and Snohomish County that provided baseline hydraulic models and data used to conduct the study. The authors wish to thank an anonymous reviewer that significantly improved the quality of the final manuscript.

FINLEY CREEK ALLUVIAL FAN GEOMORPHIC AND HYDRAULIC ANALYSES AND IMPLICATIONS FOR RESTORATION

Jeanne E. Godaire, Geomorphologist, Bureau of Reclamation, Denver, Colorado, jgodaire@usbr.gov; Sean Kimbrel, Hydraulic Engineer, Bureau of Reclamation, Denver, Colorado, skimbrel@usbr.gov

INTRODUCTION

Finley Creek, located on the Olympic Peninsula in western Washington, is a tributary of the Quinault River upstream of Lake Quinault. Previous observers have noted recent progressive lateral movement of the channel toward the eastern side of the Finley Creek alluvial fan, and aggradation and perching of the channel in the vicinity of the North Shore Road Bridge. The relationship between Finley Creek and the Quinault River is one of a long-term dynamic interaction between a large alluvial fan and mainstem river. The current sediment production from Finley Creek is of critical concern due to ongoing dredging at North Shore Road Bridge and the potential environmental effects of the dredging both upstream and downstream of the bridge (NPS, 2005) and sediment deposition and lateral Quinault River channel migration (GeoEngineers, 2011). Previous studies on Finley Creek have documented historical channel change using rectified aerial photography (Bountry et al. 2005) and the problems associated with aggradation and erosion on sections of Finley Creek (Kennard, 2009; Smillie, 2001; Jackson and Smillie, 1994).

The objectives of this study are to (1) provide a geomorphic analysis of conditions on Finley Creek in order to place current conditions into a long term context and to identify areas of potential avulsion and lateral erosion; and (2) conduct hydraulic modeling of various scenarios to guide the evaluation of alternatives for addressing aggradation near the North Shore Road Bridge and improvement of aquatic habitat on Finley Creek.

SETTING

Finley Creek flows from its headwaters in Olympic National Park to the south through a steep and narrow canyon with step-pool channel morphology. The stream emerges onto the Finley Creek alluvial fan, where channel morphology is braided at intermediate to high flows. Finley Creek joins the Quinault River just upstream of Quinault Lake near Quinault, Washington (Figure 1). Kestner Creek and Canoe Creek flow onto the Finley Creek alluvial fan on its western edge. The tributaries currently do not have a surface connection with Finley Creek but contain groundwater flow which is likely partially sourced from Finley Creek.

Flood frequency flows calculated indirectly by National Stream Statistics (Knowles and Sumioka, 2001) indicate a high-end 2-year event for Finley Creek is on the order of 2,500 ft^3/s while a 100-year flow is approximately 6,150 ft^3/s. A recently installed staff gage with time-lapse photography at the canyon mouth has continuously recorded stage. Flows of 1,557 and 1,240 ft^3/s through 2013 and 2014 have been measured at the Finley Creek Bridge—these flows are on the order of annual to 1.25-yr events and have been contained within the main channel of

Finley Creek. High flows mainly occur during the rainy season which on the Olympic Peninsula spans the months of October through March.

The Finley Creek alluvial fan is a moderate gradient, humid fan with a seasonally fluctuating discharge. Fluvial processes dominate on the fan and within its main channels; debris flow processes are dominant in the headwaters where steep tributaries join the main stem. The Finley Creek alluvial fan can be divided into an upper fan and lower fan based on changes in gradient and fan morphology (Figure 1). The upper fan is a higher gradient fan with one or two main channels that flow between interfluves stabilized by vegetation and soil development. These interfluves are young alluvial fan terraces, which have been abandoned by Finley Creek through avulsion and minor incision. The fan terraces consist of interbedded sand and gravel fluvial units. The upper fan is bounded by Pleistocene glaciofluvial deposits on the eastern edge and bedrock with steep gradient tributaries on the western edge. The lower fan is a lower gradient system with distributary channels that diverge from the main channel, some of which dissipate on the fan surface and others which deliver sediment to the Quinault River.

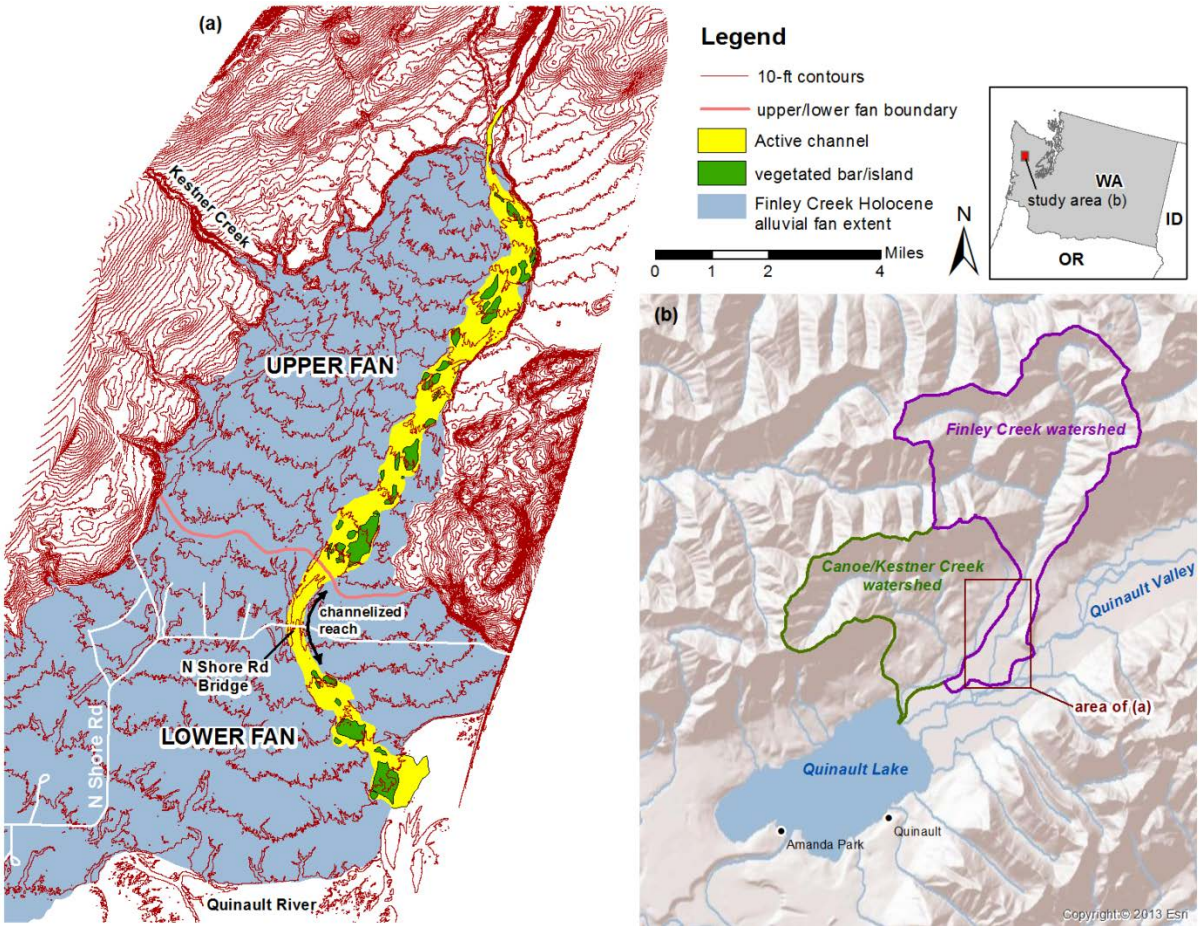

Figure 1 Location map showing (a) Finley Creek alluvial fan and (b) physiographic setting of study area.

Channel morphology of Finley Creek varies based on position within the alluvial fan and the amount of manipulation, and can be characterized in three segments: upper fan, lower fan and a channelized reach at the upstream part of the lower fan. On the upper fan, the main channel of Finley Creek is braided with high relief between the thalweg and top of unvegetated bars (Figure 2). Channel complexity is high with small pool and riffle areas during low flow. During high flow, the channel transitions to a braided morphology with abundant large woody debris and gravel bars. Mid-channel islands with immature vegetation such as alders and conifers occupy portions of the main channel and are transient features that are modified during high magnitude flows.

On the lower fan, the main channel is composed of a single braided channel that conveys the majority of flow to the Quinault River. Several large mid-channel islands exist with immature to mature vegetation (Figure 2). Many of these islands have been formed as the channel has scoured around older landscape features and isolated areas of the older alluvial surfaces as islands. Therefore the older character of the islands is in contrast to the immature islands in the active channel of the upper fan. In many locations, lacustrine sediment is exposed under the younger alluvium now contained on the islands in the lower fan. Prior to channel manipulation, the lower fan was largely a distributary system, where smaller channels branched from the main channel issuing from the upper fan. Blockage of many of the distributary channels by man-made berms or levees on the lower fan has prevented surface flow into many of the historical distributary channels, although several of these channels continue to convey baseflow from shallow groundwater. In the channelized reach in the vicinity of the North Shore Road Bridge, where the channel is constrained by levees, the channel is single thread with low relief and low complexity, and is a much narrower channel than the other reaches (Figure 2). Large woody debris is not abundant, partially due to clearing during gravel excavation.

METHODS AND RESULTS

Various methods are employed to answer the study questions. Geomorphic and hydraulic analysis methods used in this study are:

- surficial mapping
- geomorphic change detection (Wheaton et al., 2010)
- mapping of potential sites of lateral erosion and channel avulsions
- numerical hydraulic modeling

Surficial mapping: The mapping for this project focuses on surficial deposits on the Finley Creek alluvial fan and highlights how recently surfaces have been activated by Finley Creek. Each map unit is a complex of ages; for instance, areas that have been active historically may include areas of older alluvium that have not been completely overprinted by historical lateral channel erosion or deposition. On the lower fan, deposits may also include underlying lacustrine sediment that is related to higher stages of Quinault Lake during the early to middle Holocene (~10-6ka). Mapping was performed remotely using historical channel mapping from Bountry et al. (2005), post-2005 channel mapping, 2011 LiDAR surface morphology and 2011 NAIP digital photography. Areas along the active channel were field checked; limited field checking was performed in areas away from the active channel. Where possible, exposures of the different alluvial deposits were described and photographed.

The youngest map units include the Finley Creek active channel and vegetated gravel bars and the Kestner Creek active channel and bars (Figure 3). The active channel map unit includes the area on Finley Creek alluvial fan that was actively being reworked by fluvial processes in 2011, the dates of the aerial photography and LiDAR. This includes the low flow and high flow channels, and unvegetated gravel bars. Vegetated bars or islands occur as mid-channel features with irregular surface morphology. The Kestner Creek active channel contains alluvium primarily derived from the Kestner Creek drainage, but may contain alluvium derived from Finley Creek as well, as it appears that the two drainages merged on the west side of the fan prior to the time covered by the historical channel mapping.

Historical alluvium includes areas on the Finley Creek alluvial fan that have been occupied historically since the late 1800s by either the main channel or distributary channels of Finley Creek (Bountry et al. 2005). The map units may include areas of older alluvium that have not been completely modified by historical channel activity. The historical alluvium is grouped into four main units based on the time period over which the area was actively being reworked by the main channel or distributary channels of Finley Creek (Figure 3): Historical alluvium III (post-1960), Historical alluvium II (1939-2002), and Historical alluvium IB (pre-1960) and IA (~1890s). Historical alluvium II contains overlapping time periods with III and IB because the time in which this area was occupied spans both units. The general pattern in historical alluviation has been a progressive shift of the active Finley Creek channel to the west on the fan, which was initiated by the log jams constructed by homesteaders in the late 1800s and into the 1930s at the canyon mouth on the upper fan to block flow from entering the western channels (Historical alluvium 1A and 1B). On the lower fan, levees were built near North Shore Road

Bridge in more recent decades to block flow from entering the western distributary channels (Historical alluvium II).

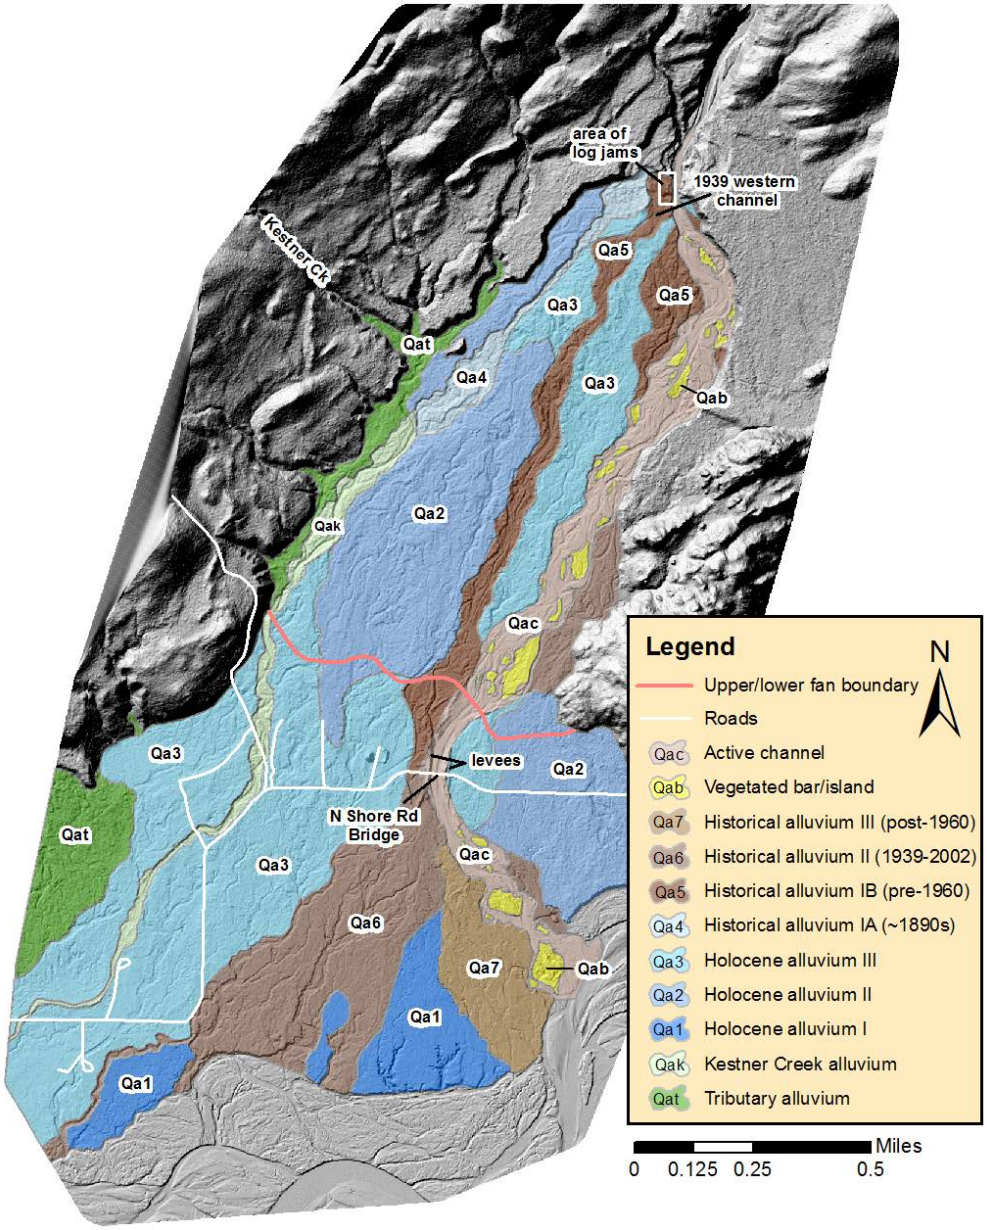

Figure 3 Surficial geologic map of Holocene units, Finley Creek alluvial fan. Basemap is a hillshade derived from 2011 LiDAR.

Holocene alluvium is mapped as three separate units based on surface morphology, soils and relative height above the active channel of Finley Creek. The units are numbered I, II and III in order of relative decreasing age. These units generally predate historical aerial photography and historical maps and therefore reflect areas of the fan that were active prior to the late 1800's. Based on limited radiocarbon data, these units appear to span the Late to Middle Holocene if underlying lacustrine units are included in the age estimate (<6ka) (Bountry et al., 2005).

Geomorphic Change Detection, patterns of erosion and deposition: Geomorphic Change Detection (GCD) software (V5.0, https://sites.google.com/a/joewheaton.org/gcd/home), which is based on the theory presented in Wheaton et al. (2010) was used to detect changes in erosion and deposition using changes in elevation between the 2002 and 2011, the dates of the LiDAR datasets (Figure 4). GCD was also used to develop a sediment budget along Finley Creek. Once the two datasets were converted into orthogonal and concurrent rasters, a threshold of 20 cm was applied to the DEM of difference, which was generated by taking the differences in the grid point elevations in 2002 and 2011. For the entire active channel area (active channel and vegetated islands map units), results show the alluvial fan had net deposition of more than 300,000 yd^3 in the 9 years between 2002 and 2011.

Areas of interest were further delineated in ArcGIS (Figure 4). Upstream of the North Shore Road Bridge (upper fan and upstream portion of lower fan), net deposition was 215,000 yd^3, in which 244,000 yd^3 of deposition and 29,700 yd^3 of erosion were calculated between the two datasets. There has been net erosion from the glacial terrace (labeled glacial terrace area, Figure 4) of -40,000 yd^3 based on 79,900 yd^3 of erosion and 39,900 yd^3 of deposition. The sediment budget calculations during this time period (2002-2011) show that the majority of sediment deposition is from headwater sources (e.g. landslides) since there is no sediment source within the fan (such as bank erosion) that shows net erosion similar to the net deposition in the active channel. The active channel in the channelized reach experienced net erosion (-7,000 yd^3) over the 9 year span, although this area was actively managed during this time period. In 2002 LiDAR (Oct 30th), the channel had just been excavated and in 2011 LiDAR (Nov-Dec), some deposition had already occurred following excavation. An increase in the volume of the berms or levees is also detected, with the river right levee gaining 14,000 yd^3, and the river left levee gaining 3,600 yd^3. Deposition in the western distributary area (labeled lower fan distributary area) is detected, with net erosion in the active channel downstream of North Shore Road Bridge to Quinault River (10,000 yd^3). In all areas downstream from North Shore Road Bridge (lower fan), net deposition (128,000 yd^3) is detected between 2002 and 2011.

Potential for future channel change, lateral erosion and channel avulsion: Finley Creek alluvial fan is a dynamic system, and has continued to evolve throughout the historical period. Channel change is a natural part of the Finley Creek system and will need to be considered in any recommendations for future management alternatives. The identification of areas most prone to lateral erosion and avulsion are important to identify and evaluate as part of identifying restoration alternatives. Areas of lateral erosion were identified on the basis of vertical stream banks observed and mapped during 2013 fieldwork (Figure 5). Vertical banks of unvegetated sediment are indicative of actively eroding areas and are typically located along outer bends in the channel where shear stress on banks is the highest. These areas are likely to continue to erode as long as the active channel is located in a similar position. Most areas of Finley Creek that are prone to lateral erosion are located along the western side of the active channel, where the channel is actively eroding. Areas prone to toppling are located along the eastern side of the upper fan active channel where fluvioglacial deposits crop out in the glacial terrace. This area has been eroding laterally since about 1952; however, undercutting at the channel level has caused toppling of the surface soil, depositing underlying sediment and large trees at the base of

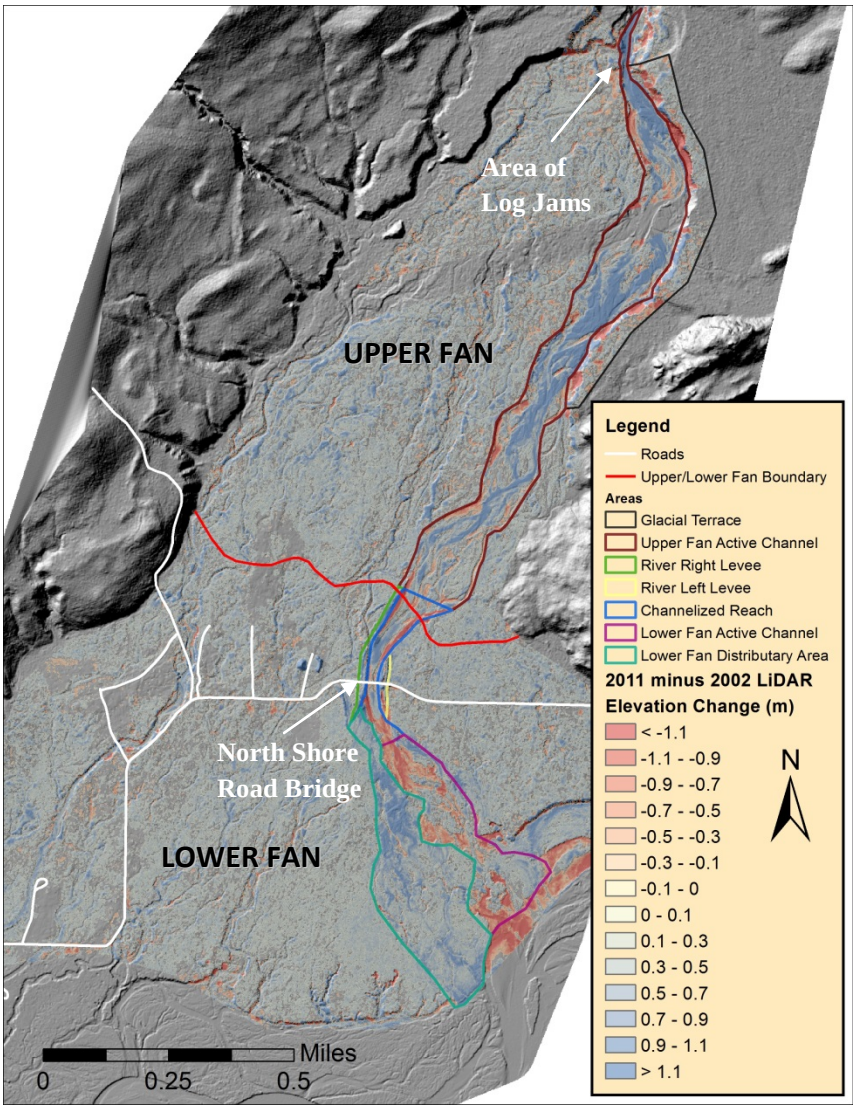

Figure 4 Erosion and deposition patterns of Finley Creek between 2002 and 2011 identified using Geomorphic Change Detection software.

the bluff. In addition, unraveling of the mostly unconsolidated glacial sediments has also generated a large amount of debris in the channel that provides some measure of bank protection along the eastern side of the channel on the upper fan. However, retreat of the bluff could continue through physical weathering and detachment of unconsolidated materials at the base of the bluff.

Channel avulsions could promote abandonment of some areas along the stream in which case the lateral erosion would shift to different areas than those shown in Figure 5. Areas of potential avulsion are located where the channel is most likely to shift position by abandoning its present channel for a new course (black circles in Figure 5). A channel avulsion could also occur where the distribution of flow and sediment shifts to a new location without completely abandoning, but leaving much less flow in, the old channel.

Potential avulsions areas were defined based on:

- Areas of low elevation adjacent to the active channel, especially those located along outer bends in the channel
- Presence of geologically recent or historical channels in overbank areas that have flow only in larger floods, but could be accessed by main channel flow
- Channels inundated in overbank areas as shown by the hydraulic model results
- Evidence for splays of the main channel, which indicate overbank inundation and preferred flow paths during high flows

Other areas of potential avulsion were identified that were not adjacent to the active channel in order to identify low elevation areas where the main channel could avulse if human constructs such as berms or levees were removed (white circles in Figure 5). These areas could also be avulsion areas even if human constructs are maintained, but the avulsion may take considerably longer to occur.

The area with the most potential for channel avulsion is located along the western side of the active channel upstream from the North Shore Road Bridge (area # 4, 5 and 10). This is an extensive area of low elevation where the current Finley Creek channel is perched above its surrounding floodplain, and held in place by man-made berms (area #10). When compared to surficial mapping (Figure 3), the avulsion areas are located mostly in areas that are mapped as historical alluvium.

Numerical hydraulic modeling: A fixed-bed two-dimensional (2D) numerical hydraulic model, SRH-2D (Lai, 2008), was employed to capture the inundation extent and hydraulic properties of flood flows experienced on the Finley Creek alluvial fan. Over the entire alluvial fan, only surface hydraulics are simulated, although observations indicate that there is significant surface water and groundwater interaction on the alluvial fan. Six different steady flows from the 1.5- to the 100-year discharge are simulated on the 2011 LiDAR surface, with the downstream stage-discharge boundary condition based on a modified HEC-RAS model of the Quinault River used in Bountry et al (2005). Manning roughness values were assigned to various areas including the channel (0.025-0.035), densely vegetated floodplain (0.1), sparsely vegetated floodplain (0.04), road prism (0.02), and structure footprints (0.08).

Lacking gaged discharge and measured water surface elevations for model calibration, a sensitivity test of the assumed water surface elevation was performed varying channel roughness and flood frequency. Modeling results of existing conditions for the 2- and 100-year events indicate that these flows are confined primarily to the active channel (Figure 6). Various restoration ideas developed with the consensus of the stakeholders can be simulated with the 2D numerical hydraulic model, such as the removal of various anthropogenic features (e.g. levees and log jams), which reduces the confinement of flows across the alluvial fan (Figure 6). Restoration ideas include removal of the historical log jams on the west side at the canyon mouth (Figure 3), removal of a portion of the western levee upstream of North Shore Road Bridge, construction of 7 to 8 road crossings through the road prism and raise of the road prism above the 100-year water surface elevation.

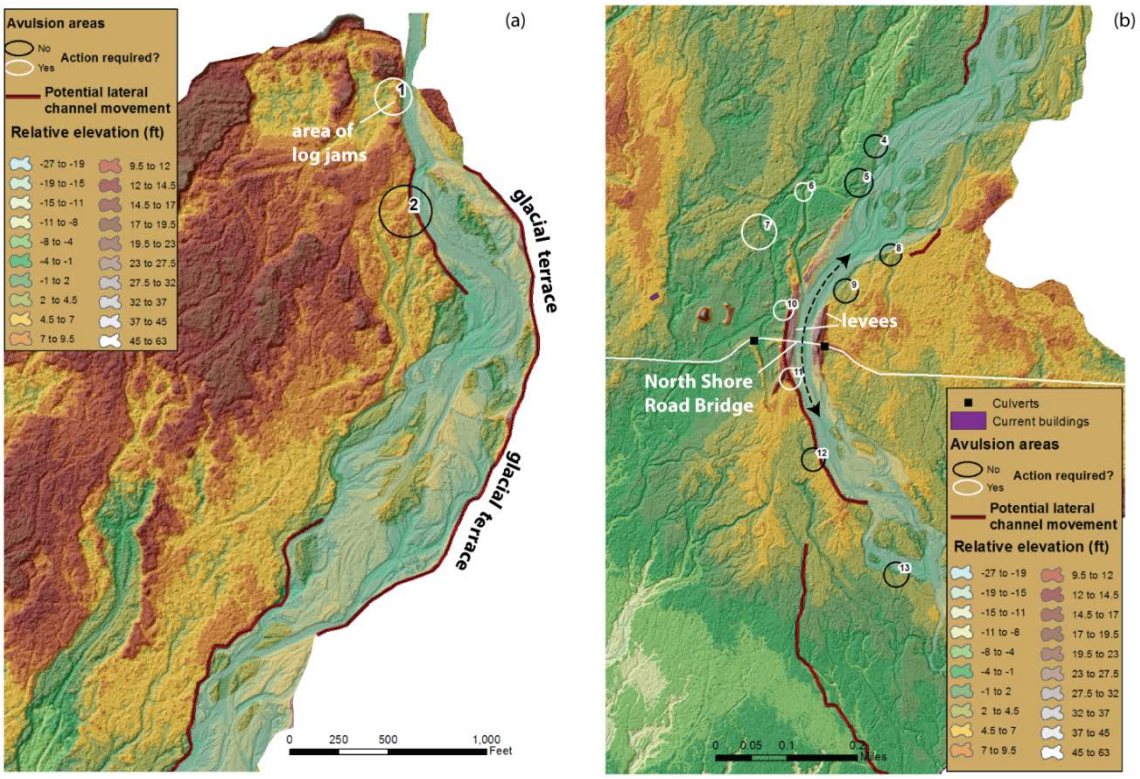

Figure 5 Finley Creek potential avulsion and lateral erosion areas. (a) upper fan; (b) lower fan. The avulsion areas are based on 2011 relative elevation map and field verification in 2014. The areas of potential lateral erosion were identified during field work in 2013. Avulsion areas are shown as circles; black circles show areas where man-made features do not block the channel from avulsing. White circles show areas where man-made features would either need to be removed or eroded before an avulsion could occur. Dashed line with arrows shows the channelized reach. The 2011 active channel is shown in light blue overlaid on the relative elevation map.

SUMMARY OF PRESENT CONDITIONS

Prior to human manipulation, Finley Creek existed as a multi-thread system that flowed through islands of alluvium with weakly developed soils and mature vegetation. With a natural decrease in gradient on the lower fan, flows became more distributary, depositing sediment on the fan surface and delivering sediment to the Quinault River. With the help of human constructs such as levees, repeated excavation of the channel, log structures and berms, the Finley Creek channel on both the upper and lower fan has been restricted to one main channel with intermittent mid-channel islands and immature vegetation and has shifted progressively to the east beginning in the late 1800s. In recent years (2002-2011), the main channel of Finley Creek on the upper fan has been dominated by deposition; the channel on the lower fan has been dominated by erosion. Landslides in the form of large debris avalanches appear to occur every few decades in the canyon upstream of the alluvial fan and are a periodic but persistent sediment source to the Finley Creek channel on the upper fan. Streambank erosion of the glacial terrace along the east

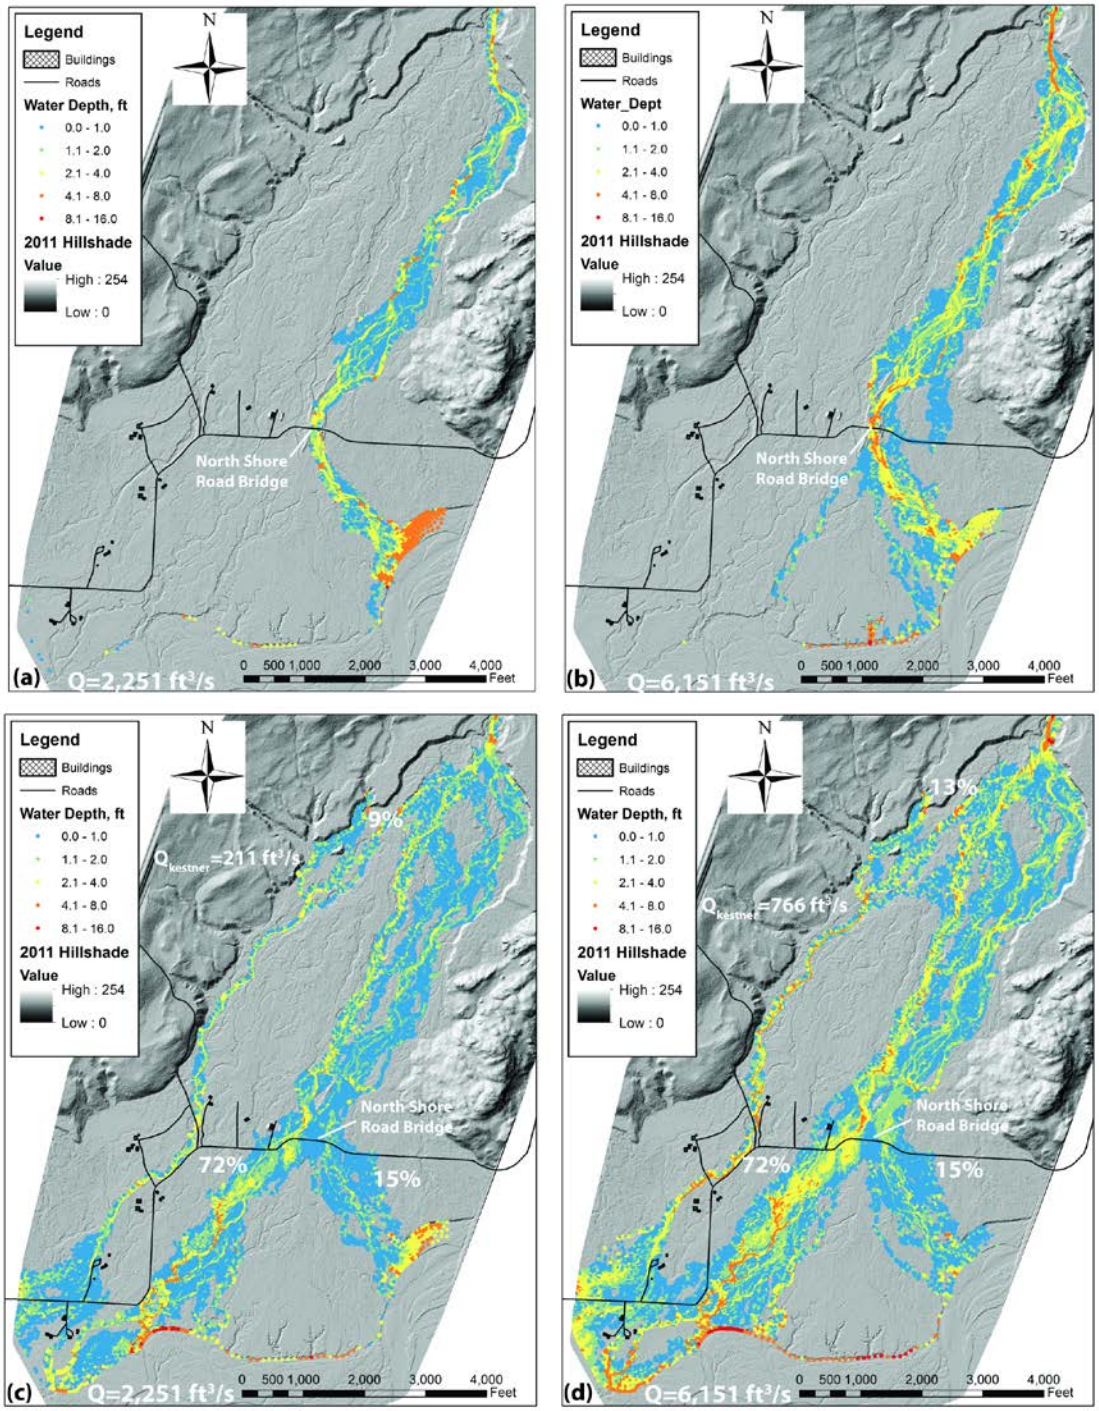

Figure 6 Hydraulic modeling results. (a) Existing condition (2011) 2-year discharge; (b) Existing condition (2011) 100-year discharge; (c) Example restoration condition, 2-year discharge and (d) Example restoration condition, 100-year discharge. Both restoration conditions (c) and (d) show modeling results with the removal of western levee at the North Shore Bridge and the log jam at canyon mouth and construction of channel crossings through North Shore road prism and raise of the road prism above the 100-year water surface elevation. Percentages show the distribution of flow among the various flow paths.

boundary of the upper fan and alluvial fan materials along the channel in the upper and lower fan area also provide sediment but total volume from these sources is not as large as the sediment contributions from the landslides. The area in the vicinity of the North Shore Road Bridge (the channelized section) has experienced net erosion likely because the channel has been excavated on an annual basis to increase channel conveyance under the bridge, however, sediment quickly refills the excavated area during the rainy season from November through February. Areas of potential avulsion are located mostly along the west side of the active channel on both the upper and lower fan at pre-existing historical channel paths. The 1939 western channel branch near the canyon mouth is not as likely to be an avulsion path even if the historical log jam is removed because the active channel appears to have incised in this location following the abandonment of the western channel. A major upstream landslide with large wood and a large sediment pulse would be necessary to cause an avulsion in this area.

IMPLICATIONS FOR RESTORATION

Hydraulic modeling of existing conditions shows that flows up to the 100-year magnitude are largely contained within the existing Finley Creek channel. Therefore, restoration alternatives will need to include active or passive removal of levees that block flow from entering former distributary areas on the lower fan. Restoration alternatives are currently being explored with coordination with local stakeholders. As an example, modeling of the 2-year and 100-year discharges show that if the western levee at the North Shore Bridge is removed and the channel aggrades 3 ft based on previous depths of channel filling following excavation, the following changes occur:

- Increased inundation in North Shore Road area primarily east of the current channel location and potential for flow on lower fan in west channel.
- Additional flow in western historical channels (Historical alluvium IA and IB) as a result of aggradation and west levee erosion/removal in which flow spreads across lower fan (50/50 split). Flow remains east of North Shore Road north-south trending section and there is no flooding of current structures.

Allowing flow onto the western part of the fan should reduce aggradation in the vicinity of the North Shore Road Bridge and also increase flow into historical channels and therefore habitat availability for various aquatic species. To accommodate flow and sediment across the North Shore Road in order to allow for year round road usage, the construction of seven to eight stream crossings in the road prism, with possibility of a road prism raise above the water surface elevation of the modeled 100-year discharge are included in the model (Figure 6c and 6d). Forded crossings, temporary bridges, and/or permanent bridge crossings are also potential alternatives that will be further investigated.

Active restoration by means of removing the log jam blocking the prehistorical channel at the canyon mouth would allow flows into 1890’s, 1939, and current channels, increasing flows into nearby Kestner Creek and reducing flow in Finley Creek at North Shore Road Bridge. Flow is mostly in western channel on the lower fan (70%+). With this scenario, some flow connectivity with Kestner Creek and the western part of alluvial fan causes possible overtopping of the North

Shore Road near known free-standing structures. Options for either protecting this area with structures or relocating structures would need to be considered for this restoration alternative.

Analyses that were key to the investigation of the alluvial fan are the surficial mapping and relative elevation mapping of the fan to define prehistoric and historic channels, and also to identify trends in lateral migration and potential avulsion areas. 2D numerical hydraulic modeling is key to identifying existing active flow paths during higher flows and for developing a snapshot of future active flow paths given various future actions on the alluvial fan. Challenges in developing a more sustainable road crossing across an alluvial fan requires the implementation of multiple crossings which allow for migration of the active channel across the fan with enough capacity to pass large flows that transport woody material and sediment. A better understanding of the surface water and groundwater interactions on the alluvial fan through coupled hydraulic modeling would be desirable for future analyses and would aid in the evaluation of aquatic habitat on Finley Creek and associated tributaries.

WILDFIRE-INDUCED FLOODING AND EROSION-POTENTIAL MODELING: EXAMPLES FROM COLORADO, 2012 AND 2013

Steven E. Yochum, Hydrologist, US Forest Service, National Stream & Aquatic Ecology Center, Fort Collins, CO, steveneyochum@fs.fed.us; **John B. Norman, Soil Scientist**, NRCS, Soil Survey Division, Fort Collins, CO, john.norman@co.usda.gov.

prepared for the 5th Federal Interagency Hydraulic Modeling Conference
April 19-23, 2015, Peppermill Hotel, Reno, Nevada, USA

Abstract: Flooding and erosion potential for the High Park, Black Forest and West Fork Complex wildfires, in Colorado, were modeled using the Natural Resources Conservation Service (NRCS) curve number (CN) and Revised Universal Soil Loss Equation (RUSLE) methodologies. The CN technique, implemented within HEC-HMS, estimated direct runoff from rain events for both pre- and post-fire conditions, to develop estimates of increased flood hazard and potential threat to life and property. A spatial version of RUSLE was developed to predict pre- and post-fire sediment yields for each 10x10 meter area for hydrologic flow paths connected to the burn area. The pre- and post-fire CN runoff and RUSLE sediment erosion estimates were summarized at strategically-located pour points within and downstream of the wildfire burn areas. Results were computed at 96 pour points for the High Park Fire (87,000 acres), 52 pour points for the Black Forest wildfire (14,300 acres), and 70 pour points for the West Fork Complex wildfire (109,000 acres). Post-fire conditions were simulated to result in 100-year floods from 10-year rainfall events in the most severely-impacted watersheds and up to 70 to >200 times of sediment expected on an annual basis. The results are most appropriately used in a comparative manner, between catchments.

INTRODUCTION

The 2012 and 2013 Colorado wildfire seasons resulted in 20 substantial fires, including the West Fork Complex, Black Forest, and High Park (Figure 1) wildfires. Wildfires induce substantially increased flooding and erosion potential, with resulting impacts to life and safety, transportation and water supply infrastructure, property, and ecosystems. To address these issues, land managers, planners, and emergency response officials need prompt and spatially-explicit predictions of expected increases in flooding and sedimentation.

Figure 1 High Park Fire as viewed from Fort Collins, on day 1.

In response to requests from local, state, and federal agency partners, flooding and erosion potential for the High Park, Black Forest and West Fork Complex wildfires were modeled. The NRCS curve number (CN) and Revised Universal Soil Loss Equation (RUSLE) methodologies were implemented. The CN technique estimated direct runoff from rain events for both pre- and post-fire conditions, to develop estimates of increased flood hazard and potential threat to life and property. A spatial version of RUSLE was developed to predict pre- and post-fire sediment yields for each 10x10 meter area for hydrologic flow paths connected to the burn area. The pre- and post-fire CN runoff and RUSLE sediment erosion estimates were summarized to strategically-located pour points within and downstream of the wildfire burn areas. The magnitude of change in sediment yield and runoff were calculated for every pour point, to facilitate interpretation.

An overview of the implemented methods and results are provided, to assist other scientists and engineers with the task of providing officials with estimates of increased flooding and erosion potential after a wildfire. Similar approaches have been implemented by other workers (Livingston et al. 2005; Springer and Hawkins, 2005; Larsen and MacDonald, 2007; Rulli et al. 2013). Other tools are preferred by some practitioners (Canfield et al. 2005, Goodrich et al. 2005); Kinoshita et al. (2014) and Chen et al. (2013) provide comparisons between the results of differing methods. Due to limitations in modeling tools and data availability, and limits in scientific understanding of wildfire hydrology processes, these analysis results are most appropriately used in a relative manner for comparing runoff and sediment liberation potential between catchments. Despite this limitation, the provided methods do produce quantifiable results that are helpful for the informed development of response and restoration priorities, to protect life, property, and infrastructure in the hectic months that follow a wildfire.

METHODS

Wildfires cause hydrologic shifts for a number of years. Substantially increased runoff and sediment production result from the loss of vegetation and soil cover, as well as from hydrophobicity, where the fire-induced vaporization of hydrophobic compounds causes water to collect on the soil surface and run off, instead of infiltrate. The lack of vegetation interception and soil infiltration, from the loss of surface roughness from ground litter and hydrophobicity, can shift the rainfall response from infiltration-dominated processes to surface runoff-dominated processes. For example, watershed impacts due to recent wildfire caused a Swiss catchment to produce 100-year to 200-year runoff discharges from a 10-year rainfall event due to changes in infiltration capacity (Conedera et al. 2003), though scale effects with greater runoff enhancement in smaller catchments and tendencies towards overestimation in larger catchments have been noted (Stoof et al. 2011). Hydrophobicity, which tends to be more prevalent with increased sand content and lower soil water content, has been found to weaken within a few months of a fire but persist for at least 22 months in ponderosa and lodgepole pine forests of the Colorado Front Range (Huffman et al. 2001). Post-fire sediment yield is most dependent on ground cover, with percent ground cover explaining more than 80 percent of the variability in sediment yield (Benavides-Solorio and MacDonald 2001). Soil burn severity is hence fundamental for predicting sediment yield increases.

Predictions of post-fire sediment yield rely on mathematical models such as Revised Universal Soil Loss Equation RUSLE (Renard et al., 1997), Water Erosion Prediction Project WEPP (Elliot, 2004) and GeoWEPP (Renschler, 2003), as well as professional judgment (Robichaud et al., 2000). These methods have varying advantages and disadvantages for estimating the spatial distribution of post-fire soil loss, but all methods can require large amounts of time and energy to estimate soil loss and its associated risks over large spatial extents. With wildfires becoming more pronounced in the wildland-urban interface, rapid watershed management actions to protect sociological concerns, water quality, and ecosystem health are needed. This need for a rapid response to evaluate and manage post fire soil loss has increased the interest in using Geographic Information System (GIS) technology to spatially model post fire sediment yields. This has produced toolsets that use the above models as engines to estimate soil loss rates spatially.

Rainfall-runoff modeling was performed to simulate the expected flood response of the streams draining the wildfire areas. Additionally, predictions of post-fire sediment yield were developed using RUSLE. The implemented methods are presented below. Additional details are provided in the project reports (Yochum 2012; Yochum and Norman 2014).

Runoff Modeling

Runoff modeling was performed using the program HEC-HMS (version 3.5). The NRCS curve number (CN) technique for estimating direct runoff from rain events, combined with the NRCS dimensionless unit hydrograph method, was implemented. As documented in NRCS (2004b), the NRCS method for estimating direct runoff from individual storm rainfall events is of the following form:

$$Q = \frac{(P - I_a)^2}{(P - I_a) + S} \text{ if } P > I_a \quad (1)$$

$$Q = 0 \qquad \text{if } P \le I_a \quad (2)$$

where Q is the depth of runoff (inches), P is the depth of rainfall (inches), I_a is the initial abstraction (inches), and S is the maximum potential retention (inches). The equation derivation is not physically based but does respect conservation of mass (NRCS 2004b).

The Curve Number (CN) is defined as:

$$CN = \frac{1000}{10 + S} \quad (3)$$

The initial abstraction was initially described and has traditionally been used as:

$$I_a = 0.2S \quad (4)$$

To reflect the decreased storage of a fire impacted soil surface (due to a reduction of depression storage from the elimination of soil litter), the initial abstraction was assumed to be 0.1S for post-wildfire conditions in catchments that were substantially burned (>50% moderate + severe soil burn severity). Catchments that were not substantially burned were modeled with the standard I_a of 0.2S. The impact of the I_a adjustment on CNs was ignored; for the high CN (post-wildfire) conditions, smaller shifts in CN due to changes in I_a can be expected (Woodward et al. 2003).

The CN is a simple catchment-scale method that gives simplified results at a stream outlet, with more accurate results expected for larger, higher-intensity rain events. The method is

documented is in the NRCS National Engineering Handbook, Part 630, Hydrology, Chapters 9 and 10 (NRCS 2004a, NRCS 2004b), in Rallison (1980), as well as in numerous other publications. However, little quantitative information has been published of the database on which it was developed (Maidment 1992). In general, the method was developed for rural watersheds in various parts of the United States, within 24 states; was developed for single storms, not continuous or partial storm simulation; and was not intended to recreate a specific response from an actual storm (Rallison, 1980).

An overview of the general weaknesses of the CN method is provided in Hawkins (2014). Specifically in regard to rainfall-runoff modeling for wildfire areas, the reliability of the CN method for predicting peak flow from forested, mountainous watersheds is debatable. Forested watersheds in unburned conditions may be dominated by saturation-excess overland flow, where runoff is produced from relatively small and variable portions of a catchment when rainfall depths exceed the soil capacity to retain water. Newly burned catchments, on the other hand, may likely be dominated by infiltration-excess (Hortonian) overland flow, where surface runoff is generated when rainfall intensity is greater than soil infiltration capacity, and flow runs down the hillslope surface. Evidence of this surface runoff is provided by such features as surface rilling on freshly-burned hillslopes. Rainfall-runoff modeling performed in the San Dimas Experimental Forest (Chen et al. 2013) found that pre-fire runoff predictions were more accurate using the CN method, while KINEROS2 performed better for post-fire conditions. These results suggest fundamental shifts in runoff mechanisms between pre- and post-fire conditions, complicating modeling strategies. CN values are not well known for burned conditions, which is a primary source of potential error. Additionally, spatial rainfall variability due to orographic forcing can lead to additional modeling uncertainty, for the CN method as well as other rainfall-runoff modeling tools.

Despite the method's shortcomings, due to its relative simplicity, achievable data requirements on large scales, and the relatively-short timeframe needed to develop a model, as well as at least qualitatively-reasonable results when compared to actual post-fire runoff events, the CN method is a preferred tool for predicting the flow responses of wildfire areas. The best use of the modeling results is through comparison of different catchments flood response to identical rainfall events, for the prioritization of areas of concern. The use of peak flow ratios (i.e. post-fire peak flow/pre-fire peak flow) can be the most effective tool for comparisons.

CN

Curve numbers are values less than 100, with higher values corresponding to catchments with lower infiltration rates and higher runoff potential. In general, CN assignments are typically made using guidance provided in NRCS (2004a). CNs were assigned throughout the modeled catchments according to hydrologic soil group, vegetative type, and soil burn severity (Table 1). Soil burn severity is a dominant factor in CN assignments in burned areas. The average catchment CN was computed using an aerial averaging methodology. Catchment size was limited to areas that have similar runoff characteristics, and, where possible, to 2000 acres. As catchment size increased, CNs were computed for adjacent and serial catchments and flows were modeled, routed downstream, and combined with lower catchments to predict flow at downstream points of interest (Figure 2).

Table 1 CN assignments.

Cover Description	**A** HSG				**B** HSG				**C** HSG				**D** HSG

Wetland	98	98	98	98	98	98	98	98	98	98	98	98	98	98	98	98

Hydrologic soil group (HSG) classifications were selected using soils data published in the NRCS SSURGO (Soil Survey Geographic) database. Using this method, soil are classified as being either A, B, C, or D type, where A allows the most infiltration and least runoff and D allows the least infiltration and greatest runoff. Vegetation type, from SWReGAP (Southwest Regional Gap Analysis Project) land cover mapping, was included in the CN assignments used for the modeling. Soil burn severity is the principle driver for increasing flow in runoff predictions. For these wildfires, soil burn severity was measured using the BARC process from satellite imagery.

A fair ground cover condition was generally assumed for the unburned values (Table 1) abstracted from NRCS (2004a), though a good ground condition was assumed for herbaceous/grassland. The CN values for burned conditions were primarily compiled from various grey literature and unpublished sources; they are approximate. Research is needed to better define these values.

Rainfall, Lag Time, Flow Routing, and Sediment Bulking

Rainfall depths used in the modeling were extracted from NOAA Atlas 14, Vol 8 (Perica et al. 2013), for the West Fork and Black Forest fire areas, and from NOAA Atlas 2, Volume 3 (Miller et al. 1973) for the High Park fire area. Six-hour rainfall durations and NRCS Type II rainfall distributions were assumed for the West Fork Complex Wildfire while 1-hour durations and TR-60 distributions were implemented for the Black Forest and High Park Wildfires. Areal reduction factors were applied as detailed in Miller et al. 1973. Where applied, these area reductions were implemented in all catchments; flow may be underpredicted in the smaller, upper catchments of such drainages.

Lag time (L), which is required to generate a hydrograph using the NRCS unit hydrograph methodology, was computed using the watershed lag method (NRCS 2010). The lag equation is:

$$L = \frac{l^{0.8}(S+1)^{0.7}}{1900Y^{0.5}} \tag{5}$$

, where l is the flow length (ft), Y is the average watershed land slope (%), and S is the maximum potential retention (in),

$$S = {}^{1000}\!\!\diagup\!\!_{cn'} - 10 \tag{6}$$

, where *cn'* is the retardance factor and is approximately equal to the CN. This method allows the rapid computation of differing lag times for pre- and post-fire conditions, reflecting the physical mechanism of more rapid flow response during post-fire conditions.

A Muskingum-Cunge procedure was used to route flow from upper catchments to the stream outlets. This 1-dimensional method allows for flow attenuation in the computations but does not provide a numerical solution of the full unsteady flow routing equations, as provided in such computational models as HEC-RAS. In each reach, flow routing was estimated using a single simplified cross section, channel slope, and Manning's *n* roughness estimates. Manning's *n* was selected using a visual estimation procedure, with a quality control step to assure that to maintain subcritical or approximately critical velocity was maintained, reflecting an assumption that existing or new channel bedform development prevents reach-average supercritical flow.

A simple multiplication factor was applied to the post-fire flood predictions to account for sediment bulking in the debris flows. For burned catchments, this multiplication factor was assumed to be 1.25 if the severe plus moderate soil burn severity aerial extent was greater than 50%, and 1.1 for catchments with between 15 and 50% soil burn severity.

Sediment Modeling

The RUSLE model was chosen to estimate pre- and post-fire sediment erosion rates. The RUSLE models (pre and post fire) are based on a spatial version of RUSLE outlined in Theobald et al. (2010) and Litschert et al. (2014). The ATREW methods entail calculating RUSLE (Equation 7) the standard way using widely available fine resolution spatial datasets to approximate the 6 RUSLE factors. The ATREW report provides guidance on parameterizing the RUSLE *C* and *P* factors based on commonly used landcover datasets (e.g., USGS National Landcover Dataset and USFS Existing Vegetation Dataset), as well as equations that scale GIS based terrain analysis for the *L* and *S* factors.

The advantages of this approach are (1) simple model parameterization using nationwide spatial datasets; (2) production of a sedimentation rate raster (each raster cell has a sedimentation rate); and (3), evaluate the resulting sediment yield rasters spatially to help prioritize soil treatment zones and emergency resource allocation. The RUSLE equation is:

$$A = R \cdot K \cdot L \cdot S \cdot C \cdot P \qquad (7)$$

where *A* is the average annual unit-area (tons per hectare per year), *R* is the rain erosivity factor (Mj mm/(ha h yr)), *K* is the soil erosivity factor, *L* is the slope length factor (m), *S* is the slope steepness factor, *C* is the cover management factor (>= 0), and *P* representing the management factor (>= 0). The sediment modeling entailed 4 general steps: (1) collection of geospatial dataset for the greater burn area (Table 2); (2) development of spatial RUSLE factors for pre and post fire conditions; (3) calculate RUSLE for pre- and post-fire scenarios (ArcGIS Raster Calculator); and (4) attribute computation points and values at risk with pre- and post-fire sedimentation rates. Pre- and post-fire sedimentation rate estimates were executed within a GIS using terrain analysis tools to calculate slope length (*L*) and steepness (*S*) factors with simple map algebra statements used to compute rainfall erosivity (*R*), soil erodibility (*K*) and cover management (*C*) factors from ancillary spatial datasets. The soil/cover management (*P*) factor was not incorporated in the analysis due to a lack of spatial information on management activity in the burn area. For each of the five RUSLE factors used, a 10-meter resolution raster dataset was

generated. The five RUSLE factor rasters where multiplied together to calculate the local (cell level) sedimentation rate. The local sedimentation rate values were accumulated downslope via a flow direction raster (Yochum and Norman 2014) and averaged by the contributing area above each raster cell. This results in the final sedimentation rate raster with values representing the average cumulative sedimentation rate in tons per year over 30 years for each scenario.

The rain erosivity (*R*) factor raster was generated by rasterizing the EPA EMAP HUC 8 polygon shapefile to a raster containing *R* factor values. The *R* factor raster was held constant between the pre- and post-fire scenarios due to a lack of information about change in rain erosivity values and the EPA EMAP values are based on 30 year averages. The HUC 8 *R* factor raster was masked out to match the cell size and processing extent.

Table 2 Spatial datasets sources used for the six RUSLE factors.

Factor	Source
R	U.S. Enviromental Protection Agency EMAP-West RUSLE Factors
K	USDA NRCS Web Soil Survey SSURGO spatial and tabular data
L & S	USGS National Elevation Dataset
C	USGS National Gap Analysis Program 30 meter landcover
P	Parameter not used in analysis due to lack of good spatial data

The development of soil erodibility (*K*) factor raster entailed summarizing KFFACT (SSURGO table attribute) to NRCS SSURGO map units and then rasterizing the map units in the same manner as the *R* factor. KFFACT (property of a soil horizon) was summarized to map unit delineations by calculating a depth/area weighted average based on horizon depths up to 15 centimeters and the component percent within a map unit. This was accomplished through queries developed in the SSURGO database downloaded from the USDA Geospatial Data Gateway website. The *K* factor raster was held constant for both scenarios even though burn severity alters soil erodibility. Altering soil erodibility based on burn severity between scenarios could be incorporated in future models but would require additional research.

The *L* and *S* factor were calculated jointly (*LS*) using basic terrain analysis methods outlined in Theobald et al. (2010) using a 10 meter elevation model. These methods include calculating a percent slope, aspect (radians), and accumulated upslope length. The accumulated upslope length process entailed accumulating number of contributing raster cells to a given cell based on the overland flow paths from the flow direction raster. The resulting slope, aspect and upslope length rasters were transformed using equations developed by Winchell et al. (2008, Equation 8) and Nearing (1997, Equation 10). These equations scale the values derived from the above terrain analysis to better fit within the frame work of the RUSLE equation and ensure that the units are correct. The slope length scaling equation is

$$LS_{i,j} = S_{i,j} * \frac{(A_{ij}+D^2)^{m+1} - A_{ij}{}^{m+1}}{X_{i,j}^{m+2} \cdot D^{m+2} \cdot 22.13^m} \quad (8)$$

, where LS_{ij} is the transformed slope length, D is the cell size of the analysis (10 meters), X aspect transformation (Equation 9), m slope transformation (Equation 10) and $S_{i,j}$ is the slope transformation function derived by equation 11. Aspect transformation were computed through:

$$X_{i,j} = \sin \alpha_{i,j} + \cos \alpha_{i,j} \quad (9)$$

, where $X_{i,j}$ is the transformed aspect values for raster cell *I* and *alpha* is aspect (radians clockwise from north) for raster cell *I*. Radians was used instead of degrees from north to prevent negative values from occurring when calculating COS of aspect in ESRI ArcGIS. The slope transformation is

$$\beta = \frac{\frac{\sin\theta_{i,j}}{0.0896}}{3(\sin\theta_{i,j}^{0.8}+0.56)} \quad (10)$$

, where *theta* is percent slope and the *m* coefficient is calculated by taking the ratio between *beta* and one plus *beta* ($\beta / 1 + \beta$).

The slope length ($LS_{i,j}$) factor raster was developed using the Nearing (1997) equation (Equation 8) in conjunction with equations 9, 10 and 11 to account for aspect and slope dynamics to better scale large flow path values (accumulated slope length). This is necessary because the accumulated flow path raster (A_{ij}) can have very large values which inflate sedimentation estimates. The *S* factor raster was developed by transforming percent slope using equation 11. Equation 11 scales slope values to reduce inflated soil loss values especially for slopes greater than 50%. As with the *R* and *K* factors the *L* and *S* factors were held constant between the pre and post fire models. The *S* factor transformation is computed as

$$S_{i,j} = 1.5 + \frac{17}{1+e^{(2.3-6.1*\sin\beta)}} \quad (11)$$

, where *beta* is the mean slope angle (Equation 10).

The *C* factor parameterization for the pre- and post- fire scenarios was developed using various source tables from different documents related to RUSLE. The pre-fire scenario parameterization involved developing a lookup table that assigns the existing landcover types (Southwest ReGAP) within the greater burn area their associated *C* factors (Yochum and Norman 2014). Table 3 in this project report was compiled by Theobald et al. (2010) for the ATERW report and provides a broad spectrum of landcovers found in most landcover datasets and can be modified based on local knowledge. The post-fire *C* factor parameterization entailed modifying the pre- burn *C* factor raster based on burn severity classes derived from the Burned Area Reflectance Classification (BARC) image. This process consisted of assigning the BARC burn severity classes *C* factor values (low burn = 1.03, moderate burn = 2.25 and high burn 3.75) (Larsen et al., 2007) that were then used to modify the pre-fire *C* factors by summing the two rasters together. Larsen et al. (2007) estimated that high burn severity area *C* factors changed by four hundred percent but didn't estimate moderate and low burn severity changes. *C* factors changes were selected using professional judgment.

The final sedimentation rate models for the pre- and post-fire scenarios were generated by first multiplying the 5 factors, accumulating the multiplied values downslope via the flow direction raster, and calculating an area weighted sedimentation rate. The area weighted sedimentation rate is calculated by dividing the accumulated sedimentation rate by the total accumulated drainage area (Yochum and Norman 2014). This aspect approximates the transportation of sediment from areas where sediment originates (steep slopes or burned areas) to areas that dampen sediment transport due to decreases in slope, unburned areas or flow distance. This assumes that sediment yields decreases from source areas downslope as slope decreases and distance increases.

RESULTS AND DISCUSSION

The results from the these three sets of models provided useful estimates of post-fire flooding and sedimentation rates that officials have used to prioritize management activities to reduce risk to life, property and infrastructure. Due to modeling limitations, the results are most appropriately used in a relative manner, comparing runoff and sediment liberation potential between catchments.

The 70 pour points for West Fork Complex wildfire (109,000 acres) indicate that severely burned catchments would experience a 50- or 100-year flood from a 10-year rainfall event and that 25-year rainfall events would produce more than 12 times the peak flow at some locations (Figure 2). Example maps produced for the project report are illustrated (Figures 3 and 4). The sediment modeling predicts that, on average, all catchments will experience 130 times more sediment, with one burn area (Papoose wildfire) accounting for 65% of the total sediment predicted to be delivered to the Upper Rio Grande river from the two fires.

Results at ninety six pour points were computed for the High Park wildfire (87,000 acres). Post-fire conditions were commonly predicted to induce 50- or 100-year floods from 10-year rainfall events across the High Park burn area, with the 25-year rainfall event expected to yield up to up to 10 times the pre-fire peak flow. Additionally, sediment yields were predicted to be 73 times

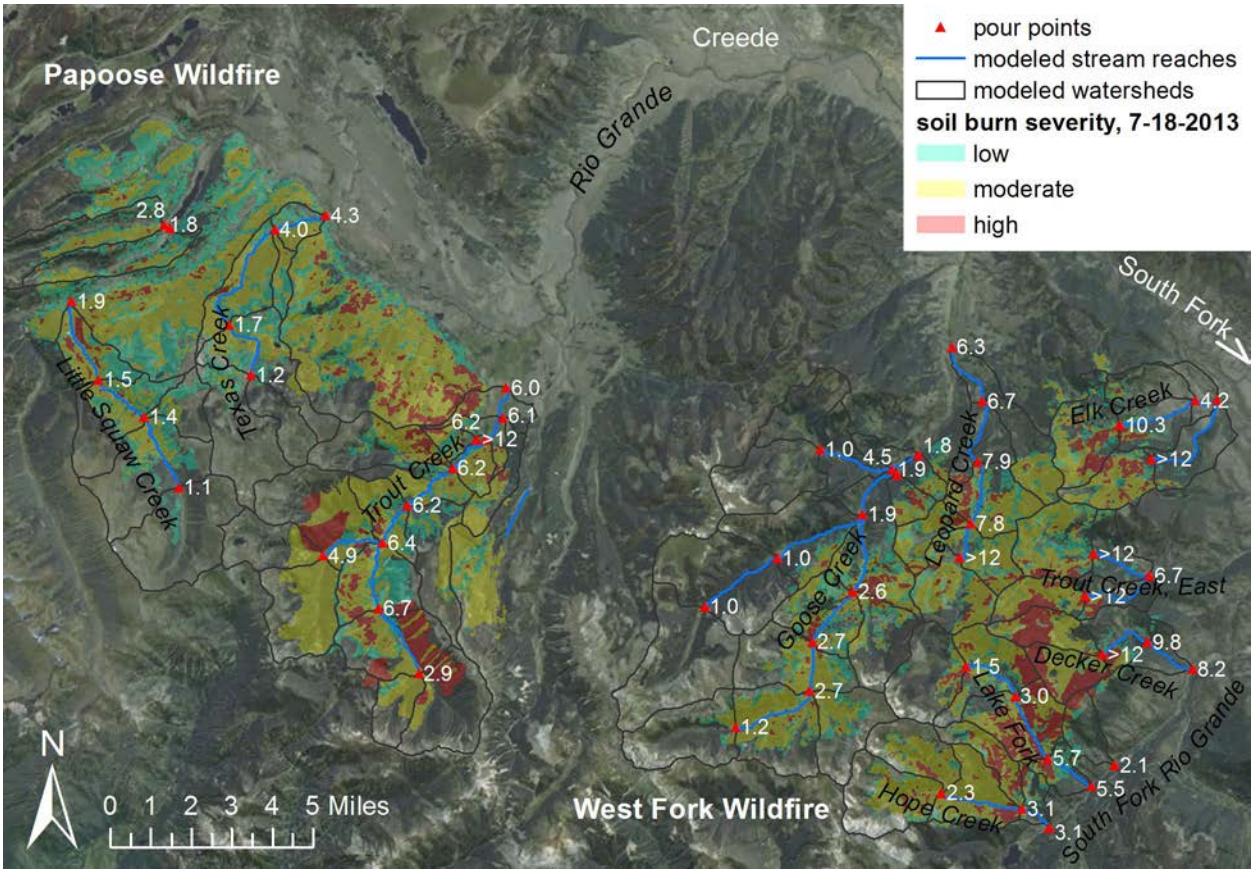

Figure 2 West Fork Complex wildfire peak flow magnification ratios (25-year rain event).

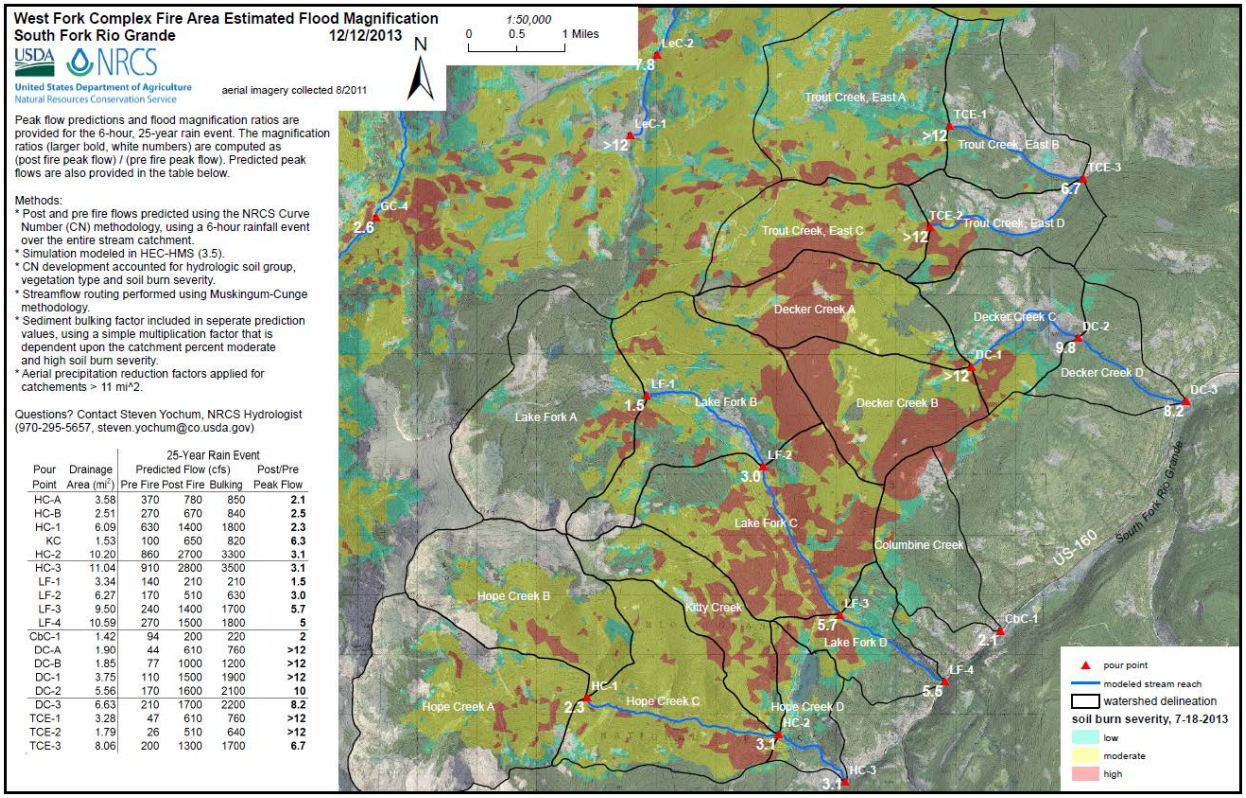

Figure 3 Example map providing pre- and post-fire flood predictions for the S. F. Rio Grande.

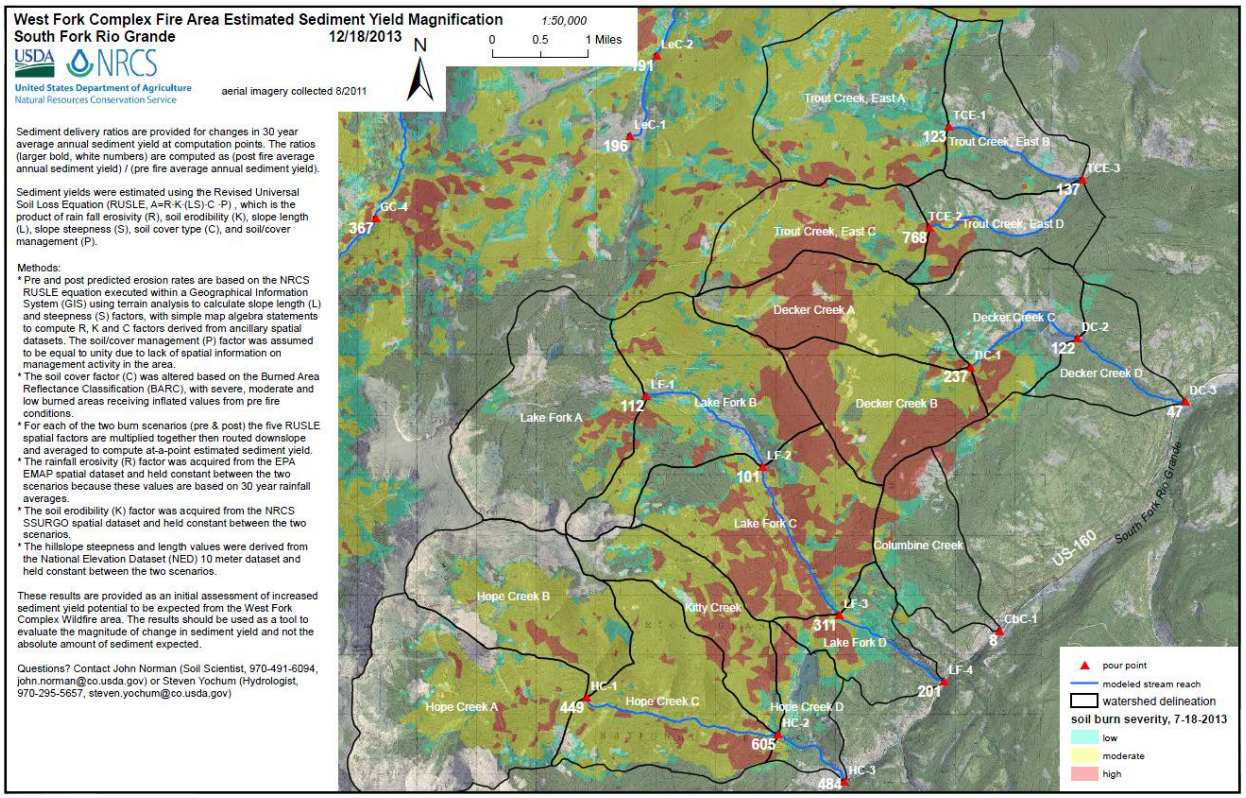

Figure 4 Example map providing pre- and post-fire erosion predictions for the S. F. Rio Grande.

greater than pre-fire conditions, with five catchments of the South Fork of the Cache La Poudre River having sediment magnification rates greater than 200.

Results at the 52 pour points for the Black Forest wildfire (14,300 acres) indicated that values at risk would experience a 100- or 200-year flood event from a 10-year rainfall event, with up to 15 times the pre-fire peak flow expected for the 25-year rainfall event. Sediment yield estimates predict sediment rates 75 times greater than pre-fire conditions with 15 values at risk having sediment magnification rates greater than 200.

CONCLUSIONS

Flow and sediment modeling was performed for the High Park (2012), Black Forest (2013) and West Fork Complex (2013) Wildfires. The results from the these three sets of models have provided useful comparative estimates of post-fire flooding and sedimentation rates (with respect to pre-fire conditions) that officials have used to prioritize management activities to reduce risk to life, property and infrastructure.

Substantial automation of the relatively-simple computational tools used to develop these estimates is possible; with support for the development or refinement of automation tools, results at the spatial scale presented in this report are likely feasible within the relatively-short Burn Area Emergency Response (BAER) process timeline.

ACKNOWLEDGEMENTS

Numerous individuals have contributed fieldwork, review, and other support for the modeling presented in this report. These individuals include David Levinson, Kari Sever, Sam Streeter, John Andrews, Claudia Hoeft, John Segars, Dustin Jager, Randy McKinley, Dan Moore, Jonas Feinstein, Rodney Clark, and Beau Temple. Their assistance has been highly appreciated.

NRCS POST-FIRE HYDROLOGIC MODELING IN NEW MEXICO 2012

Daniel S. Moore, P.E., Hydraulic Engineer, USDA-NRCS, Portland, Oregon, dan.moore@por.usda.gov

Abstract Wildfire can ravage enormous areas of the landscape and initiate extensive efforts among many agencies to combat the active event. Post-fire consequences also require attention, as the sudden watershed changes wrought by fire leave communities vulnerable to much larger floods, sedimentation, and debris flow. The Natural Resources Conservation Service (NRCS) in New Mexico played an important role both during and after large wildfires in the summer of 2012. Rapid application of the Emergency Watershed Protection (EWP) program funded several temporary USGS precipitation collection stations in the burned watersheds to help forewarn communities of possible flooding. Forest Service Burned Area Emergency Response (BAER) teams provided rapid assessment of the expected hydrologic consequences of the fire. NRCS followed up with detailed watershed modeling of Whitewater Creek, so that expected flood peaks and sedimentation could be quantified. Subsequent extreme storm events occurred in September 2013 in Whitewater Creek, New Mexico, and in Colorado's Front Range, the latter making national news. Development of the NRCS post-fire hydrologic analysis is detailed herein, with output including model performance of the 2013 observed event.

INTRODUCTION

Lightning sparked several outbreaks of wildfire in May 2012 that joined to became the largest in New Mexico recorded history. Lack of road access and the steep terrain of the Gila Wilderness Area hampered containment efforts, allowing the individual fires to grow rapidly. By the end of May, they had become one large wildfire known as the Whitewater-Baldy Complex.

The rugged landscape was not the only reason these fires escaped control. The watershed had already been under extreme drought conditions, with very little snowfall during the two previous winters. Air temperatures at the time of the outbreak were well above average, and high winds contributed to the merging of the fires. In early June, the Whitewater-Baldy Complex was only about 18 percent contained. By mid-June, containment increased to 56%. For about three months, the wildfire burned Ponderosa, Pinon/Juniper, and mixed conifer forests with relatively low burn temperatures. Rainfall in mid-July finally helped fire fighters gain momentum, with 95% containment attained in late July.

The wildfire burned about 465 square miles. The USDA Forest Service estimated final burn severity for the area within the fire perimeter to be 14 percent high, 12 percent moderate, 55 percent low or unburned, and 20 percent unknown (due to inadequate satellite imagery). Figure 1 shows the general location of the wildfire.

The NRCS Emergency Watershed Protection (EWP) program funded the installation of monitoring gages in the Whitewater-Baldy Complex burn area, to provide early warning to downstream communities of flood potential. The intensity of the wildfire and its large area prompted the Forest Service, in cooperation with the United States Geological Survey (USGS),

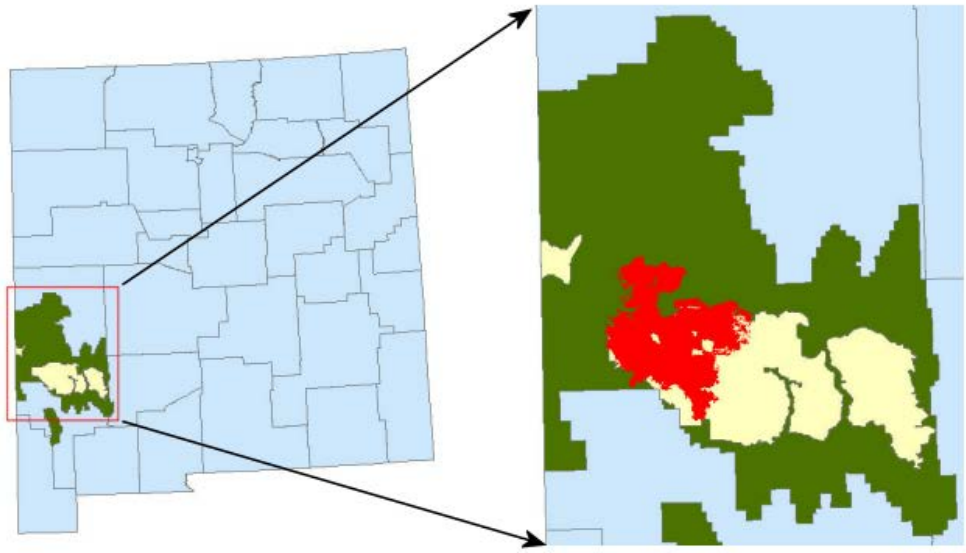

Figure 1 SW New Mexico, Gila National Forest (green), Gila Wilderness area (yellow), Whitewater-Baldy Complex wildfire (red).

to seek EWP funding from NRCS. The NRCS New Mexico State office worked with the New Mexico Department of Homeland Security and Emergency Management, which acted as the EWP local sponsor. USGS installed a streamflow gage on Whitewater Creek, near the Catwalk Recreational Area (figure 2). That station also received a precipitation gage. The location of the existing NRCS snow telemetry (SNOTEL) site is also shown in figure 2, along with additional precipitation gages installed by USGS using EWP.

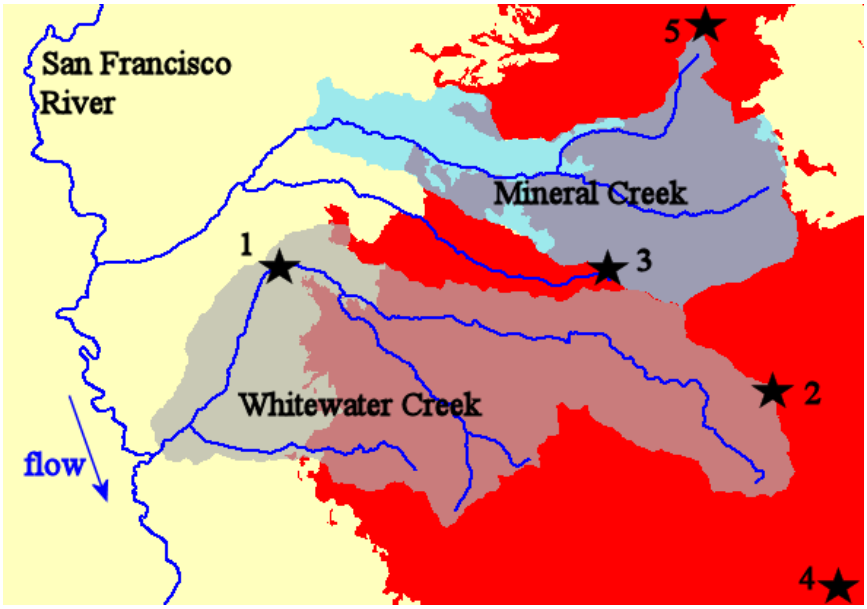

Figure 2 Gages in the burn area (red): Silver Creek Divide SNOTEL site (3), streamflow and precipitation at Catwalk (1), precipitation at Hummingbird Saddle (2), Mogollon Baldy Lookout (4), and Bear Wallow Lookout (5).

NRCS also performed a hydrologic analysis to assess flood potential for the community of Glenwood. In recent years New Mexico residents experienced flash flooding after wildfire. Hypothetical floods examined were pre-fire, post-fire immediately after the burn, and post-fire, one year later. Data from the newly installed precipitation and streamflow gages were used to verify that the hydrologic model produced reasonable results.

HYDROLOGIC MODELING DETAILS

After selecting a software application for watershed modeling, the hydrologist has key decisions to make about how to represent the landscape. These are an attempt to guide the model in partitioning precipitation between infiltration (and other losses) and runoff, and secondly, transforming remote runoff to an outlet hydrograph. The NRCS hydrologic model WinTR-20 employs the curve number runoff method, with curve numbers (generally between 30 and 99) that affect runoff volume (USDA-NRCS, 2004). Curve numbers are a subarea index, which includes losses to transpiration and ponding. Within the US Army Corps of Engineers model, HEC-HMS (USACE-HEC, 2013), these losses can be specified separately. The model provides several infiltration options, including curve numbers, and the Green-Ampt method. The latter is an attempt to model the physical infiltration process using soil characteristics such as hydraulic conductivity.

The draft NRCS National Technical Note Hydrologic Analysis of Post-Wildfire Conditions (USDA-NRCS, 2014), currently under review, provides a comprehensive guide to hydrologic modeling of post-wildfire conditions. The hydrologic model of Whitewater Creek, New Mexico, discussed in this paper is included in the technical note as a case study. The hydrologic modeling choices selected for Whitewater Creek were the HEC-HMS model, with Green-Ampt infiltration, and a user-specified unit hydrograph for runoff transformation.

Issues Particular to Post-Wildfire Modeling

The hydrologist has several challenges with burned watersheds. Adequate historical data records generally do not exist. The often remote and mountainous watersheds may never have been gaged or studied for rainfall-runoff behavior, which would establish indices such as curve numbers or peaking factors for synthetic unit hydrographs (UHs). Even if they were gaged, the gages would have to survive wildfire events to be available for monitoring the sudden watershed changes caused by the fire. New gages can be rapidly installed after an event, such as occurred for the Whitewater-Baldy Complex fire, but rarely is this action taken, and such data cannot provide insight into pre-fire runoff behavior.

Research literature to date does not provide post-wildfire modeling guidance that would remove much hydrologic judgement from the effort. The NRCS technical note (USDA-NRCS, 2014) gives several tables of post-wildfire runoff curve numbers (CNs) that have been compiled from previous hydrologic modeling efforts. Generally, these CNs have been selected using hydrologic judgement rather than being data-derived. One study of ten Appalachian forested watersheds, that did use data, found measured CNs varied significantly from published suggested values (Tedela, et al., 2012). The study also found very wide confidence limits for the measured values. One watershed, with a measured mean CN of 57, had 95 percent confidence interval of 32 to 83.

Other data-driven studies also found inability to achieve a stable CN value (Hawkins, 1993, and Springer and Hawkins, 2005).

Another source of uncertainty in hydrologic modeling of mountain watershed is in the use of synthetic unit hydrographs that include a user-specified peaking factor. The unit hydrograph transformation algorithm in WinTR-20 has a default peaking factor which applies to U.S. watersheds of average flow slopes and landscape storage effects. Mountain watersheds tend to have much steeper slopes and fewer storage effects than average. A hydrologist using WinTR-20 has the option to change this peaking factor, but the program does not make it obvious when it should be changed, and retaining the default is the likely practice, even for mountain watersheds. When using HEC-HMS the hydrologist cannot select an SCS peaking factor, but has only two hydrograph shape options: standard (the default peaking factor) and "Delmarva", a hydrograph shape developed by NRCS for the Delaware, Maryland, and Virginia peninsula, and often used for Eastern U.S. coastal watersheds. (A larger range of optional peak factors is planned for HEC-HMS version 4.1.)

To escape the need for a peak factor estimate, the hydrologist may consider other synthetic unit hydrograph options available in HEC-HMS. But similar user-entered factors are also required with those synthetic UH choices. For example, the Clark synthetic UH transform requires the user to specify a "storage coefficient" which, according to the user manual (USACE-HEC, 2013), may be determined from regional studies. The Snyder synthetic UH transform requires a "peaking coefficient" obtained, according to the user manual, "…using the best judgement of the user, or possibly from locally-derived relationships to watershed physical features."

The HEC-HMS model does offer a UH transform method that may get around the peaking factor issue: the user-derived UH. Of course, measuring the UH applicable to any given watershed requires data, but a synthetic UH may be derived if the user can determine an adequate time-area histogram of the watershed. Even without rainfall and runoff data, geographic information systems (GIS) may give the hydrologist the best handle on the shape of the mountain watershed hydrograph. Good resolution digital elevation models (DEMs) enable the land slope to be defined. More and more pertinent digital geographic data is becoming available, such as soil type, land cover, vegetation, and even burn extents and severities. The ArcGIS raster calculator (ESRI, 2010) enables the modeler to estimate flow velocities for overland flow slopes, collector channels, and major streams, and then travel times from any point in a watershed. This option was used for the Whitewater Creek study.

Soil hydrophobicity may be the most difficult effect of wildfire to model, and thereby the greatest source of uncertainty. The NRCS technical note discusses the phenomenon extensively, with numerous references, such as DeBano (2000) and Huffman, et al. (2001). Wildfire can result in soils becoming water repellent, but the pertinent landscape aspects vary widely and are not very quantifiable. Certain vegetation types, when burned, provide gaseous hydrocarbons that condense in cooler soil layers. Soil texture plays a role, in that coarse-grained soil is more susceptible than finer-grained soil.

Soil burn severity may have an important role in the strength of water repellency at a given location and the geographic extent. However, even as water repellency is created, the depth into

the soil of the top of the hydrophobic layer varies, and the thickness of that layer varies. Along with those unknowns comes variability in the time after a wildfire event that the hydrophobic characteristics persist.

The hydrologic modeler has a few reasonable options for estimating hydrophobic extent, but the uncertainty thrown into the runoff model is large and unquantifiable. For example, using GIS, a layer for soil burn severity could be combined with soil and vegetation layers to estimate where hydrophobic soil may exist, but the correlation may not be very good. Uncertainty also remains about whether hydrophobic soil restricts infiltration completely or only partially, and whether a sub-basin should be considered 100 percent hydrophobic or whether some lower fraction should be used. Relating to post-fire sedimentation, more erosion would tend to result from areas where loose soil exists above the hydrophobic layer, and rainfall on the unprotected soil can perch on the hydrophobic layer and run off similarly to a parking lot pavement. Again, the volume of such erosion would be highly uncertain.

As a result of all this uncertainty, the modeler must incorporate estimates about hydrologic conditions which cannot be verified. These estimates, along with the scarcity of gages, contribute to the fact that the hydrologic model cannot be calibrated. Model results will be reasonable, but the modeler should document areas of unknown variability. If post-wildfire data stations exist, such as in Whitewater Creek, the data can be used to adjust model input and examine the difference between modeled and measured runoff. However the geographic extent of the station network would generally remain too sparse for true model calibration.

Whitewater Creek Hydrologic Model

The total watershed area of Whitewater Creek upstream of the San Francisco River is 54.5 square miles. Upstream of the new Catwalk streamgage (figure 3) the drainage area is 36.2 square miles. Figure 3 shows how the basin was sub-divided for the hydrologic model. The inset of figure 3 is a single upstream sub-basin, shown in figure 4. Much of this discussion will focus on this sub-basin, as every other sub-basin is modeled similarly.

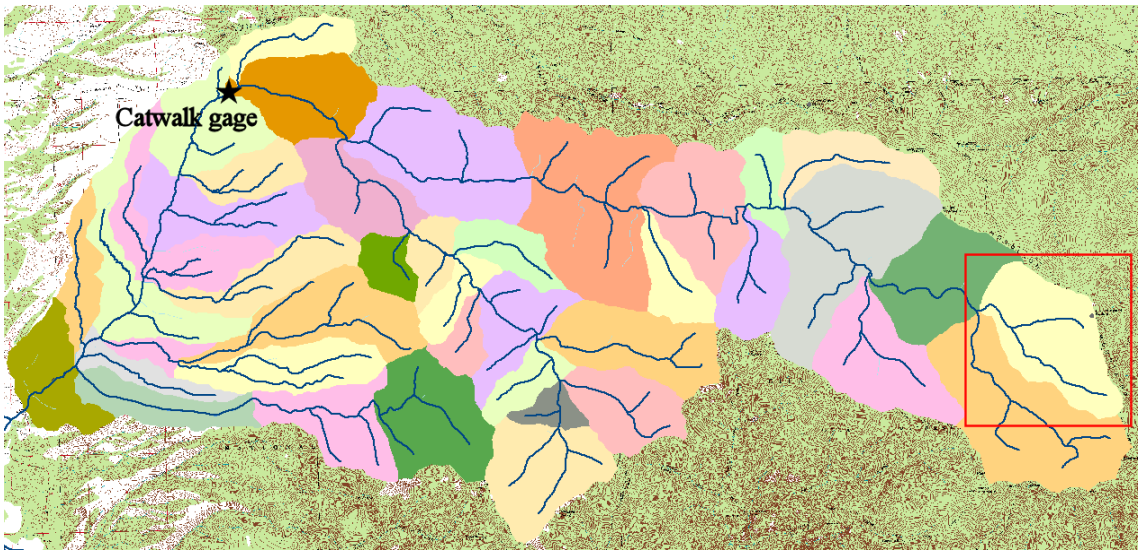

Figure 3 Whitewater Creek sub-areas, with inset of Baldy Fork (see figure 5).

For Green-Ampt infiltration, HEC-HMS requires soil data for initial moisture content, saturated content, matric suction, and hydraulic conductivity. Being within the Gila Wilderness, spatially distributed soil data are not available. However, a soil survey for part of Catron County outside the wilderness is available (USDA-SCS, 1985). The document shows that a typical soil of the area is the Tolman Series, for which the texture of the top two inches is described as cobbly loam, with permeability ranging between 0.6 to 2 inches per hour. For the entire watershed, the Green-Ampt parameters were estimated based on this soil type, with reference to the technical note table of hydraulic characteristics by soil texture. The assumed soil texture was loamy sand with porosity of 0.42 cubic inches of pore space per cubic inch of soil. Initial moisture content was assumed to be near field capacity, or 20 percent of the porosity. Wetting front suction was estimated at 4.33 inches and hydraulic conductivity 0.86 inches per hour.

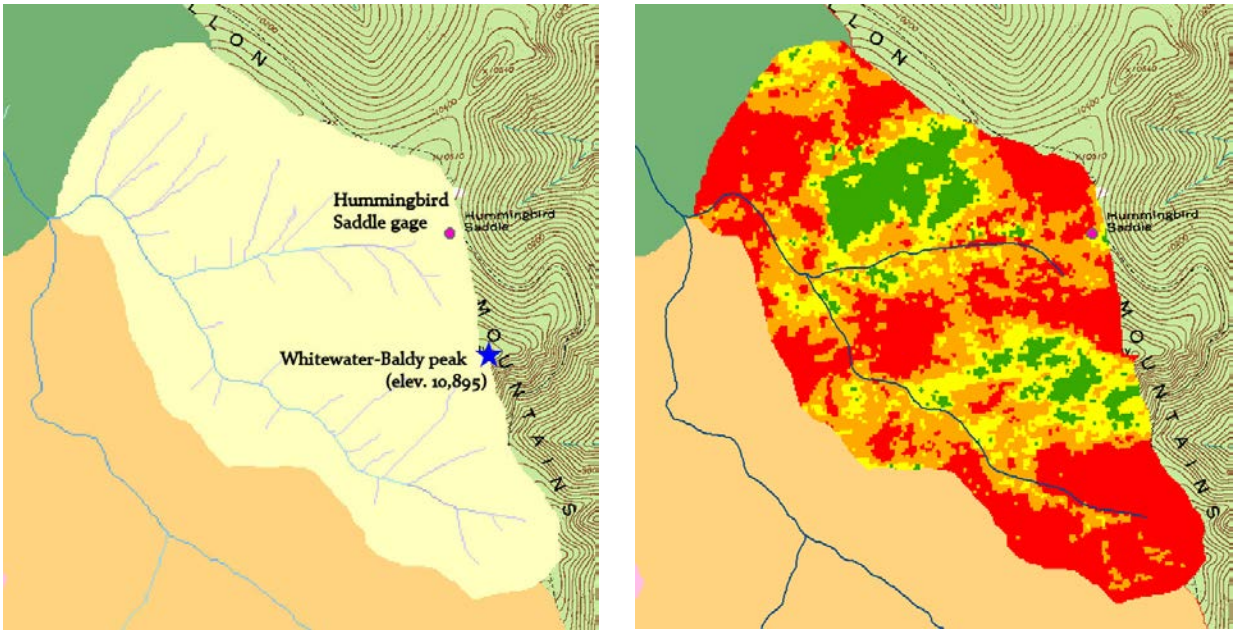

Figure 4 Baldy Fork sub-basin with burn severity raster on the right, (red = high, orange = medium, yellow = low, green= no burn).

Transformation of downstream runoff was accomplished using a unit hydrograph for each sub-basin derived from a GIS-estimated time-area histogram. Flow velocity for each ten-meter DEM cell was determined using Manning's equation, with a partitioning of cells into the catagories of overland flow, shallow-concentrated flow, or channel flow. The category was based on distance from the headwater ridge of each flowline. NRCS guidance (USDA-NRCS, 2010) suggests that overland flow will extend only up to 100 feet before transitioning to shallow-concentrated flow, which may extend another 1000 feet before becoming channelized. Separate Mannings roughness values are assumed for the different flow categories and for different types of vegetation or soil for each cell. In addition, burn severity was taken into account. (See figure 4).

Figure 5 shows the time band raster for Baldy Fork, derived using the ArcGIS raster calculator. Further details of the time-area histogram derivation is provided in USDA-NRCS (2014). The

time band table in figure 5 shows the number of cells that drain to the outlet in each 5-minute band. These data are copied to a spreadsheet and a time-area histogram created. Further spreadsheet manipulations result in the unit hydrograph shown in figure 6. Note that varying the conditions for travel time rasters results in separate unit hydrographs for pre-fire conditions, post-fire conditions immediately after the fire, and conditions after one year of healing.

The NOAA National Weather Service Precipitation Frequency Data Server (NOAA, 2013) was recently updated for New Mexico. Due to the flashy character of Southwest U.S. storms, a six-hour duration was selected for analysis, with rainfall amounts in table 1.

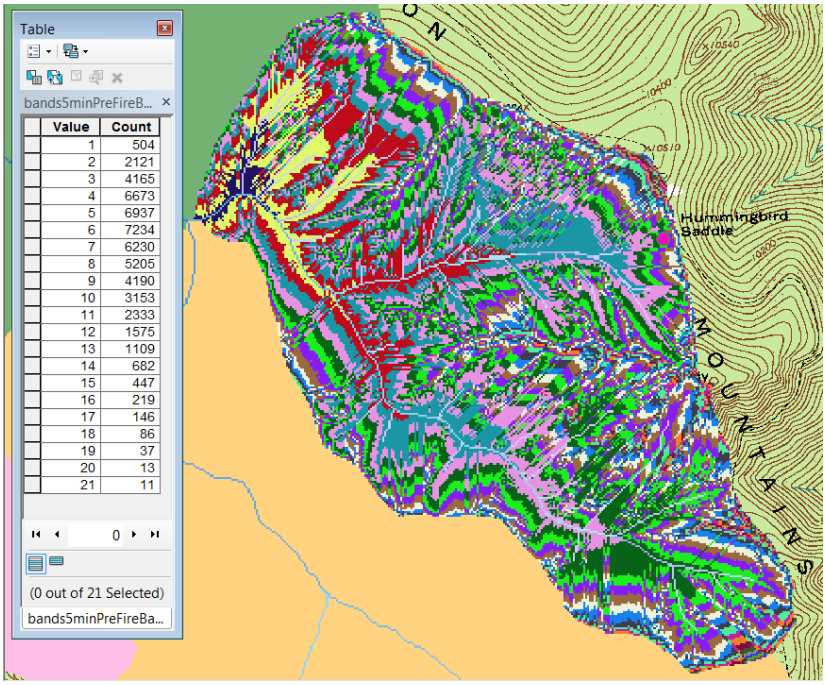

Figure 5 Twenty-one 5-minute travel time bands for Baldy Fork, with inset attribute table.

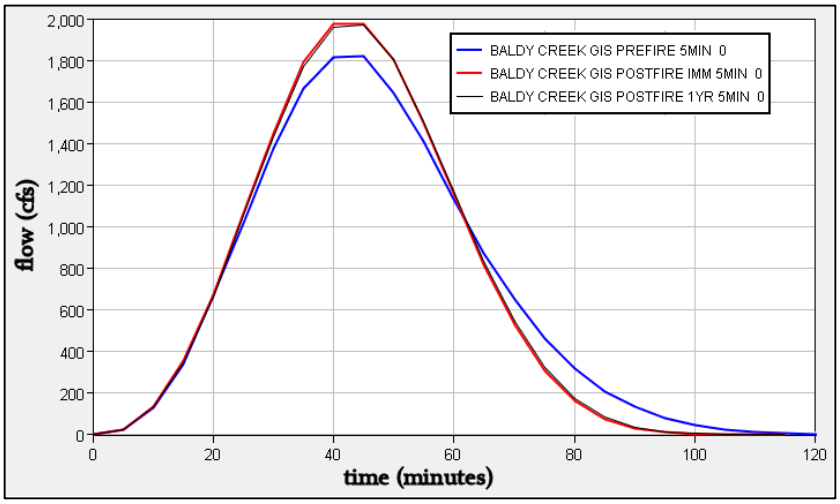

Figure 6 Synthetic GIS-derived unit hydrographs for Baldy Fork.

Table 1 Whitewater Creek watershed 6-hour duration storm totals

watershed area	precipitation		
	2-year (inches)	25-year (inches)	100-year (inches)
upper Whitewater	1.54	2.73	3.49
SF Whitewater	1.42	2.49	3.19
lower Whitewater	1.20	2.12	2.73

These rainfall amounts were distributed in time using a New Mexico variation of the standard NRCS Type II storm distribution. (The New Mexico variant results in a slightly higher peak than the NRCS Type II and causes the peak to occur earlier in the duration.) In addition, an areal reduction factor (ARF) was applied to the rainfall values of Table 1, based on the graph in figure 7, from Osborne, Lane, and Myers (1980). The Walnut Creek Experimental Watershed of figure 7 is near Tuscon Arizona, about 180 miles from Whitewater Creek, but in the same hydrographic region. Similar areal reduction is expected. The marked drop off of precipitation with distance, shown in figure 7, indicates that typical storms in the US Southwest are not large enough to cover the entire watershed of a size like Whitewater Creek. Typical storms may be 10 to 12 km in diameter, while Whitewater Creek is about 22 km wide, east to west. The storm centerings for the Whitewater Creek model are shown in figure 8, with locations selected which result in the largest runoff effect.

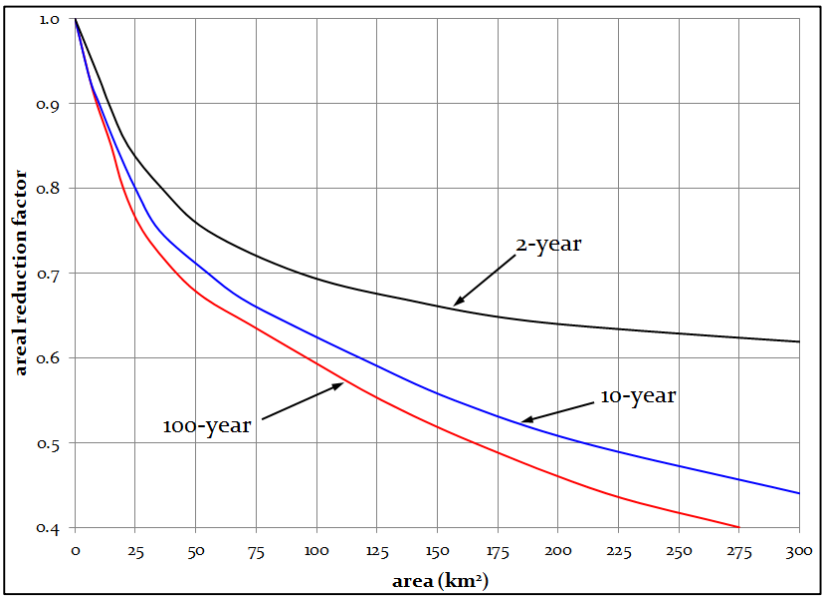

Figure 7 Areal reduction factors developed for 6-hour duration storms at Walnut Gulch AZ Experimental Watershed (modified from Osborn, Lane, and Myers 1980)

This analysis did not attempt to model sedimentation, but relied on a USGS report specifically concerning the Whitewater Baldy Complex wildfire (Tillery, Matherne, and Verdin, 2012) that estimated high probabilities in Whitewater Creek of debris flows from 30-minute duration

rainfall events for recurrence intervals of 2-year, 10-year, and 25-year. The report provides a map of Whitewater Creek sub-basins and their estimated propensity to generate sediment due to the wildfire. This information was used in this case study to bulk the modeled clear flow hydrographs, depending on their origin.

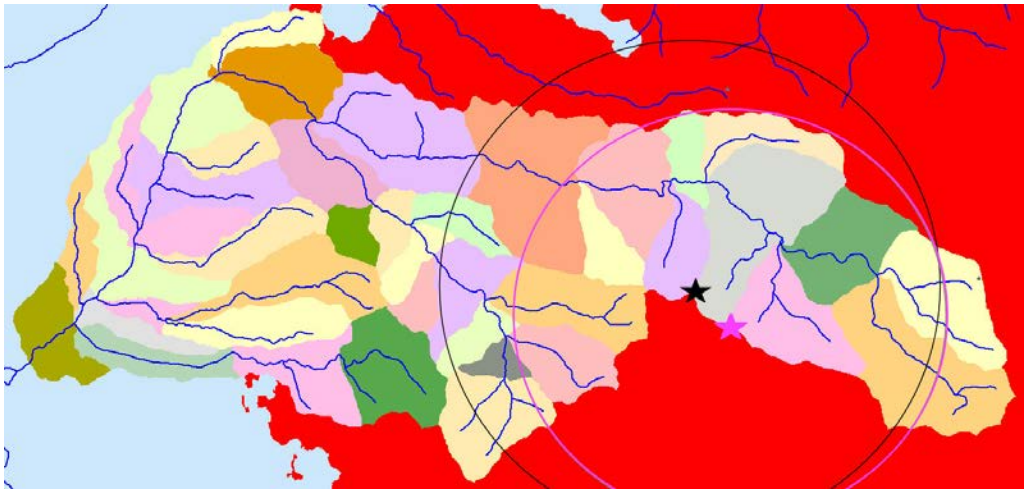

Figure 8 Storm centerings: UpperGrouse, 6 km radius (black), UpperLipsey, 5 km radius (pink)

MODEL RESULTS AND DISCUSSION

The HEC-HMS model can produce hydrographs for any of the sub-basin outlets of figure 3, but only the USGS gage at Catwalk (figure 2, gage 1) and the creek outlet to the San Francisco River (near Glenwood) are shown here. Three watershed scenarios were examined, pre-fire, immediately post-fire, and post-fire after one year of healing. Table 2 shows that varying storm center location and storm size (5- or 6-km radius) does not produce widely different results. Figure 9 shows the 100-year hydrograph at Glenwood for the 6-km radius storm.

Table 2 Model output: hydrograph peaks in cfs with areal reduction centerings from Figure 9.

storm	location	Grouse centering (6km radius)			Lipsey centering (5km radius)		
		pre-fire	post-fire (immed.)	post-fire (one year)	pre-fire	post-fire (immed.)	post-fire (one year)
100-yr	gage	10149	15734	14623	9246	15052	13500
100-yr	Glenwood	8776	14391	13245	7916	13899	12431
25-yr	gage	4384	9703	8696	4589	8654	7765
25-yr	Glenwood	3854	8713	7674	3934	7919	7060
2-yr	gage	31	4346	2878	56	3723	2405
2-yr	Glenwood	31	4121	2734	46	3555	2308

The observed event of 14-15 September, 2013, was modeled using the post-fire after one year scenario. The event magnitude was more rare than a 1,000-year recurrence, as shown in table 3. Some evidence of storm areal extent is provided by the fact that the Hummingbird Saddle gage during this event received minimal precipitation. The storm seems to have occurred closer to the

gage. Between 9 pm and midnight, while the Catwalk gage was recording 6.10 inches of rainfall, the Hummingbird Saddle gage received zero. For the three hours after midnight, rainfall at Catwalk dropped off considerably (0.75 inches, total) and Hummingbird Saddle recorded a similar total (0.93 inches). The Silver Creek Divide SNOTEL site (figure 2, gage 3) recorded precipitation of about two inches for that 24-hour period. (The SNOTEL precipitation gage is a cumulative collection cylinder, with historical records of daily observations.)

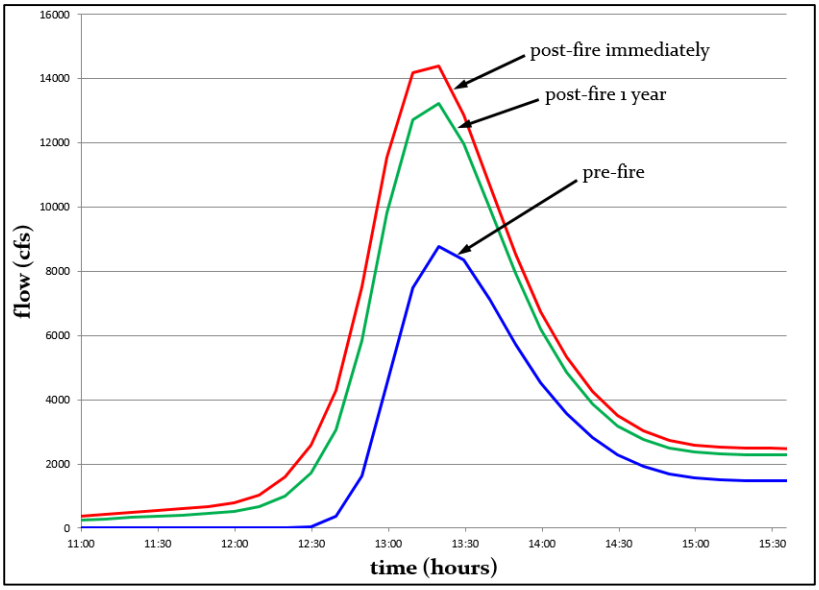

Figure 9 Model results, 100-year hydrographs at Glenwood for 6km radius storm.

Table 3 Observed storm event measured at Catwalk gage (blue) with NOAA precip-frequency.

storm centering at SF Whitewater confluence (rainfall in inches)							
	recurrence-->						
duration	50-year	100-year	200-year	500-year	1000-year	gage	14-15 Sep
1-hour	1.83	2.04	2.24	2.5	2.71	**3.01**	9-10 pm
2-hour	2.02	2.27	2.52	2.86	3.14	**4.09**	9-11 pm
3-hour	2.12	2.38	2.66	3.04	3.35	**6.10**	9-midnight
6-hour	2.48	2.8	3.14	3.61	3.99	**6.85**	9pm-3am

Areal reduction for the various storm frequencies (table 2) were of the "fixed" type, whereby the reduced rainfall value is applied to the entire storm area. These are not considered applicable to observed storms. In the absence of observed storm ARFs for the area, the reductions applied to the observed precipitation of September 2013 were taken from fixed ARF of figure 7; however the precipitation value applied to any given sub-basin was a reduction of the centered maximum value, proportional to the distance of the sub-basin from the storm center (assumed to be near the confluence of the upper Whitewater and SF Whitewater Creek, upstream of the Catwalk gage, figure 3).

The resulting model hydrograph at the USGS Catwalk gage, compared to the observed, is shown in figure 10. The two graphs are so remarkably close that the following points should be noted.

The model parameters were not adjusted in order to make the output match the observed. The same watershed scenario for postfire, after one year, was used here as for the modeling of recurrence flows. However, the model hydrographs of figure 10 is the result of only one possible scenario of storm size and centering. Other centerings could be justified using the same observed data. The assumed reduction of hydrophobic effect for the one year post-fire condition seems to have been in the ballpark, but the widespread nature of unknowns makes for difficulty judging which assumptions were better than others.

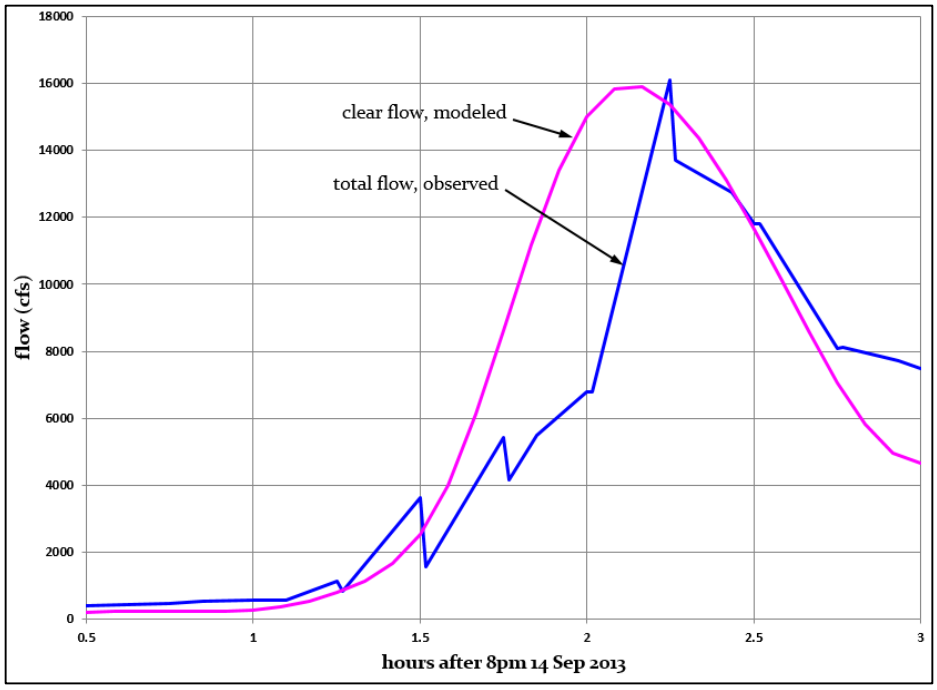

Figure 10 Catwalk gage modeled versus observed for the storm of 14-15 September 2013.

CONCLUSIONS

This case study has shown that reasonable model results can be obtained using the modeling options of HEC-HMS, Green-Ampt infiltration, and GIS-derived synthetic unit hydrographs. The extent of hydrophobicity and its effect on runoff remains a major source of uncertainty, but the assumptions made for Whitewater Creek, informed by detailed mapping of burn severity, appear to have resulted in a useful model.

HILLSLOPE EROSION AND SMALL WATERSHED SEDIMENT YIELD BEFORE AND AFTER FIRE IN SOUTHERN CALIFORNIA

Peter M. Wohlgemuth, Hydrologist, USDA Forest Service, Pacific Southwest Research Station, Riverside, California pwohlgemuth@fs.fed.us

Abstract: In 2002, a wildfire burned over an ongoing sediment flux study in the steep, chaparral-covered foothills of the San Gabriel Mountains of southern California. The study area had previously burned in 1960. Southern California experiences a Mediterranean climate with cool wet winters and hot dry summers. Average annual rainfall for the study area is 714 mm (80-year record) with an average two-year 30-minute peak intensity of 29 mm hr^{-1}. Hillslope erosion was measured in 30 cm collector traps. These traps were serviced multiple times per year to distinguish wet season from dry season erosion. Small watershed (1-3 ha) sediment yield was measured behind earthen debris dams. Three of the study watersheds were in mixed chaparral vegetation and one was in type-converted grass. One of the chaparral watersheds was burned in a prescribed fire in 2001 and did not re-burn in the wildfire. Hillslope erosion and small watershed sediment yield data were collected for 7 or 8 years prior to burning then for 5 or 6 years following fire, including the complete post-fire erosion record. Continuous rainfall was measured in a centrally-located weighing bucket recording raingage. Rainfall, both totals and intensities, was generally below average during the study period, especially immediately after the fires. Prior to fire, hillslope erosion was considerable, was an order of magnitude less under grass vegetation compared to chaparral, dry season erosion was equal to wet season erosion in all watersheds, but sediment yield was only minor and associated with high rainfall years at the watershed scale. In the first post-fire year, both hillslope erosion and small watershed sediment yield increased by 1-2 orders of magnitude over pre-fire levels and all parts of the landscape responded similarly. Hillslope erosion rates and small watershed sediment yields returned to pre-fire levels and patterns within two to three years post-fire. The magnitude and patterns of erosion following a prescribe burn in chaparral was very similar to those following a wildfire, although the recovery curve was somewhat flatter after the prescribed fire. Future studies will test a variety of predictive models against the current dataset as a benchmark to evaluate their performance as a tool for planning and risk assessment in southern California chaparral watersheds.

INTRODUCTION

Fire has been a part of the southern California landscape since before recorded history and is the disturbance event which drives much of the environmental response in southern California (Sugihara and Barbour 2006). Chaparral and coastal sage scrub vegetation communities have adapted to periodic burning and some species may require fire in order to reproduce (Keeley 2006). Furthermore, fire drives much of the surface erosion experienced across the landscape. With the removal of both the vegetation cover and the protective layer of organic litter post-fire hillside slopes are initially susceptible to dry ravel erosion and subsequently to raindrop splash (Rice 1974). Fire also alters the physical and chemical properties of the soil – bulk density and water repellency – promoting surface runoff at the expense of infiltration (DeBano 1981). This enhanced post-fire runoff removes more soil material from the denuded hillsides and can mobilize sediment deposits in the stream channels to produce debris flows with tremendous erosive power (Wells 1987). Post-fire accelerated erosion eventually abates as the re-growing

vegetation canopy and root system stabilize the hillslopes and provides protection against the agents of erosion (Barro and Conard 1991). However, in the interim, wildfires coupled with heavy winter rains can produce floods and debris flows that threaten human life, property, and infrastructure (roads, bridges, utility lines, communication sites) far downstream from the burn area itself. This places an extra burden on land managers and hazard protection agencies that must be able to predict post-fire watershed response and mitigate against any potentially negative consequences to these values at risk.

Although the patterns of post-fire erosion in southern California are generally understood, uncertainty about the magnitude of post-fire erosion events limits our ability to predict specific post-fire watershed responses. Prediction, usually in the form of numerical modeling, is only possible with a sufficient understanding of the quantitative effects of fire on erosion processes. Fortuitously, a wildfire on the San Dimas Experimental Forest burned over an ongoing sediment flux study and provided an opportunity to document and quantify the effects of fire on hillslope erosion and sediment yield in small watershed units in a semiarid, chaparral-covered, steepland environment. Results of this research could serve as a benchmark against which to test or evaluate existing models of post-fire erosion for the southern California area.

STUDY AREA

The San Dimas Experimental Forest (SDEF) is a nearly 7000 ha research preserve administered by the USDA Forest Service, Pacific Southwest Research Station, and has been the site of extensive hydrologic monitoring for over 80 years (Dunn et al. 1988). Established in 1933, with its headquarters at Tanbark Flat (34^{o} 12’ N latitude, 117^{o} 46’ W longitude) the SDEF is located in the San Gabriel Mountains, about 45 km northeast of Los Angeles, California (Figure 1).

Elevations in the study area range from 750 to 1050 meters and topography consists of a highly dissected mountain block with steep-walled canyons and steep channel gradients. Bedrock geology in the SDEF is dominated by Precambrian metamorphics and Mesozoic granitics that produce shallow, azonal, coarse-textured soils (Dunn et al. 1988). The SDEF experiences a Mediterranean-type climate, characterized by hot, dry summers and cool, moist winters. Temperatures range from -8^{o} C to 40^{o} C. Mean annual precipitation, falling almost exclusively as rain, is 714 mm (80-year record), but rain during individual years can range from 252 to 1848 mm. Over 90 percent of the annual precipitation falls between the months of November and April (Wohlgemuth 1996). The two-year 30-minute peak rainfall intensity (an index of rainfall erosivity) for the study area is 29 mm hr^{-1} (Bonnin et al. 2011).

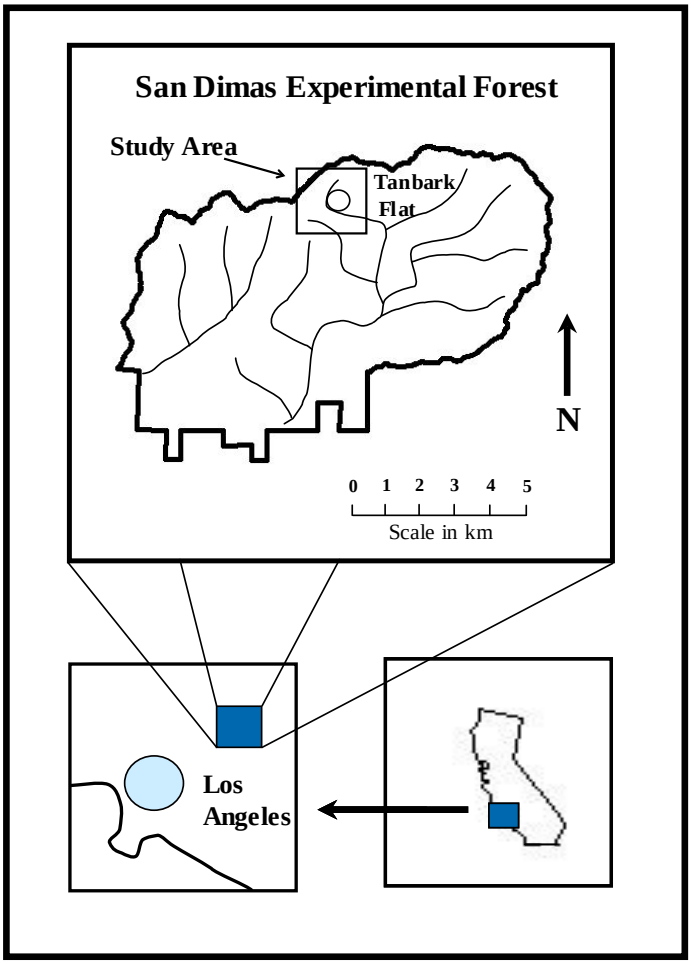

Figure 1 Location map of the San Dimas Experimental Forest.

Native vegetation in the SDEF consists primarily of mixed chaparral. Plant cover on south-facing slopes ranges from dense stands of chamise (*Adenostoma fasciculatum*) and ceanothus (*Ceanothus* spp.) to more open stands of chamise and black sage (*Salvia mellifera*). North-facing hillsides are dominated by scrub oak (*Quercus berberidifolia*) and ceanothus, with occasional hardwood trees – live oak (*Quercus agrifolia*) and California laurel (*Umbellularia californica*) – occurring on moister shaded slopes and along the riparian corridors (Wohlgemuth 2006). Fuel loadings of mature chaparral on the SDEF ranged from 110 to 135 Mg ha^{-1} (40-50 t ac^{-1}) (Ottmar et al. 2000). Management treatments following a wildfire in 1960 involved the vegetation type-conversion of some native chaparral watersheds to a mixture of perennial grasses. It was thought that type-conversion would aid in future fire control and would enhance water yield (Rice et al. 1965). To assist in the grass establishment, regenerating shrubs were sprayed with herbicides. These perennials included a variety of wheatgrass species (*Agropyron spp*.), Harding grass (*Phalaris tuberosa* var. *stenoptera*), big bluegrass (*Poa ampla*), smilo grass (*Piptatherum miliaceum*), veldt grass (*Ehrharta calycina*), and blando brome (*Bromus hordaceous*) (Corbett and Green 1965). By 2002, substantial amounts of buckwheat (*Eriogonum fasiculatum*) and

black sage had also established on the type-converted watersheds. Fuel loadings on the converted watersheds prior to the 2002 wildfire were 14-27 Mg ha^{-1} (5-10 t ac^{-1}) (Ottmar et al. 2000).

In 1994, a study was initiated to quantify sediment fluxes through several small (1-3 ha) headwater catchments in the SDEF that last burned in the 1960 wildfire (Wohlgemuth 1996). One of these chaparral watersheds was burned in a prescribed fire of moderate to high severity in 2001 (Wohlgemuth and Hubbert 2008). Following a winter drought and a hot, dry summer, almost all of the SDEF burned in a wildfire in late September 2002. A smoke plume that rose almost vertically indicated an absence of wind, which allowed the fire to burn relatively slowly, permitting longer fire residence times that resulted in substantial soil heating. In most parts of the SDEF, the fire burned at high severity, consuming all the aboveground biomass and leaving only the skeletons of the largest stems (Napper 2002). The areas that burned in the 2001 prescribed fire did not re-burn in the 2002 wildfire. Both fires burned over the aforementioned sediment flux study, providing a unique opportunity to quantify hillslope erosion and small watershed sediment yield following fire on the same sites for which there were extensive pre-fire measurements.

METHODS

In the sediment flux study, four small watersheds were selected to measure hillslope erosion: three in native chaparral vegetation and one in type-converted grass (Wohlgemuth 1996). Hillslope erosion was sampled using sheet metal collector traps (Figure 2) with a 30 cm aperture (Wells and Wohlgemuth 1987). Seventy-five traps sampled unbounded plots on both vertical hillslope transects and at the slope/channel interface in each watershed. The traps were installed in summer 1994. Sediment was collected for 7 years prior to the prescribed burn and 8 years prior to the wildfire. Sediment collection continued through the fifth (wildfire) or sixth (prescribed burn) post-fire winter. Hillslope erosion is expressed as a yield: the air-dried mass of collected debris per square meter of potential contributing area normalized to an annual rate based on the length of the collection period (kg m^{-2} yr^{-1}). The median value from these sediment collectors was used as a measure of central tendency for comparisons. These traps were serviced multiple times per year to distinguish wet season hillslope erosion lasting approximately four months from dry season hillslope erosion lasting about eight months.

Sediment was also trapped and measured behind earthen dams (Figure 3) constructed after the 1960 wildfire (Rice et al. 1965). These debris basins were re-activated in winter 1994. Sediment yields were calculated using an engineering end-area formula (Eakin 1939) based on repeated sag tape surveys of permanent cross sections (Ray and Megahan 1978). Sediment yield was measured for 7 or 8 years prior to and 5 or 6 years following the prescribed burn or wildfire as described above. Sediment yield was normalized by contributing area to account for catchments of different sizes and aggregated to annual totals (m^3 ha^{-1} yr^{-1}).

A centrally located weighing raingage recorded precipitation amounts and intensities throughout the study period.

Figure 2 Hillslope erosion sediment collector trap.

Figure 3 Debris basin for trapping small watershed sediment yield.

RESULTS AND DISCUSSION

Rainfall: Rainfall is the ultimate driver of all hydrologic erosion, both on the hillside slopes and in the channels of ephemeral streams. Annual rainfall totals and peak 30-minute intensities for the duration of the study period are arrayed in Table 1. During this period, both the highest (1848 mm) and the lowest (252 mm) rainfall totals of the entire 80-year record were experienced. Generally, high annual totals correlated positively with peak 30-minute intensities, but there were some notable exceptions (Table 1). Of the 13 years of study, only four exceeded the annual average rainfall and only four exceeded average peak intensity. The prescribed burn was followed by the record low annual total but with a peak intensity slightly above average, while the wildfire was followed by a sub-normal annual total and a peak intensity that was only half the long-term average (Table 1).

Hillslope Erosion: Surface erosion yields from the collector traps are arrayed by watershed and season in Table 1. Prior to fire, hillslope erosion was considerably less under the type-converted grass vegetation than the native chaparral, as previously reported (Wohlgemuth 1996, 2006). This difference may be explained by the density of plant stems providing barriers to surface erosion: chaparral typically has a density of about 1 stem per square meter while the grass has a density of thousands of stems per square meter, creating a variable resistance to the processes of

erosion between the two vegetation types. Furthermore, the amount of dry season erosion and wet season erosion was roughly equal in the unburned condition (as opposed to their yields over unequal time spans as displayed in Table 1). The protection afforded by the plant canopies and extensive litter layers prevented surface runoff on the unburned hillsides except during the most intense rainstorms. Thus wet season hillslope erosion was muted on the unburned landscape, being no greater than ravel, the pervasive erosion process during the dry season (Rice 1974).

Table 1 Median (n=75) hillslope erosion yields (kg m^{-2} yr^{-1}) by watershed and season. I_{30} is peak 30 minute rainfall intensity. Watershed Chaparral 3 was burned in a prescribed fire one year prior to the wildfire. Numbers in italics are post-fire values.

			Watershed							
	Rainfall		Grass		Chaparral 1		Chaparral 2		Chaparral 3

In the first post-fire year, despite low rainfall totals (prescribed fire) or intensities (wildfire), yields of surface erosion increased by 1-2 orders of magnitude compared to pre-burn rates (Table 1), as the vegetative barriers were incinerated by fire and resistances to the forces of erosion were removed. Moreover, the pre-fire difference in yield between grass and chaparral vegetation disappeared, as fire eliminated any differential resistances among the vegetation types resulting in a very similar erosion response. However, in the immediate post-fire environment, wet season hillslope yield was substantially greater than dry season yield (Table 1), likely caused by the alterations in soil characteristics which affect post-fire hillslope hydrology and increased surface runoff (DeBano 1981).

In subsequent post-fire years the patterns of pre-fire surface erosion returned. Yield was once again greater under chaparral vegetation than under grass (Table 1), although the chaparral values were much smaller than in the pre-fire environment. Some of this reduction is likely due to the proliferation of re-growing near-surface vegetation (Barro and Conard 1991), but it could also reflect the loss of the easily mobilized sediment that exposed a less erodible material at the surface, effectively reducing the sediment supply (Wohlgemuth and Hubbert 2008). In addition, by the third post-fire year, dry season hillslope yields were greater than wet season yields (Table

1). This rapid return to pre-fire patterns suggests that recovery to hillslope erosion baseline levels can occur very quickly in this southern California locale.

Intuitively, wet season hillslope erosion should be related to rainfall. However, there is no discernable relationship between annual rainfall total or peak intensity and wet season hillslope erosion, either before or after fire (Table 1). This suggests that although rainfall is a necessary driver, hillslope sediment yield is governed more by the landscape sensitivity and differential resistances to the agents of erosion.

Small Watershed Sediment Yield: Sediment yield in the debris basins is arrayed by watershed in Table 2. Pre-fire watershed sediment yield was minor and associated with high rainfall years. More often than not, the annual sediment yield from these small watersheds was zero (Table 2). Prior to fire, watershed sediment yield was less in the grass vegetation than the chaparral (Table 2), presumably associated with the greater hillslope erosion, sediment delivery, and channel loading under the shrub vegetation. Immediately following fire, despite the low rainfall values, watershed sediment yields increased by 1-2 orders of magnitude over pre-fire levels (Table 2). Field observations confirmed both an extensive rill network, indicating the delivery of water and sediment from the burned hillsides, and channel scour of the existing in-channel deposits of stored sediment. Furthermore, first-year post-fire sediment yield from these small watersheds was roughly similar for both vegetation types, suggesting again the removal of differential resistances to promote a nearly equal erosion response. In subsequent post-fire years, watershed sediment yield was minor, associated with high rainfall, and greater in chaparral catchments compared to type-converted grass drainage basins. This very rapid return to pre-fire patterns of small watershed sediment yield again suggests that this environment can recovery very quickly to baseline conditions.

Table 2 Annual sediment yield (m^3 ha^{-1} yr^{-1}) by watershed. I_{30} is peak 30 minute rainfall intensity. Watershed Chaparral 3 was burned in a prescribed fire one year prior to the wildfire. Numbers in italics are post-fire values.

Prescribed Fire Versus Wildfire: Prescribed burns are conducted under more moderate conditions of weather and fuel moisture to prevent an unplanned and costly fire escape. It is therefore generally assumed that the erosion response to a prescribed fire should be less than that from a wildfire (Loomis et al. 2003). However, for comparable chaparral-covered catchments in this study, the patterns of post-fire hillslope erosion and small watershed sediment yield are very similar: an immediate spike in sediment production followed by a quick return to baseline levels (Tables 1 and 2), perhaps suggesting that some threshold of landscape response is exceeded by all fire in these chaparral environments. The greater wet season hillslope erosion values following the wildfire compared to the prescribed fire (Table 1) can be explained by the total rainfall values but also by the time of burning. The prescribed fire burned in mid-May while the wildfire burned in late September. With initial heavy storms of the rainy season typically commencing in November or December, the areas of the prescribed fire had more time to heal, including some vegetation re-growth, than did the areas that burned in the wildfire. The prescribed-burn area was therefore better able to resist the hydrologic forces of winter storms than the freshly-burned hillsides after the wildfire. However, the prescribed fire has a slightly flatter recovery curve (2 years) than the wildfire (1 year), suggesting that the response to these two different types of fires is not identical (Table 1), perhaps reflecting the differences in rainfall totals and intensities.

A Benchmark for Post-fire Erosion Models: The value of this study is that it quantifies long-term hillslope erosion and small watershed sediment yield from the same plots and sites both before and after fire. As such, it provides a benchmark to evaluate the performance of predictive models of post-fire sediment yield from southern California chaparral environments. These models, which run the gamut from strictly empirical (Universal Soil Loss Equation; Wischmeier and Smith, 1978) to physically-based (Water Erosion Prediction Project; Laflen et al. 1991), are used by land management and hazard protection agencies to estimate the magnitudes of post-fire erosion events. Future work will involve the testing of a variety of predictive models against this dataset to evaluate their performance as a tool for planning and risk assessment in southern California chaparral watersheds.

SUMMARY

The timing and patterns of hillslope erosion and small watershed sediment yield were quantified when a prescribed fire and a subsequent wildfire burned over a sediment flux study, providing pre-fire and post-fire erosion values for the exact same sampling units, including the complete post-fire erosion record. The data suggest that, although there is not an exact correspondence, for this southern California chaparral locale erosion on the hillsides and the output from small catchments are remarkably similar: a 1-2 order of magnitude increase in immediate post-fire erosion over pre-fire yields followed by a relatively rapid recovery to baseline levels. Grass vegetation produced less erosion than comparable chaparral areas prior to fire, most likely because of differences in stem densities and channel loading, but these differences were erased immediately after fire and the landscape appeared to be eroding equally. Wet season hillslope erosion was especially enhanced following fire, most likely due to attendant changes in soil characteristics that promote overland flow. Although there appeared to be a relationship between rainfall and small watershed sediment yield, there seemed to be no association between wet

season hillslope erosion and either total rain or peak rainfall intensity. In chaparral vegetation the response to a prescribed fire was very similar to that of a wildfire, although there was a slightly flatter recovery curve following the prescribed burn, perhaps because of different rainfall patterns. This suggests that some threshold of landscape response is exceeded by all fire in these southern California chaparral environments.

Abstract: Increased sedimentation following wildland fire can negatively impact water supply and water quality. Understanding how changing fire frequency, extent, and location will affect watersheds and the ecosystem services they supply to communities is of great societal importance in the western USA and throughout the world. In this work we assess the utility of the InVEST (Integrated Valuation of Ecosystem Services and Tradeoffs) Sediment Retention Model to accurately characterize erosion and sedimentation of burned watersheds. InVEST was developed by the Natural Capital Project at Stanford University (Tallis et al., 2014) and is a suite of GIS-based implementations of common process models, engineered for high-end computing to allow the faster simulation of larger landscapes and incorporation into decision-making. The InVEST Sediment Retention Model is based on common soil erosion models (e.g., USLE – Universal Soil Loss Equation) and determines which areas of the landscape contribute the greatest sediment loads to a hydrological network and conversely evaluate the ecosystem service of sediment retention on a watershed basis. In this study, we evaluate the accuracy and uncertainties for InVEST predictions of increased sedimentation after fire, using measured post-fire sediment yields available for many watersheds throughout the western USA from an existing, published large database. We show that the model can be parameterized in a relatively simple fashion to predict post-fire sediment yield with accuracy. Our ultimate goal is to use the model to accurately predict variability in post-fire sediment yield at a watershed scale as a function of future wildfire conditions.

INTRODUCTION

Fire suppression and the increased accumulation of fuels over the last century has led to a greater risk of high severity wildland fires for many watersheds of the western USA. Future climate change in the form of warmer temperatures and altered precipitation regimes may further increase wildfire potential (Flannigan et al., 2000, Westerling et al. 2006). Wildfire can impact watersheds through changes in the timing and amount of runoff, and increased erosion and sedimentation (Miller et al., 2011). These processes can negatively affect water quality, water supply, and other important ecosystem services such as sediment retention, which is a measure of the capacity for a watershed to withstand erosion and sedimentation.

When fire occurs on a landscape, burning immediately alters the existing distribution and structure of vegetation (Larsen et al., 2009). Vegetation can slow down overland flow of water and reduce the erosive force and sediment transport capacity of water. Vegetation can also trap and filter sediment transported by water. Collectively, these characteristics of vegetation contribute to the ability of a watershed to retain sediment, which results in the afore-mentioned ecosystem service. Combustion of vegetation thereby reduces watershed sediment retention.

Burning also directly alters soil characteristics (González-Pérez et al., 2004). Depending on the intensity of heat during a fire, soil organic content can be reduced and clay particles can become aggregated into fine silt-sized particles (Giovannini et al., 2001). The loss of organic material and a litter layer that otherwise provide a protective shield to the soil surface can increase soil erosion through increased exposure to rain splash, decreased infiltration, and increased sheet wash and rill erosion (DeBano, 2000). Intense heat also changes the carbon and nitrogen balance in soil, and can trigger a reduction in microbial activity (Choromanska and DeLuca, 2002). Collectively, these factors can increase erodibility of soil post-fire. In addition to post-fire changes in vegetation, increased erodibility further decreases watershed sediment retention.

The ability to efficiently and accurately model sediment retention at the scale of individual watersheds for a large number of watersheds is important (Miller et al., 2011). It provides a tool for resource managers to better understand and simulate how fire effects on vegetation and soil may affect the ecosystem service of sediment retention or conversely, post-fire sediment yield. The InVEST suite of ecosystem service models are an open source, stand-alone platform developed by Stanford University as part of the Natural Capital Project. The Sediment Retention model is designed to evaluate sediment retention at a watershed scale to enable the assessment of tradeoffs for natural resource management decisions (Tallis et al., 2014). The Sediment Retention model can be used to simulate how changes in vegetation and soil erodibility, which occur as a function of landscape processes such as fire, may affect watershed sediment retention or sediment yield. Moreover, the InVEST predictions under different scenarios of vegetation and soil condition can be evaluated as indicators of the potential relative change in the ecosystem service as a function of wildfire. The GIS-based Sediment Retention model implements the Universal Soil Loss Equation (USLE) (Wischmeier and Smith, 1978) to predict annual potential erosion at the pixel scale and annual sedimentation and retention at the watershed scale. The model takes into account landform, climate, soil, and vegetation properties. Users can also assess the influence of different vegetation types and soil properties.

For the western USA, Moody and Martin (2009) completed a comprehensive and exhaustive review and synthesis of measured post-fire sediment yields (Figures 1 and 2). Their study divided the western United States into four regions based on rainfall regimes: Pacific, Sub-Pacific, Arizona, and Plains, which vary by seasonal distribution of rainfall; and with sub-categories of Extreme, High, Medium, and Low rainfall intensity. Within these regions they identified all of the published measurements of post-fire sediment yield. The synthesis identified 135 measurements in 43 unique watersheds (defined at the Hydrologic Unit Code 8 “HUC-8” level) that spanned post-fire episodes from 1927 to 2007. They further identified whether the measurements were conducted on hillslope or channel landscape positions, whether they were conducted at point or plot scales, and whether they targeted a specific range of particle size

and/or transport mechanism. This resulted in a classification of each measurement into one of four types: Hillslope Points (H-Pt), Hillslope Plots (H-Plot), Channel Suspended Sediment (CSS), and Channel Volume (C-V) measurements (Moody and Martin, 2009). The Moody and Martin (2009) synthesis of post-fire sedimentation provides a baseline of field data to calibrate sediment yield predictions made with the InVEST Sediment Retention model in our study (Figures 1 and 2).

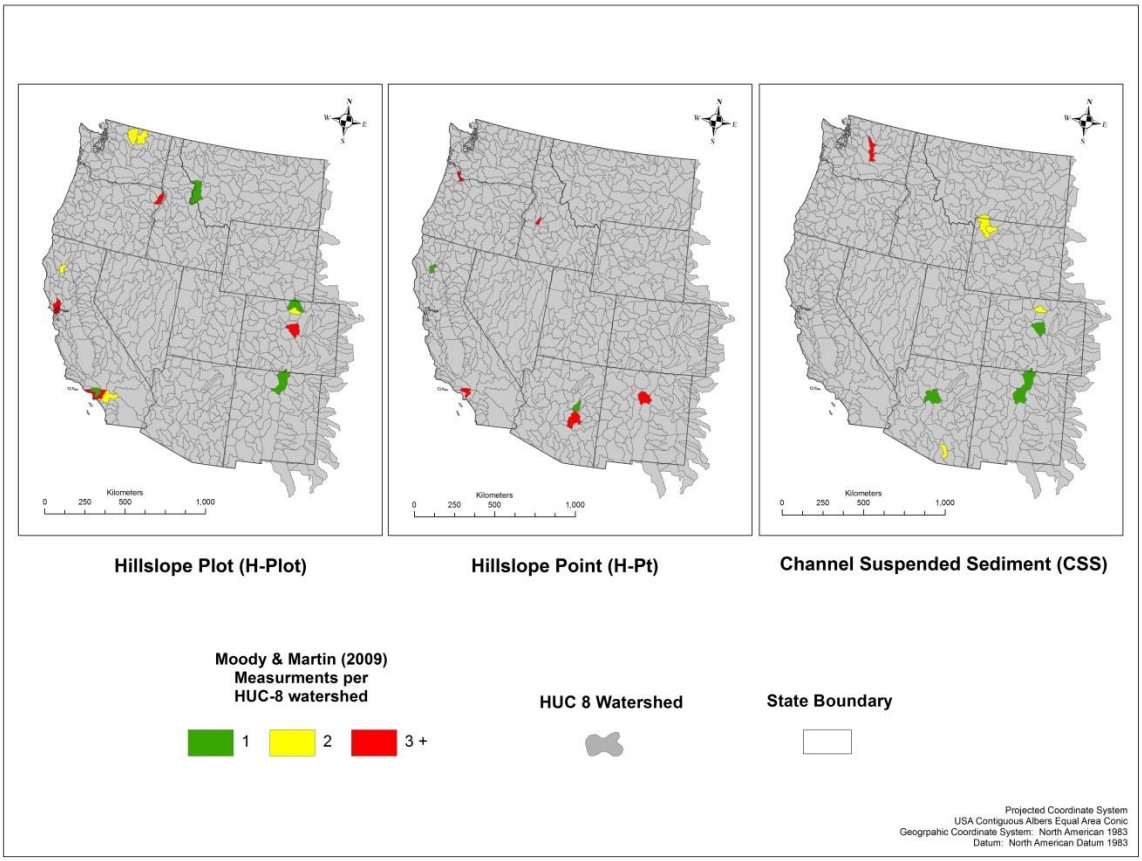

Figure 1 Number of hillslope plot (H-Plot), point (H-Pt), and channel suspended sediment (CSS) measurements synthesized by Moody and Martin (2009) per HUC-8 watershed in the western USA.

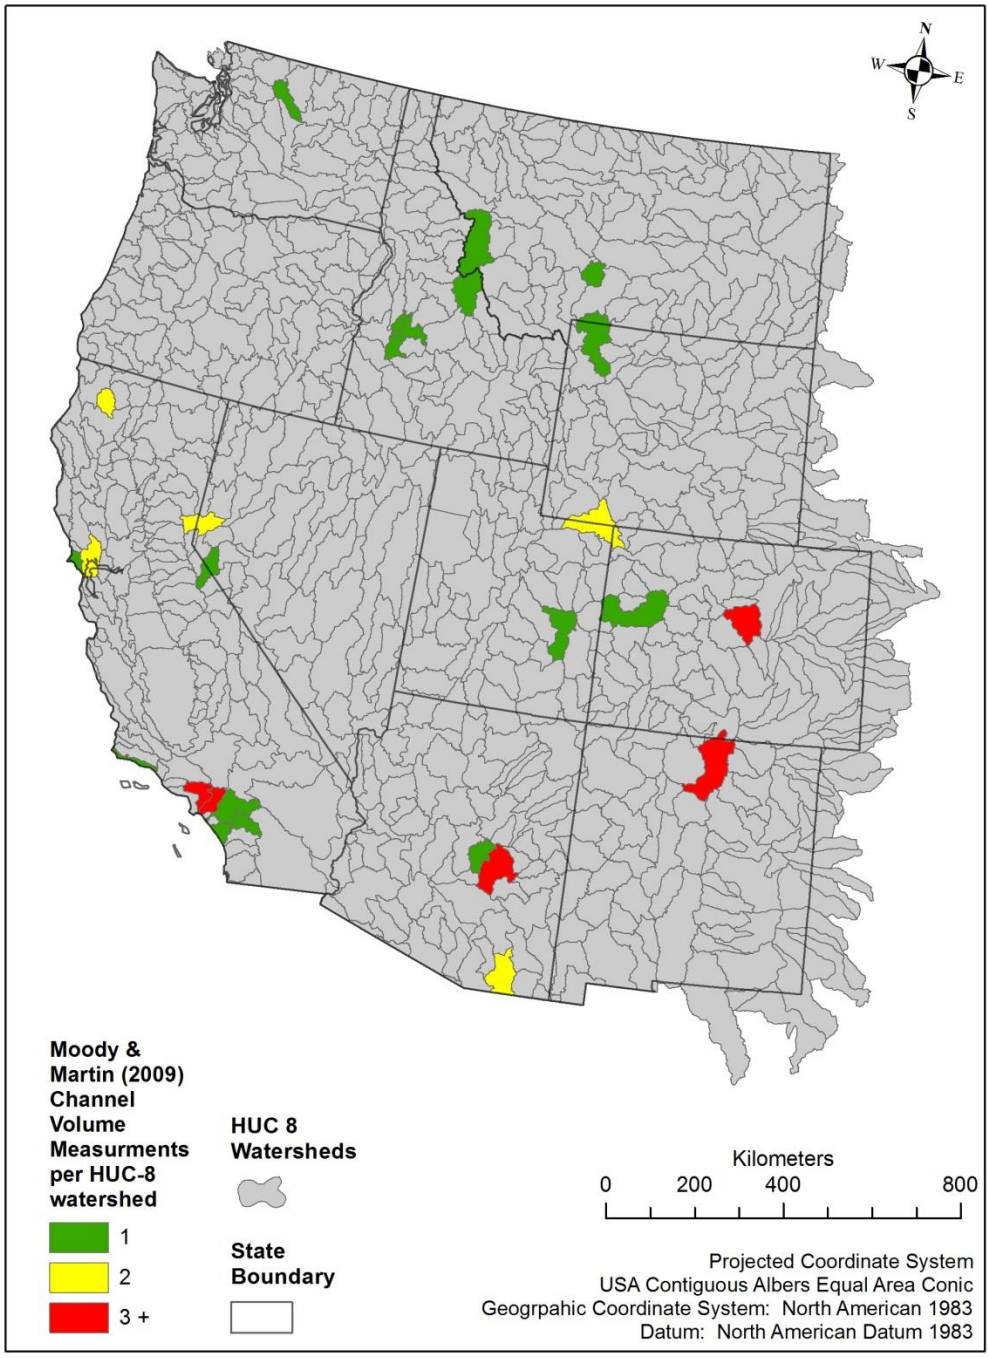

Figure 2 Number of channel volume (CV) measurements synthesized by Moody and Martin (2009) per HUC-8 watershed in the western USA.

OBJECTIVE

In this study, our primary objective was to parameterize and calibrate the InVEST Sediment Retention model to predict post-fire sediment yield at a watershed-scale as accurately as possible. We used measured post-fire sediment yields for watersheds reviewed in the Moody and Martin (2009) synthesis as the baseline calibration data set. We evaluated the relative ability of the model to accurately predict sediment yield for the 4 different types of measurements identified by Moody and Martin (2009). Because the Sediment Retention model is a watershed-scale model we hypothesized that it would most accurately predict measurements made within channel landscape positions (CSS or C-V), which presumably integrate over a greater upslope area of the watershed, than measurements made on hillslopes at plots (H-Plot) or points (H-Pt) within the watershed. Moreover, we hypothesized that the Sediment Retention model would most accurately predict channel volume (C-V) as opposed to channel suspended sediment (CSS) measurements because the model is not designed to target the more narrowly defined range of particle size fractions of sediment transported in suspension. Therefore, we first determined the best-fit parameter set for the particular measurement type that we identified as most appropriate through tests of the aforementioned hypotheses. Then we used the calibrated Sediment Retention model to predict sediment yield response to wildfire for all HUC-8 watersheds across the western United States.

METHODS

We predicted watershed sediment yield (tons/HA) with the InVEST Sediment Retention model for watersheds delineated at the HUC-8 level in the western USA (USGS, www.water.usgs.gov). In order to predict sediment yield, the Sediment Retention model requires Digital Elevation Model (DEM), land use/land cover (LULC), Soil Erosivity (R-Factor), and Soil Erodibility (K-Factor) raster datasets. The model requires a vector dataset that defines the watershed boundaries, and several user-defined tables that characterize important biophysical characteristics of the watersheds.

We used a 90 m resolution DEM (USGS, seamless.usgs.gov) with stream networks from the USGS National Hydrography Dataset (USGS, nhd.usgs.gov) “burned” in and small holes filled using the InVEST toolbox for ArcGIS. We used the National Land Cover Dataset (NLCD) 2006 (USGS, www.mrlc.gov) which has 16 land cover classes at 30 m resolution as the LULC raster.

The R-factor is a climatic indicator that estimates the kinetic energy of rainfall at the maximum 30 minute intensity. We converted an R-Factor vector layer produced by the Environmental Protection Agency (EPA) at the HUC-8 scale (EPA, www.epa.gov), to a 30-m R-Factor raster using a (multiplication) factor of 17.02 to convert from imperial to metric units (Tallis et al., 2014).

The K-Factor is an estimate of soil erodibility as a function of soil development and horizonation, texture, organic matter, and permeability. This was created from the State Soil Geographic Database (STATSGO) K-Factor vector data (USDA, Natural Resources Conservation Service; www.nrcs.usda.gov) and transformed into a 30-m raster dataset.

The Sediment Retention model requires a biophysical table characterizing response by land use/land cover type. Variables in the table include the sediment retention efficiency value which characterizes the relative ability of the vegetation type to slow down overland flow and trap and filter sediment transported by water. The sediment retention efficiency is a floating point index from 0 to 1, where 0.0 = minimum, and 1.0 = maximum, sediment retention. The biophysical table also includes the cover-management factor (C), and the support practice factor (P) values from the USLE. The C and P factors are important agricultural metrics that account for cover crop management and tilling practices, but were not integral to this study. As our study focused on pre- and post-fire conditions for a range of landcover types throughout the western USA, C and P factors were left at default values for all classes and all watersheds (Tallis et al., 2014).

A sediment threshold table containing information about expected reservoir lifetime, water volume, and annual sediment load is required for the intended assessment of the effect of sedimentation on hydropower, but not necessary to modify for our predictions of sediment yield. For the purpose of the table, we treated each watershed as the catchment area for a single reservoir and left default values in place (Tallis et al., 2014).

The Sediment Retention model takes into account a user-defined threshold flow accumulation number, which is the number of upstream pixel cells that must flow into a cell before it is counted as part of the stream network. The threshold flow accumulation number is therefore important for accurately characterizing the watershed drainage network. The Sediment Retention model also requires a slope threshold, which is included to account for agricultural landscapes on steep hillslopes. We heuristically experimented with different values for these variables but ultimately used the default of 1000 cells for threshold flow accumulation, and 75% slope threshold (Tallis et al., 2014).

We first predicted sediment yield for each HUC-8 watershed in the western USA using the aforementioned data and recommended default settings (Tallis et al., 2014). Next, we adjusted vegetation and soil characteristics in the input datasets in order to predict sediment yield for simulated post-fire characteristics of vegetation and soil. We specifically set the sediment retention efficiency value (i.e., of vegetation) to 0.0 for each watershed in the biophysical table, and we increased the soil erodibility (K) by one order of magnitude. These sediment retention and soil erodibility values were intended to simulate an extreme effect of fire in which the ability for vegetation to retain sediment is negated and soil erodibility is dramatically increased. These sediment retention efficiency and soil erodibility values were found heuristically to best predict measured sediment yield in the synthesis by Moody and Martin (2009). We compared sediment yield predicted with the InVEST model using the adjusted sediment retention and soil erodibility values to measured sediment yield reported in Moody and Martin (2009) for each HUC-8 watershed that contained at least one reported sediment yield measurement. We compared predictions to measurements aggregated by type (H-Pt, H-Plot, CSS, C-V) for each watershed. For watersheds with more than 1 measurement of a given type we calculated the mean of measured values of post-fire sediment yield by measurement type (which in some cases included unique measurements of the same type and within the same watershed but from multiple fires during the past century). To evaluate the accuracy of model predictions we focused on watersheds that had at least 3 post-fire measurements per type (Figures 1 and 2), and compared the mean measured post-fire watershed sediment yield to the yield predicted with the InVEST

Sediment Retention model using linear regression and by calculating an average prediction error (Root Mean Squared Error – RMSE).

RESULTS

InVEST model predictions of post-fire sediment yield were not significantly related to sediment yield measurements made with the C-SS, H-Plot, or H-Pt methods and reported in Moody and Martin (2009) (results otherwise not shown). The model accurately predicted mean post-fire sediment yield for those watersheds (n = 5) with at least 3 discrete channel volume (C-V) measurements reported in the Moody and Martin (2009) synthesis (Figure 3). The model accurately predicted approximately 50% of the variability in the mean C-V measurements. The RMSE average prediction error for these 5 watersheds (N ≥ 3 post-fire C-V measurements) was 149.29 tons/HA. The variance of reported channel volume measurements appeared to be large for some watersheds (e.g., standard error bars for measurement means in Figure 3) relative to the average prediction error of the model. Maps in Figures 4 and 5 show predicted sediment yield for all HUC-8 watersheds of the western USA based on: 1) the default parameters (Figure 4) for the InVEST Sediment Retention model (described in Methods section); and 2) the adjusted sediment retention efficiency and erodibility (K) values intended to simulate post-fire vegetation and soil conditions (Figure 5).

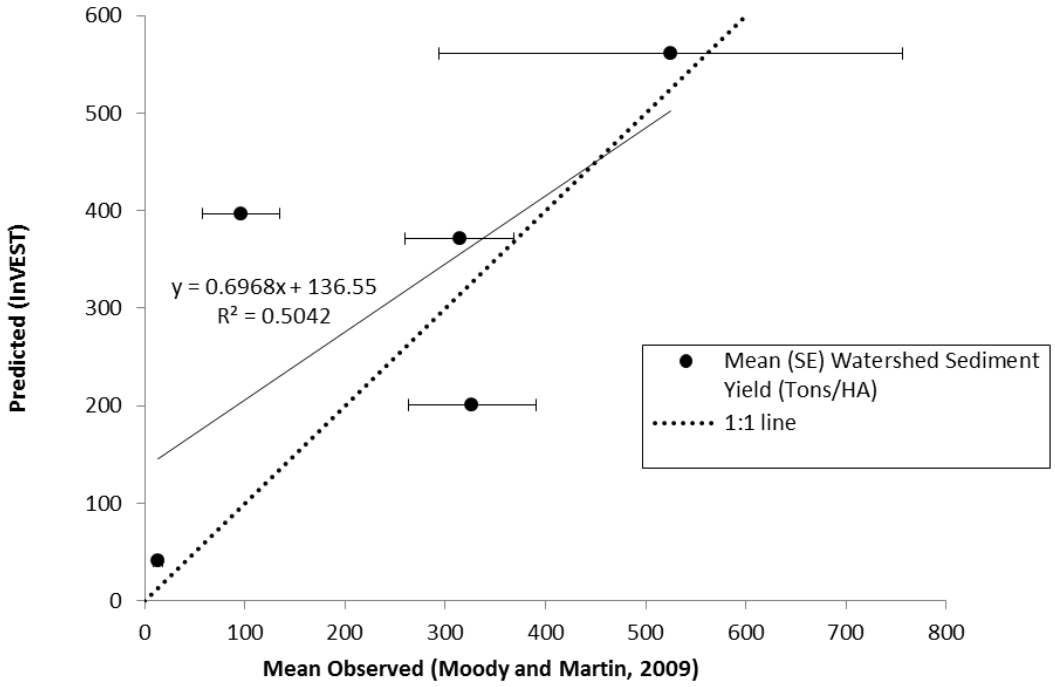

Figure 3 Post-fire sediment yield (tons/ha) predicted with InVEST plotted as a function of mean measured post-fire channel volume sediment yield for watersheds with at least 3 measurements reported in Moody and Martin (2009).

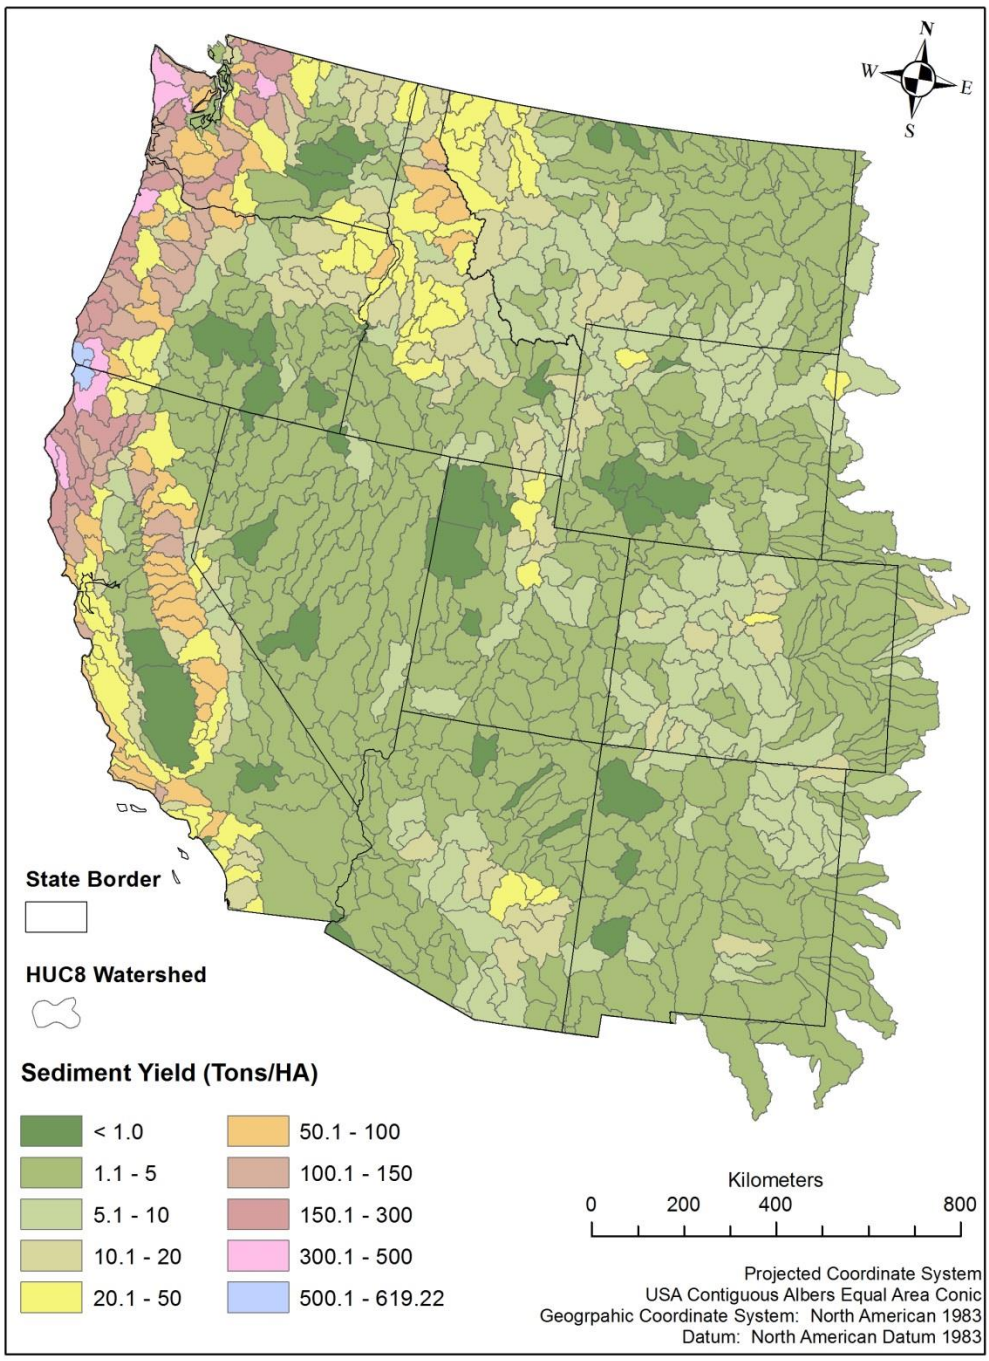

Figure 4 InVEST modeled sediment yield (tons/ha) for all HUC-8 watersheds using normal (default) input parameters.

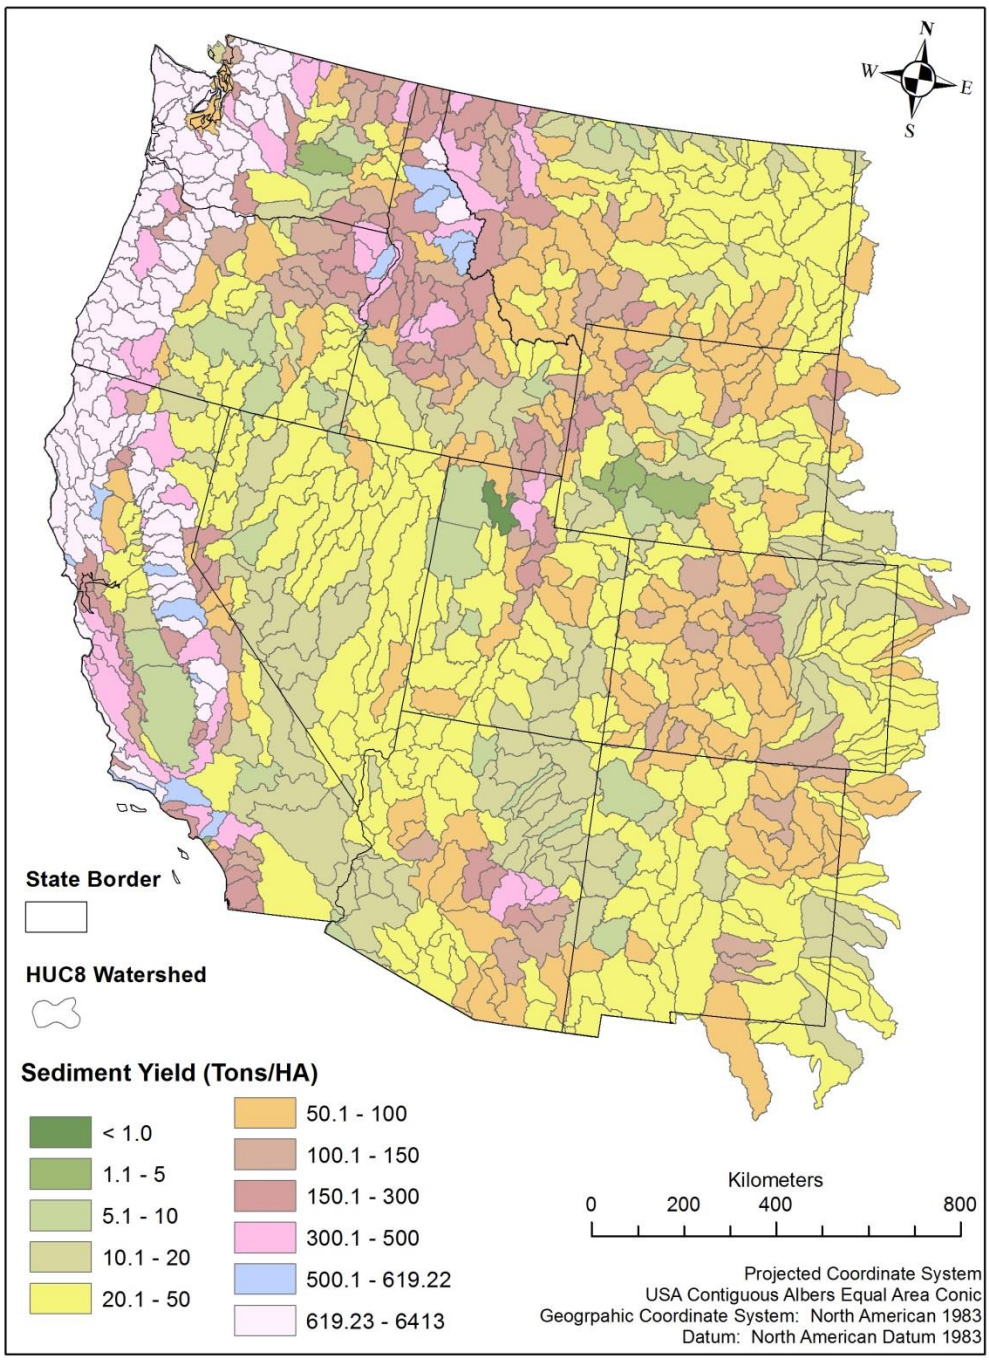

Figure 5 InVEST modeled sediment yield (tons/ha) for all HUC8 watersheds using input parameters modified to simulate post-fire conditions.

DISCUSSION

We evaluated the relative ability of the InVEST Sediment Retention model to accurately predict 4 different classes of post-fire sediment yield measurements synthesized for the western USA by Moody and Martin (2009). Channel volume measurements were the only measurement type for which we determined a significant relationship between model predictions and measured values of post-fire sediment yield. One explanation for why the InVEST Sediment Retention model might predict channel volume measurements with accuracy is because it is a watershed-scale model and measurements made within channel landscape positions are likely to integrate over a larger upstream area and are thus more comparable to the model domain; compared for example to measurements made on hillslopes (plots or point locations) within the watershed. The Sediment Retention model is not designed to predict specific ranges of particle sizes and therefore might also more accurately predict variability in channel volume measurements because they are not comprised of, or constrained to, a specific and narrow particle size range.

Relevant limitations of the model for predicting post-fire sediment yield are that it is based on the USLE and is designed to predict sedimentation as a function of sheet-wash erosion processes, but not from other erosion processes such as rilling, gullying, debris flows or other mass-wasting events (Tallis et al., 2014). The sediment retention efficiency index value that is parameterized by the model user for each LULC class has been identified as another potential limitation for prediction accuracy because few spatially explicit data at the relevant watershed scale are available to accurately characterize the biophysical interactions between vegetation, erosion, and sedimentation (Tallis et al., 2014). There are also few spatially explicit data that describe how the K factor varies as a function of fire within and among watersheds across such a large region; though soil erodibility is certainly known to increase with burning (DeBano, 2000; Giovannini et al., 2001).

Our parameterization of the model resulted in predictions that explained variability in post-fire sediment yield at a watershed-scale for the channel volume measurement type reviewed by Moody and Martin (2009). We anticipate that the methodology presented here for predicting post-fire sediment yield with the InVEST Sediment Retention model will have utility for evaluating the relative, potential vulnerability of watersheds to increased sedimentation as a function of future changes in wildfire frequency and occurrences throughout the western USA.

CONCLUSION

The InVEST Sediment Retention Model provides a GIS platform to efficiently model sediment yield and the ecosystem service of sediment retention at a watershed scale for a large number of watersheds. In this study, we showed that the model can be parameterized in a relatively simple fashion to predict post-fire sediment yield using site data where sediment yield measurements are characteristic of watershed-scale erosion and sediment delivery. Future work will focus on using the InVEST suite of models to assess tradeoffs for natural resource management decisions and to evaluate the potential vulnerability of watersheds throughout the western USA to post-fire sedimentation as a function of future changes in wildfire frequency and occurrence.

UTILITIZATION OF ECOHYDROLOGIC MODELS IN FLOODPLAIN FISH PASSAGE AND HABITAT RESTORATION EVALUATION

Joshua A. Israel, Fish Biologist, U.S Bureau of Reclamation, Sacramento, CA. jaisrael@usbr.gov; Paul Bergman, Fisheries Biologist, Cramer Fish Sciences, Auburn, CA, pbergman@fishsciences.net; Chris Campbell, Ecohydrologist, CBEC Inc., West Sacramento, CA, c.campbell@cbecoeng.com; James Newcomb, Senior Environmental Scientist, Department of Water Resources, West Sacramento, CA, James.Newcomb@water.ca.gov; Maninder Bahia, Water Resource Engineer, Department of Water Resources, West Sacramento, CA, Maninder.Bahia@water.ca.gov

Abstract: Ecosystem restoration programs are playing an essential role in listed species management in California's Central Valley. Currently, the US Bureau of Reclamation and California Department of Water Resources are planning actions, evaluating alternatives, and assessing biological benefits of the Yolo Bypass Salmonid Habitat Restoration and Fish Passage Program as part of the Biological Opinion with NOAA-Fisheries required as part of operations of the Central Valley Project and State Water Project. Hydraulic modeling efforts for the evaluation of alternative fish passage structures and habitat restoration are critical elements of the assessment and optimization frameworks being undertaken. A two dimensional hydraulic model of the Yolo Bypass was constructed to undertake quantitative assessments of salmonid population response. This modeling indicates the importance of finer scale 3D modeling to inform juvenile population responses to potential project designs for structures increasing floodplain connectivity with the Sacramento River. Various biological metrics are being assessed using these hydraulic models to evaluate the benefits and limitations of floodplain restoration and fish passage alternatives for fishery resource recovery.

INTRODUCTION

Significant modifications have been made to the historic floodplain of California's Central Valley for flood damage reduction purposes and water supplies. The resulting losses of rearing habitat, migration corridors, and food web production for fish have significantly hindered native fish species that rely on floodplain habitat during part or all of their life history. The Yolo Bypass (Bypass), which currently experiences at least some flooding in approximately 80% of years, still retains many characteristics of the historic floodplain habitat that are favorable to various fish species. In approximately 70% of years, Fremont Weir overtops connecting the Bypass to the Sacramento River along its northern boundary, and Sacramento flows join flows from western tributaries. In approximately 10% of years, localized flooding is due to western tributary contributions only. The primary function of the Bypass is flood damage reduction, with most of it also managed as agricultural land. The Bypass has also been identified by several State and federal entities as a potential site for habitat restoration to ease pressure on and increase benefits to threatened and endangered fish species.

On June 4, 2009, the National Marine Fisheries Service (NMFS) issued its Biological Opinion and Conference Opinion on the Long-term Operation of the Central Valley Project (CVP) and State Water Project (SWP) (NMFS Operation BO). The NMFS Operation BO concluded that, if

left unchanged, CVP and SWP operations were likely to jeopardize the continued existence of four federally- listed anadromous fish species: Sacramento River winter-run Chinook salmon, Central Valley spring-run Chinook salmon, Central Valley steelhead, and Southern Distinct Population Segment (DPS) North American green sturgeon. The NMFS Operation BO sets forth Reasonable and Prudent Alternative (RPA) actions that would allow continuing SWP and CVP operations to remain in compliance with the federal Endangered Species Act (ESA). These include restoration of floodplain rearing habitat, through a "notched" channel that increases seasonal inundation within the lower Sacramento River basin. A second objective is to reduce migratory delays (i.e.: upstream adult fish passage, agricultural crossing modification, Lisbon Weir improvements) and stranding of fishes. A significant component of these risk reduction actions is lowering a section of the Fremont Weir (Figure 1) to allow juvenile fish to enter the bypass and adult fish to more easily ascend this hazard.

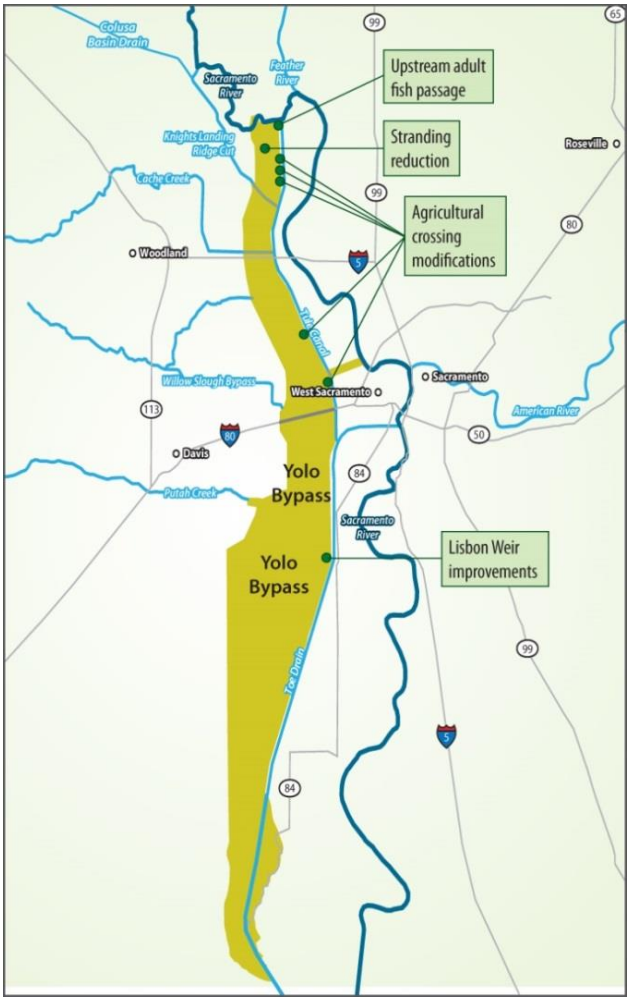

Figure 1 Yolo Bypass locality for projects increasing seasonal inundation and reducing adult straying and stranding.

Currently, the planning and environmental compliance process is considering a reasonable range of alternatives for implementing this RPA action. This includes a number of projects that are common elements, which will reduce stranding and migration delays, and other projects that represent potentially uniquely designed facilities with distinct benefits and risks for achieving

fisheries benefits. This presentation focuses on two modeling efforts underway to quantitatively assess the potential benefits of restoration actions for juveniles life stages of salmonids on ESA-listed fish populations. While other efforts are underway to use these models to benefits from alternative designs for adult passage, these results will not be discussed in this presentation. This presentation includes fishery benefit results from completed physical and biological modeling, discussion of a key uncertainty in our model, and description of our 2015's study to inform better modeling to reduce this uncertainty.

METHODS

MODELS: An interagency hydraulic modeling technical team evaluated a set of potential two-dimensional (2D) hydraulic models for use in evaluating different potential configurations of Fremont Weir gate and channel "notches" to allow larger and more frequent floodplain inundation events in the Bypass. The team ranked the models based on their model capabilities, other considerations, and optional model capabilities. Attributes characterized included performance, cost, public domain, breadth of user base, and model longevity. TUFLOW ranked high, and was selected based on its high performance, relative low cost, growing agency user base, Geographic Information System (GIS) interface, and quick run time. Technically favorable aspects with TUFLOW also included its ability to solve the full 2D shallow water equation, to provide numeric stability even with wetting and drying, to compute flows using weir equations automatically, and to allow support for hydraulic structure under potential operational control.

The model domain (see Figure 2) extends along the Sacramento River from River Mile (RM) 118 just south of the Tisdale Bypass near Wilkins Slough to RM 12 near Rio Vista and includes the entire Yolo Bypass. The domain extends 7 miles to the north along the Feather River and into the Sutter Bypass. The Feather-Sutter boundary was located far enough to the north of the flow split between the Yolo Bypass at Fremont Weir and the Sacramento River at Verona to minimize model boundary effects at the flow split (and the proposed gated channel at Fremont Weir). The domain includes the Sacramento Weir at RM 63 and extends 22 miles to the east along the American River to just below Nimbus Dam. The domain also includes various North Delta sloughs (i.e., Elk, Sutter, Miner, Steamboat, Haas, Cache, Lindsey, and Barker) and a boundary connection with the Delta Cross Channel and Georgiana Slough at RM 27.

The model domain is comprised of a combination of one-dimensional (1D) channels and 2D grids. The 1D channels describe the flow of water in the major sloughs, creeks, and rivers bordering or bisecting the flood control bypasses and are represented with a series of cross sections. The 2D grids describe the flow of water within the flood control bypasses when channel capacity is exceeded, flood control weirs are activated, and restricted height levees are overtopped. The TUFLOW model includes three separate 2D grids. The cell sizes for the grids are 400 feet-, 200 feet-, and 100 feet-square, which provide elevation values every 200 feet, 100 feet, and 50 feet, respectfully. The 200 foot grid covers the majority of the 2D domain. The 100

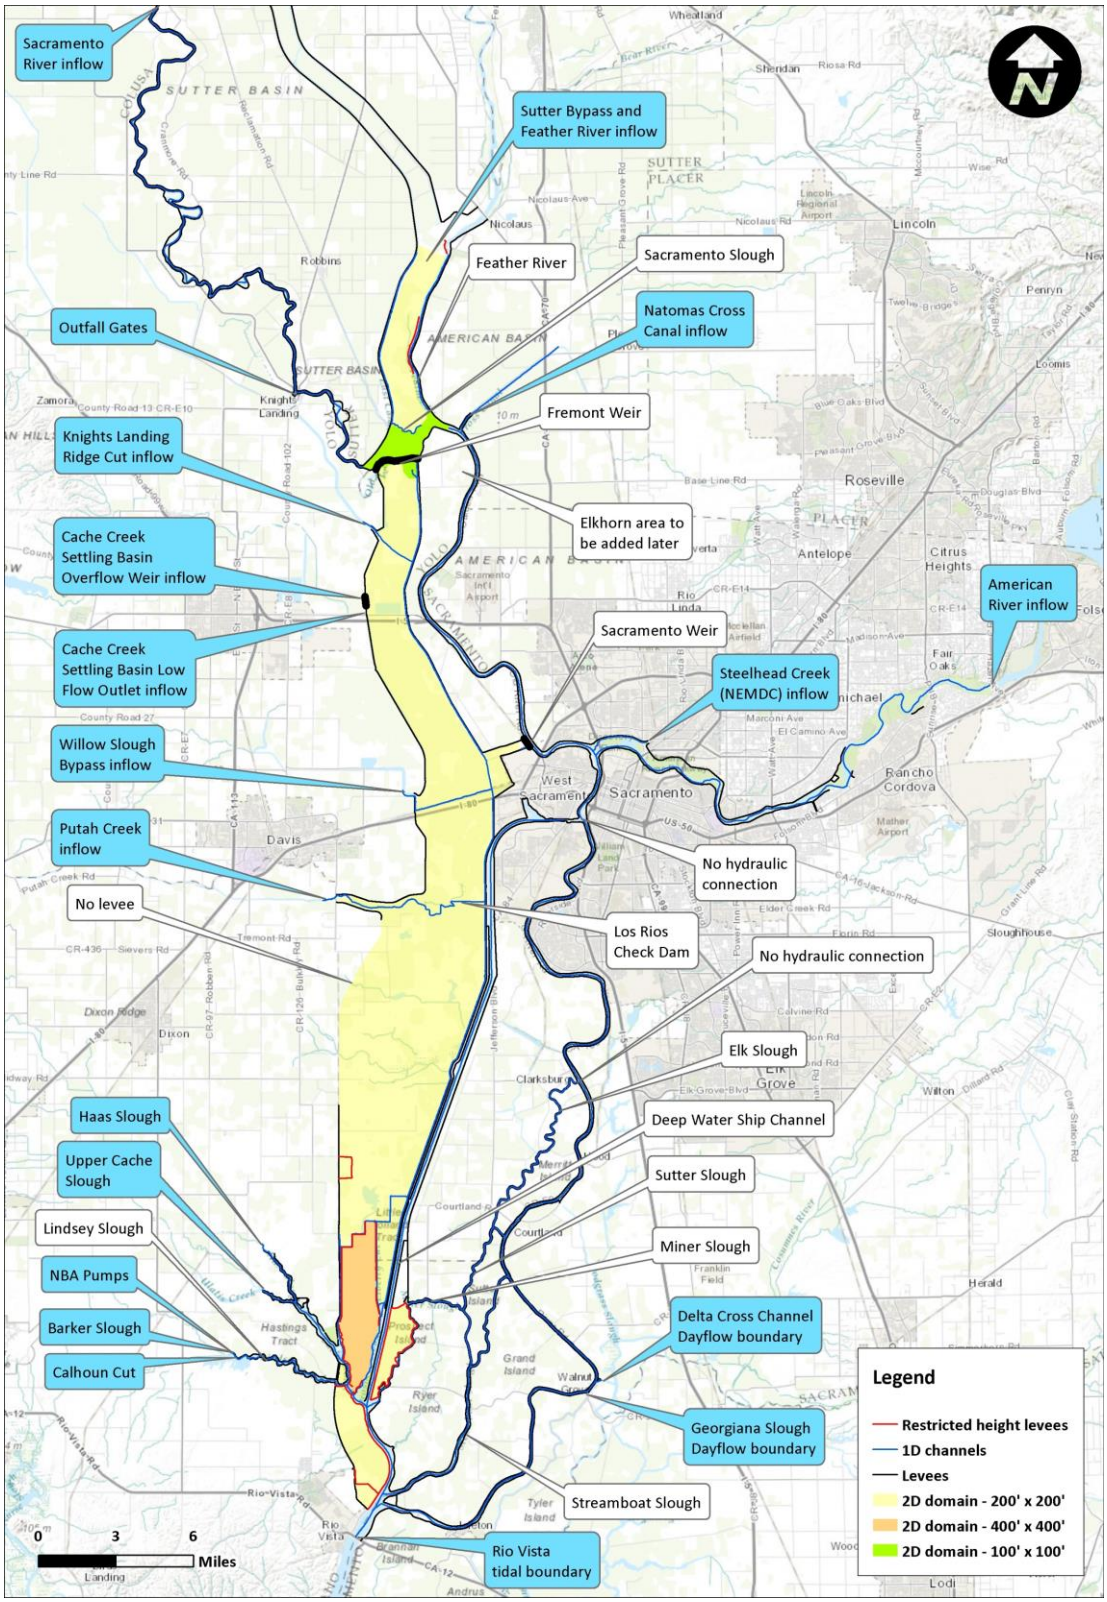

Figure 2 TUFLOW model domain and boundary locations. (Prepared for DWR by HDR and cbec).

foot grid represents the section of the Sacramento River between Knights Landing and Verona. The 400 foot grid represents Liberty Island. Each grid has elevations at each cell centroid, edge mid-point, and cell corner giving nine elevation values per cell. Multiple grids were used to vary the cell size spatially to balance required resolution and reduced runtimes. The grid elevations are assigned within the TUFLOW model based upon a Digital Elevation Model (DEM) with modifications to enforce localized features on the working agricultural landscape within the bypass. Exhaustive efforts were made to characterize boundary conditions, which were previously data limited, such as the west side tributaries, hydraulic structures in the Bypass, and Feather River and Sutter Bypass condition.

Long term daily hydrologic data was prepared for water years 1997 through 2012 to serve as existing conditions for the TUFLOW model. Inundation duration, frequency, and acreage were modeled for three potential alternative "notch" configurations relative to existing conditions (Table 1). These data were processed for the fisheries team to provide depth and velocity magnitude raster datasets covering the Bypass. Also, these results were processed into daily average discharge values for the Fremont Weir (including channel flows), the Sacramento at Verona, and the Sacramento River at Freeport.

Table 1 Small, medium, and large Fremont Weir notch configurations modeled.

Fremont Weir Notch	Small	Medium	Large	Existing
Bottom width (ft)	20	22.5	22.5	NA
Invert elevation (ft)	14	17.5	14	33

The Fisheries Benefit model keeps track of key life stage demographics resulting from potential restoration alternatives (Table 1). Its components include: (1) *model entry* – the abundance, size and timing of juvenile salmon entering the model; (2) *Yolo Bypass entrainment* – the entrainment of juvenile salmon onto the Bypass; (3) *rearing* – the life stage of juvenile salmon on the Bypass or in the mainstem Sacramento River ; (4) *emigration* – the downstream migration of juvenile salmon from Rio Vista, CA to San Francisco (Bay) entry; (5) *ocean residence* – the residence of salmon in the ocean; (6) *upstream migration*– the upstream migration of returning adults from the Bay upstream to Fremont Weir on the Sacramento River. Function and parameter values taken from appropriate literature and regional studies were used in the model. The assumption that juvenile fish are entrained from the Sacramento River onto the Yolo Bypass in proportion to the flow entering the Bypass was utilized, since no other information exists regarding this value.

METRICS: The utility of biological-physical coupled models to aid in this assessment is providing information on metrics useful for discerning benefits for ESA-listed species. Reclamation and DWR reviewed potential metrics prior to undertaking modeling, and thus were able to tailor models to emphasize results that are useful for comparing potential notches to existing conditions. Results from the hydraulic modeling are being used for independent consideration of attaining desirable inundated acreage targets and other landscape ecosystem metrics (Table 3). Results from the biological modeling, which are based upon the hydraulic model results, are being used for assessing population metrics useful for evaluating how the viability of salmon populations are impacted by these actions (Table 3).

MODELING OF A NON-PHYSICAL FISH BARRIER

Marcela Politano, Research Engineer, IIHR – Hydroscience & Engineering, The University of Iowa, Iowa City, IA, marcela-politano@uiowa.edu; Ezequiel Martin, Assist. Research Scientist, IIHR – Hydroscience & Engineering, The University of Iowa, Iowa City, IA, juan-martin@uiowa.edu; Yong Lai, Hydraulic Engineer, Technical Service Center, Bureau of Reclamation, Denver, CO, ylai@usbr.gov; Merlynn Bender, Hydraulic Engineer, Technical Service Center, Bureau of Reclamation, Denver, CO, mbender@usbr.gov; Dave Smith, Research Ecologist, US Army Corps of Engineers, Vicksburg, MS.

Abstract: Non-physical barriers (NPBs) are used to deter fish from entering an undesirable pathway without restricting flow. NPBs are commonly comprised of a bubble curtain, low-frequency sound, and hi-intensity light-emitting diode (LED) Modulated Intense Lights (MILs). In this study a 3D numerical model was developed to predict bubble, sound and light fields in the vicinity of an NPB. A Boussinesq approach was used to account for the reduction of density in the zones where bubbles are present. A simplified diffusive model for the sound intensity was developed. Two methods are proposed for light, one for high attenuation/scattering conditions based on P-N models and the other for low scattering conditions based on the superposition of analytical solutions for elementary one-dimensional cases. To validate the solvers, several experiments were simulated. A sample model application to a simplified NPB located in Georgiana Slough in the Sacramento River is presented and discussed.

INTRODUCTION

Non-physical barriers (NPBs) use behavioral stimuli such as bubbles, low-frequency sound, and high-intensity light-emitting diode (LED) Modulated Intense Lights (MILs) to deter fish from entering undesirable locations. The sound is concentrated within the bubble curtain due to the difference in the velocity of sound of water and air to prevent sound saturation. Lights projected onto the bubble curtain improve visibility for fish swimming in the direction of the curtain. This NPB arrangement is typically referred to as a Bioacoustic Fish Fence (BAFF).

The migration of juvenile salmonids in the San Joaquin and Sacramento Rivers is of great environmental interest due to decline of native species. Fish diversion into the Delta may result in delayed migration, elevated risk of predation, exposure to poor water quality conditions, and mortality in pumping facilities. The California Department of Water Resources (CDWR) and the U.S. Bureau of Reclamation (Reclamation) proposed to use a NPB to reduce the diversion of juvenile salmonids from the Sacramento River into the interior and south Delta. The effectiveness of NPBs in deterring fish is variable, depending on the location, barrier geometry, and river flows. NPB can also have unintended effects, such as increased predation upstream and downstream of the barrier. All the above increase the environmental risk requiring site specific study and evaluation. In this study a numerical model for a NPB was developed to better understand the effect of the barrier on the Sacramento River hydrodynamics and support the design and operation of a NPB to deter and direct fish movement.

NUMERICAL MODEL

In this study, we first developed the model equations to simulate the bubbles, sound and light fields. The model equations were then implemented into the open source code OpenFoam (Weller et al. 1998). OpenFoam is a collection of C++ libraries, based on object oriented programming, designed for continuum mechanics applications. A new solver, pisoFoamBLS, which includes simplified models for predicting bubbles, sound and light fields near a non-physical fish barrier, was developed based on the code pisoFoam using a modular approach. Several studies related to implementation of different solvers in OpenFoam may be found in the literature (Hussein 2009, Kassem et al. 2011, Flores et al. 2013, among others) and repeated herein.

MODELING OF BUBBLES

Mathematical Modeling

A bubbly flow, i.e., a discrete gas phase in a continuous fluid, is formed in bubble curtains. As illustrated in Figure 2, bubbles injected in an initially quiescent medium induce a motion in the liquid similar to that observed in buoyancy-induced flows. Three distinct zones can be observed in a bubble curtain:

1. The primary bubble zone: where bubbles accelerate as they detach from the nozzle

2. The plume zone: where bubble breakup and coalescence prevail to form the plume
3. The free bubble zone: where the dynamic process of breakup and coalescence have reached an equilibrium and bubbles rise without significant size change

Measurements of gas volume fraction, bubble frequency and chord length by Castillejos and Brimacombe (1987) indicate that bubble breakup in the plume zone predominantly occurs near the injection location. Close to the free surface, the bubble velocity decreases as liquid moves tangent to the free surface, which enhances coalescence and promotes larger bubble sizes.

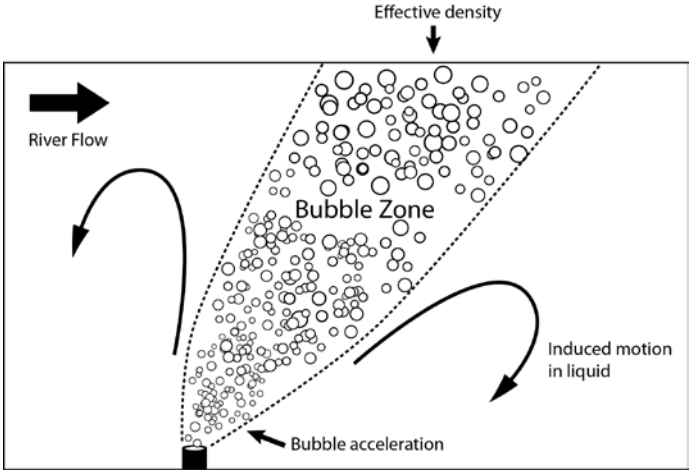

Figure 1. Induced liquid motion for a bubble curtain in a river

Most of bubble plume models found in the literature are intended for the free bubble zone region. The current modeling effort is based on the model presented by Buscaglia et al. (2002). The authors used a two-fluid approach assuming an incompressible mixture gas-liquid phase. In this approach, the Navier-Stokes equations are restored, significantly simplifying the formulation. The main advantage of this model is that an equation for the gas phase is included and therefore the shape of the bubble zone can be predicted. Future model improvements such as inclusion of a bubble size distribution, breakup and coalescence, bubble dissolution, bubble compression, bubble induced turbulence, etc., can easily be incorporated into the model using this formulation. Following Buscaglia et al. (2002), density differences are neglected except where they appear in the term multiplied by the acceleration due to gravity resulting in:

$$\nabla \cdot \vec{u}_m = 0 \tag{1}$$

$$\rho_l \frac{\partial}{\partial t}\vec{u}_m + \rho_l \nabla \cdot \left(\vec{u}_m \vec{u}_m\right) = -\nabla P + \nabla \cdot \left[\tau_m^{\mathrm{Re}} + \tau_m\right] + \rho_m \vec{g} \tag{2}$$

Eqs. (1) and (2) can be solved to compute pressure and velocity of the mixture phase with any single-phase CFD solver adding a source term in the momentum equation $\vec{S}_m = -(\rho_l - \rho_g)\alpha \vec{g}$. In this study an isotropic turbulence model $k-\varepsilon$ was used for turbulence closure. The gas velocity was obtained from the momentum equation for the gas phase. Inertia, gravity force and viscous shear stresses are significantly smaller than liquid-gas interfacial forces due to the small density and viscosity of the gas phase and are usually neglected. In this particular application, drag is the most important interfacial force and lift and virtual mass can be neglected resulting in:

$$-\nabla\left(P + \frac{2}{3}k\right) + \frac{3}{8}\frac{C_g^D}{R}\vec{u}_r\left|\vec{u}_r\right| = 0 \tag{3}$$

In a bubble curtain, bubble size can change due to breakup, coalescence, mass transfer and pressure variations. In this study, an equation for the bubble number density was used:

$$\frac{\partial N}{\partial t} + \nabla \cdot \left[\vec{u}_g \, N \right] = \frac{\nu^t}{Sc} \nabla^2 N_g \tag{4}$$

The bubble volume at a given position can be calculated from $v_b = \frac{P_c}{P} \frac{4}{3} \pi R_c^3$, where P_c and R_c are the pressure and radius at the injection point. The bubble zone can be determined using the gas volume fraction, which can be obtained from the mass conservation equation for the gas phase $\alpha = \frac{4}{3} \pi R^3 N$.

Model Comparison with Experiments

The model was used to simulate an experiment by Grevet et al. (1982) in which a water-filled cylindrical tank was agitated by a gas bubble stream, and compared against velocity data measured inside the tank. The modeled tank radius, *R*, was 0.3 m and the water height, *H*, 0.6 m. Bubbles were injected into the quiescent liquid through an orifice of 0.0127 m (0.5 inch) at a flowrate of 205 cm^3/s. Only one fourth of the tank was simulated to reduce grid size and computational time. Symmetry boundary conditions were used on the sides. Grid size was approximately 10^5 nodes. Since bubble velocities were not measured, it is assumed that bubbles enter the domain at their terminal velocity. Reasonable agreement was found between model predictions and experimental data for three axial positions (Figure 2). As rising bubbles leave the injector, they generate an inward flow at the left bottom side of the tank. The bubble stream then generates an upward flow in the center of the tank and a large clockwise vortical structure at the upper right side, with negligible radial velocities. The rising bubble velocity is terminated at the free surface and the liquid vertical moment is converted to horizontal flow. The horizontal flow is blocked by the tank wall and is redirected downward along the side wall. The model is considerably less accurate near the walls, but since wall interaction is not important in a bubble curtain, grid refinement was not performed to capture the velocity profile near the walls. The proposed model assumes one variable bubble size. Implementation of a bubble size distribution is expected to improve model accuracy. Figure 3 shows the gas volume fraction distribution in the tank. For the low gas volume fraction injected, bubbles concentrated in the core of the tank, rise almost uniformly in a nearly straight line. Near the injector, bubble velocity increases due to the upward liquid flow in the center of the tank. This local increase of the liquid velocity causes a reduction of the gas volume fraction. Conversely, bubble velocities are reduced near the free surface resulting in a local increase of the gas volume fraction.

MODELING OF SOUND

Mathematical Modeling

The acoustic field in a domain can be represented by an equation of acoustic energy conservation:

$$\frac{\partial W}{\partial t} = -\nabla \cdot \boldsymbol{I} - D \tag{5}$$

where W is the acoustic energy and $\boldsymbol{I}$ the acoustic energy flux. The last term in the RHS represents dissipation effects. In this study a method was developed to deal with the strong changes in fluid properties introduced by the presence of the bubble barrier as well as the multiple surfaces that partially absorb the sound signals at the boundaries. The diffusive equation used in architectural acoustics was identified as a viable candidate to fulfill these requirements. A Fick's law-type relation is postulated between the energy flux and the energy density, $\boldsymbol{I} = -\boldsymbol{D_W}\nabla W$, which adapted to give a dependence of the dissipation on W rather than $\boldsymbol{I}$, transforms the conservation equation for sound energy to:

$$\frac{\partial W}{\partial t} = -\nabla \cdot (\boldsymbol{D_W}\nabla W) - \alpha_W^2 |\boldsymbol{D_W}| W + S_W \tag{6}$$

where a general distributed source term S_W has also been included. A new parameter, an anisotropic diffusion coefficient $\boldsymbol{D_W}$, has been introduced, for which modeling is required. The expression for the dissipation term is such that the exponential decay of a plane wave in an isotropic media is recovered. Following Picaut (2002), absorption is modeled as a boundary condition. Picaut et al. (1999) proposed a diagonal tensor related to length-scale of domain for the diffusion coefficient:

$$\frac{D_{xx}}{\ell_x} = \frac{D_{yy}}{\ell_y} = \frac{D_{zz}}{\ell_z} = D_{3D} \tag{7}$$

with the diffusion proportional to sound speed ($D_{3D} \sim c$). Eq. (6) is a standard diffusion equation for which solution methods are well established and can be readily implemented in OpenFoam. Certain features of the sound field are lost by using this approach, such as the appearance of interference patterns and the rapid evolution of the sound field that can be found with the ray tracing method. However, it is questionable that those features are of significant importance for the current application, as it is expected that the cases of interest will be quasi-steady in both bubble-encapsulated and non-encapsulated sound fields as the fluid velocity is much smaller than the speed of sound, and the sound source are non-pulsating in time.
A set of linear attenuation coefficients and speed of sound data for bubbly flows presented by Silberman (1957) were used in this study.

Model Comparison with Experiments

The data presented by Würsig et al. (2000) represent one of the few reported field experiments with useful, albeit scarce, data for model validation. Sound levels produced by a pile-driving hammer in shallow waters were measured with and without a bubble curtain designed to mitigate the sound. Measurements of background noise are also available, but there is no measurement of sound levels near the source or inside the bubble curtain area. A slab geometry with an average depth of 8 meters was simulated. In Figure 4, the measured data on April 26, 1996 is shown along with the simulated results. The authors reported an overall sound level for frequencies spanning 100 Hz to 25.6 kHz, as well as results for the different one-octave bands. Notable differences in attenuation by the bubble curtain occur for the different frequencies, but it was found that the reported average trend for all frequencies is consistent with the results for low frequencies (as the sound intensity is largest for the 400 Hz octaves), and a representative frequency of 400Hz was chosen to perform the simulations. A uniform source for the background noise and an additional source near the coordinates' origin were obtained. The relationship between the wall attenuation coefficient and the diffusion parameter was established using the expression proposed by Silberman (1957). An extremely low value of $D_{yy}/D_{rr} = 1.6\text{x}10^{-4}$ was found from the experimental data, and as shown in Figure 4, the predicted decay matches well with the data. Finally, a mean gas volume fraction was estimated from the reported flow rate, assuming a terminal bubble velocity and a corresponding plume spreading angle. The resulting bubbly region is a ring, 25 m in diameter and 0.5 meter in thickness, with an estimated gas volume fraction of 0.02. It is reported that the resulting attenuation by the bubble barrier is about 3 to 5 dB, which agrees well with the estimated attenuation. The simulations required a smaller value of gas volume fraction to match the data of 0.003. When experimental data become available, further simulations and analyses should be performed to identify the reason for this discrepancy.

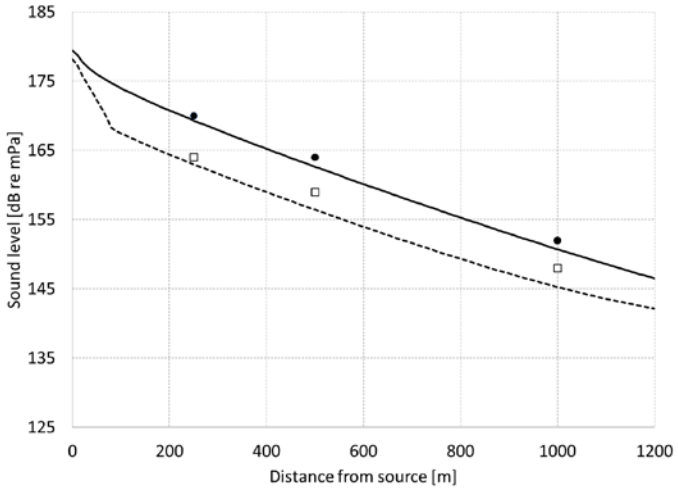

Figure 4. Sound levels in a slab. Symbols: Würsig et al. (2000) experimental data (black circles: bubble curtain off; white squares: bubble curtain on) and lines: simulation results

MODELING OF LIGHT

Mathematical Modeling

Calculations of light intensity can be extremely resource-intensive and are typically done using Monte Carlo simulations; or are based on semi-analytical approximations to an integro-differential equation. The latter approach was used in this study. The fundamental equation describing the light field in a continuous media is called the radiative transfer (RT) equation. The RT conservation equation balances the changes of spectral radiance (L) in a given direction with the processes that can modify it: *absorption*, *scattering* and *emission*. The attenuation of the beam is given by the *absorption*, defined by the absorption coefficient $a_{\mathrm{E}}(\boldsymbol{x},\lambda)$ times the radiance and all the scattering *out* of the beam direction that can be approximated as $-b_{\mathrm{E}}(\boldsymbol{x},\lambda)L$, with b_{E} the average of the volume scattering function. The elastic (i.e., without a change of wavelength) *scattering* for other directions *into* a given direction constitutes a source and is represented as an integral that accounts for all the contributions over all possible 4π solid angle directions to a given one. Finally, *emission* may correspond to an actual source or due to inelastic scattering from other wavelengths, and can be expressed as a general source s_{E}, per steradian. The complete RT equation can be written as (Mobley, 2001):

$$\Omega\nabla L(\boldsymbol{x},\theta,\varphi,\lambda) = -c_{\mathrm{E}}(\boldsymbol{x},\lambda)L(\boldsymbol{x},\theta,\varphi,\lambda) + \int_{4\pi} L(\boldsymbol{x},\theta',\varphi',\lambda)\beta_s(\boldsymbol{x},\theta',\varphi',\theta,\varphi,\lambda)d\Omega' + s_{\mathrm{E}}(\boldsymbol{x},\theta,\varphi,\lambda) \quad (8)$$

with β_s is the angle dependent volume scattering function and c_{E} the sum of a_{E} and b_{E}. Eq. (8) contains both an integral on the solid angle and spatial derivatives which can be very difficult to solve explicitly. In this study, the scalar irradiance, E, obtained by integration of L, was used. Extensive literature exists on different methods implemented to solve Eq. (8). In this study, two methods were implemented. A superposition of elementary solutions is proposed when scattering effects are not important and a P-1 model for high attenuation and/or scattering.

Certain apparent optical properties such as the diffuse attenuation coefficient can be approximated as a function of intrinsic properties for certain simple cases (Kirk, 2003; Kirk, 2006). Two simple solutions for the scalar irradiance can be found for planar and point sources by simple integration of Eq. (10):

$$E(z) = E_0\exp(-Kz) \quad (9)$$

$$E(r) = \frac{r_0^2}{r^2}E_0\exp(-Kr) \quad (10)$$

In the superposition of elementary solutions method, multiple elementary solutions are automatically combined to produce a light field that approximates the solution of RTE:

$$\nabla\cdot(\mathbf{u_E}E) = S_{\mathrm{E}} - KE \quad (11)$$

where $S_{\mathrm{E}} = 4\pi s_{\mathrm{E}}$, and K is the diffuse attenuation coefficient. To recover the solutions presented before (Eqs. 9 and 10), a dimensionless vector field is defined as $\mathbf{u_E}$ = (0,0,-1) for a plane source emitting in the z negative direction and $\mathbf{u_E} = \mathbf{e_r}$ the radial unit vector for the point source case. By presenting the solution as a result of a numerical integration it is possible to introduce more complex geometries and also variability of the attenuation factor, which can be calculated independently of the solution. With this simple scheme it is possible to reproduce background illumination due to natural daylight as a plane source, as well as including the stroboscopic lights of the barrier as point sources.

P-N models use a diffusive representation of the RTE, and as such its range of validity is for conditions with high attenuation and/or scattering (Sazhin et al., 1996). In general, P-N models are based on the expansion of the solution to RTE in orthogonal series of spherical harmonics. For the P-1 model only the first and third terms of the series are kept resulting in:

$$-\sum_{i=1}^{3}\frac{\partial}{\partial x_i}\frac{1}{3(a_{\mathrm{E}}+b_{\mathrm{E}})}\frac{\partial L^{(0)}}{\partial x_i} = 4\pi s_{\mathrm{E}} - a_{\mathrm{E}}L^{(0)} \quad (12)$$

Attenuation and absorption coefficients available in USEPA (2000) and Mobley (2001) as a function of water molecules, chlorophyll, inorganic matter and colored dissolved organic matter were used.

For a bubbly flow, the effect of the bubbles in the attenuation of light must also be considered. For most cases, it can be assumed than the bubble's radius R is much larger than the wavelength of the incident light. This condition is known as the geometric optic limit, for which both the geometric approximation and the Mie theory of scattering will predict the same far-field solution for the interaction of a plane wave and a single large sphere (Randrianalisoa and Baillis, 2014). It is a good assumption to neglect the absorption within the bubble and only consider the scattering contribution (Shamoun et al., 1999). For multiple scatters, the interaction between particles can be neglected if the characteristic spacing between particles is large compared to both the wavelength and the particle radius. In that case, the scattering characteristics can be obtained as a summation of the individual contributions. The resulting extinction coefficient due to bubbles is $c_{\mathrm{b}} = \frac{3}{4}\frac{\alpha}{R}$:

In this study reflections at the boundaries from the original sources were implemented using a cosine emission law.

Model validation

Some simple geometries were run to validate the implemented models and to highlight the differences between the two models. Unfortunately, no data for controlled bubbly flows were identified that could be simulated, other than some information on attenuation coefficients that was already included in the modelling process.

The dimensionless irradiance field for two point sources in a closed cavity were simulated. First reflections are possible in the bottom boundary only. The model predicts the irradiance reduction with the radial distance shown in Eq. (10) (Figure 5). Total irradiance shown on the left frames is the summation of incidente (middle frame) and reflected (right frame) irradiances. This case shows the feasibility of representing the modulated intense lights (MILs) for the fish barrier as the solution of superimposed single point sources.

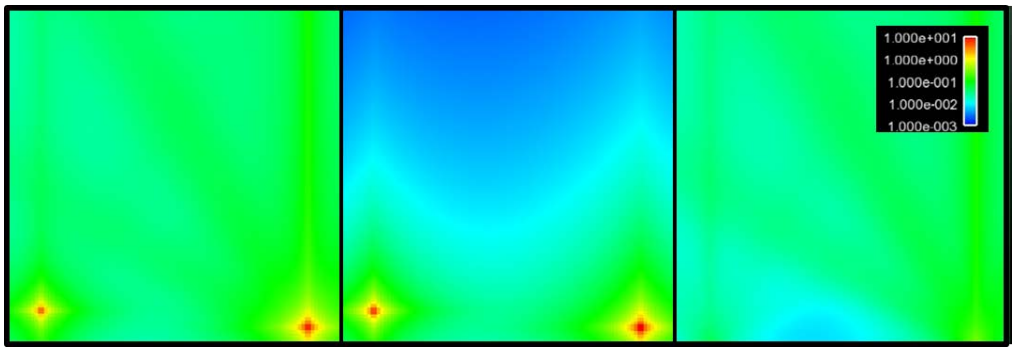

Figure 5: Total irradiance (left), incidente (middle) and reflected (right) from two point sources near the bottom of a cavity

The focus of the validation of the P-1 model was to demonstrate the effect of bubbles on the distribution of the irradiance. Figure 6 shows the basic profile for the case where no bubbles are present. As expected, the irradiance decays radially from the source with an equivalent diffuse attenuation coefficient $K = (3a_{\mathrm{E}}c_{\mathrm{E}})^{1/2}$. Two possible boundary conditions are shown in Figure 6 for the boundary closest to the source, the partial reflective condition (left frame) and full reflective conditions (right frame). As expected, the latter results in larger values for E, but given the rapid decay of the irradiance most differences between the two cases are localized to the region immediate to the source and very close to the boundary.

The deformation of the radial pattern due to the presence of a bubble curtain is shown in Figure 7. The extension of the curtain is shown with dashed lines. Several values of gas volume fraction with fully reflecting boundary were considered. The main effect of the bubbles is to concentrate the light field into a smaller region and with a larger maximum value for E. The distribution of the light field varies radically depending on whether the light source is contained in the bubble curtain, in which case very little illumination escapes the curtain, or whether the source is placed near the curtain, in which case bubbles act as a reflector.

SIMULATION OF A NON-PHYSICAL FISH BARRIER

Simplified Georgiana Slough

A main channel with two bifurcations and a non-physical fish barrier upstream of the smallest stream was simulated to test the capability of the proposed model to predict the flow field and bubble, sound and light fields in the vicinity of a fish barrier (Figure 8). The geometry of the Georgiana Slough in the Sacramento River was used (McQuirk and Reeves, 2012). Since bathymetric information was not available a constant water depth of 9.1 m was used. This value was selected based on information of underwater sound measurements that were taken between 2.9 m to 14.6 m (McQuirk and Reeves 2012). In this paper a simulation using typical conditions in the Sacramento River upstream of the Georgiana Slough is presented. Flowrates upstream and downstream of the curtain were 334 m^3/s and 132 m^3/s, respectively. Small bubbles of 0.8 mm (0.03 inch) diameter were injected at the bottom of the river at a pressure of 1.91 10^5 Pa and at 25 ^{o}C. The diffusion coefficient was set using Eq. (12), with constant $D_{3D} = 0.1c_{water}$, l_z=10 m and l_x=l_y=200 m, a mixed boundary condition was imposed on the bottom and the side walls, and release conditions at the surface. Sound sources operating in the range 5-600 Hz with a mean sound level of 152 dB re 1μPa were installed in the field near Georgiana Slough (McQuirk and Reeves, 2012). A far field value (~200 m) of about 110 dB re 1μPa was reported. In this study, nineteen sound projectors were located immediately downstream of the bubble barrier and

each projector was modeled as a constant source of acoustic energy density of 0.01 W/m. Four lights sources of 10 W/m^3 were included upstream of the bubble barrier.

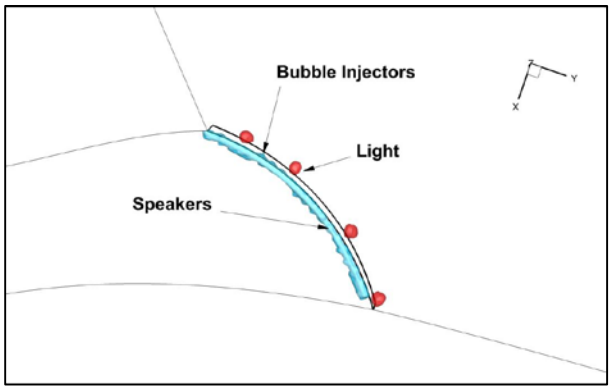

Figure 8. Simulated fish barrier

Figure 9 shows slices near the river bed (a), in the mid plane (b) and at the free surface (c). Vectors were interpolated in an equally-spaced structured mesh to enhance visualization. Bubbles significantly modify the flow pattern near the curtain. Two phenomena affect the gas volume fraction distribution; the most important is the buoyancy that drives bubbles toward the free surface and the other is the downstream convective transport by the river. The latter is significant at high river velocities and can be noted downstream of the curtain where the plume is directed towards the left bank. Upstream of the curtain and at small depths, the liquid velocity reverses direction due to the horizontal surface flow created when the plume reaches the free surface.

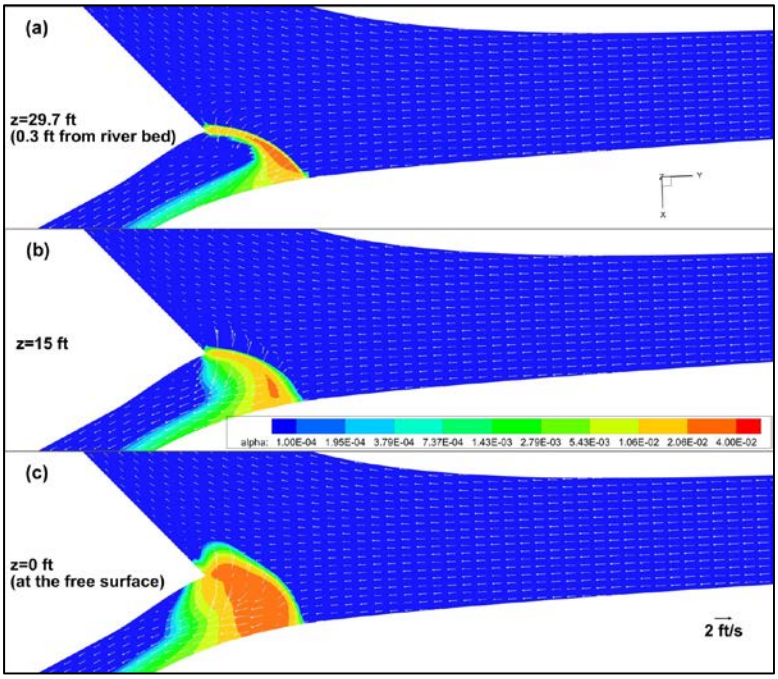

Figure 9. Gas volume fraction and velocity vectors at (a) 9 m (29.7 ft), (b) 4.5 m (15 ft) and (c) 0 m (0 ft)

Figure 10 shows flow characteristics near the bubble curtain. The frames in the top and middle show gas volume fraction isosurfaces and distribution of gas volume fraction at slices through the middle of the channels, respectively. Bubbles are transported away from the plume center by the strong surface current induced by the gas phase. The gas distribution and flow pattern are not symmetric relative to the bubble plume center due to the geometry and convective

transport by the river flow. Streamlines colored by velocity magnitude in the bottom frame show back flow near the inner wall of the larger branch towards the bubble curtain.

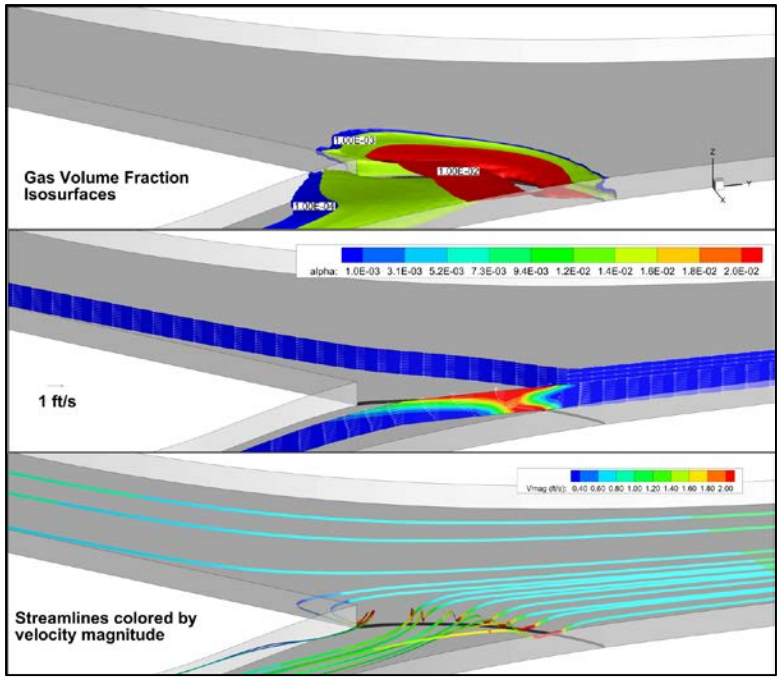

Figure 10. Gas volume fraction isosurfaces (top), gas volume fraction distribution in each river branch (middle), and streamlines colored by velocity magnitude (bottom)

Figure 11 shows the gas distribution and recirculation zones generated by the bubble curtain. As the bubble plume rises through the water column it entrains ambient water inducing two recirculating zones. Near the injector, the gas volume fraction is reduced as bubble velocity increases due to entrained liquid into the plume. On the other hand, near the free surface, the gas volume fraction increases for two phenomena, one is the increment in bubble volume due to decompression and the other is the reduction of liquid vertical velocity near the free surface. Note that since slip velocity increases with bubble size, a larger relative velocity is expected near the free surface. However, this effect is less important than the reduction of liquid velocity by the free surface.

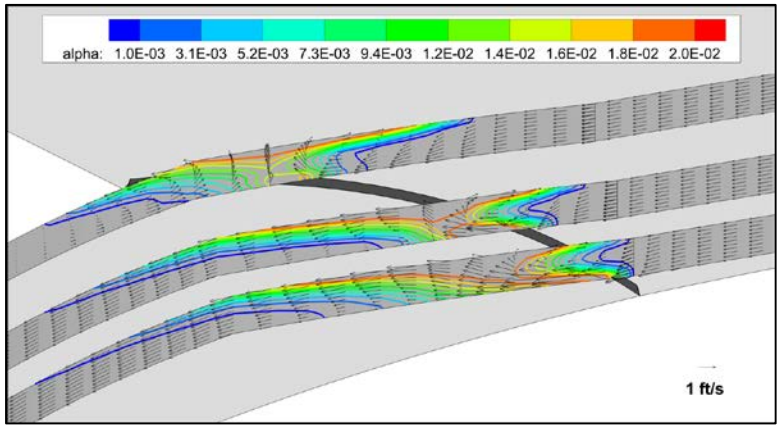

Figure 11. Gas volume fraction and velocity vectors near the bubble curtain

Figure 12 shows isosurfaces of sound energy. Bubbles encapsulate the sound within the fish barrier. However, some differences in the level of sound are observed due to increased sound attenuation by bubbles transported near the outer wall along the smaller channel.
Figure 13 shows the irradiance generated by the high-intensity LED MILs predicted with the superposition of elementary solution method (a) and P1 model (b). Light scattering and absorption by the bubbles results in an appreciable concentration of light within the fish barrier.

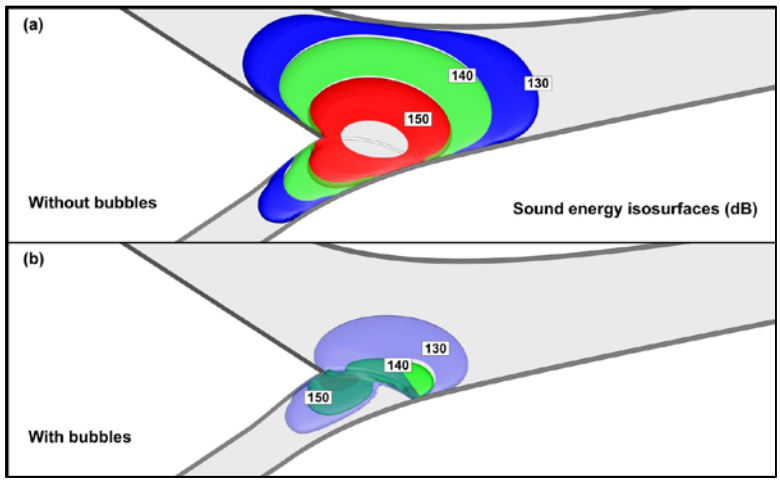

Figure 12. Isosurfaces of sound energy. Before bubble injection (a) and with bubble curtain (b)

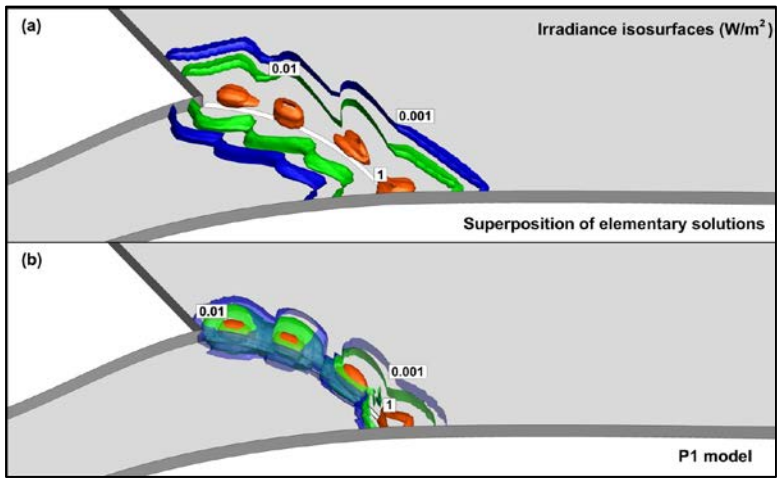

Figure 13. Isosurfaces of irradiance. Before bubble injection (a) and model P-1with bubble curtain (b)

CONCLUSIONS AND FUTURE DIRECTIONS

Numerical models for predicting the hydrodynamics, bubble, sound, and light distributions near a non-physical fish barrier were developed. The models were implemented using a modular approach in the open source code openFoam. A Boussinesq approach was used to account for the reduction of density in the zones where bubbles are present. The effect of the bubbles on the sound and light fields were considered through attenuation coefficient models found in the literature. Simple geometries were simulated to validate the implementation of the models. Model results for a non-physical fish barrier located in a bifurcation similar to Georgiana Slough indicate that the bubble plume has a strong effect on the flow pattern near the barrier. The resulting large-scale recirculations and increased accelerations near the barrier are expected to influence fish migration route. Sound and light are strongly coupled with the bubble plume. Bubbles effectively encapsulate both sound and light within the barrier region. According to the model, the effectiveness of bubbles to attenuate sound depends on the position of the speakers relative to the bubble plume. Since

the bubble plume location depends on the induced liquid movement as well as downstream transport by the river, optimal location of speakers is a function of the river flowrate and gas injection rate through the diffusers.
Additional research needs to include a full set of experimental data and monitoring near a fish barrier, at several river and barrier operational conditions, for better quantification of important variables. Examples include measurements of gas volume fraction, bubble size, river depth, liquid velocities, and sound and light fields. The complex three-dimensional nature of the problem will require measurement stations at several transects near the barrier. This is essential to fully validate and improve the developed numerical tool and identify areas where future modeling effort should focus.

IMPACTS OF ROCK WEIRS ON FISH SWIM PATH SELECTION AND FATIGUE LEVLES

David L. Smith, Research Ecologist, US Army Corps of Engineers, Engineer Research and Development Center, Vicksburg, MS, david.l.smith@usace.army.mil; R. Andrew Goodwin, Research Environmental Engineer, US Army Corps of Engineers, Engineer Research and Development Center, Portland, OR, Vicksburg, MS, Andy.Goodwin@usace.army.mil; Yong Lai, Research Hydraulic Engineer, United States Bureau of Reclamation Technical Services Center, Denver, CO, ylai@usbr.gov; John M. Nestler, Senior Scientist, Badger Technical Services, Vicksburg, MS, John.m.Nestler@usace.army.mil

Abstract: The addition of rock weirs and other features is a common approach to stream restoration. We evaluate fish response to a pair of rock weirs installed in the Little Snake River, WY and explore the consequences of their presence in the stream in terms of fish movement and fish fatigue using a model. We model upstream fish movement of 5 size classes of salmonids, and use commonly accepted swim speeds and fatigue estimates to evaluate upstream movement. Fish can transition from a sustained to a prolonged or burst swim speed based on a local acceleration threshold. The flow field was computed using the model U2RANS and the resulting velocities averaged 1.4 m/s with a maximum of 3.8 m/s. We find that the largest fish are readily able to pass through the channel with low fatigue levels, while the smallest fish are unable to pass and have high fatigue levels. Moderate sized fish have two modes with some fish passing readily and with little fatigue while others don't pass and have high fatigue levels. The proportion of prolonged and burst swimming was highest for large fish. The results suggest that the rock weirs produce complex three-dimensional flow fields whose impacts depends on fish size and behaviour. Future work should focus on fish movement data collection near real stream restoration structures coupled with hydrodynamic modeling with U2RANS or other codes.

INTRODUCTION

Fragmentation and other effects of water resources development cause loss of populations and species of river fishes (Nilsson et al. 2005). Many species conservation and ecosystem restoration programs incorporate channel modifications such as rock weirs, intended to improve fish habitat, into their projects. Effective design criteria for incorporation of rock weirs into streams is based on stream stability and other engineering considerations and typically do not have a solid understanding of fish behavioral response to hydrodynamic consequences of rock weirs. Design criteria based solely on means of simple hydraulic variables may not capture the full behavioral repertoire of animals evolved to move in spatially and temporally complex aquatic environments. Rock weirs may be movement barriers to fish due to high velocities or excessive elevation change. If rock weirs are barriers to fish this may have fish population consequences because movement is disrupted or otherwise limited.

Fish employ at least three recognized swim behaviors during upstream migration: sustained, prolonged and burst swimming (Hoar and Randall 1978). Sustained swimming is generally employed over long time periods (hours, days) and is energetically efficient. Prolonged and burst swimming are short term (seconds, minutes) energy intensive behavior employed in high energy environments. Our goal is to mathematically represent upstream migration and quantify the

contribution of prolonged and burst swimming to passage by various sized fishes. We do this by: 1) using a computational fluid dynamics (CFD) CFD model of a restoration feature in a natural river; 2) simulating various sized fish implementing a mix of sustained and prolonger/burst swimming in complex hydraulic environments, and 3) analysis of resulting swim speeds, fatigue levels and passage success.

METHODS

A detailed CFD model is used to realistically simulate the hydrodynamic pattern in a selected section of river. The output of the CFD model is linked to a fish swim path selection model that creates virtual fish programmed to respond to hydrodynamic variables using Eulerian-Lagrangian-Agent Methods (ELAMs - Goodwin et al. 2006, 2013). The swim path selection model can be programmed with different behaviour rules that each represents a different assumption about the movement of observed fish. The outputs of competing movement rules can be evaluated for realism and explanatory power using techniques similar to those used for real fish. Virtual fish tracks can be analysed for swim distance, distance over ground, track complexity, track direction, passage rate past a fixed location (e.g. a fishway exit or an arbitrary finish line within the channel), and other useful descriptive measures. Species- and size-specific fatigue times based on swim speed and duration were derived from the literature.

Site Description and Computational Fluid Dynamics Model: We selected a 56-m long reach of the South Fork Little Snake River with a maximum width of about 5-m. This reach was characterized by steep slope, complex flow pattern (Figure 1A) with 3-D flow, two hydraulic jumps, and a wide range of depths and velocities created by a two u-shaped rock weirs (Figure 1B). To simulate this site, we used U^2RANS (Lai et al. 2003; Lai et al. 2004), a 3-D, unsteady, nonhydrostatic, model useful for simulating complex flow patterns in steep, geomorphically diverse river channels. The numerical mesh consists of about 160,000 cells with mixed hexahedrons and wedges. Maximum modeled pool depths are 1.6 m, maximum velocities at the weirs are greater than 3 m/s, and mean water velocities are 1.6 m/s (Figure 1).

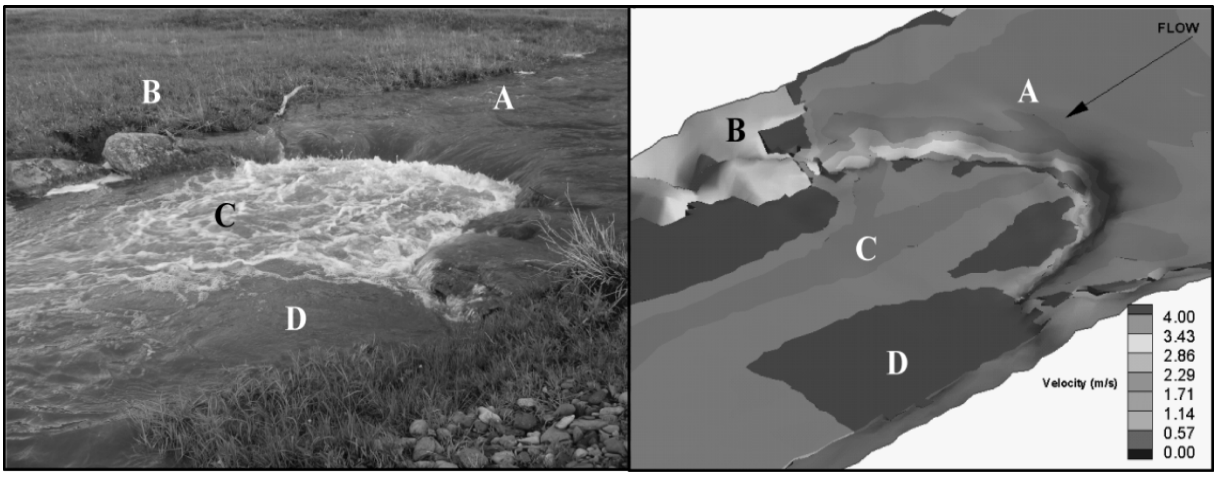

Figure 1 Photo and computational representation of the domain used to evaluate upstream fish movement. Point A shows approach to supercritical drop (height = 0.4 m) flow and velocities of 3 m/s. Point B shows complex rocks incorporated into the model. Point C is a high velocity jet of 2 m/s. Point D shows a low velocity zone (0.4 m/s).

Modeled Fish and Swimming Algorithm: We modelled fish with a default behavior of swimming upstream at a sustained speed of 2.0 body lengths per second (BL/s) using methods of Goodwin et al. (2006). Sustained upstream swimming is represented as a biased correlated random walk with turning angles drawn from a range of 0 to 5 degrees in the *xy* plane. We trigger a combined prolonged and burst swimming behavior (6 to 10 BL/s) using an acceleration threshold of 0.04 m/s^2. Both the sustained and prolonged/burst behaviors result in the fish swimming into the local flow vector. We manually calibrated the acceleration trigger by noting that a fish should implement swim strategies that minimize prolonged and burst swimming (to minimize fatigue) while still providing for upstream movement and ultimately passage through the domain.

One hundred fish per size class (0.38-, 0.52-, 0.63-, 0.73-, and 0.84-m) were parameterized with the size and swimming characteristics of upstream migrating steelhead (*Oncorhynchus mykiss*). A time step of 0.01 seconds was used because the domain is physically small and complex and larger time steps yield correspondingly less informative tracks. For example, given a time step of 0.1 seconds, a 0.84 m fish swimming at a maximum of speed of 10 BL/s can cover 0.84 m or roughly 20% of the channel width. The resulting swim path would miss much of the finer scale hydraulic complexity. Segments of virtual fish tracks exhibiting predicted swim velocities greater than 10 BL/s (occasionally occurs in small CFD domains for numerical reasons) were removed from the analysis during post processing. Simulation runs were terminated after 800 seconds because all fish had exited the model domain. Positions (*x*,*y*,*z*), swim speeds (BL/s and speed over ground (SOG), and the proportion of each behavior (sustained and prolonged/burst swimming) and fatigue (instantaneous and cumulative) were computed.

We estimated fatigue time using the well-known data on steelhead swimming and fatigue from Paulik et al (1957). Fatigue times are computed for modeled fish using estimates of swim speed (BL/s) as

$$lnT = -0.48 * swim\ speed\ \left(\frac{BL}{s}\right) + 6.466 \quad (1)$$

where *T* is fatigue time in seconds. The equation extends from approximately 1.5 to 7 BL/s. For speeds under 1.5 BL/s we specify *T* as 3600 seconds, or the upper time limit for sustained swimming. We extend the relationship beyond 7 BL/s to 10 BL/s. This does not imply that fish can only maintain sustained swimming for 3600 seconds. However, 3600 seconds yields a mathematically small estimate of fatigue for a given time interval suggesting long sustained swim times. Fatigue (%) for each time step was computed as

$$\left(\frac{t}{T}\right) \times 100 \quad (2)$$

where *t* is the model time interval in seconds. Cumulative fatigue time was simply the instantaneous fatigue time (%) summed over the intervals *t* by fish and stratified by fish size.

RESULTS

Mean cumulative fatigue varies by fish size with the larger fish accumulating the least fatigue and passing through the domain the fastest (Figure 2A). Larger fish, swimming at a sustained 2 BL/s, also have the highest mean SOG (Figure 2B). Larger fish have the highest passage rate

(~90%) while the smallest fish have the lowest (0%) (Table 1). Conversely, smaller fish implement the highest percentage of sustained swimming and the lowest percentage of prolonged/burst swimming (Table 1). This is due to the longer time smaller fish spend in the domain compared to larger fish (Figure 2C). To control for time and highlight the fatigue experienced by each size class of fish, we calculated the cumulative fatigue experienced by a fish per second and note that it is highest for the 0.38 size fish (Figure 2C).

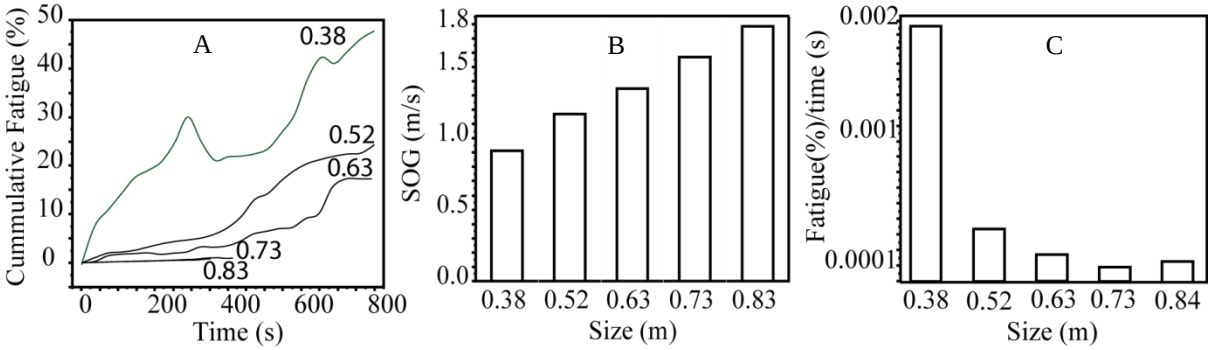

Figure 2 Mean cumulative fatigue (frame A), speed over ground (frame B), and accumulated fatigue per second (frame C) for each fish size class.

Table 1. The behavior and passage of the five size classes of fish

Size (m)	Sustained (%)	Prolonged/Burst (%)	Passage (%)
0.38	89	11	0
0.52	90	10	31
0.63	87	13	66
0.73	83	17	90
0.83	79	21	93

DISCUSSION

We show that it is possible to explore relationships among site specific geomorphology and hydraulic patterns with important biological attributes associated with fish behavior and fish passage. For example, larger fish pass at higher percentages and in shorter times than the smaller fish and the larger fish have higher SOG estimates than smaller fish. The inverse relationship between passage percentage and mean fatigue is also consistent with expectations as we would not expect fatigued fish to pass effectively. More subtlety, the simulation suggests that fatigue is not a simple correlate of swim speed. If it were, we would expect to observe that those fish that execute the most prolonged and burst swimming would also be the most fatigued. The smallest fish executed the least prolonged and burst swimming (Table 1) yet were the least successful at passage and were the most fatigued. We believe this reflects a complex dependency on fish size (and hence SOG) and the local hydraulic environment. We also note that there remains a basic question on how a fish decides, with incomplete knowledge of its environment, to transition from

sustained swimming to prolonged or burst swimming. Our premise was that prolonged and burst swimming should be not exceed the minimum needed to achieve passage. Embedded in this premise is the assumption that a fish knows the location and distance to the end point of the hydraulically challenging domain. This assumption may not be accurate, however. Improved methods of describing the decision process and behavior transitions and are needed.

Fatigue time analyses are common in the fish passage and fish swimming literature and are often used in conjunction with swimming speed information to estimate maximum distance a fish can swim in a given velocity field. Such analyses often assume uniform velocity such as might be found in a simple prismatic channel. With interest in complex natural fishways, stream restoration design and the burgeoning data available on fish movement via telemetry suggest that descriptions of fish behavior in complex, continuous velocity fields are needed. We have demonstrated one method that achieves the integration but acknowledge that much works remains to validate the approach.

Finally we note that the modelled river exhibited a range of hydraulic conditions with many point velocities exceeding the nominal swim speed criteria for adult steelhead of less than 0.6 m/s and vertical drops of 0.4 m (NMFS 2001). We demonstrated that passage was possible for some fish but not others in this environment. We conclude that simple velocity criteria may be difficult to apply in complex hydraulic environments with a wide range in velocities. Our results show that the combination of sustained and prolonged/burst swimming behaviour allows fish to pass through domains that simple criteria rule out. Further, it is possible to optimize the design using methods outlined in this study. This is a potentially important improvement over existing methods because rivers continue to be impacted by human activities and the need for effective mitigation has never been greater.

FISH MOVEMENT NEAR INFRASTRUCTURE EMERGES FROM NATURAL RIVER ARCHITECTURE

R. Andrew Goodwin, Research Environmental Engineer,
U.S. Army Engineer R&D Center, Portland, OR, Andy.Goodwin@usace.army.mil

Abstract: Decades of empirical studies have identified many factors that affect the relationship between fish movement and water flow. How water flow pattern shapes the movement trajectories of fish near infrastructure remains unknown, however, and this knowledge gap impacts the success of existing and near-future engineered structures that are meant to improve the long-term health of fish populations. We present field evidence and an analysis of a hypothesis that describes fish movement near infrastructure in terms of naturally evolved behavior in free-flowing rivers for navigating heterogeneity arising from river architecture, where river architecture is defined as the geometric sum of contributions from the riverbed and embedded objects. The hypothesis assumes that fish modulate experienced changes in water acceleration (exchanges of force with the flow field) as the fish transits heterogeneity in the river. The acceleration-duration phenomenon that we identify as important in fish movement behavior has analogies to the acceleration-duration phenomena that have been implicated in sediment motion. Thus, it may be possible to interpret the hydraulic navigation of fish in rivers using phenomena involved also in the evolution of river architecture. We discuss numerical results from the application of the hypothesis to 47 flow fields at seven sites (dams) across 14 years when fish movement was monitored. Our hypothesis suggests that with a limited evolutionary history for navigating engineered structures, fish behavior reflects their naturally evolved response in free-flowing rivers. As such, we surmise that our hypothesis is applicable to fish outside the context of dams, in natural settings and near other forms of infrastructure such as fish diversion devices (booms and non-physical barriers), marine and hydrokinetic turbines, and also has implications for habitat design.

DOUBLE COUNTING, OVER CONSERVATIVE AND MISAPPLYING SAFETY FACTORS FOR STREAM SCOUR ANALYSES

EXTENDED ABSTRACT

Scour analyses are required for stream projects such as utility crossings, bridges, streambank protection, levees and floodwalls. In lieu of sophisticated numerical models, simplified approaches are often utilized. Neglecting local scour such as at bridges, the total scour using these simplified techniques is comprised of long term, general, bend, dune formation, and thalweg formation. There are no specific guidelines for application of safety factors for each of these components. Some techniques have safety factors inherently built into them but are not evident, often resulting in over conservative answers when additional safety factors are added. Some general scour methods include combinations of bend, dune and thalweg formation. These additional inclusions are often not evident or well documented, resulting in the unintended addition of these components and thus "double counting." In some cases, the computed scour depth is small (or zero) and the safety factor (often by adding an arbitrary scour depth) is applied to this small scour depth whereas the safety factor should have been applied to important variables that produced the total scour depth.

The safety factor is often applied only to the sum of the scour components thus giving equal "uncertainty" weighing to all the scour components. In most cases, with the use of engineering judgment, historic perspective, examination of how the scour techniques were developed, and the evaluation of the risks involved as a result of possible failure, one can estimate the appropriate safety factor for each scour component to come up with the total scour.

This presentation gives information on which techniques have safety factors inherently in them and what components are already included in the techniques. The presentation also gives guidelines on which variables should be used for application of safety factors and a suggested procedure to assure that scour components are appropriately combined.

THE UPPER BOUND OF PIER SCOUR DEFINED BY SELECTED LABORATORY AND FIELD DATA

Stephen T. Benedict, Hydrologist, U.S. Geological Survey, Clemson, South Carolina, benedict@usgs.gov
Andral W. Caldwell, Hydrologist, U.S. Geological Survey, Columbia, South Carolina, acaldwel@usgs.gov

Abstract The U.S. Geological Survey, in cooperation with the South Carolina Department of Transportation, conducted several field investigations of pier scour in South Carolina and used that data to develop envelope curves defining the upper bound of pier scour. To expand upon this previous work, an additional cooperative investigation was initiated to combine the South Carolina data with pier-scour data from other sources and evaluate the upper bound of pier scour with this larger data set. To facilitate this analysis, a literature review was conducted to identify potential sources of published data on pier scour, and selected data were compiled into a digital spreadsheet consisting of 569 laboratory and 1,858 field measurements. These data encompass a wide range of laboratory and field conditions and represent field data from 23 states within the United States and six other countries. This extensive database was used to define the upper bound of pier-scour depth, with respect to pier width, encompassing both laboratory and field data. The envelope curve provides a simple but useful tool for assessing the potential maximum pier-scour depth for pier widths of about 30 feet or less.

INTRODUCTION

The U.S. Geological Survey (USGS), in cooperation with the South Carolina Department of Transportation (SCDOT), collected 179 field measurements of clear-water pier scour and 141 measurements of live-bed pier scour in South Carolina (Benedict and Caldwell, 2006; 2009), with nominal pier widths ranging from 0.8 to 9 feet (ft). These data were used to develop field-derived envelope-curves that reflect the upper bound of clear-water and live-bed pier scour for bridges in South Carolina, using pier width as the primary explanatory variable. To expand upon this previous work, the USGS and SCDOT initiated an additional cooperative investigation to combine the South Carolina data with pier-scour data from other sources and evaluate upper-bound relations within this larger data set. A literature review was conducted to identify potential sources of pier-scour data, and selected data were compiled into a database consisting of 569 laboratory measurements and 1,858 field measurements from 23 states within the United States and six other countries (Benedict and Caldwell, 2014). These data substantially extended the nominal pier-width range (0.05 to 64 ft) and spatial extent associated with the South Carolina data. They provide a means to develop an improved upper-bound pier-scour envelope curve having broad application. Pier width has been noted by various investigators (Laursen and Toch, 1956; Melville and Coleman, 2000; Mueller and Wagner, 2005; Ettema and others 2011; and Arneson and others 2012) to be a primary variable that influences pier-scour depth, and therefore, pier width was the only explanatory variable used in the envelope curve. This paper presents preliminary findings providing a brief description of (1) the laboratory and field database, (2) the upper-bound envelope curve of pier-scour based on the compiled database, (3) the comparison of this upper-bound curve with the South Carolina pier-scour envelope curves, and (4) conclusions.

LABORATORY AND FIELD DATABASE

Benedict and Caldwell (2014) developed a digital pier-scour database, called the 2014 USGS Pier Scour Database (PSDb-2014), consisting of 569 laboratory and 1,858 field measurements compiled from selected authors. The laboratory data are measurements taken from 17 previous investigations and originally compiled by Sheppard and others (2011). Through a screening process that included data review and statistical analysis, Sheppard and others (2011) identified 441 of the laboratory measurements, with no skew to flow, that approximated equilibrium scour depths for the given flow, pier geometry, and sediment characteristics. These screened laboratory data provide a reliable source for evaluating the upper-bound relations of pier scour and were used in the current (2015) investigation to initially determine a pier-scour envelope curve. The field data were compiled from 32 previous publications and reflect measurements collected in 23 states within the United States and six other countries. A subset of 727 field measurements included in the PSDb-2014 was previously screened by Sheppard and others (2011), and identified as likely approximating equilibrium scour depths. From this subset of screened data, 410 field measurements with pier skews equaling zero degrees, or with adequate information to evaluate the influence of pier skew, were selected and used to corroborate and extend the pier-scour envelope curve defined by the laboratory data. An additional 558 pier-scour data, measured during high flows and having the previously noted selection criteria, were chosen from the remaining PSDb-2014 field measurements, and used as validation data to verify the pier-scour envelope curve defined with the screened laboratory and field data. [Note: Field measurements used in this investigation with piers skewed to flow were adjusted by dividing the scour depth by the pier-skew coefficient as determined from Arneson and others (2012).] Additional information regarding the PSDb-2014 and its associated report (Benedict and Caldwell, 2014) is available at the following web address: http://pubs.usgs.gov/ds/845.

THE UPPER BOUND OF PIER SCOUR IN LABORATORY AND FIELD DATA

Figure 1 displays the relation of pier-scour depth with respect to pier width using the 441 screened laboratory measurements identified by Sheppard and others (2011). A log-log scale is used to better display the upper bound of the data. With only two exceptions, the upper bound displays a well-defined relation as shown by the line in figure 1. The two data points that slightly exceed the line are associated with high Froude numbers (1.2 and 1.5). Jain and Fischer (1979) note that the flow conditions associated with these two measurements were very turbulent and unsteady, making the measurements questionable. Therefore, these two data points were excluded in defining the upper bound of the data. If the laboratory data in figure 1 are capturing the upper bound of pier-scour depth that is expected in the field, it would be reasonable to expect that the upper bound of the field data would conform to the extension of the line in figure 1.

Figure 2 shows the relation of scour depth and pier width for the 410 screened field data, previously described, using the same format as figure 1 with an extension of the envelope curve derived from the laboratory data. While there is more scatter in the upper bound of the screened field data than that of the laboratory data, it conforms well to the envelope curve of the laboratory data, indicating that the laboratory envelope curve provides a reasonable definition of the upper bound of pier scour in the field as well as the laboratory. There are two field measurements that exceed the envelope curve with exceedance values of 0.3 and 2.5 ft. The

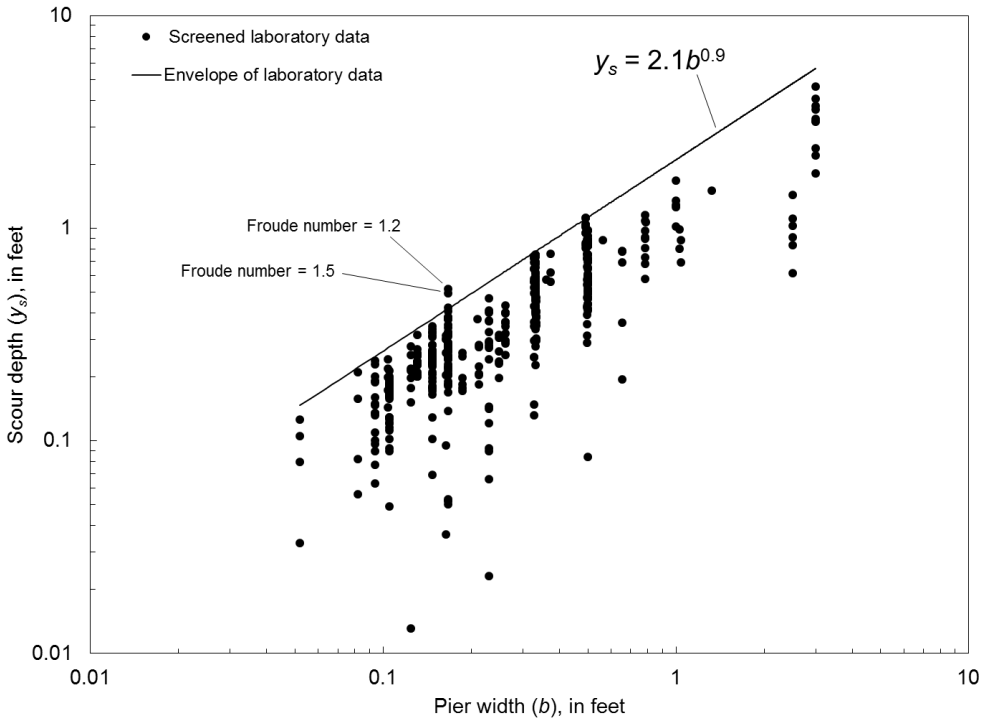

Figure 1 Relation of scour depth to pier width for the screened laboratory data.

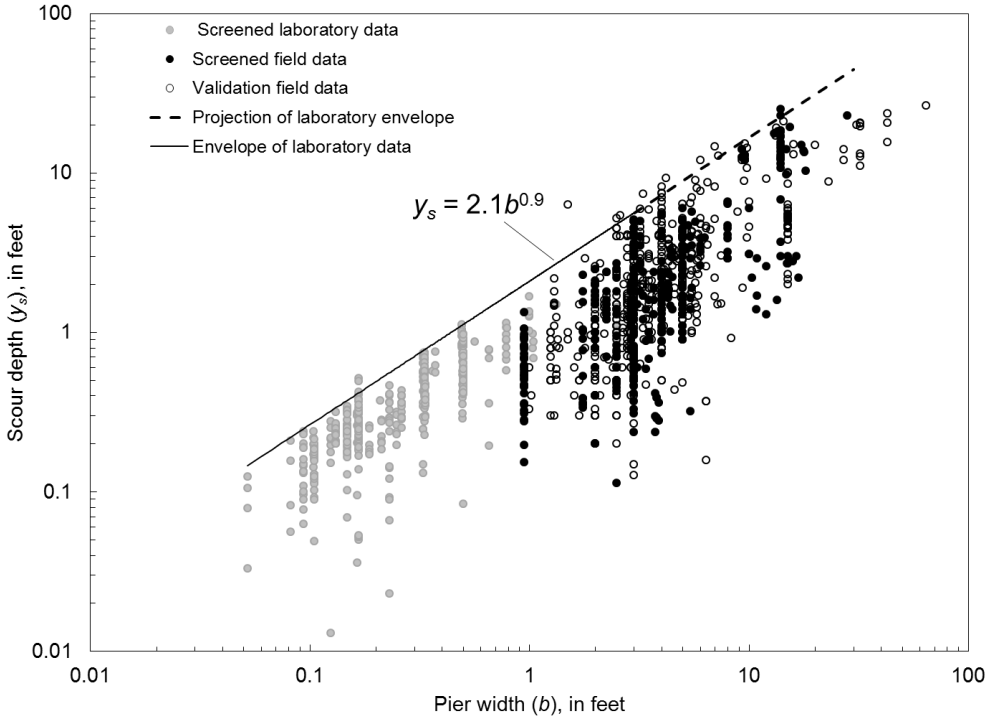

Figure 2 Relation of scour depth to pier width for the screened laboratory and field data, and validation field data.

complexities of the field, combined with the harsh measuring environment, make it difficult to measure pier scour to the same degree of accuracy as that of the laboratory, and therefore, it is expected that some field measurements may exceed the upper bound of the laboratory data. Because the exceedance values are small, no adjustment was made to the envelope curve to account for these two data points. The 558 validation field data measured during high flows as previously described, also are shown in figure 2. Only 11 of the validation data exceeded the envelope curve with small exceedance values ranging from 0.2 to 3.3 ft, with a median exceedance of 0.9 ft. The validation data provide further confirmation that the envelope curve shown in figure 2 is reasonable. The envelope curve in figure 2 represents preliminary findings for the current (2015) investigation and is subject to change.

COMPARISON WTIH THE SOUTH CAROLINA PIER-SCOUR ENVELOPE CURVES

Benedict and Caldwell (2006; 2009) developed clear-water and live-bed pier-scour envelope curves to be used as supplementary tools for evaluating the potential for pier scour at bridges in South Carolina. The format of the South Carolina pier-scour envelope curves are similar to those shown in figures 1 and 2 with pier width used as the primary explanatory variable. An objective of the current (2015) investigation is to evaluate the South Carolina envelope curves with the PSDb-2014 database to determine if they are reasonable or need modification. Figures 3 and 4 show the South Carolina pier-scour envelope curves for clear-water and live-bed scour conditions, respectively, along with the preliminary upper-bound envelope curve derived from the PSDb-2014 database. The South Carolina pier-scour envelope curves fall in close proximity to the PSDb-2014 envelope curve, indicating that the South Carolina pier-scour envelope curves

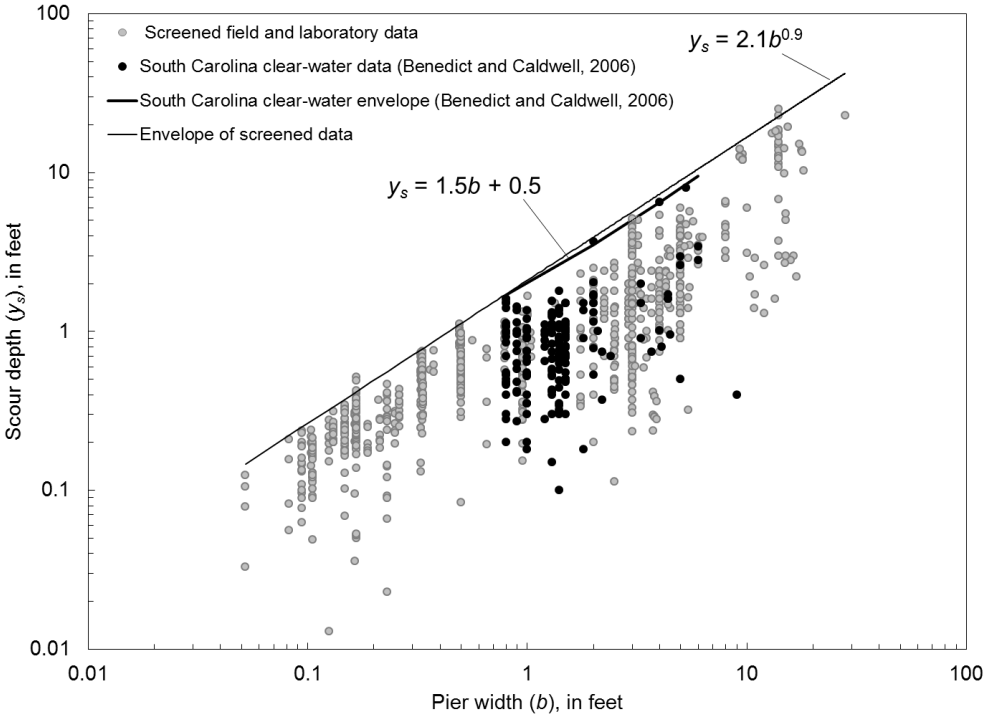

Figure 3 Comparison of the South Carolina clear-water pier-scour envelope curve to the upper-bound envelope curve derived from the screened laboratory and field data.

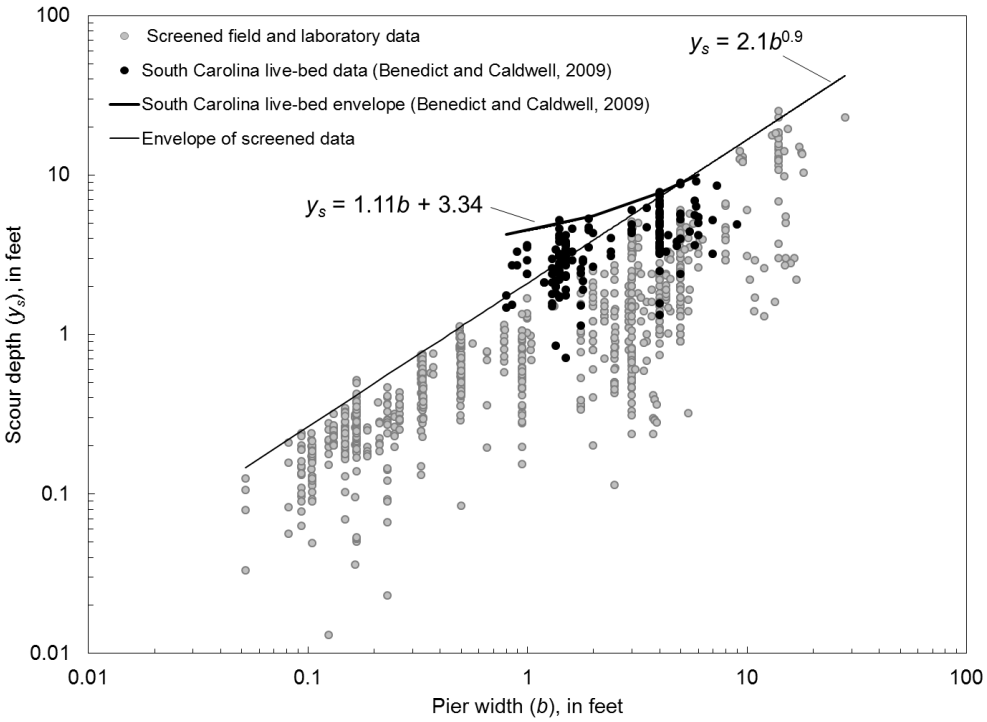

Figure 4 Comparison of the South Carolina live-bed pier-scour envelope curve to the upper-bound envelope curve derived from the screened laboratory and field data.

are reasonable. The small exceedance of the live-bed envelope curve (figure 4) can be attributed to the use of ground-penetrating radar that tends to have a larger measurement uncertainty (Benedict and Caldwell, 2009), which can lead to overestimates of scour. Current guidance and limitations for using the South Carolina pier-scour envelope curves can be found in Benedict and Caldwell (2006; 2009).

CONCLUSIONS

Current methods for predicting pier-scour depth have some uncertainty, and therefore, should be assessed for reasonableness. One way to make such assessments is by comparing predicted scour to historical field measurements. The recent investigations of pier scour in South Carolina demonstrate how a strategic sample of historic field data can be used to develop regional bridge-scour envelope curves for assessing scour potential. The preliminary pier-scour envelope curve based on the PSDb-2014 database indicates that the South Carolina bridge-scour envelope curves are reflecting a reasonable upper bound of pier scour under field conditions in South Carolina. The preliminary PSDb-2014 pier-scour envelope curve (figure 2) includes a larger range of pier widths and is therefore likely applicable to a broad range of pier widths. The South Carolina pier-scour envelope curves can be used as supplementary tools for assessing potential maximum pier-scour depth in South Carolina, and the preliminary PSDb-2014 pier-scour envelope curve likely will be applicable to a broader range of pier widths, inside as well as outside of South Carolina. Because of the complexity of scour, caution and judgment should be used in the application of the envelope curves presented in this paper, and they should not be relied upon as the only tool for assessing pier-scour potential. One can best assess anticipated scour by

compiling and studying the available information for a given site, bringing sound engineering principals to bear on the final estimate of anticipated pier-scour depth. Additional guidance and limitations for using the South Carolina pier-scour envelope curves can be found in Benedict and Caldwell (2006; 2009).

THE UPPER BOUND OF ABUTMENT SCOUR DEFINED BY SELECTED LABORATORY AND FIELD DATA

Stephen T. Benedict, Hydrologist, U.S. Geological Survey, Clemson, South Carolina, benedict@usgs.gov

Abstract The U.S. Geological Survey, in cooperation with the South Carolina Department of Transportation, conducted a field investigation of abutment scour in South Carolina and used that data to develop envelope curves defining the upper bound of abutment scour. To expand upon this previous work, an additional cooperative investigation was initiated to combine the South Carolina data with abutment-scour data from other sources and evaluate the upper bound of abutment scour with the larger data set. To facilitate this analysis, a literature review was conducted to identify potential sources of published data on abutment-scour, and selected data, consisting of 446 laboratory and 331 field measurements, were compiled for the analysis. These data encompassed a wide range of laboratory and field conditions and represent field data from six states within the United States. The data set was used to evaluate the South Carolina abutment-scour envelope curves. Additionally, the data were used to evaluate a dimensionless abutment-scour envelope curve developed by Melville (1992), highlighting the distinct difference in the upper bound for laboratory and field data. The envelope curves evaluated in this investigation provide simple but useful tools for assessing the potential maximum abutment-scour depth in the field.

INTRODUCTION

> *Scant situations of hydraulic engineering are more complex than those associated with scour in the vicinity of a bridge abutment, especially one located in a compound channel. Accordingly, few situations of scour depth estimation are as difficult (Ettema and others, 2005).*

The complexity of abutment-scour processes has made it difficult to formulate prediction methods, and few would dispute the above assessment by Ettema and other (2005). Current scour-prediction equations largely consist of semi-empirical relations developed from simplified laboratory investigations (Sturm and others, 2011), and the performance of these equations can vary (Wagner and others, 2006; Benedict and others, 2007; Lombard and Hodgkins, 2008). While overprediction occurs frequently (and at times excessively), underprediction also is of concern. Because of the uncertainty in scour prediction, Hydraulic Engineering Circular No. 18 (HEC-18; Arneson and others, 2012) recommends that computed scour be evaluated for reasonableness by comparing with available historical data at or near the site of interest. Based on such an evaluation, the predicted scour can be modified if deemed appropriate. The wisdom and benefit of using historical flow and scour data to evaluate predicted scour is unquestionable. However, such data are frequently unavailable making the evaluation recommended in HEC-18 difficult, if not impossible. One way to address this issue of limited historical data is through the use of upper-bound envelope curves derived from laboratory and field measurements of abutment scour. While such envelope curves are not site (or near site) specific, they display the general trends for the upper bound of abutment scour over a wide range of conditions, providing a tool to help assess the maximum potential for scour. Envelope curves for abutment scour have been previously developed for laboratory and field data. With respect to laboratory data, Melville (1992) developed envelope curves using dimensionless variables associated with

selected laboratory data (96 measurements). With respect to field data, the U.S. Geological Survey (USGS), in cooperation with the South Carolina Department of Transportation (SCDOT), developed envelope curves for selected field data (209 measurements) in South Carolina (Benedict, 2003). These previous investigations demonstrate how envelope curves can be developed and used for assessing the maximum abutment-scour potential. To expand upon the previous work by Benedict (2003), the USGS and SCDOT initiated another cooperative investigation to compile additional laboratory and field data from other existing sources, and evaluate the upper-bound trends of abutment scour within this larger data set. A literature review was conducted to identify potential sources of abutment-scour data, and selected data were compiled into a digital database consisting of 329 field and 446 laboratory measurements. These data significantly extended the range of the data previously used by Benedict (2003) and Melville (1992), providing a means to evaluate the previously developed envelope curves. This paper presents preliminary findings providing a brief description of (1) the field and laboratory data used in the investigation, (2) the comparison of the field data with the Melville (1992) dimensionless envelope curve, (3) the evaluation of selected South Carolina abutment-scour envelope curves with additional field data, and (4) conclusions.

FIELD AND LABORATORY DATA

All of the field data, compiled from the previously noted literature review, were collected by the USGS and included 15 measurements from the USGS National Bridge Scour Database (NBSD; USGS, 2001), 92 measurements from the moderate-gradient streams of the South Carolina Piedmont with cohesive sediments (Benedict, 2003), 106 measurements from the low-gradient streams of the South Carolina Coastal Plain (none are tidally influenced) generally with sandy, non-cohesive sediments (Benedict, 2003), 93 measurements from the small, steep-gradient streams of Maine with coarse sediments (Lombard and Hodgkins, 2008), and 23 measurements from the low-gradient streams of the Alabama Black Prairie Belt with cohesive sediments (Lee and Hedgecock, 2008). Most of these data are historical scour measurements, similar to post-flood measurements, and are assumed to represent the maximum abutment-scour depth that has occurred at the bridge since construction. The field data are largely associated with clear-water scour conditions where sediments do not refill the scour holes as flood waters recede, providing justification for this assumption. Because the scour measurements were made during low-flow conditions, one-dimensional flow models were used to estimate the hydraulic properties. The post-flood nature of the scour measurements, in conjunction with the estimated hydraulics, makes these data less than ideal. These limitations should be kept in mind when using the USGS field data in any analysis. While the limitations of the USGS abutment-scour field data are acknowledged, this is currently (2015) the best available set of field data, and the large number of measurements (329) should be sufficient to gain insights into the general trends of abutment scour in the field. In addition to the USGS field data, two abutment-scour measurements at Interstate 70 crossing the Missouri River (Parola and others, 1998), associated with the 1993 flood also were included. The Missouri River data are perhaps the largest measured riverine abutment-scour depths in the United States (30 feet (ft) at the bridge and 56 ft upstream from the bridge) and were strongly influenced by a levee breach located approximately 350 ft upstream from the abutment. Additionally, the site has a drainage area of 500,000 square miles (mi^2). In contrast, the maximum drainage area for the South Carolina data is 8,830 mi^2 with a median value of approximately 100 mi^2. The adverse flow conditions and substantially larger drainage

area of the Missouri River site contribute to the larger scour depths than those of the South Carolina data. While the Missouri River data do not represent typical abutment scour, they were included in the analysis for perspective.

In addition to field data, 446 laboratory measurements of abutment scour reported by selected authors, including 96 measurements from Melville (1992), 191 measurements from Palaviccini (1993), 80 measurements from Sturm (2004), 17 measurements from Briaud and others (2009), and 62 measurements from Ettema and others (2010), were incorporated into the database. The data from Melville (1992) and Palaviccini (1993) were compiled from multiple authors of previous investigations, and are not listed here for brevity. The laboratory data are largely associated with non-cohesive sediments, with the exception of the Briaud and others (2009) investigation, which used cohesive sediments. Additionally, the data primarily represent clear-water scour conditions with the exception of 28 measurements from Ettema and others (2010) that represent live-bed scour conditions.

THE MELVILLE (1992) UPPER-BOUND ENVELOPE CURVE COMPARED WITH LABORATORY AND FIELD DATA

Melville (1992) used 96 laboratory measurements collected in rectangular flumes at threshold clear-water scour conditions to develop an envelope curve of abutment-scour depth (figure 1). The curve is based on the relation of relative scour depth (D_{sadj}/y) to relative abutment length (L/y), where D_{sadj} is the measured abutment-scour depth adjusted for the effect of abutment shape [see Melville (1992) for details on this adjustment], L is the abutment (also called embankment) length blocking flow, and y is the approach-flow depth. Melville (1992) noted that the upper bound of D_{sadj}/y generally increased with increasing L/y, and identified three abutment-length categories where the rate at which scour increased varied. These categories, identified in figure 1, included short abutments ($L/y \leq 1$) with the smallest scour potential, long abutments ($L/y \geq 25$) with the largest scour potential, and intermediate abutments between these values. The selected laboratory data from Palaviccini (1993), Sturm (2004), Briaud and others (2009), and Ettema and others (2010) also are shown in figure 1. All of the laboratory data falls within or close to the Melville (1992) envelope curve, indicating that the envelope curve is a reasonable representation of the approximate upper bound of abutment scour for laboratory data.

Figure 2 shows the previously described field data plotted with the Melville (1992) laboratory data and envelope curve. While the upper bound of the field data ($4.25y$) is significantly smaller than the laboratory data ($11y$), it is notable that this upper bound conforms well to the general shape and breakpoints associated with the Melville (1992) envelope curve. Based on this pattern, an envelope curve of the field data was drawn parallel to the laboratory envelope curve using the same breakpoint at the transition from intermediate to long abutments. The field data encompass the range of the three abutment-length categories; however, they are heavily weighted toward the long-abutment category where the potential for scour is greatest. The one Maine measurement that significantly exceeds the field-data envelope curve was collected using ground-penetrating radar (GPR), which is a useful tool for measuring scour. However, the interpretive nature of this method introduces uncertainty into the scour measurement which can lead to overestimates of scour (Benedict and Caldwell, 2009). The Missouri River data, the largest scour depths

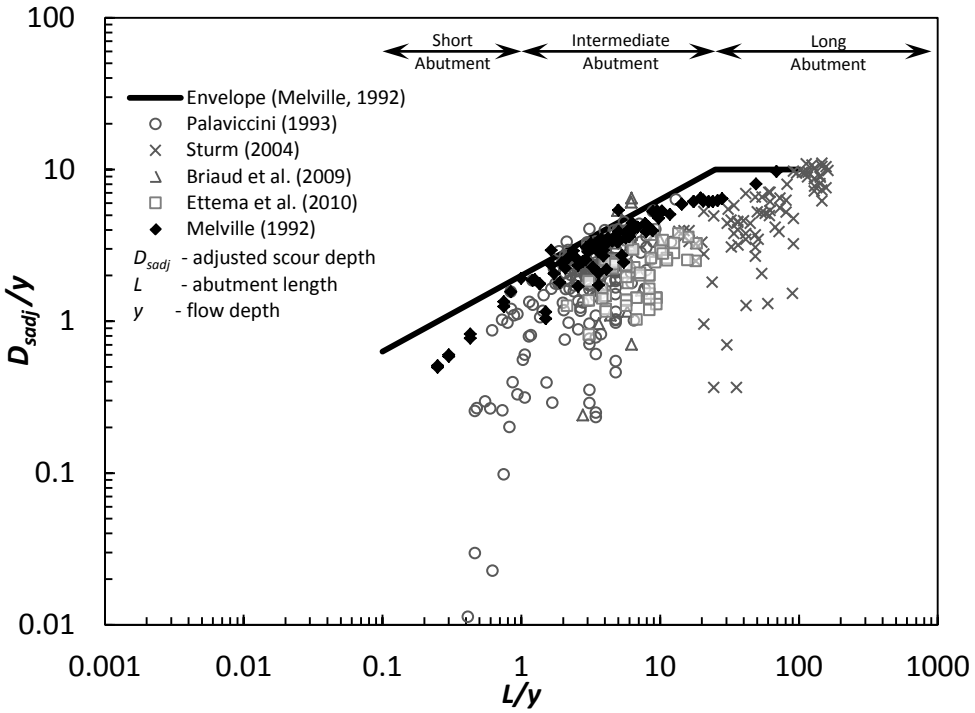

Figure 1 Relation of the relative scour depth (D_{sadj}/y) to relative abutment length (L/y), for selected laboratory data.

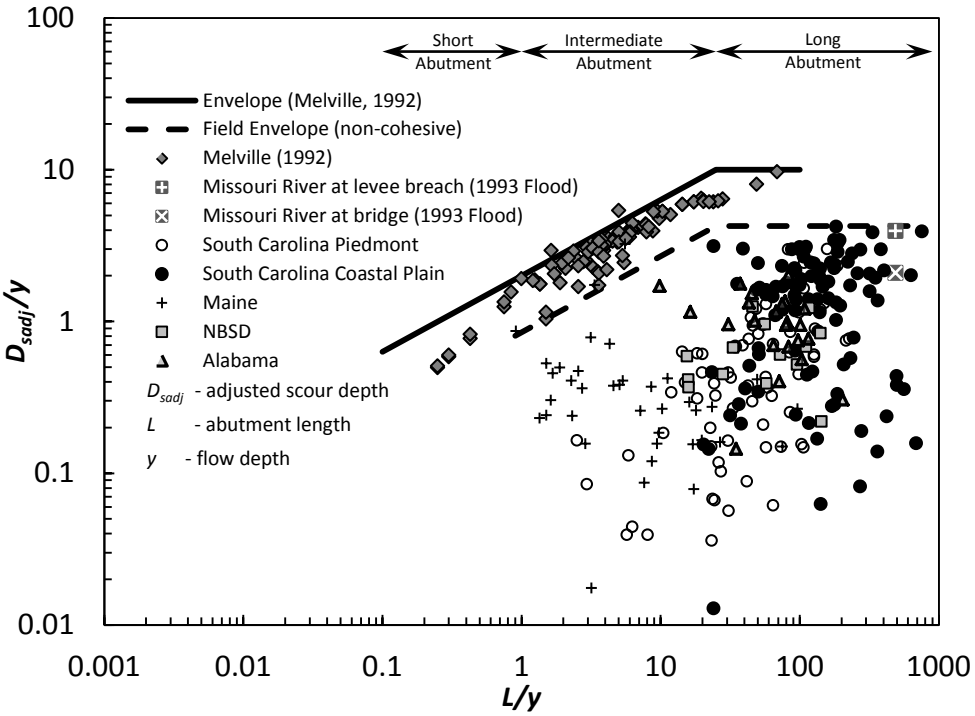

Figure 2 Relation of the relative scour depth (D_{sadj}/y) to relative abutment length (L/y), for selected laboratory and field data.

in this investigation, fall within the field envelope curve, providing a measure of confidence that the field envelope curve is reasonable. The significant difference in the upper bound of relative scour for the laboratory and field data, as shown in figure 2, is likely caused by multiple factors. The primary reasons for the discrepancy are thought to be short flow durations insufficient to produce equilibrium scour; approach-flow velocities significantly below threshold conditions for sediment motion that produce smaller scour depths than velocities at threshold conditions; and non-uniform sediments more resistant to scour.

VERIFICATION OF SELECTED SOUTH CAROLINA ABUTMENT-SCOUR ENVELOPE CURVES

Benedict (2003) used 209 field measurements of clear-water abutment scour to develop envelope curves for the Piedmont and Coastal Plain of South Carolina to be used as supplementary tools for evaluating the potential for abutment scour at bridges in South Carolina. Two envelope curves were developed for each region with one envelope curve using the geometric contraction ratio as the primary explanatory variable and the other curve using the abutment (or embankment) length blocking flow. Both variables are known to be strong explanatory variables for abutment-scour depth (Melville and Coleman, 2000; Benedict, 2003), thus providing justification for their use as explanatory variables. The geometric contraction ratio is a dimensionless variable that represents the severity of the contraction created by the bridge, with 0.0 being no contraction and 1.0 being 100-percent blockage. Larger geometric contraction ratios will tend to produce larger abutment-scour depths. The embankment length, measured from the edge of the floodplain to the abutment toe, is a relative measure of the blocked flow passing by the abutment with longer embankment lengths tending to block more flow, producing larger abutment-scour depths. As an example of these curves, figure 3 shows the South Carolina abutment-scour envelope curves with respect to the geometric contraction ratio for the Piedmont and Coastal Plain.

All of the previously noted field data are shown on this figure, with the exception of the largest Missouri River measurement, which was excluded for the purpose of the figure scale. With the exception of two data points, all of the field data falls within the Piedmont envelope curve with most of the data falling within the Coastal Plain envelope curve, providing a measure of validation for these curves. The one Maine data point that exceeds the envelope curve, as noted previously, was measured using GPR, giving some explanation for its exceedance. The exceedance of the Missouri River data can be attributed, in part, to the levee breach and the much larger drainage area, and highlights the importance of limiting the application of the South Carolina bridge-scour envelope curves to site characteristics similar to the South Carolina data used to develop them. Current guidance and limitations for using the South Carolina abutment-scour envelope curves can be found in Benedict (2003).

CONCLUSIONS

Current methods for predicting scour have some uncertainty, and therefore, should be assessed for reasonableness. One way to make such assessments is by comparing predicted scour to field measurements of historical scour. The recent investigations of scour in South Carolina

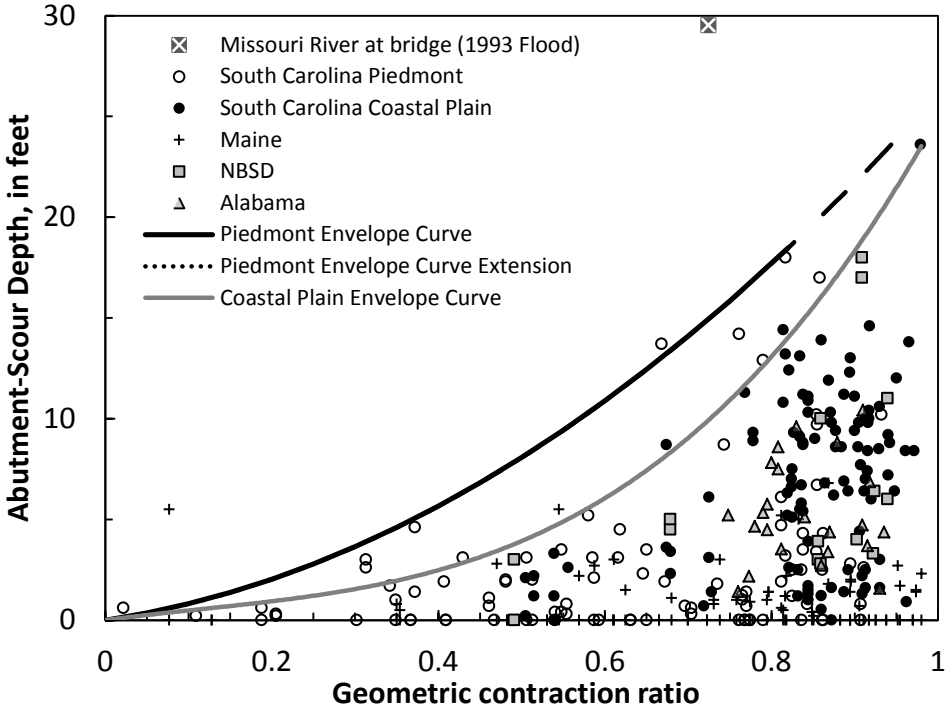

Figure 3 The South Carolina abutment-scour envelope curves with respect to the geometric contraction ratio compared with selected field data.

demonstrate how a strategic sample of historical field data can be used to develop regional bridge-scour envelope curves for assessing scour potential. The verification of these envelope curves with field data from other sources indicates that the South Carolina bridge-scour envelope curves are reflecting the upper bound of scour under field conditions in South Carolina. However, the exceedance of the Missouri River data highlights the importance of limiting the application of the South Carolina bridge-scour envelope curves to site characteristics similar to the South Carolina data used to develop the curves. A comparison of the field data with the laboratory data indicates that the upper bound of relative-scour depth in the field is significantly lower than the laboratory data, which likely is caused by the differing flow and sediment characteristics between these two environments. Because of the complexity of scour, caution and judgment are needed in the application of the envelope curves presented in this paper, and they should not be relied upon as the only tool for assessing abutment-scour potential. One can best assess anticipated scour by compiling and studying the available information for a given site, bringing sound engineering principals to bear on the final estimate of anticipated abutment-scour depth. Current guidance and limitations for using the South Carolina abutment-scour envelope curves can be found in Benedict (2003).

ABSTRACT

This paper presents theory and laboratory findings regarding the hydraulic performance of baffle-post structures used as a means for controlling flow in open channels. Such structures comprise one to two parallel rows of posts that extend slightly higher than the anticipated depth of flow, and offer a useful means for retarding flow in various channel situations where there is a need to reduce flow energy, possibly to reduce flow capacity to transport bed sediment and manage channel morphology. The laboratory findings were obtained using a tilting flume that produced data and observations on non-dimensional headloss and discharge coefficients and flow retardance (backwater flow profiles) associated with varying geometry of baffle-post structure. This information is of use in evaluating the extent to which a baffle-post structure, by retarding an approach flow, reduces the capacity of an approach flow to convey bed sediment and, thereby, promote channel bed aggradation.

INTRODUCTION

This study focuses on the hydraulic performance of baffle-post structures, illustrated in Figure 1. These structures act to slow or retard an approach flow, spread the flow across an approach channel, and sometimes disrupt large-scale turbulence structures in approach flows. They do so primarily by locally increasing flow resistance, reducing approach-flow velocities, and dissipating flow energy. The hydraulic performance of baffle-post structures, however, has received little attention. In particular, there appear to be no prior studies relating the geometric characteristics of baffle-post structures to hydraulic performance such as expressed using common indices, notably discharge and headloss coefficients associated with flow through baffle-post structures in open-channel flow.

By slowing or retarding an approach flow, and locally dissipating flow energy, baffle-post structures are used fairly often to help maintain the grade of a channel, and possible elevate and flatten the grade. This function is accomplished by the posts slowing and deepening the approach flow, letting flow and washload sediment pass, but causing a proportion of the approach bedload sediment transport to deposit on the channel bed upstream of the baffle-post structure.

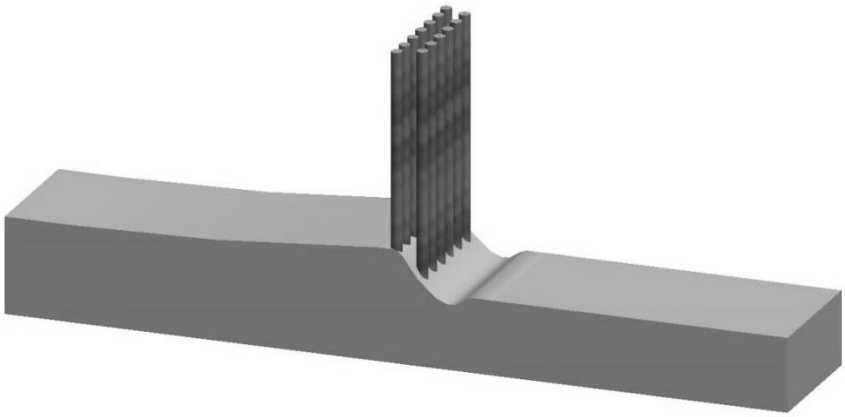

Figure 1: A Baffle post structure comprising a double row of posts spaced so as to suitably slow or retard an approach flow

The basic baffle-post structure consists of one to two rows of vertical posts. Depending on application, the post can be dowel timber, metal posts or rods, or tree trunks. When used in alluvial river channels, the posts typically are driven into the channel bed; in certain industrial uses, and laboratory flumes, the posts may be fixed to a base plate or cap block. The posts themselves usually are evenly spaced, with a second row staggered so that its posts align between those in the upstream row.

This paper briefly reviews the theory associated with the hydraulic performance of baffle-post structures, shows general trends for values of discharge coefficient and headloss related to them, and presents useful data for estimating the backwater extent (or M1 gradually varied flow profile) produced. This information is needed for evaluating the extent to which a baffle-post structure, by retarding an approach flow, reduces the capacity of an approach flow to convey bed sediment and, thereby, promote channel bed aggradation.

BACKGROUND THEORY

The essential function of a baffle-post structure is to retard an approach flow, slowing it, spreading it, and dissipating a portion of its energy. However, because flow at a baffle-post structure is non-uniform the analysis of structure hydraulic performance entails several simplifying approximations enabling baffle-post structure design to meet performance requirements within acceptable limits. The main requirement of interest for baffle-post structures in alluvial channels is the increase in water depth immediately upstream of the structure. A depth increase is associated with retarding of the approach flow so as to reduce the flow's capacity to transport bed sediment.

The hydraulic performance of a baffle-post structure can be evaluated in terms of the conservation of energy and continuity principles applied between the three flow cross sections indicated in Figure 2:

1. Between sections 0 and 1, where 0 indicates uniform approach flow well upstream of the structure, and 1 indicated a section immediately upstream of the structure; and,
2. Between sections 1 and 2, where 2 indicates the contracted section within the structure.

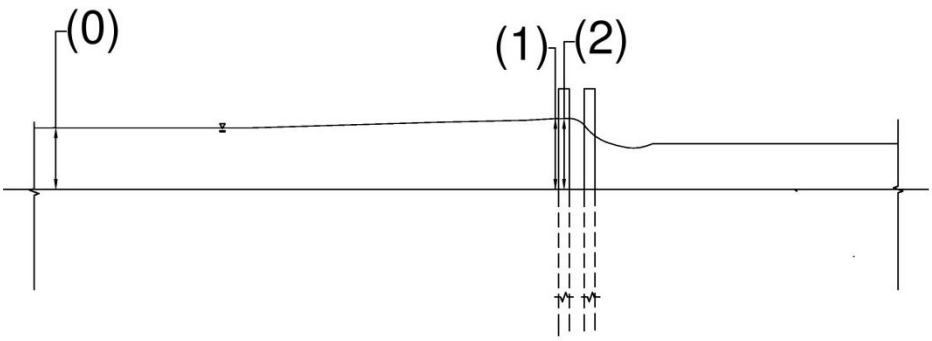

Figure 2: Three flow sections referenced for a double-row, baffle post structure

The specific energy diagram is a useful concept for explaining the hydraulic performance of a baffle-post structure. When the channel contracts, increasing the unit discharge, $q > q_0$, a set of curves exist, each with increasing value of critical depth, y_c, and E_{min}. Eventually, the contraction reaches critical width whereby E_{min} coincides with the initial specific energy, E_0. Associated with this critical flow depth is a critical width, b_c, defined as the maximum contraction the flow can pass through without becoming choked. In other words any constrictions narrower than b_c will produce an "overcritical" contraction so that there is not enough energy to maintain the given flow rate through the constriction. The critical width can be calculated as:

$$b_c = \left(\frac{3}{2}\right)^{3/2} \frac{Q}{\sqrt{gE_0^3}} \tag{1}$$

When the effective width of the flow constriction is less than b_c, the contraction acts as a "choke," as the available specific energy, E_0, is unable to pass the flow through the contraction. The flow backs up producing an M1 (backwater), gradually varied flow water surface profile, so as to elevate the magnitude of specific energy required to pass the flow through the contraction. The flow within the contraction stays critical, as the approach flow only backs up to the extent that generates the minimum energy needed to pass the given rate of flow through the contraction. The downstream flow may be supercritical or subcritical depending on the downstream conditions.

The additional energy becomes evident in the increased depth of flow at the contraction, and relatedly the energy increment, ΔE, needed to get the flow through the contraction. Figure 3 indicates the increase in specific energy and associated water depth upstream of the contraction. The increase in specific energy is dissipated as flow turbulence when the flow passes through the contraction and in a hydraulic jump formed immediately downstream of the contraction.

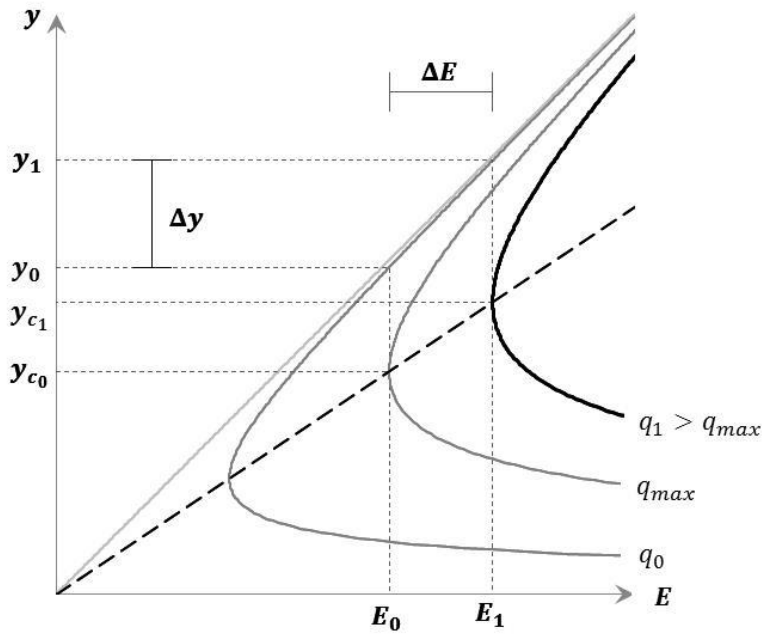

Figure 3: The increase in specific energy and upstream water level needed to pass the choked flow.

The additional energy, ΔE, needed to pass a give flow rate through a choked contraction can be evaluated in terms of the specific energy adjustments between sections 0 and 1: i.e.,

$$\Delta E = (y_1 - y_0) + \frac{q_0^2}{2gy_1^2} - \frac{q_0^2}{2gy_0^2} \tag{2}$$

Here, y_0 is the normal depth of flow for the uniform section well upstream of the structure, and y_1 is flow depth at section 1. Accounting for the headloss associated with flow resistance and the backwater curve, the headloss associated with the structure is:

$$\Delta E = h_{Lbaffle} = h_{L0} - h_{L0-1} = \left\{\left(\frac{fL}{8}\right)\left[\frac{(y_1/y_0)^3-1}{y_0(y_1/y_0)^3}\right]\right\}\left(\frac{u_0^2}{2g}\right) \tag{3}$$

It is common to express a local headloss, h_L, in terms of a headloss coefficient, C_L, and an average approach velocity, U_0, such as

$$h_L = C_L\left(\frac{u_0^2}{2g}\right) \tag{4}$$

Here

$$C_L = \frac{(y_1-y_0)+\frac{q_0^2}{2gy_1^2}-\frac{q_0^2}{2gy_0^2}}{\left\{\left(\frac{fL}{8}\right)\left[\frac{(y_1/y_0)^3-1}{y_0(y_1/y_0)^3}\right]\right\}\left(\frac{u_0^2}{2g}\right)} = \frac{1}{\left\{\left(\frac{fL}{8}\right)\left[\frac{(y_1/y_0)^3-1}{y_0(y_1/y_0)^3}\right]\right\}} C_L' \tag{5}$$

The term is a cumbersome expression relating to flow resistance in the approach to the structure, and shows that a unique value headloss coefficient, C_L, does not exist for a baffle-post structure.

DIMENSIONAL ANALYSIS

To work around the complications related to the non-uniform nature of the flow at a baffle-bar structure, it is useful to resort to dimensional analysis, which also offers a framework for assessing how approach-flow conditions and baffle-bar structure influence the hydraulic performance of baffle-bar structures. The dominant variables influencing flow and energy dissipation through a baffle-bar structure can be assembled and stated in the following functional manner:

$$f(N, D, s, l, Y_0, q_0, B, g, \nu) = 0 \tag{7}$$

Where N is the number of baffle bar rows, D is the baffle bar diameter, s is the lateral spacing, from center to center, of the baffle bars, l is the streamwise spacing, from center to center, of the baffle bars, y_0 is the flow depth at section 0, q_0 is the unit discharge at section 0, B is the width of the channel,g is the unit gravity constant, and ν is the kinematic viscosity of water.

Eq. (7) assumes fully turbulent flow with neglible surface tension effects. Applying the general principles of dimensional analysis, dimensionless relationships can be formed for C_L and C_D. Additionally, a dependent parameter of practical design interest is the depth increase parameter, y_1/y_0, as this parameter is usually required in order to select the geometric layout and dimensions of a baffle-bar structure. Therefore, an important functional relationship for design is,

$$\frac{y_1}{y_0} = f_D\left(N, \frac{s}{D}, \frac{l}{D}, \frac{y_0}{D}, Fr_0\right) \tag{8}$$

The laboratory experiments conducted for this study explore the relationship between the parameters in this equation.

LABORATORY EXPERIMENT

Experiments were conducted to determine the influences of baffle-post geometry (number of rows, post spacing and post diameters) on the hydraulic performance of baffle-post structures. The hydraulic parameters of interest are C_L' and y_1/y_0. They involved a re-circulating open channel flume that was 9.70m long, 0.20m wide and 0.36m deep at Colorado State University's (CSU) Hydraulic Laboratory.

The baffle-post models comprised cylindrical wooden dowels attached to a piece of wood secured to the top of the flume. The structure geometry was developed assuming 0.30m baffle post diameters for the prototype. Using a morphologic relationship, the posts were sized using a width ratio of 18 (prototype/model), which is based on a relaxed scaling approach used in the Mount Saint Helens GBS physical model. A 19.2 width ratio was adopted for practical purposes, as dowels are only available in standard sizes.

For single-row structures, post diameter and streamwise spacing were fixed. Only the relative lateral spacing $\frac{s}{D}$, was varied from 1.5 to 6.4. Experiments of single-row structures included two Froude numbers $(Fr_0 = 0.15, 0.45)$ and four relative depths. All three parameters (lateral spacing, streamwise spacing, and post diameter) were altered for the double row structure. Three

different relative depths were experimented at a range of Froude numbers ranging from 0.10 to 0.58.

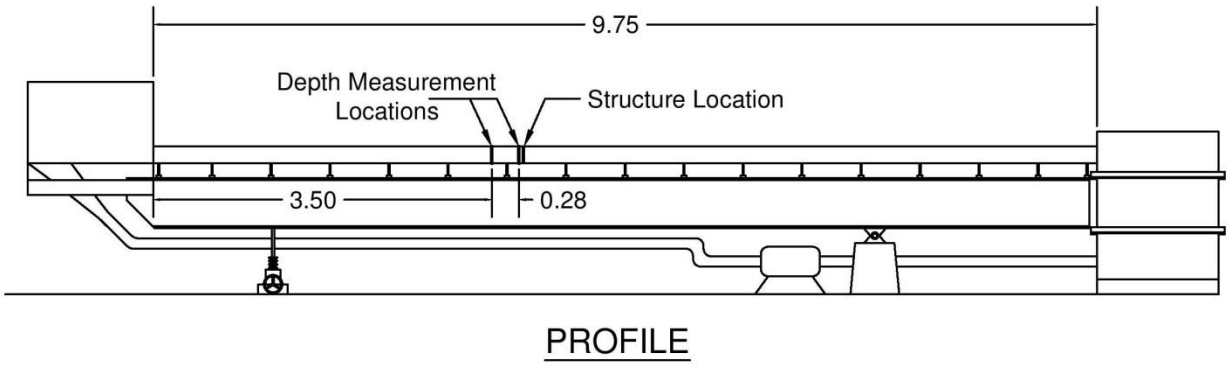

Figure 4: Profile view of the flume showing measurement locations for flow depths and velocities. Dimensions are in meters.

LABORATORY OBSERVATIONS AND DATA

The full set of observations and data are reported by Ubing (2015). This paper briefly describes the flow field at baffle-post structures, outlines the general trends obtained for the headloss coefficient, C_L', and a selection of data for the normalized flow depth increase y_1/y_0.

Flow Field at Baffle-Post Structures. When approaching the structure the flow transitions from uniform flow conditions into gradually varied flow conditions, where the depth is increasing gradually–until it reaches the maximum depth, directly upstream of the structure. Figure 5 illustrates the flow field. The depth increases to increase the specific energy upstream of the structure to pass the given flow discharge though the structure. At this point within the control volume, the velocity within the channel is the lowest. The flow accelerates through the structure, due to the width constriction. Directly downstream of the structure, the flow continues to accelerate, resulting in a rapid decrease in flow depth, eventually reaching the point of minimum flow depth, or maximum flow velocity. This location varies in its magnitude as well as its streamwise distance from the structure. Finally, the flow will gradually or rapidly increase, depending on initial flow conditions and the structure geometry. If choked flow conditions occurred, and the downstream depth become critical, it is likely that a hydraulic jump will occur within this section.

Figure 5: Side view of the flow field at a double-post baffle-post structure

Headloss Coefficient. The general impacts of structure geometry on the uniform flow headloss coefficient, C_L', are shown in Figure 7. Overall, C_L' decreased as the Froude number increased, because of the relationship between $C_L'$and Fr_0 indicated in Eq. (5). Lateral spacing, or *s/D*, has the greatest impact on C_L', causing the headloss coefficient to increases as lateral spacing decreases. As streamwise spacing increased, the headloss coefficient also decreased, but to a lesser extent. Finally, an increase in post diameter resulted in a slight increase in headloss coefficient. The discharge coefficient remained relatively constant over the experimented range of Froude numbers.

Closer spacing results in higher roughness through the baffles due to an increase in turbulence. When the flow openings are smaller, the flow vortices developed due to the baffle bars are closer together and more likely to interfere with each other, which results in a more turbulent flow and higher internal energy dissipation. The primary driver of an increase in energy dissipation is a direct result of higher blockage ratio, as shown in Figure 6. The additional baffle posts obstruct a larger flow area, producing higher resistance to flow, thus dissipating more flow energy.

At lower Froude numbers, the headloss coefficient also varied with relative depth, especially at smaller relative lateral spacing. Physically, the decrease in headloss coefficient with an increasing relative depth can be explained by the magnitude of the various vortices. At small relative depths, the downflow and horseshoe vortex will collide with the channel bottom, resulting in an increase in turbulence, which will further dissipate the energy within the flow. However, as the depth increases, the horseshoe vortex moves up the water column, no longer interacting with the channel bottom.

The relative depth appeared to have minimal impacts at the larger Froude number, due to the direct relationship between relative depth and energy dissipation. The relative change in water surface elevation produced by a structure increases as y_0/D increases. Therefore, both the velocity head, $\frac{u_0^2}{2g}$, and the energy dissipation, ΔE, increase, resulting in a less variable headloss coefficient. Furthermore, at a higher Froude number both the horseshoe and roller vortices are

much stronger and larger and possibly interacting at all three relative depths. Therefore, the additional energy dissipation as a result of the colliding flow paths is likely observed at all three relative depths, resulting in negligible differences in the headloss coefficient through the structure.

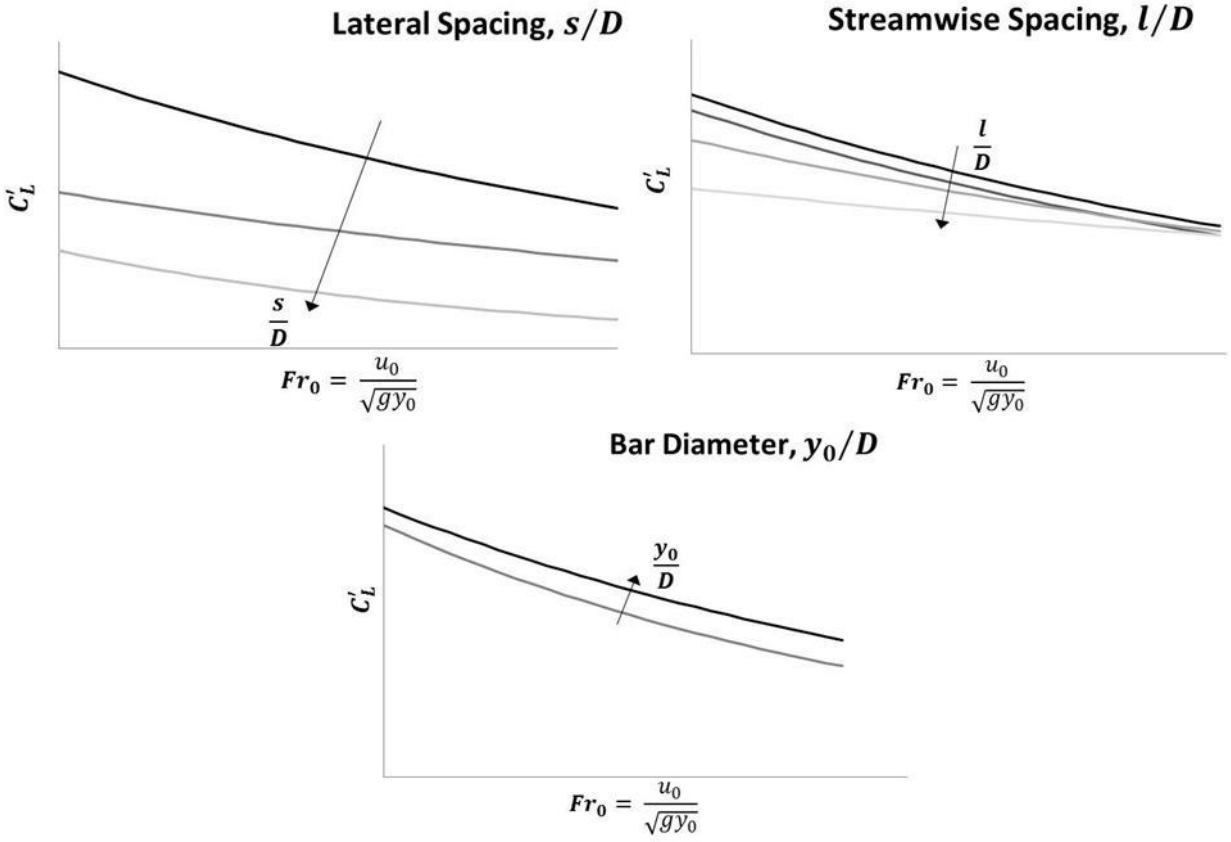

Figure 6: Schematic presentation of the general trends obtained for headloss coefficient C ′L *(Data in Ubing 2015)*

Backwater (Flow Retardance) Effect, y_1/y_0. The trends shown in Figure 7 illustrate how post spacing, *s/D*, and Froude number of approach flow, Fr_0, influence the values of the flow depth parameter y_1/y_0. Thus, the baffle-post structures created the backwater flow which acts to slow or retard an approach flow. The structures used to obtain the data for this figure entailed posts set at a streamwise spacing of *l/D* = 2. The value of y_0 for an approach flow (or flow prior to installation of a piffle-post structure) can be calculated, using say the Manning's equation, and then together with the value of Froude number, Fr_0, for the approach flow, the flow depth, y_1, at the baffle-post structure estimated using Figure 7. From the flow depth at the structure, y_1, the upstream dimensions of the backwater flow profile (M1 flow profile) can be calculated. In due course this backwater profile can be interpreted for its effect on the capacity of the approach flow to convey bed sediment.

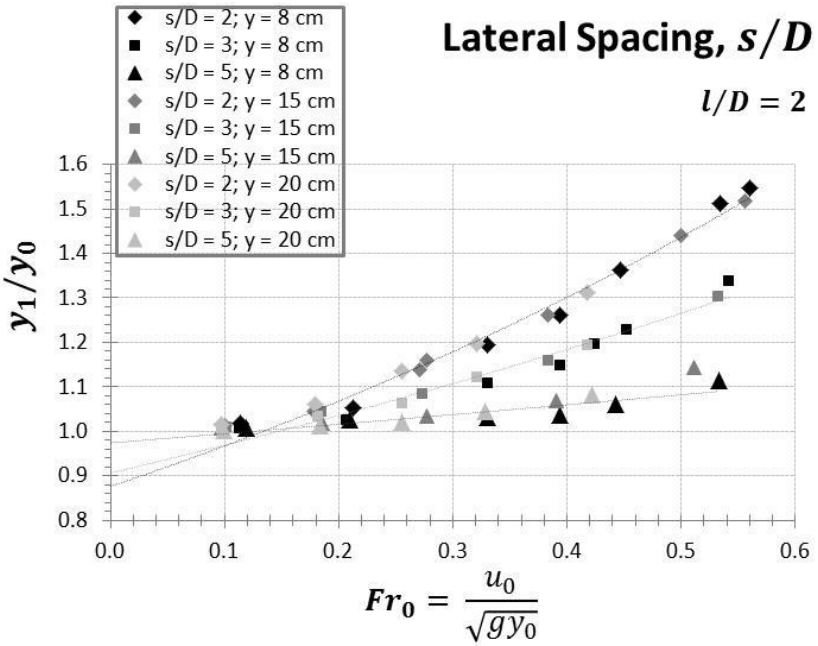

Figure 7: The variation of flow depth parameter y_1/y_0 for a double-row baffle-post structure with rows spaced at l/D = 2. The additional parameter in this figure is y_0/D, which exerts only a very small effect for the range of values investigated.

An important consideration in the use of baffle-post structures is the need for rock armoring to be placed around the base of the posts and the immediate downstream region where the flow passes through a hydraulic jump. The details related to tis consideration are presently under investigation at CSU.

CONCLUSIONS

This paper presents early observations regarding the impacts of geometric characteristics on the hydraulic performance of a baffle post structure. The observations, from laboratory experiments show that lateral spacing had the largest impact on the headloss and discharge coefficients; whereas, the post diameter and streamwise spacing appear to have near negligible impacts on the headloss and discharge coefficients. Relative flow depth impacted the headloss coefficient only at lower Froude numbers due to the magnitude of various flow vortices. At larger Froude numbers, the vortices are larger and stronger; therefore, colliding at three relative depths. In general, the headloss coefficient decreased as the Froude number increased. However, the discharge coefficient remained relatively constant within the range of tested Froude numbers.

Choked flow conditions only occurred at higher Froude numbers, with smaller relative lateral spacing. At smaller Froude numbers, the discharge through the channel was not large enough to induce choked flow conditions through the effective width of the structure. As the discharge increased and the critical width of the flow increased, the contraction became large enough to "choke" the flow.

Further work is needed to investigate other relevant aspects of the structure geometry such as baffle shapes, staggered rows, and random configurations. Also, further work is needed to determine the bed-protection needs to inhibit local scour at a baffle-post structure. Investigation

to the impact of the roughness of the baffle posts should be made to determine if the tree post will influence the energy dissipation through the structure. Additional experiments studying the impacts of variable diameter within a single structure is recommended as available materials may not provide uniform baffle posts. Finally, tests were conducted with initial Froude numbers varying between 0.10 and 0.58, all of which are within the region of subcritical flow. Supercritical flow does not occur often over large spatial extents in nature. However, the author recommends testing the structure in supercritical flow conditions to determine if the headloss coefficient curve deviates when $Fr > 1.0$.

The limitations inherent in determining general trends for discharge and headloss coefficients indicate that further investigation will benefit from an approach by means of dimensional analysis identifying the functional relationships between these parameters and approach-flow and structure geometry. Also of practical importance is the relationship between approach flow depth and flow depth at the structure, y_1/y_0; this parameter is significant in determining the backwater effects produced by a baffle-post structure.

ACKNOWLEDGEMENTS

This study was conducted as part of a background effort for a larger project aimed at designing and testing a series of grade-building structures for possible use in the Toutle River in Washington. The information presented here has yet to be further developed for potential use in this larger project, which is funded by the Portland District of the U.S. Army Corps of Engineers.

SUSPENDED-SEDIMENT TRANSPORT AND STORAGE: A DEMONSTRATION OF ACOUSTIC METHODS IN THE EVALUATION OF RESERVOIR MANAGEMENT STRATEGIES FOR A SMALL WATER-SUPPLY RESERVOIR IN WESTERN COLORADO

Cory A. Williams, Hydrologist, U.S. Geological Survey, Grand Junction, CO; Rodney J. Richards, Hydrologist, U.S. Geological Survey, Grand Junction, CO; Kent Collins, Hydraulic Engineer, Bureau of Reclamation, Lakewood, CO

Abstract: The U.S. Bureau of Reclamation (USBR) and local stakeholder groups are evaluating reservoir-management strategies within Paonia Reservoir. This small reservoir fills to capacity each spring and requires approximately half of the snowmelt-runoff volume from its sediment-laden source waters, Muddy Creek. The U.S. Geological Survey is currently conducting high-resolution (15-minute data-recording interval) sediment monitoring to characterize incoming and outgoing sediment flux during reservoir operations at two sites on Muddy Creek. The high-resolution monitoring is being used to establish current rates of reservoir sedimentation, support USBR sediment transport and storage models, and assess the viability of water-storage recovery in Paonia Reservoir. These sites are equipped with in situ, single-frequency, side-looking acoustic Doppler current meters in conjunction with turbidity sensors to monitor sediment flux. This project serves as a demonstration of the capability of using surrogate techniques to predict suspended-sediment concentrations in small streams (less than 20 meters in width and 2 meters in depth). These two sites provide the ability to report near real-time suspended-sediment concentrations through the U.S. Geological Survey National Water Information System (NWIS) web interface and National Real-Time Water Quality websites (NRTWQ) to aid in reservoir operations and assessments.

INTRODUCTION

The U.S. Bureau of Reclamation and local stakeholder groups are evaluating reservoir-management strategies within Paonia Reservoir. This small reservoir fills to capacity (live storage capacity is 15,553 acre-feet) each spring and requires approximately half of the snowmelt-runoff volume from its sediment-laden source waters, Muddy Creek (Bureau of Reclamation, 2014). Paonia Reservoir supports agriculture along the North Fork Valley. Reductions in water-storage capacity in the reservoir through time from sedimentation are affecting reservoir operation procedures (timing of reservoir fill and drawdown procedures to flush sediments interfering with gate operations) and may threaten continued operations of the reservoir. Storage losses also limit the availability of late-summer irrigation water for downstream diversions, especially during dry years when precipitation and natural sources of water become most scarce. Management strategies to mobilize sediments within the reservoir are in development. Active sediment removal techniques, such as dredging, are costly; therefore, an assessment of alternate management strategies, including passive removal techniques, is being evaluated. Sediment monitoring to characterize incoming and outgoing sediment flux during reservoir operations is needed to establish current rates of reservoir sedimentation, support USBR sediment transport and storage models, and assess the viability of water-storage recovery in Paonia Reservoir.

The U.S. Geological Survey (USGS), Bureau of Reclamation (USBR) and local stakeholder groups, including the North Fork Water Conservancy District and Fire Mountain Canal and Reservoir Company, are evaluating reservoir-management strategies with a goal of maintaining or increasing water-storage capacity within Paonia Reservoir. Two high-resolution (15-minute data recording interval) suspended-sediment monitoring sites were installed to monitor suspended-sediment flux into and out of Paonia Reservoir along Muddy Creek. The data collected supports the USBR hydrodynamic modeling of sediment transport and storage within, and downstream of, the reservoir.

The use of optical and acoustic surrogate techniques to characterize suspended-sediment flux can be highly effective in many river systems (Wood, 2014; Rasmussen *et al.*, 2009). Combinations of acoustic backscatter, acoustic attenuation, optical backscatter (turbidity), and seasonal effects are used to test the utility of these parameters as surrogates for suspended-sediment concentration on Muddy Creek. This project serves as a demonstration of the capability of these surrogate techniques to be used in small streams, less than 20 meters in width and 2 meters in depth, with suspended-sediment concentrations ranging from less than 10 to greater than 20,000 milligrams per liter (mg/L).

METHODS

Two USGS water-quality sites were established near Paonia Reservoir: Muddy Creek above Paonia Reservoir, CO – 385903107210800; and Muddy Creek below Paonia Reservoir, CO – 385626107212000) (fig. 1). Each site was instrumented with a 1.5 megahertz (MHz) side-looking Acoustic-Doppler Velocity Meter (ADVM) with voltage regulator, turbidity meter, automatic-pump sampler, and satellite telemetry. Suspended-sediment samples were collected from April 2013 to October 2013.

Suspended-sediment samples were collected using the equal-width-increment (EWI) method at 10 locations along the channel cross-section and were then composited for analysis (U.S. Geological Survey, 2006). Samples were collected using (1) a cable-suspended US D-74 depth integrated suspended-sediment sampler with quart glass bottle sampling container; or (2) a US DH-81 attached to US D-95 tetrafluoroethylene (TFE) cap and nozzles with a 3-foot wading rod and a 1-liter fluorinated ethylene propylene (FEP) bottle sampling container depending on flow conditions. Automatic-pump samples were collected in 1-liter polypropylene bottles. EWI and pump samples were sent to the USGS Iowa Water Science Center sediment lab for analysis (Guy, 1969). Approximately 15 EWI samples and 200 pump samples were collected at each site and were analyzed for concentration with additional grain-size analysis. Pump samples were analyzed for percent finer than 0.063 millimeters (mm), and suspended-sediment concentrations were adjusted using 'box coefficients' to correct these point-concentrations to represent cross-section average concentrations based on EWI/pump concentration pairs and streamflow (Edwards and Glysson, 1999). A full grain-size analysis was done on all EWI samples. Turbidity data were collected by using an optical turbidity meter using monochrome near infra-red LED light (780 – 900 nanometer wave length) with a detection angle of 90 degrees reported in formazin nephelometric units (FNU). The meter was operated and the data processed according to guidelines described in Wagner *et al.* (2006). Additional post-processing of the turbidity record was done to correct erroneous turbidity values, typically from fouling from filamental algae. A calibration check was completed in the lab after the instrument was removed for the season and a calibration drift correction was applied if necessary.

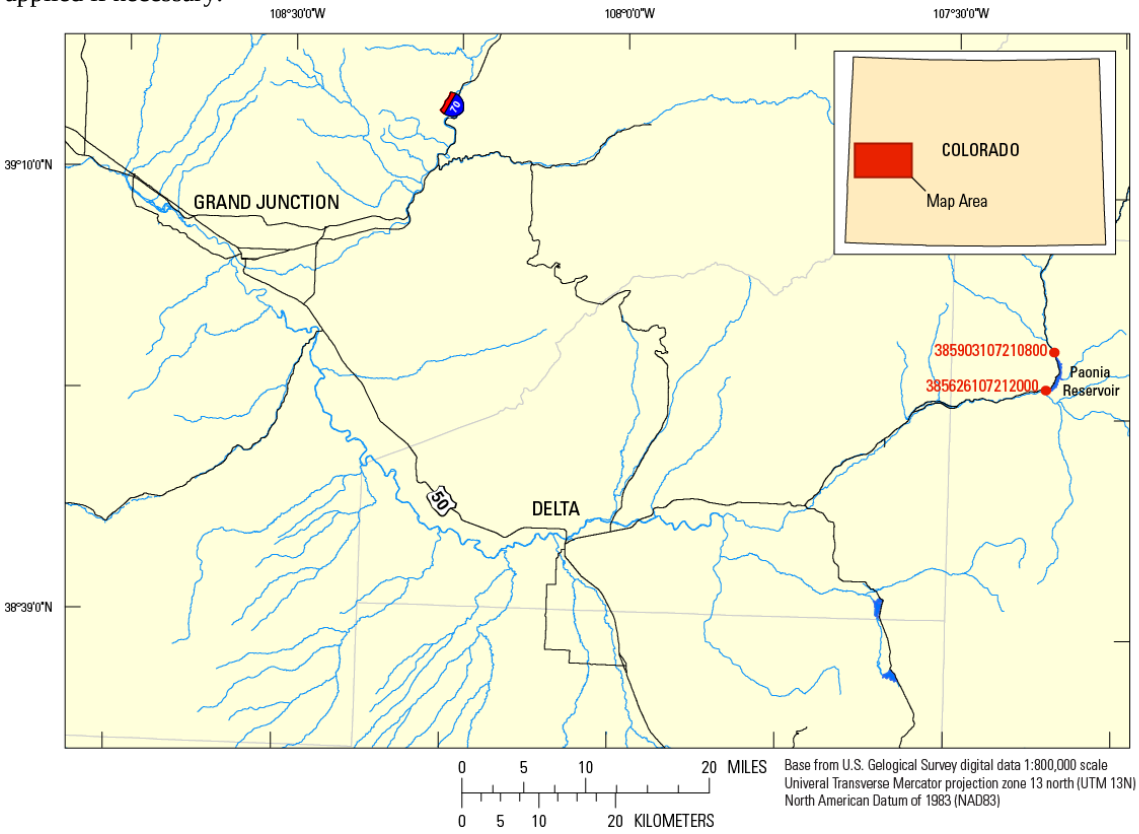

Figure 1 Map showing the location of Paonia Reservoir, and the location of USGS water-quality stations and station numbers in the North Fork Gunnison River Basin, in Western Colorado.

The multi-cell acoustic data collected by the ADVM (1,500 MHz side-looking instrument, 2.25–meter blanking distance along beam, 10 cells, 0.50-meter cell size along beam, 25° beam angle) are post-processed in a series of steps. During the deployment of the instrument, it became necessary to reconfigure the blanking distance to a length of 0.75-meters (along the beam) on August 29th in order to characterize the high-sediment concentrations associated with late-summer monsoon rain events. This was necessary because of excessive acoustic signal losses owing to the high sediment concentrations. Calculations for corrected acoustic backscatter and acoustic sediment attenuation followed the methodology outlined in Topping *et al.* (2004; 2006), Wright *et al.* (2010), and Wood and Teasdale (2013). Acoustic backscatter was corrected for losses including beam spreading (Downing *et al.*, 1995), fluid absorption (Urick, 1975), and near-field corrections (Downing *et al.*, 1995) resulting in a "fluid-corrected backscatter" profile across the 10-cell ensonified volume. The sediment attenuation was calculated from the slope of the fluid-corrected backscatter profile and represents transmission losses due to scattering, absorption, and attenuation due to sediment effects (Urick, 1975). Removing the losses from sediment attenuation from the "fluid-corrected backscatter" yields a "normalized-acoustic backscatter." Sediment attenuation and the average "normalized-acoustic backscatter" have been used in other studies to represent the suspended-silt-and-clay (fines) and suspended-sand portions of the suspended-sediment concentrations, respectively (Topping *et al.*, 2004; 2006, Wright *et al.*, 2010; Wood and Teasdale, 2013).

Suspended- sediment concentration predictions for the two sites were used to calculate the incoming and outgoing suspended-sediment load at Paonia Reservoir. A total suspended-sediment and suspended fines (<0.0625 mm) concentration and load were calculated at Muddy Creek above Paonia Reservoir, CO; and a total suspended-sediment concentration and load were calculated at Muddy Creek below Paonia Reservoir, CO. The suspended sand concentration and load (if present) was calculated as the difference between the total suspended-sediment concentration and load and the fine suspended-sediment concentration and load.

Above Paonia Reservoir: Muddy Creek above Paonia Reservoir, CO, is located approximately 1,000 m upstream of the reservoir (U.S. Geological Survey, 2014). The system is dynamic with large seasonal changes in streamflow and suspended-sediment concentration, especially during monsoonal-rain events. High suspended-sediment concentrations are common during the snowmelt-runoff period and late-summer monsoon season with suspended-sediment concentrations exceeding 20,000 mg/L.

A step-wise regression analysis was used to find the best-fit regression model based on normalized-acoustic backscatter, sediment attenuation (hereafter, *SedAtt*), turbidity (hereafter, *Turb*), and seasonality terms (Helsel and Hirsch, 2002). The final linear regression models for total suspended-sediment concentration and fine suspended-sediment concentration are:

$$\ln(totalSSC) = 4.7102 - 0.2261\ln(Q) + 0.7967\ln(SedAtt) + 0.6914\ln(Turb) + 3.3129(Sin) - 0.3699(Cos) \quad (1)$$

$$\ln(finesSSC) = 4.2950 + 0.7987\ln(SedAtt) + 0.7776\ln(Turb) + 3.7232(Sin) - 0.5886(Cos) \quad (2)$$

where *totalSSC* is the predicted total suspended-sediment concentration, in milligrams per liter (mg/L); *finesSSC* is the predicted suspended-sediment concentration for grain sizes less than 0.063 mm, in mg/L; *Q*, is streamflow, in cubic feet per second; *SedAtt* is the sediment attenuation, in decibels per meter; *Turb* is the turbidity 0–1,600, in formazine nephelometric units (FNU); *Sin*, is the sine wave component and *Cos*, is the cosine wave component of a Fourier Series seasonality term. A bias correction factor (smearing) was applied to each transformed prediction (Helsel and Hirsch, 2002). The linear regression diagnostics for the regression models are presented in table 1 and table 2.

Below Paonia Reservoir: Muddy Creek below Paonia Reservoir, CO, is located immediately downstream of Paonia Reservoir. The system is regulated and releases are governed by downstream water rights. The reservoir is filled in the spring during the snowmelt-runoff period and excess water spills over the spillway once the reservoir is at capacity. Releases during the summer and fall are from an elevated release structure (tower) within the reservoir. Due to the height and position of the tower in the reservoir dead pool, sand-sized sediments (0.063–2 mm) were not observed in waters leaving the reservoir in 2013.

A step-wise regression analysis was used to find the best-fit regression model based on backscatter, attenuation, turbidity, streamflow, and seasonality terms. The final linear regression model for total suspended-sediment concentration (very little sand was observed at this site, therefore no separate fine suspended-sediment model was needed) is:

$$totalSSC = 3.2215 + 0.5856(Turb) \quad (3)$$

where *totalSSC* is the predicted total suspended-sediment concentration, in mg/L, and *Turb* is the turbidity 0–1,600, in FNU. The linear regression model diagnostics are presented in table 1.

RESULTS

Above Paonia Reservoir: Predictions of total suspended-sediment are plotted against measured concentrations in figure 2. The regression analyses (eq. 1) indicates that for concentrations between 0 and 2,000 mg/L the predictions are very near the mean response; however, as the predicted concentration increases above 6,000 mg/L, greater error in the predictions are evident in the widening of the 95-percent confidence intervals (fig. 2B).

Overall, the predictions of total suspended-sediment concentration are near the mean response with a residual standard error of 1.35 mg/L (table 1), indicating that the loads calculated from the predictions are generally well defined (fig. 2). Additional sampling of conditions at higher concentrations in future years will provide improved characterization and opportunities for additional regression model refinement or continued validation of regression predictions.

The predicted fine suspended-sediment concentrations derived from equation 2 follow the same general trend as the total suspended-sediment concentrations. Predicted fine suspended-sediment concentrations below 2,000 mg/L are near the mean response with increases in error for predictions of greater concentrations. Similar to the predicted total suspended-sediment concentration, the relation of predicted and measured concentrations remains near the mean response with a residual standard error of 1.28 mg/L (table 1), indicating that the loads calculated from the predictions are generally well defined (fig. 3). Additional sampling of conditions at higher concentrations in future years will provide improved characterization and opportunities for additional regression model refinement or continued validation of regression predictions.

The total suspended-sediment concentrations vary throughout the year along with the grain size of the particles (fig. 4). Higher concentrations of total suspended sediment are observed in April and May during snowmelt runoff. During this period, larger portions of sand-sized particles are being suspended and mobilized. As the snowmelt period ends, in June, the total suspended-sediment concentration decreases rapidly and becomes much finer in grain size. Medium silt-sized to clay-sized particles dominate the system throughout much of the year. Large increases in total suspended-sediment concentration occur in the late-summer and early-fall months during monsoonal rains. These rain events produce the highest suspended-sediment concentrations of the year and are composed of silt-sized

and clay-sized particles (figs. 4 and 5). Muddy Creek becomes very turbid during these events and concentrations of suspended sediments are great enough to impede the effectiveness of the surrogate sensors. As a result, during some periods of the year, the total suspended-sediment load was estimated due to obscured turbidity and acoustic signals. Estimates of missing data were made such that the shape of the concentration peaks matched observed conditions of previous concentration peaks following techniques described in Porterfield (1972).

The temporal variations in the fine suspended-sediment concentrations are very similar to those of the total suspended-sediment predictions. During the snowmelt period, however, the fine suspended-sediments contribute less to total concentration than the sand-sized sediments, and from June through October, suspended-sediment concentration is almost entirely composed of silt-and clay-sized particles (fig. 5).

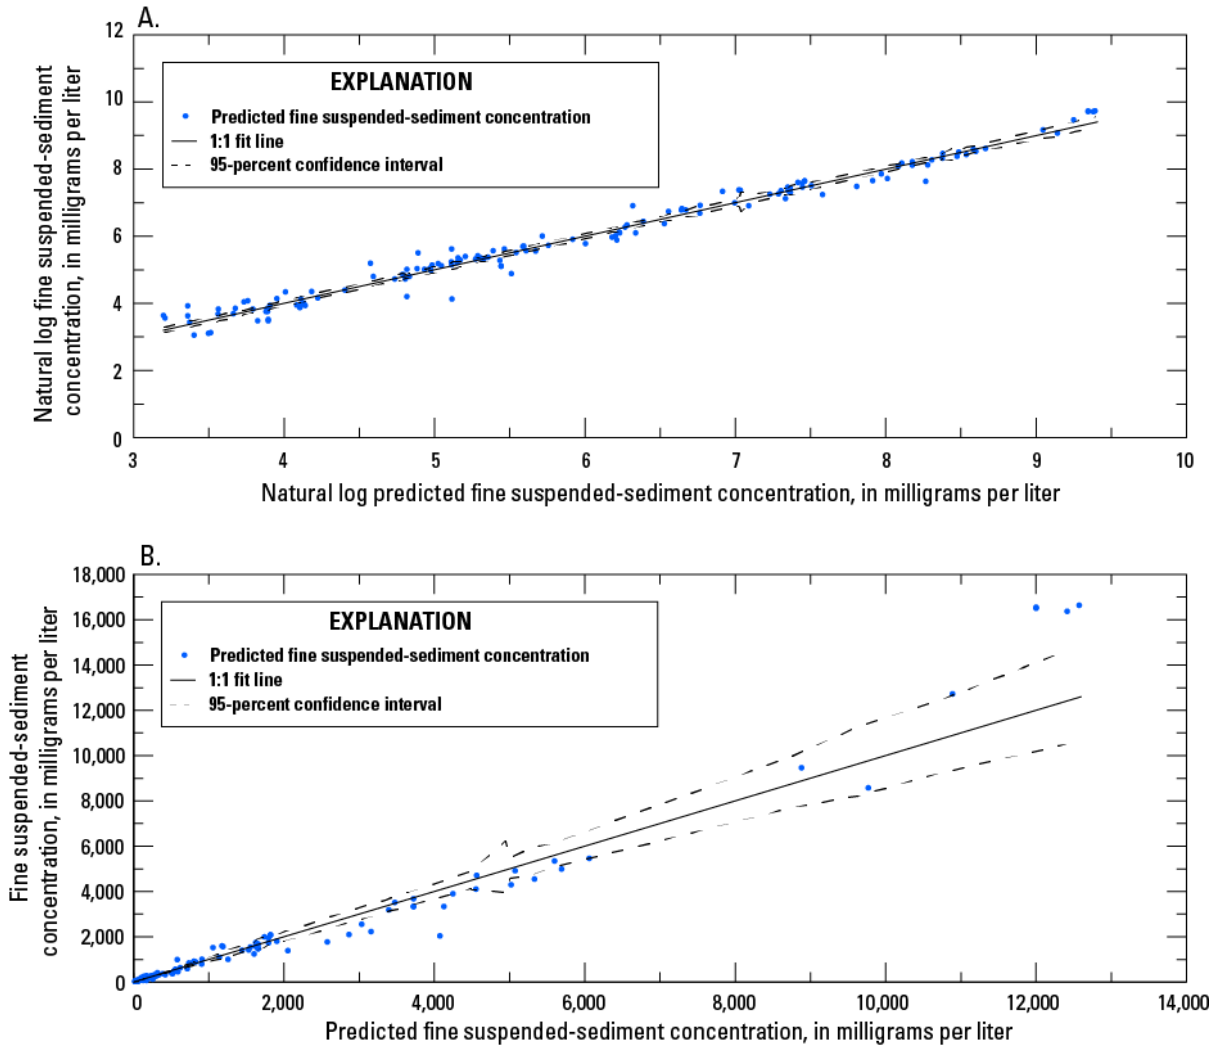

Figure 3 Relations between predicted and fine (grain size less than 0.063 millimeters) suspended-sediment concentration with 95-percent confident interval for Muddy Creek above Paonia Reservoir in (A) logarithmic, (B) and normal space, April–October, 2013.

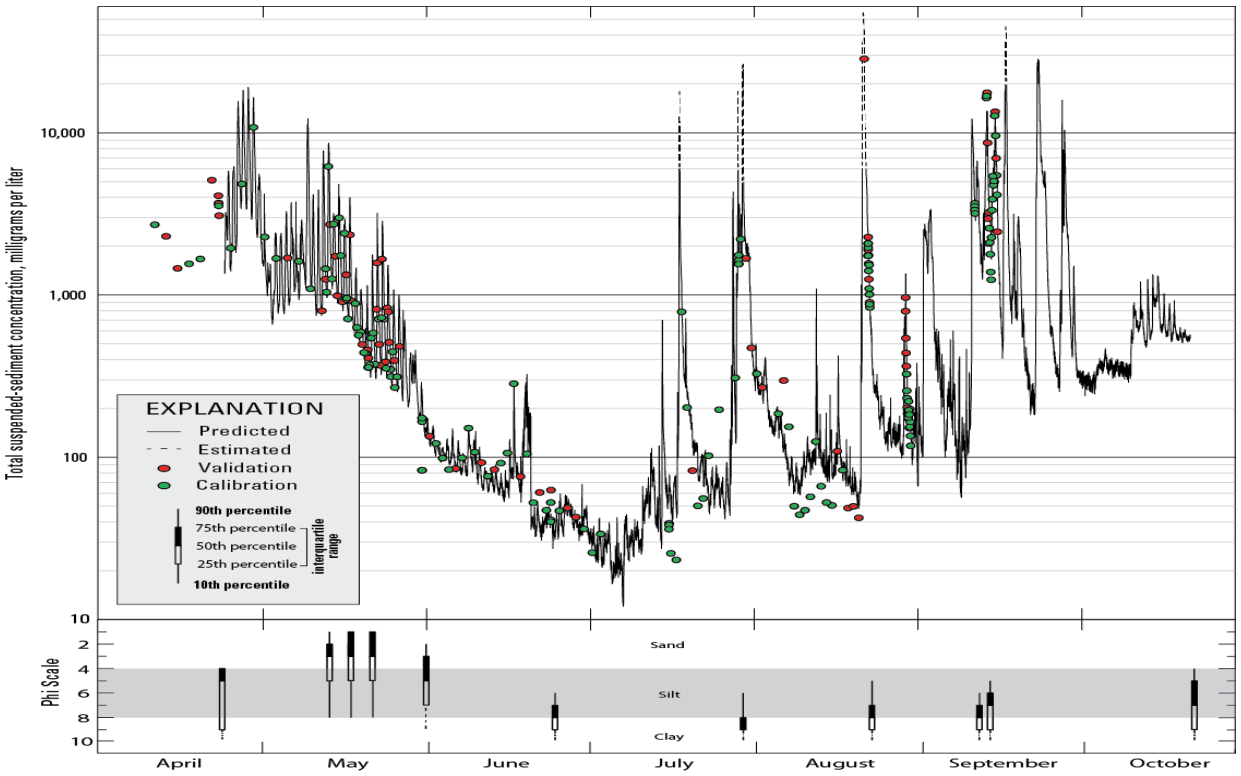

Figure 4 Predicted total suspended-sediment concentration with calibration data points, validation data points, and equal-width interval sample grain-size analyses for Muddy Creek above Paonia Reservoir, April–October, 2013.

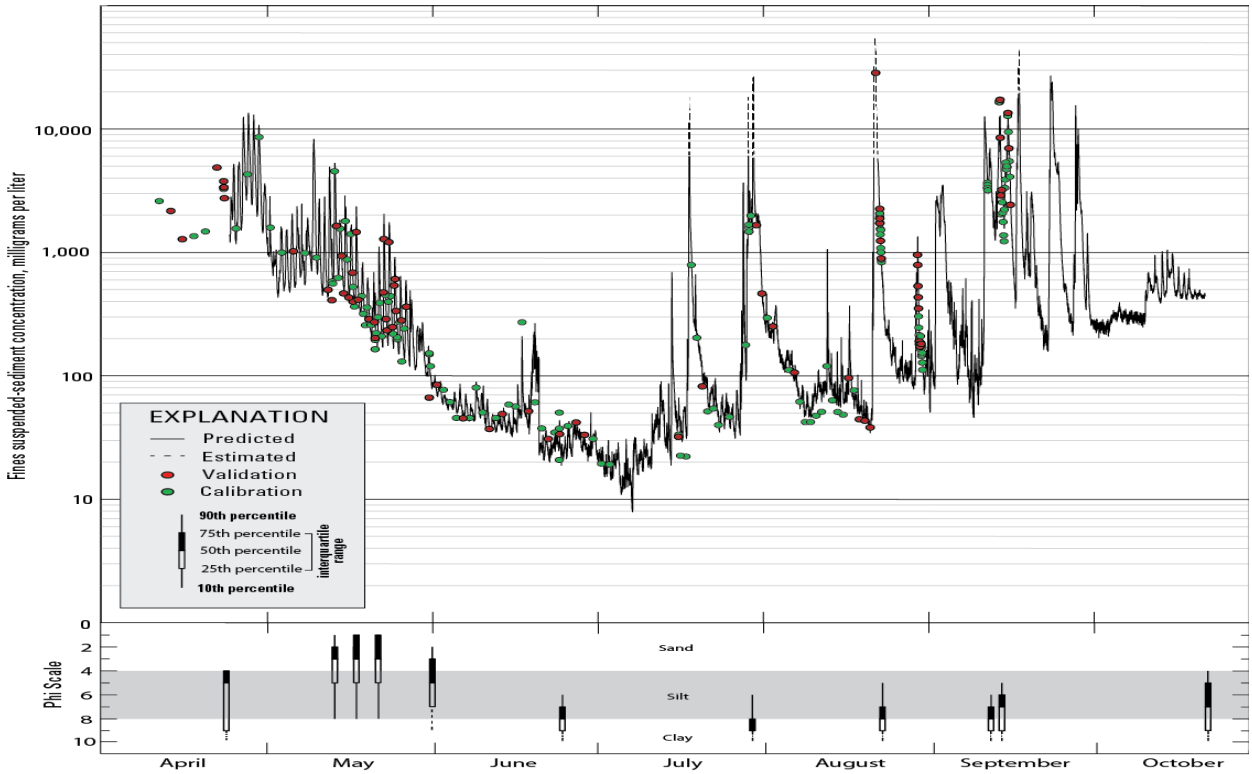

Figure 5 Predicted fine suspended-sediment concentration with calibration data points, validation data points, and equal-width interval sample grain-size analyses for Muddy Creek above Paonia Reservoir, April–October, 2013.

Below Paonia Reservoir: Predictions of total suspended-sediment concentrations are plotted against measured concentrations in figure 6. The predicted total suspended-sediment concentration from the regression analyses (eq. 3) indicates that the predictions scatter around the mean response with a residual standard error of 13.0 mg/L (table 1), indicating that the loads calculated from the predictions are well defined. The regulated nature of flows downstream of the reservoir result in less variability than suspended-sediment concentrations observed at the upstream site (fig. 7).

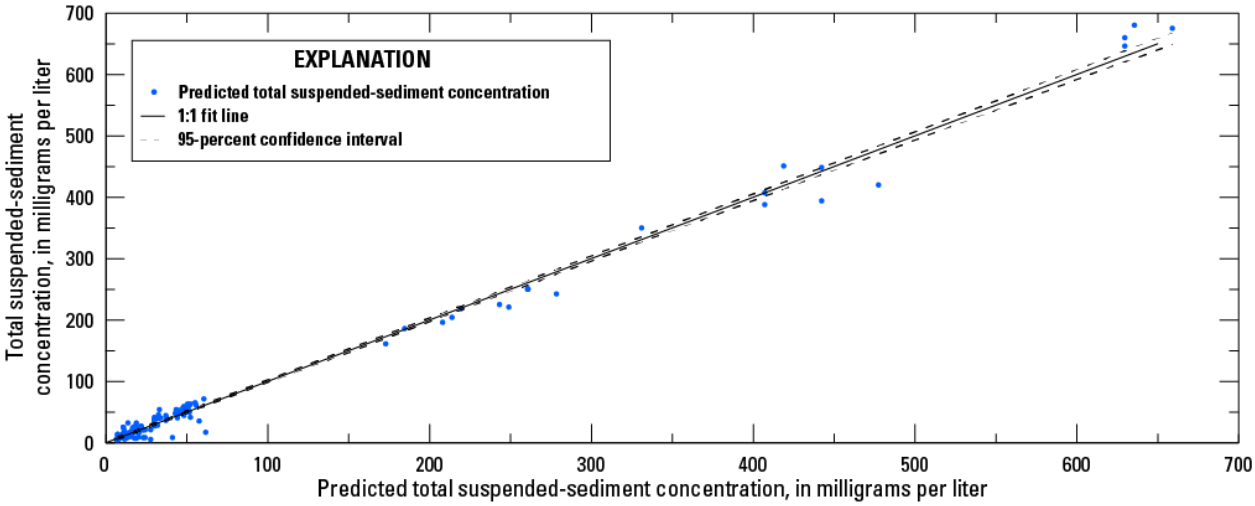

Figure 6 Relations between predicted and fine suspended-sediment concentration with 95-percent confident interval for Muddy Creek below Paonia Reservoir, April–October, 2013.

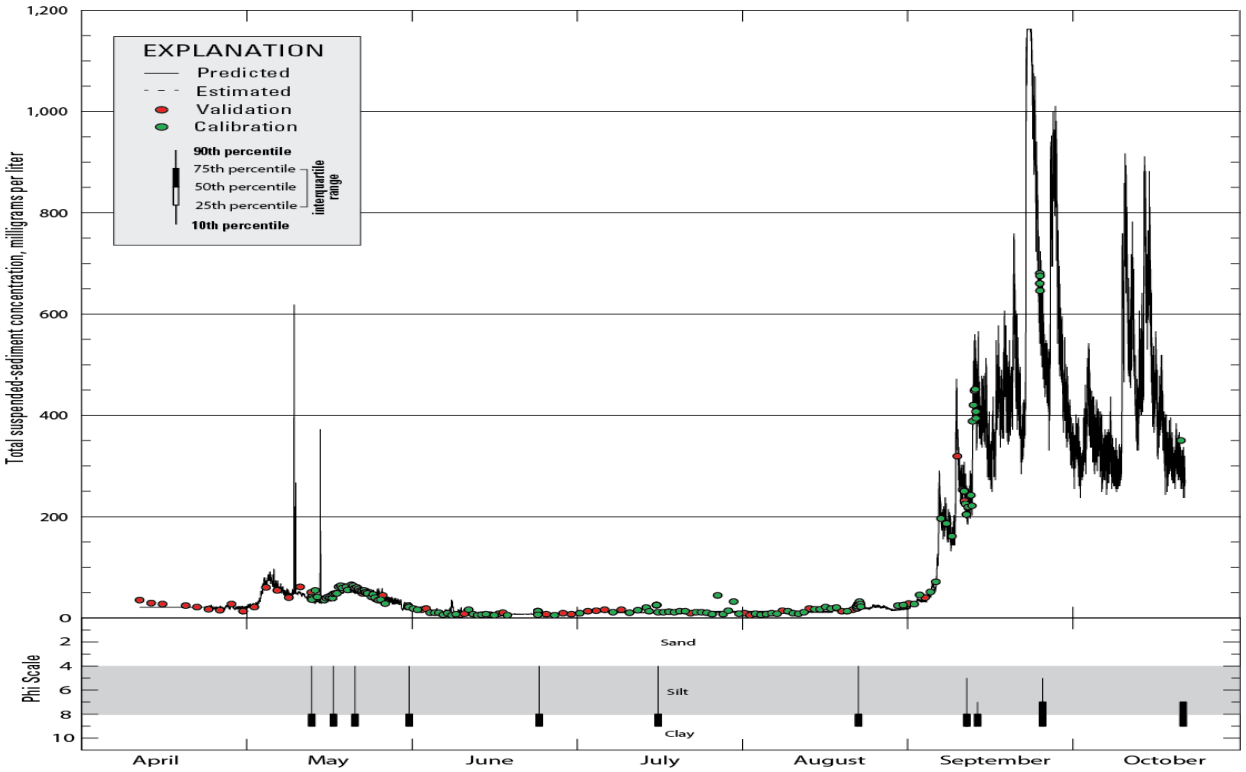

Figure 7 Predicted total suspended-sediment concentration with calibration data points, validation data points, and equal-width interval sample grain-size analyses for Muddy Creek below Paonia Reservoir, April–October, 2013.

Generally, total suspended-sediment concentrations below Paonia Reservoir remain minimal in comparison to the upstream site and are dominated by silt-sized and clay-sized sediments. Rapid, short-duration increases in total suspended-sediment concentration occur in May and are associated with the opening and closing of the gate on the outlet tower that controls water releases. In June, the reservoir is typically at full capacity and additional streamflow entering the reservoir exits through a combination of releases and spills. Reservoir geometry and sediment residence under these conditions trap much of the sediment entering the reservoir. When water levels in Paonia Reservoir are drawn down (typically by the end of the summer and early fall) greater suspended-sediment concentrations are observed as Muddy Creek meanders through newly exposed reservoir sediment deposits (fig. 7).

Sediment storage: A mass-balance analysis of incoming against outgoing total suspended-sediment load, calculated using the selected surrogate models, is shown in figure 8. Sediment monitoring in 2013 shows that approximately 75,000 tons of suspended sediment entered the reservoir (red line), and approximately 4,000 tons of suspended sediment was transported downstream (blue line). The majority of the total suspended sediment entering the reservoir occurred during snowmelt-runoff (~62,000 tons, in the light-yellow shaded region) with an additional increase occurring during the monsoon season (~12,000 tons, in the dark-yellow shaded region). The suspended-sand load (green line) also occurs during the snowmelt period with little sand being mobilized in suspension after the snowmelt period ends. The suspended-sediment load leaving the reservoir (4,000 tons) occurs later in the year and represents approximately 5 percent of the incoming load.

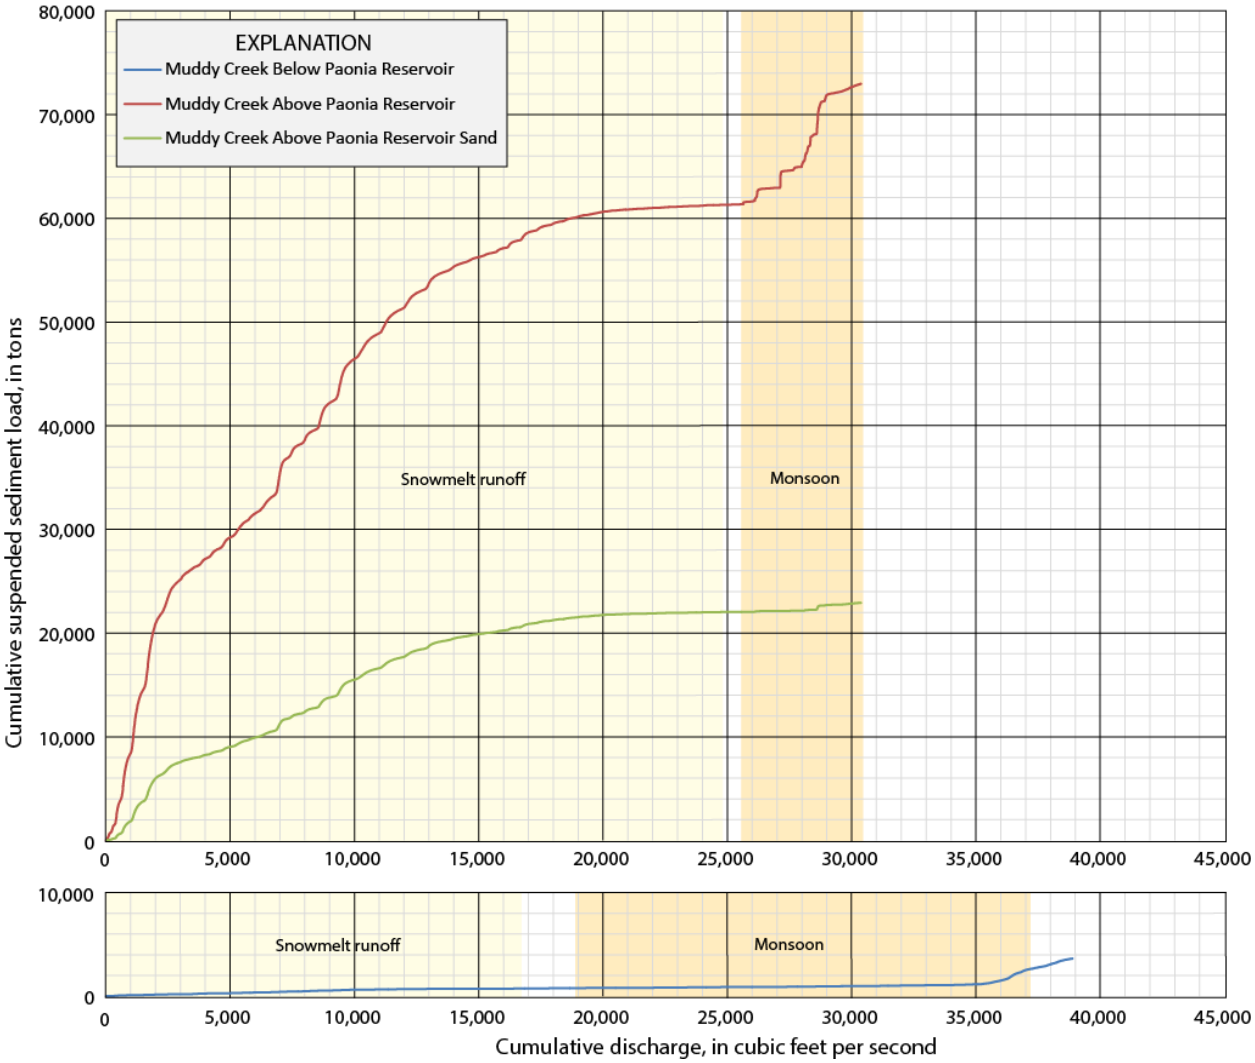

Figure 8 Mass curve of cumulative suspended-sediment load relative to cumulative discharge at Muddy Creek above Paonia Reservoir and Muddy Creek below Paonia Reservoir, April–October, 2013.

DISCUSSION

The development of regression models using suspended-sediment surrogates to characterize suspended-sediment concentration and flux is helpful in developing a management strategy to protect existing water storage and potentially increase lost storage due to sediment infilling. Based on the results from one year of observation and analyses, there is a substantial imbalance in the sediment transported into and out of Paonia Reservoir along Muddy Creek. The incoming suspended-sediment load consists of some finer sands, but silt-sized and clay-sized sediments dominate the suspended system. Most if not all of the sand portion of the incoming suspended load appears to be deposited in the reservoir. The outgoing suspended-sediment load appears to be dominated by clay-sized sediments with little to no fine-or-medium sand moving downstream of the reservoir. Differences in grain size of these sediments can be important to reservoir managers during calculation of storage-volume loss due to differences in the porosity (void spaces) associated between sediment deposits of differing grain-sizes. Additionally, the difference in grain size can be important when considering reservoir modifications to decrease retention of sediments (reservoir trap efficiency).

Using optical and acoustic high-resolution sediment monitoring to characterize suspended-sediment at Paonia Reservoir has shown to be an effective metric for evaluation of reservoir operational strategies. In 2013, substantial differences between incoming and outgoing total suspended-sediment loads indicate that mitigation efforts were largely unsuccessful. This is due, in part, to perceived limitations in the 2012 snowpack, and concerns that insufficient runoff may result in water shortages. This meant that reservoir operations during the early portion of the snowmelt runoff period were not used for sediment-flushing strategies. These flushing strategies include an approach where operations target delayed capture of later season flows for reservoir filling. The USBR hypothesizes that this operational strategy may help remove exposed reservoir sediments (while the reservoir storage level is near operational dead pool and much of the reservoir bed is exposed) because Muddy Creek is able to remobilize these deposited sediments and transport them towards the outlet tower. Reservoir filling began immediately in 2013, however, limiting options to flush sediments until late fall when reservoir levels were again exposing these sediments as water level in the reservoir fell. Additional modifications to the outlet tower may be necessary if mobilization of sand or coarser sediment is desired.

Successful monitoring of suspended sediment within this system using surrogates is useful in determining the type of management strategies that would be effective in increasing reservoir capacity or decreasing the present rate of capacity loss. Use of turbidity as a suspended-sediment surrogate within a simple-linear regression was appropriate for this study for conditions where sand-sized particles were absent. When present, sand-sized particles were not well characterized by changes in turbidity and incorporation of additional parameters (sediment attenuation, seasonality, and/or streamflow) was necessary. Exploring the relation between acoustic backscatter, sediment attenuation, turbidity, and seasonality effects has allowed for a more complex linear regression model to be developed that is effective in predicting suspended-sediment concentrations. It should be noted, however, that the regressions developed to date could change as subsequent data are incorporated into the regression under flow and reservoir management strategies of future years. Differences in seasonal streamflow patterns or reservoir management may change which combination of variables are statistically significant in predicting suspended-sediment concentrations in future monitoring efforts. Future plans for these two suspended-sediment monitoring stations include incorporation of near real-time reporting of suspended-sediment concentrations through the U.S. Geological Survey National Water Information System (NWIS) web interface (*http://watedata.usgs.gov.nwis*) and National Real-Time Water Quality websites (NRTWQ; *http://nrtwq.usgs.gov*) to aid real-time reservoir operations and assessments.

Abstract: The use of ultrasonic acoustic technology to measure the concentration of fine suspended sediments has the potential to greatly increase the temporal and spatial resolution of sediment measurements while reducing the need for personnel to be present at gauging stations during storm events. A laboratory investigation by Carpenter et. al (2009, 2014) was undertaken by the National Center for Physical Acoustics in cooperation with the USDA-ARS National Sedimentation Laboratory. In these experiments, two immersion transducers were used to measure attenuation from 20 MHz acoustic signals propagated through suspended clay (smectite and kaolinite) and silt particles (i.e. clays and silts ranging from 0.03–14 micrometer particle size diameter) for a wide range of concentrations (0.3–14 g/L). Attenuation curves for each particle classification were compared to the theoretical attenuation curves developed by Urick (1948) and Sheng and Hay (1988) for scattering as presented by Landers (2010), and a model for estimating concentration was created. Subsequently, a customized field deployable system was developed using the laboratory transducer design parameters and deployed as an acoustic surrogate monitoring fine sediment particles in suspension at Harris Bayou, in cooperation with personnel from the U. S. Geological Survey. Using the laboratory and field systems concurrently, the calibration measurements show good agreement between the laboratory grade equipment and the new prototype system. The results of laboratory calibration and testing of the prototype system at Harris Bayou will be presented.

INTRODUCTION

Growing populations and increased economic development, coupled with the effects of a warming climate, will place an increased strain on water resources. The accurate measurement of sediment transport in rivers and streams, typically associated with upland erosion, is an important and ongoing problem that affects water quality (Holeman, 1968). The use of ultrasonic acoustic technology as a surrogate method to monitor the concentration of fine suspended sediments has the potential to greatly increase the temporal and spatial resolution of sediment measurements.

METHODOLOGY

In order to improve the state of knowledge, laboratory investigations by Carpenter et. al (2009, 2014) were conducted at the National Center for Physical Acoustics with collaboration from the USDA-ARS National Sedimentation Laboratory. In the experimental setup, two immersion transducers were used to measure attenuation from 20 MHz acoustic signals propagated through suspended clay (smectite and kaolinite) and silt particles (i.e. clays and silts ranging from 0.03–14 micrometer particle size diameter) for a wide range of concentrations (0.3–14 g/L). Attenuation curves for each particle classification were compared to the theoretical attenuation curves developed by Urick (1948) and Sheng and Hay (1988) for scattering as presented by Landers (2010), and a model for estimating concentration was created assuming spherical-sized particles. The calibration curve is valid for silt-sized particles (D_{50} = 20 μm).

$$\alpha_s = SSC_v * k(\gamma - 1)^2 * \left(\frac{s}{s^2 + (\gamma + \tau)^2}\right) + \frac{k^4 * a_s^3}{5 * (1 + 1.3\,k^2 a_s^2 + 0.24\,k^4 a_s^4)} * \frac{8.686}{2} \quad (1)$$

where,

α_s is a coefficient of attenuation, measured in $\left(dB/_{cm}\right)$

SSC_v is the volumetric sediment concentration (*SSC* divided by the sediment density)

k is the wave number, $k = \frac{2\pi}{\lambda}$, where λ is the wavelength in cm

γ is the specific gravity of the sediment

a_s is the sediment radius in cm

$$s = \left[\frac{9}{4\beta a_s}\right] * \left[1 + \frac{1}{\beta a_s}\right]$$

$$\tau = \left[0.5 + \frac{9}{4\beta a_s}\right]$$

$\beta = \left[\frac{\omega}{2\nu}\right]^{0.5}$, $\omega = 2\pi f$ and ν is the kinematic viscosity of the water.

A customized field deployable system was developed using the laboratory transducer design parameters and a digital signal processor (DSP).

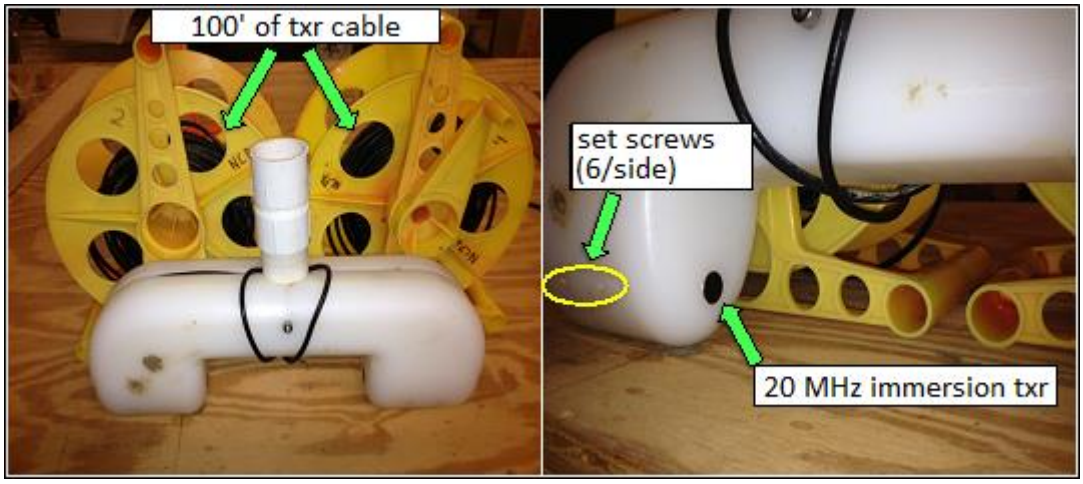

Figure 1 Field-Grade Transducer Casing

RESULTS

Using the laboratory and field systems concurrently, the calibration measurements show good agreement and a high level of reproducibility between the laboratory grade equipment and the new prototype system.

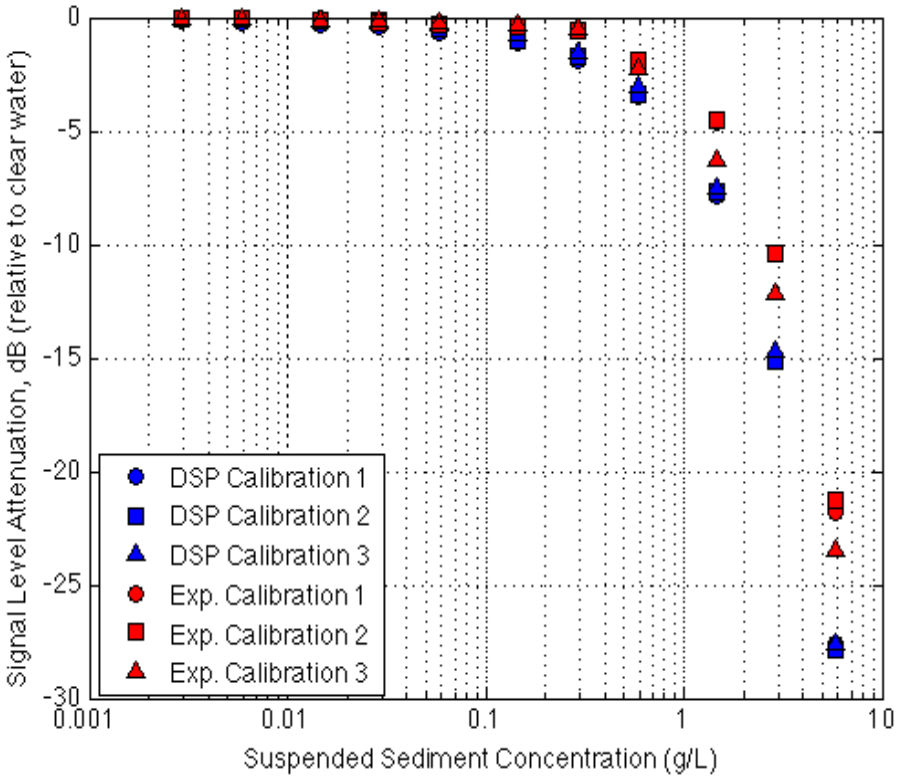

Figure 2 Comparison Plot DSP System vs. Experimental System

The red symbols represent the attenuation values computed by the verified experimental system during the three calibration experiments. The blue symbols represent the attenuation values that were found using the DSP system. Following the comparison, it was concluded the first well-defined signal drop was shown at 0.15 g/L. It is estimated that the upper detection threshold of the DSP system is ≈ 6.0 g/L.

Subsequently, the field system was deployed to monitor suspended fine sediment particles, less than 100 microns in diameter. In cooperation with personnel from the U. S. Geological Survey, the DSP system was deployed at Harris Bayou near Alligator, MS. The Harris Bayou watershed is a 71,592-acre watershed located in Bolivar and Coahoma Counties, Mississippi. The transducers were submerged in the bayou, and continuous in-situ measurements of fine suspended sediments were conducted. The acoustically measured suspended sediment concentration (SSC) data were compared with grab samples taken in predetermined intervals throughout the data collection period. Statistical methods were used to validate the accuracy of the acoustic prediction. However, field results were inconclusive, and the acoustic predictive model did not agree with the grab samples. Therefore, current studies are underway to examine the effect of water temperature on the acoustic prediction.

CONCLUSION

Multiple field trials were conducted at Harris Bayou to validate the prototype DSP system. A conversion scheme was successfully developed to convert the binary data from the field. The conversion routine can be used for future field trials. The acoustic SSC results were compared with the SSC found in the grab samples. It was shown that additional parameters, such as water temperature at near surface may be affecting the acoustic response of the system. Additional variation could result from the variation of pH, conductivity, and nutrient concentrations. This hypothesis should be evaluated in future work. It is recommended that an independent evaluation be conducted to determine if these factors have any effect on the acoustic response of the DSP system. Work is proceeding to calibrate the system with respect to temperature.

STUDYING SURROGATES TO ESTIMATE SUSPENDED SEDIMENT CONCENTRATIONS IN THE MISSOURI RIVER AT NEBRASKA CITY, NE

Extended Abstract

Jon F. Nania, Hydrologist, U.S. Geological Survey Iowa Water Science Center, Iowa City, IA, jfnania@usgs.gov

Fluvial sediments have various effects on river systems including adverse consequences for aquatic life, recreation, navigation, and reservoir storage capacity. Quantifying sediment transport is important in order to determine long-term trends in sediment transport, to understand the various effects from fluvial sediments, and to implement processes for minimizing adverse consequences. Traditionally, streamflow has been used as a surrogate to estimate instantaneous suspended sediment concentrations (SSC) and to compute sediment loads. However, streamflow alone may not be a reliable method for estimating SSC at locations that are effected by regulated flow, that have sediment inputs from a variety of sources, or have episodic sediment transport events which occur during a constant streamflow (Wood and Teasdale, 2013). Alternately, graphical methods for computing continuous concentration curves rely on interpretation supported by a subjective understanding of factors, often site-specific and undocumented, influencing sediment transport (Porterfield, 1972). To account for these factors, new techniques for using surrogates to estimate SSC are being developed and further study is needed refine these methodologies. The U.S. Geological Survey (USGS) has been studying three sediment surrogate methods at the Missouri River at Nebraska City, NE, streamgage.

The Missouri River at Nebraska City, NE, is a large river site, drainage area of 410,000 mi^2, and provides a unique study location with multiple and vastly different sediment sources. Sediment originates from the upper Missouri River with low SSC due to multiple dams, from the upper Platte River with Rocky Mountain snowmelt and lower Platte River alluvial sand, from runoff from the Loess Hills in Western Iowa with highly erodible aeolian silt soils, and from other local tributaries with agricultural runoff. This USGS streamgage, established in 1929 and operated in cooperation with the U.S. Army Corps of Engineers, is maintained by the USGS Iowa Water Science Center (IA WSC). Crews visit the site twice per week to collect measurements of streamflow and depth-integrated cross-sectional averaged SSC samples. Real-time streamflow data are computed from an established relation between stage, which is monitored real-time, and discharge which is updated routinely based on the streamflow measurements. Daily suspended sediment loads since 1957 have been computed by the USGS IA WSC using graphical methods for continuous concentration curves based on the sample results and daily streamflow, which is based on stage (Koltun and others, 2006). Averaged cross-section SSC samples since 1957 have ranged from approximately 100 milligrams per liter (mg/L) to 3,000 mg/L. Periodic analyses of the percent fine-grain material (less than 0.0625 mm) that is present in the SSC samples indicate material can vary spatially in the cross-section of the river and also vary temporally. The percent of fine-grain material ranges from less than 10 percent to over 90 percent (U.S. Geological Survey, 2014). Additional data collection for studying new surrogates at this location started in 2013 and is planned to continue through 2015 to include a variety of streamflow conditions. The additional data collection includes the installation of surrogate devices and more frequent analyses of the percent fine-grain material present in the SSC samples.

Three surrogate methods are being studied at the USGS streamgage on the Missouri River at Nebraska City, NE. These methods use turbidity, acoustic backscatter, and laser diffraction to develop a relation, by ordinary least-squares (OLS) regression, between SSC and the individual surrogate parameter. The dataset for each model is comprised of the cross-sectional averaged SSC samples and the corresponding recorded or computed surrogate values. The surrogate devices are mounted near the west bank in an area of uniform flow during a wide range of streamflow conditions. The Turbidity method uses turbidity data that are measured in formazine backscatter ratio units (FBRU) which has a broad operating range due to the data being calculated from infrared light at two backscatter angles. The turbidity data are recorded every 15 minutes by a data logger. The second method uses acoustic backscatter (ABS) measured by an acoustic Doppler velocity meter (ADVM) as a surrogate for SSC. Three ADVMs deployed at the site measure ABS recorded by a data logger every 15 minutes from each device. Two ADVMs have a frequency of 1500 kilohertz (kHz) and one ADVM has a frequency of 500 kHz. The 1500 kHz ADVMs are configured to determine if different measurement settings affect ABS during the same SSC conditions. The 500 kHz ADVM is installed to determine if model results at this site can be improved with a lower frequency. The third surrogate method uses laser diffraction technology to collect a volumetric measurement of SSC and of particle size distribution (PSD) divided into several size ranges. Water is pumped from the river for a short duration at one-hour intervals into a sample chamber where a laser is emitted through the sample volume. Logged every hour, volumetric SSC and PSD are measured depending on how the laser is diffracted through the sample volume. In addition to individual parameter models for SSC, combinations of some methods will also be used to assess models for SSC during varying particle size conditions. Combined models will determine if the different frequencies of ADVM data and the laser diffraction data for PSD together provide a better model for SSC at a site with such varying sediment sizes.

The use of surrogates at the Missouri River at Nebraska City, NE, streamgage, will provide significantly more data on sediment transport due to the frequency of the recording interval by each device. Rather than two cross-sectional averaged SSC samples per week, these surrogate methods can provide SSC information as often as data are recorded. The varying presence of fine-grain material at this site will also help refine methodologies to adjust for this condition. The results from this study will be used to identify the method that provides the best estimates for SSC in the Missouri River at Nebraska City, NE, and the applicability for use at similar locations.

INTRODUCTION

Characterizing the large-scale sedimentary make-up of heterogeneous riverbeds (Nelson et al., 2014), which consist of a patchwork of sediment types over small scales (less than one to several tens of meters) (Dietrich and Smith, 1984) requires high resolution measurements of sediment grain size. Capturing such variability with conventional physical (e.g. grabs, cores, and dredges) or underwater photographic sampling (Rubin et al., 2007; Buscombe et al., 2014a) would be prohibitively costly and time-consuming. However, characterizing bed sediments using high-frequency (several hundred kilohertz) acoustic backscatter from swath-mapping systems has the potential to provide near complete coverage of the bed (Brown and Blondel, 2009; Brown et al., 2011; Snellen et al., 2013), at resolutions down to a few centimeters, which photographic sampling could not practically achieve within the same time and with the same positional accuracy.

In shallow water, the physics of high frequency scattering of sound are relatively poorly understood, therefore acoustic sediment classification are almost always statistical (Snellen et al., 2013). Many such methods proposed to date are designed for characterizing large areas of seabed (Brown and Blondel, 2009; Brown et al., 2011) at relatively poor resolution (tens of meters to several hundred meters) and therefore rely on aggregation of data over scales much larger than the typical scales of sediment patchiness on heterogeneous riverbeds. In response to this need, Buscombe et al. (2014b, 2014c) developed a new statistical method for acoustic sediment classification based on spectral analysis of backscatter. This method is both continuous in coverage and of sufficient resolution (order meter or less) to characterize sediment variability on patchy riverbeds. Here, we apply these methods to multibeam echosounder (MBES) data collected from the bed of the Colorado River in Marble and Grand Canyons.

Sediment dynamics on the Colorado River in Grand Canyon National Park have been studied for several decades (e.g. Howard and Dolan, 1981; Rubin et al., 2002). Particular focus has been given to sandbars in large eddies downstream of tributary debris fans (Schmidt, 1990) because they are considered valuable resources by stakeholders and managers. Due to the severe limitations in sand supply imposed by Glen Canyon Dam (Howard and Dolan, 1981; Topping et

al., 2000; Hazel et al., 2006), understanding the effectiveness of sandbar management practices, such as controlled floods (Rubin et al. 2002; Topping et al., 2006; Hazel et al., 2010), and the long-term fate of sand in Grand Canyon over decadal timescales, requires construction of accurate sand budgets, which involves detailed monitoring of influx, efflux and changes in sand storage (Topping et al., 2000; Topping et al., 2010; Grams et al., 2013) and assessments of uncertainties in sand-budget calculations (Grams et al., 2013).

In order to estimate the sand budget, it is necessary to estimate what component of observed morphological changes is sand and what component is coarser. Grams et al. (2013) classified sand and coarse substrates using topographic roughness derived from digital elevation models, but the classification skill was estimated to be only 60-70%. In addition, sand bedforms had to be delineated manually, and validation was based on grain-size observations with positional uncertainties up to tens of meters. Because the morphology of the Colorado riverbed in Grand Canyon is mapped - to a large extent - using MBES (Kaplinski et al., 2009), the primary motivation for the present study is to examine how uncertainties in sand budgets can be constrained by producing maps of surface sediment types using the completely automated methods of Buscombe et al (2014b, 2014c) based on statistical analysis of MBES acoustic backscatter.

SITES AND DATA

MBES soundings, backscatter and underwater video camera images were collected in August 2013 from three short (approx. 500-1000m) reaches around sediment and flow gaging stations (Figure 1). Site 1 (hereafter, RM30), in Upper Marble Canyon at river-mile 30, is a relatively straight section of channel within the Redwall Limestone above Shinumo Wash. Site 2 (hereafter, RM61), in Lower Marble Canyon at river-mile 60, is within the Tapeats Sandstone just above the confluence with the Little Colorado River. Site 3 (hereafter, RM87), in Eastern Grand Canyon at river-mile 87, near Phantom Ranch within the Upper Granite Gorge, comprises two sections separated by a riffle and debris fan on river left. These sites were chosen to test scattering signatures of bed sediment because they collectively include a majority of the range of sediment, flow, geomorphic and geological settings found in this canyon river.

MBES data were collected using a Reson® 7125 multibeam sonar, operating at 400 kHz with a configuration that produces a 512 beam swath across a total subtended angle of 135°. This geometry permits swath widths of up to seven times the water depth. Each beam has a 0.5° across-track by 1.0° along-track angular width. Each echo is registered simultaneously by all 512 beams, which constitutes one ping. Pings are recorded up to 50 times per second. More details of sonar data collection are described in Kaplinski et al. (2009, 2014).

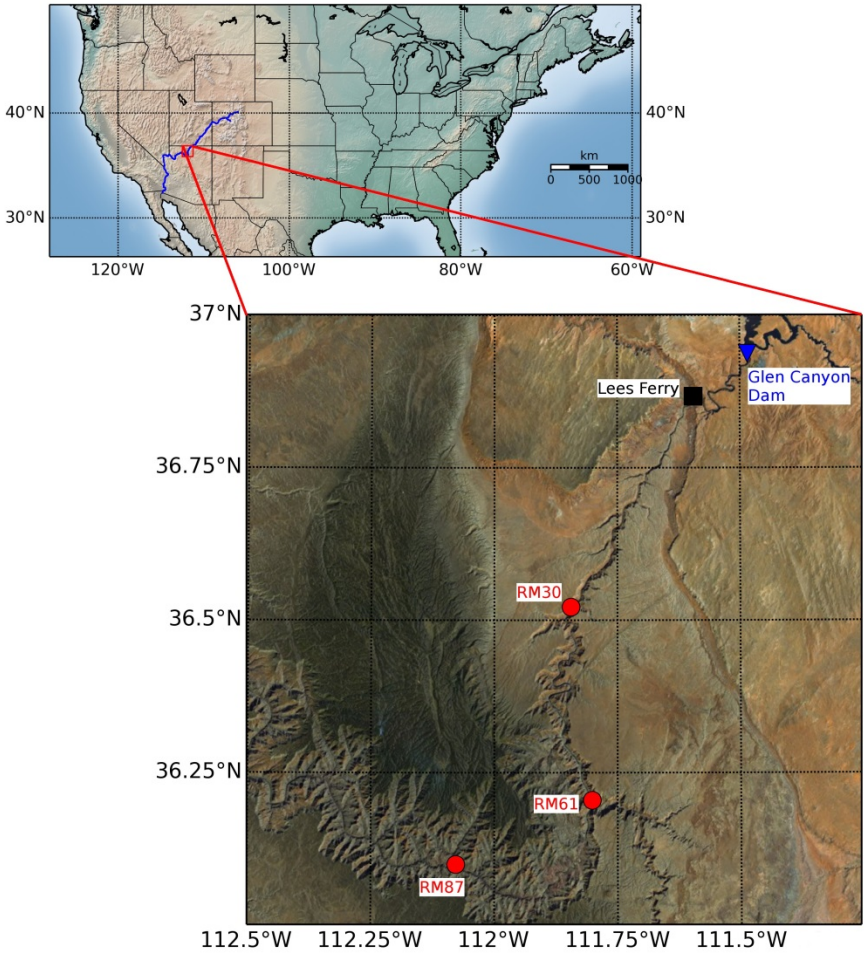

Figure 1 Map of survey locations on the Colorado River in Marble (RM30 and RM61) and Grand (RM87) Canyons.

A cabled video-microscope system was used to collected high-resolution (0.02mm/pixel) images of the bed. The system consists of a video camera fitted with macro lens, inside a protective metal housing. The transparent faceplate of the camera housing, fitted with LED lights for illumination, makes contact with the bed. Data collection involves navigating to each location, turning the boat to face the current, and lowering the video to the bed using an electric winch. The video is relayed instantly to the winch operator. For more details about the system, see Rubin et al. (2007, 2010). Coordinates of sample locations were measured by tracking the boat using a shore-based robotic laser-tracking system from established survey control points (Kaplinski et al., 2009). This method allows bed-sediment sampling at moderately high spatial density (up to tens of samples over tens of square meters) (Rubin et al., 2010) and hundreds of images can be obtained in a few hours. Another advantage of this approach over conventional physical sampling is that it samples only those sediments that are exposed on the bed surface. This is important because, given the high frequency of the MBES sound source, acoustic penetration into the bed is negligible, therefore the measured backscatter amplitude reflects the

composition of bed surface sediment (and possibly form roughness within the beam footprint) only.

The underwater video camera images were used to characterize bed-sediment, at a point, into three categories: 1) 'sand': homogeneous sandy surfaces (where no distinction was made between plane bed, ripples and dunes); 2) 'gravel': coarse substrates encompassing homogeneous gravels and sand-gravel mixtures (sand in the interstitial spaces of gravel clasts), in the size range deemed to be movable by typical flows; and 3) 'rock', a category which includes boulders, bedrock ledges, and cobbles large enough to be considered immovable by typical flows. These qualitative assessments were made by an experienced field technician operating the winch, based on both the image and the feel of the winch as the video housing hit the bed surface.

Figure 2 Underwater video images along a ~50m (river left to river right) transect at RM 30, showing typical sediment heterogeneity.

Another underwater video camera system - a towed video sled with a wider field of view, equipped with powerful lights and lasers for scale - was also used to observe the bed. These data were collected at a different time (May 2012) in the RM30 and RM61 pools, along with MBES data, and were used to assess the plausibility of sediment classifications applied to an earlier data set (outside the calibration).

DATA PRE-PROCESSING

Several quality control and quality assurance procedures are performed to ensure only high-quality amplitude data are used for bed sediment characterization. These checks, detailed in Kaplinski et al. (2009, 2014) and Buscombe et al. (2014b), include:

1. Patch tests to determine the offset angles and timing between the various system components.
2. Beam-angle tests are used to determine the uncertainty of soundings for all beam angles.
3. Quality assurance assessments performed in real time during the surveys by continuously monitoring across-track swaths and comparison between adjacent overlapping sweeps.
4. Manual sweep editing and systematically stepping through overlapping sweeps.
5. Automated spatial filtering procedures, designed to identify artifacts based on excessive bathymetric slopes; and incorrect beam locations.

The raw high-frequency echoes recorded by the receive beams MBES are corrected for beam geometry effects (angle of sound incidence and area of beam of the sloping bed) and radiometric effects (source and transmission losses) using the methods detailed in Buscombe et al. (2014b). Backscatter was corrected for water and suspended sediment attenuation using the median size and concentration of sand, and concentration of silt and clay. These were available every 15 minutes from gages in the same survey reach (Griffiths et al., 2012). It was assumed that the median silt grain size is 2 μm (Voichick and Topping, 2014). It was further assumed that sand and silt are homogeneously mixed through the water column. This assumption is physically unreasonable for sand. However, sand suspensions were so dilute so as to make negligible difference to the sediment attenuation calculation, so the assumption of homogeneous mixing was made for numerical convenience. For water attenuation corrections, measurements of temperature and salinity were also available every 15 minutes from sondes at each gaging station.

SPECTRAL ANALYSIS

Backscatter data from the three survey reaches were processed using the spectral analysis methods presented in Buscombe et al. (2014b) which use the (per beam, per ping) amplitudes of backscattered sound associated with time-of flight bathymetric soundings (range to the bed). This recorded amplitude is either the peak amplitude, or the amplitude associated with the highest phase-coherence between the source sound wave envelope and the echo wave envelope. Either way, it is considered the integral of the portion of reflected sound at incidence angle from all scatterers in the insonified area of the bed (the beam footprint).

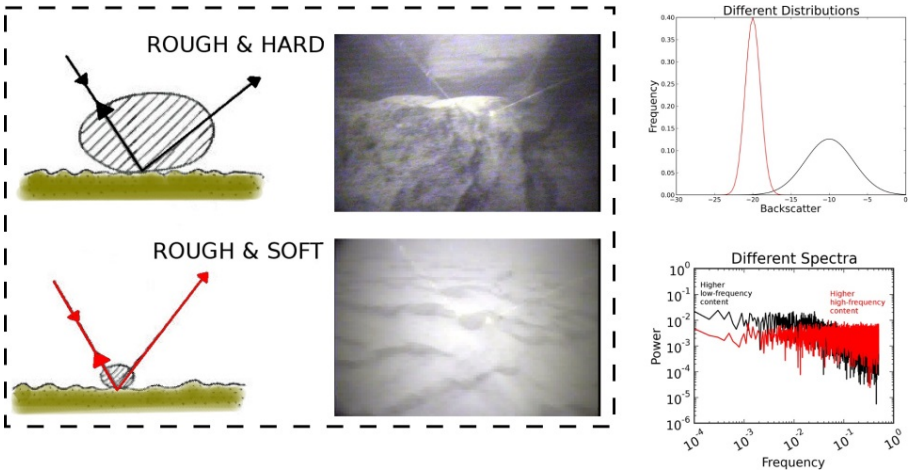

Figure 3 Schematic showing hypothesized backscatter distributions and spectra for rough/hard substrate (rock) and rough/soft substrate (rippled sand).

The method quantifies the variation in length- and amplitude-scales of backscatter over small areas of gridded surfaces, using windowed spectral (frequency domain) analysis (Figure 3). Because backscatter is a measure of the hardness (impedance) of a substrate, this approach is somewhat independent of the roughness of the topography, which may not be uniquely related to

a given substrate type (for example, the occurrence of gravel dunes). The method works by carrying out spectral analysis of gridded backscatter (the median value per grid cell) that has been detrended and tapered (Figure 4). Backscatter power spectra are computed to produce scale and amplitude metrics that collectively characterize the length scales of stochastic measures of riverbed scattering, termed `stochastic geometries' by Buscombe et al. (2014b). Backscatter aggregated over small spatial scales has spectra that obey a power-law in 1D (Figure 4). Relationships exist between stochastic geometries of backscatter and areas of rough and smooth sediments (Buscombe et al., 2014c).

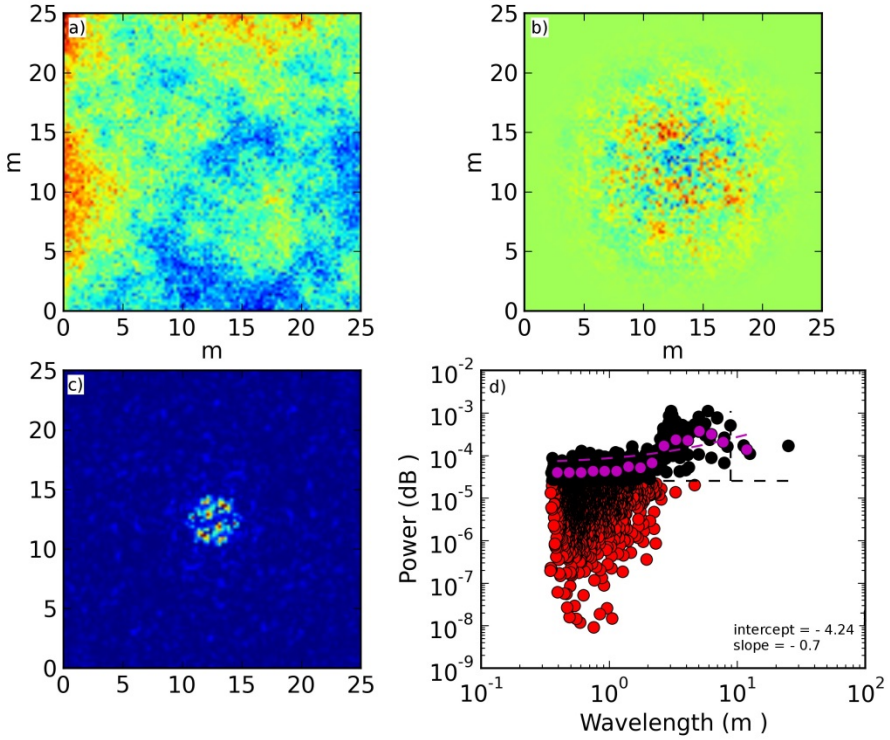

Figure 4 A window of backscatter (a) is detrended and Hann tapered (b). The 2D power spectral density of this surface (c) is collapsed to a 1D form (d) from which statistics are calculated (from the data that are statistically significant at the 95% level, shown as black dots) such as the slope and the intercept. These statistics have been shown to be sensitive to changing substrate type by Buscombe et al. (2014b, 2014c).

A grid size of 0.25 x 0.25 m was chosen for construction of surfaces because this was the smallest scale at which there were, consistently across sites, multiple usable soundings. A window size of 25 x 25 m was chosen based on examination of individual spectra and the criteria suggested by Buscombe et al (2014c). Windows are moved around the surface such that the outputs from one window are ascribed to the central cell of the window. The window is then shifted by a specified amount in space in 2 directions, and the calculations are repeated. This process is repeated until the entire surface has been analyzed by systematic windowing. A shift length of 0.25 m (1 grid cell) was chosen so the output surfaces were the same spatial resolution

as the input surfaces. In this configuration, the value in each output grid cell is the ensemble average of 1000 individual spectra for a window passing over that point.

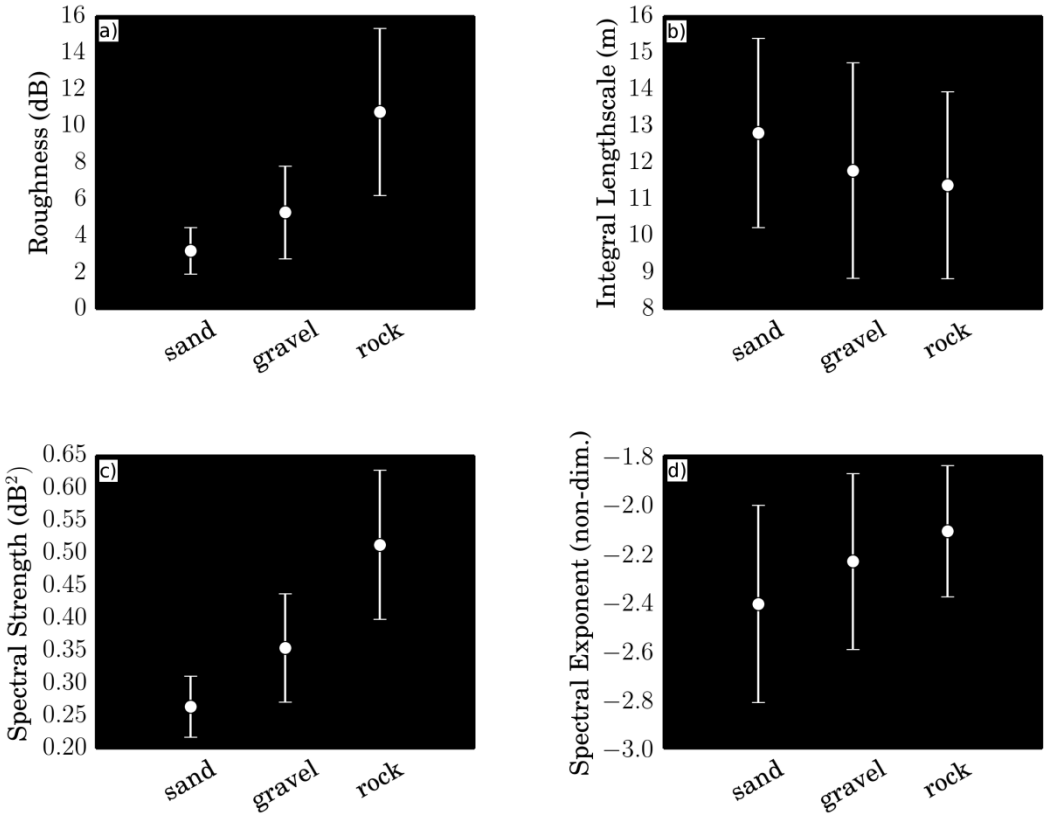

Figure 5 Example of spectral signatures of 3 different sediment substrates at RM 87. Roughness (a) is the root mean square variance in amplitude; integral lengthscale (b) is a measure of persistence; spectral strength (c) is a measure of power at low frequencies; and spectral exponent (d) is a measure of the rate of decay of power with increasing frequency. In each subplot, the dot represents the mean quantity per co-located substrate and the bars are the range of values.

SEDIMENT SPECTRAL SIGNATURES

Four parameters are calculated from each computed log-transformed spectrum, according to the methods detailed in Buscombe et al (2014b): 1) the spectral strength, ω, which is the intercept of the regression through the statistically significant portion of the spectrum, and a measure of the variance in the data at low frequencies (large wavelengths); 2) the spectral exponent, γ, which is the slope of the regression through the statistically significant portion of the spectrum, and a measure of the decay in power as a function of frequency, or the number of frequencies required to describe the data (spectral width) and therefore a measure of how complicated the data is; 3) the acoustic 'roughness', σ, which is the overall power in the spectrum over all frequencies; and 4) the integral lengthscale, which describes the lengthscale over which the surface is typically statistically significant. These 4 parameters were found by Buscombe et al (2014c) to have the

strongest correlations with co-located substrate types (Figure 5) identified in the underwater video streams. Of these, the spectral strength, exponent and roughness were used to develop an acoustic sediment classification because they have high between-substrate variability, low between-site variability, low within-substrate variability, and the magnitude of values scale with substrate size.

SEDIMENT CLASSIFICATION

Towards an aim of classifying each 0.25 × 0.25 m grid cell into three sediment types, Buscombe et al. (2014c) developed an approach based on decision tree learning. A decision tree (Breiman et al., 1984) recursively partitions the space into smaller homogeneous subsets using a set of binary condition rules such that the samples with the same labels are grouped together. The basic process is as follows: 1) for each attribute (spectral slope, strength, and roughness), find the feature that best divides the training data (attribute value at each substrate location) such as information gain from splitting on the attribute; 2) create a decision node that splits on the attribute with the highest information gain; and 3) recurse over the sub-lists obtained (at descendant nodes) by splitting on the previous decision node until no more splits are possible. More details are provided in Buscombe et al. (2014c).

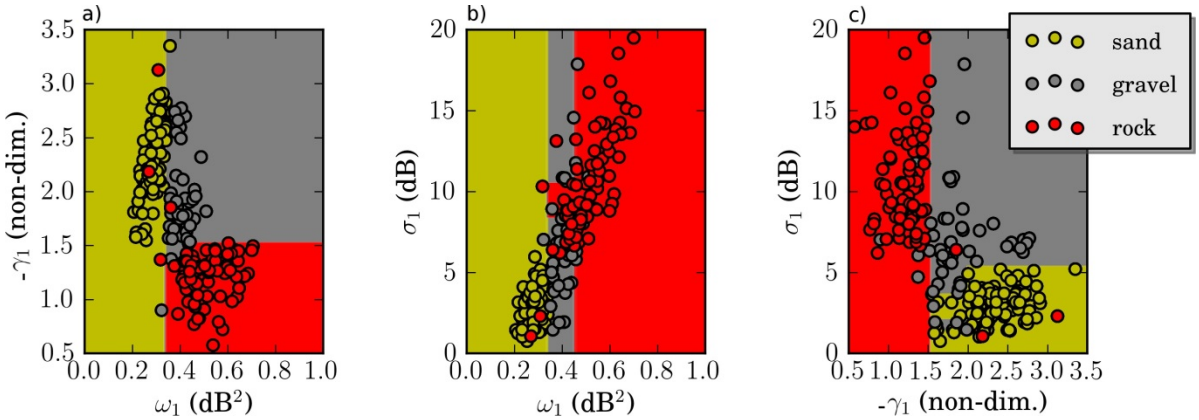

Figure 6 Decision surfaces of paired parameters based on aggregation of observations from RM30, RM60 and RM87 pools (circles), with a constraint that each decision node must have at least 50 samples: (a) ω and -γ ; (b) ω and σ; and (c) -γ and σ. The yellow, grey and red portions of the parameter space show where the decision tree would classify as sand, gravel and rock, respectively.

Classifications were carried out using a calibration based on data aggregated from all three sites (RM 30, RM 61, and RM 87). Trees were constructed with a single constraint that a minimum of 50 samples were required to be at a terminal node. The decision surface (Figure 6) shows the observations as colored markers, and a relatively straightforward partitioning of space between pairs of the 3 spectral parameters input into the decision tree algorithm. An example work flow from map of gridded corrected backscatter, to maps of spectral quantities with the same resolution, to final classification, has been provided for the RM 30 site (Figure 7). The classification skill for sand, gravel and rock is 97, 81, and 95 % respectively. Finally, another

sediment classification map is provided for RM 61 (Figure 8) overlying an aerial photo for geomorphic context.

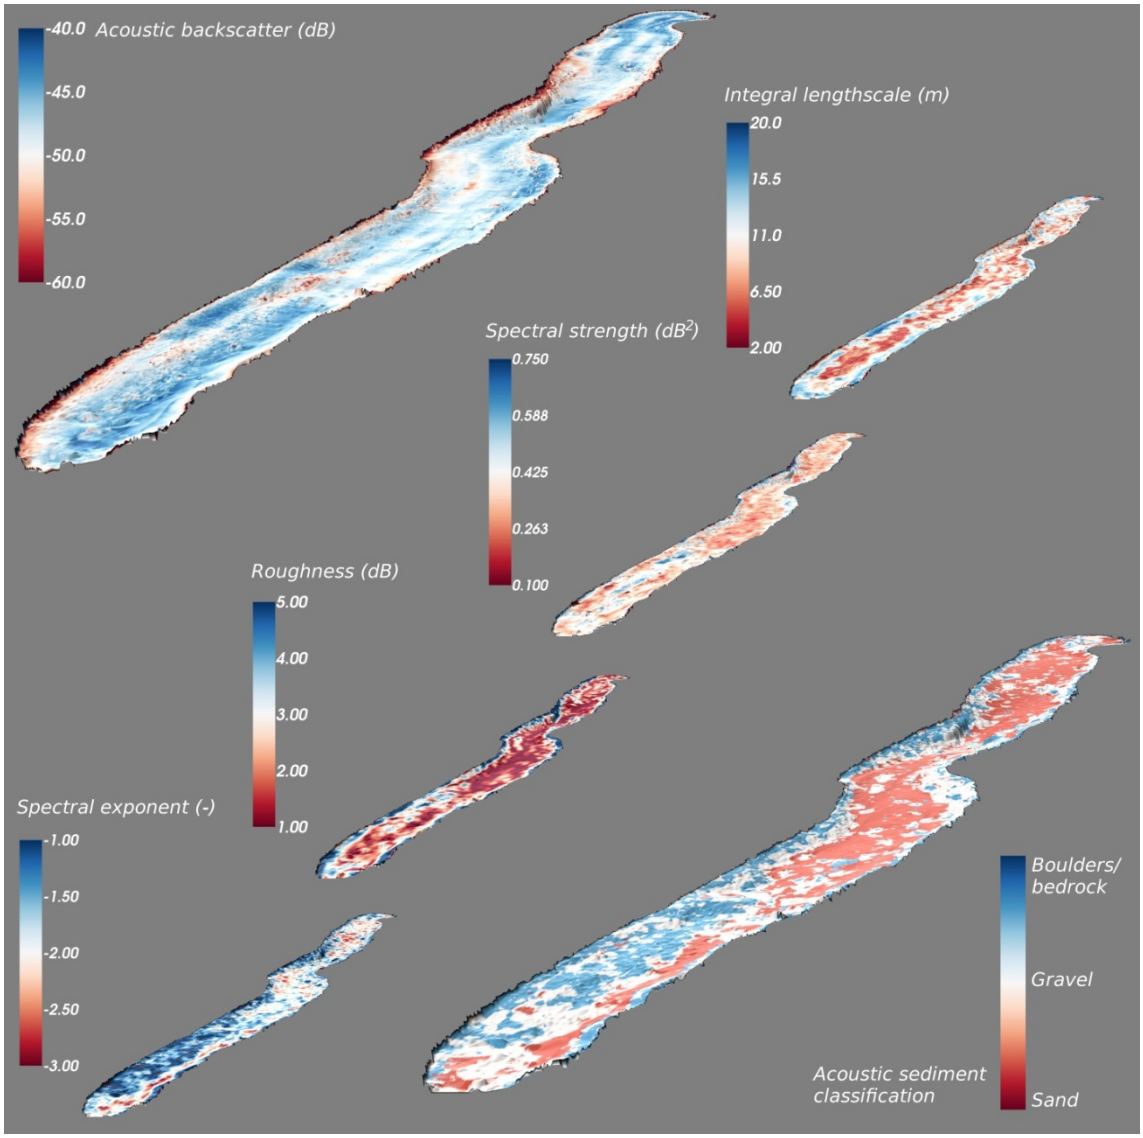

Figure 7 Example of processing stages from data collected at RM 30. Upstream to downstream is bottom left to upper right. Each map is a 3D DEM of the survey pool draped with a different quantity. From gridded acoustic backscatter (top), various maps of spatially explicit stochastic geometries (middle), derived from the windowed spectral analysis procedure, are merged in a decision tree classification to produce a map of sediment types (bottom).

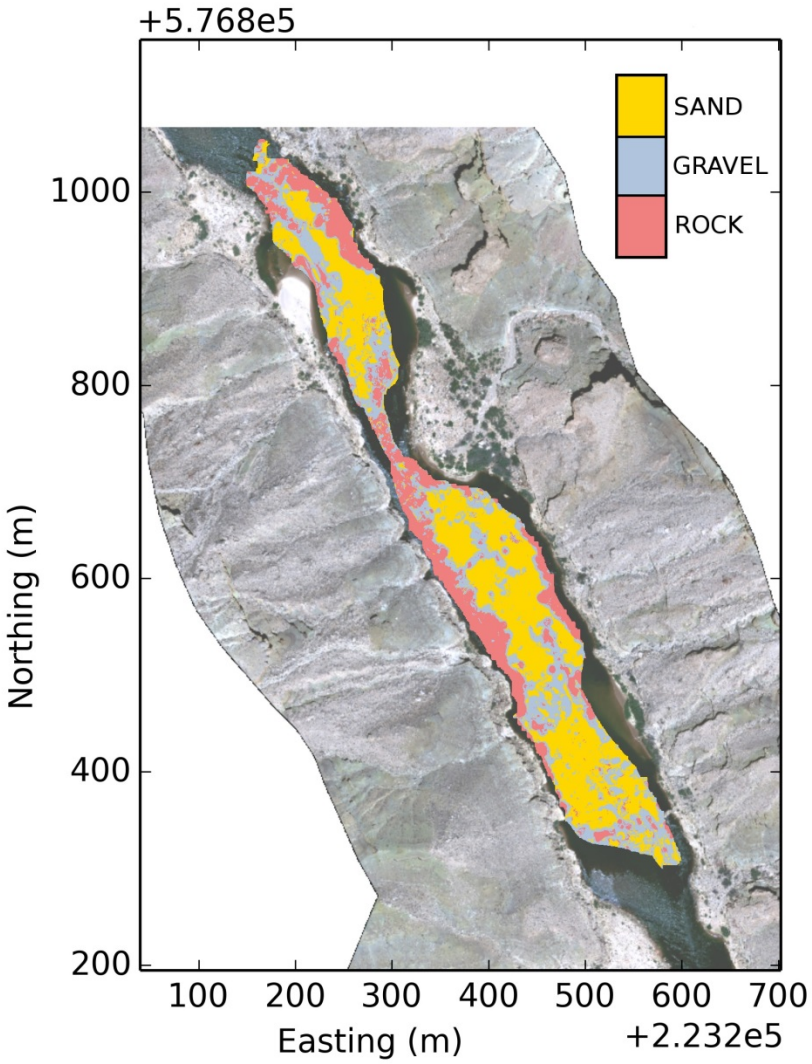

Figure 8 Example of sediment classification map at RM 61.

SUMMARY

Capturing the spatial variability in classifications of riverbed sediments is challenging using high-frequency hydro-acoustic instruments. However, the method proposed by Buscombe et al (2014b, 2014c) has been shown to be potentially useful to classify grain-scale roughness and hardness on the Colorado riverbed in Marble and Grand Canyons. The method uses high-frequency acoustic backscatter from multibeam sonar to classify heterogeneous riverbed sediments by type (sand, gravel, rock) continuously in space and at small spatial resolution.

Spatially explicit maps of the stochastic geometries (length- and amplitude-scales) of backscatter are related to patches of riverbed surfaces composed of known sediment types, as determined by geo-referenced underwater video observations. Statistics of backscatter magnitudes alone are found to be poor discriminators between sediment types. However, the variance of the power spectrum, and the intercept and slope from a power-law spectral form (termed the spectral

strength and exponent, respectively) successfully discriminate between sediment types. A decision tree approach to classifications was able to classify spatially heterogeneous patches of homogeneous sands, gravels (and sand-gravel mixtures), and cobbles/boulders with 95, 88, and 91% accuracy, respectively. This data-driven approach allows bed sediment classifications at unprecedented resolution.

APPLICATION OF CROSS-PLOT ANALYSIS ON A LEVEE USING TIME LAPSE SIESMIC REFRACTION TOMOGRAPHY AND ELECTRICAL RESISTIVITY TOMOGRAPGY.

Leti Wodajo, Graduate student, ltwodajo@go.olemiss.edu, University of Mississippi, University, MS; Dr. Craig Hickey, Associate Director for Applied Research National Center for Physical Acoustics & The University of Mississippi Research Associate Professor of Geological Engineering, University, Mississippi, chickey@olemiss.edu; Dr. Chung Song, The University of Mississippi Associate Professor of Civil Engineering, csong@olemiss.edu, University of Mississippi, University, MS.

Abstract

Out of the estimated 100,000 miles of levees in the United States a staggering 91% of these levees are not in an acceptable condition. Levee failures due to flood from hurricanes or heavy rainfalls occur without early warning and cause catastrophic damage. Therefore, the development of rapid assessment system of levees is greatly required to delineate weak locations and prioritize compromised locations. This study implements the use of surface based time-lapse geophysical methods known as seismic refraction tomography (SRT) and electrical resistivity tomography (ERT) on the Francis Levee Site. The Francis Levee site is located in Bolivar County, 0.5 miles west of Francis, Mississippi. The Francis Levee site was affected by the 2011 Mississippi river flood with multiple sand boil formations at the toe of the clay apron on the landside. Multiple geophysical surveys were conducted during spring 2014. It should be noted that similar methods of investigation are also applicable on earthen dams. The large number of dams in the Unites States and their risk of failure is alarming considering their old age and engineering design. Out of the 75,000 earthen dams in the US reported by the National Dam Inventory (2009), 56,000 are privately owned and do not undergo through investigation. This statistics necessitates the development of rapid and economical method of integrity assessment.

INTRODUCTION

The 2011 flood report by the Mississippi Levee Board, identified as many as twelve areas associated with seepage. The Francis levee site is one of the locations affected by the flood. Francis levee site (Station 150, 34° 5'9.48"N, 90°51'52.56"W) is located 0.8 kilometers west of Francis, Mississippi. During the 2011 flood event, three main sand boils were observed and mitigated by the construction of sand bag berms. After the initial mitigation, the US Army Corps of Engineers (USACE) extended the berm of the levee and constructed 16 relief wells. Figure 1 shows the location of the Francis Levee site on a Google map and an aerial photograph taken during the mitigation of the levee. This site was chosen for the geophysical study due to its close proximity to the University of Mississippi and the availability of borehole information.

Figure 1 Location of Francis Levee Site (left) and aerial photograph during mitigation (right)

Nimrod (2011) noted during the 2011 flooding the first sand boil surfaced at toe of the (berm) apron on the landside of the levee inside a drainage trench. The sand boil was mitigated with sand bags and by impounding water above the seepage area. After the first sand boil was mitigated, two additional sand boils surfaced 90 m to the northeast of the first one. Sand bags were used to mitigate these new sand boils. Figure 2 shows the locations of the three sand boils with red dots and a photograph of one of the later sand boils.

Figure 2 Location of sand boils (left) and mitigation of sand boil with sand bags (right)

The rapid assessment of the potential hazards associated with earthen dam and levee failures requires advanced screening tools to delineate, classify, and prioritize compromised locations. Screening such a large number of dams and levees requires the use of some type of remote sensing and/or geophysical technique. Geophysical methods provide a means of evaluating large areas of the subsurface rapidly. The results are can be used to optimize drilling requirements. Geophysical methods are also non-destructive and non-invasive with a simple and portable setup.

The overall objective of this study is to advance the use of remote sensing and multiple geophysical techniques for the early identification of compromised zones in levees. Geophysical monitoring and condition assessment of the Francis Levee was conducted with the use of different methods including seismic refraction tomography (SRT), electrical resistivity tomography (ERT), multichannel analysis of surface waves (MASW), electromagnetic (EM34) survey, and remote sensing surveys. The first phase of this study was conducted in the Spring 2014. Addition sets of measurement were planned for Fall 2014 during low water level but were not conducted due to weather and logistical problems.

In this paper, preliminary results from seismic refraction tomography (SRT) and electrical resistivity tomography (ERT) from the first set of surveys (Spring, 2014) at the Francis Levee site is presented. Focus will be on identifying seepage paths that start on the waterside of the levee and are responsible for the sand boil formations on the landside.

Uyank (2011) divided factors that can affect seismic velocities through soils and rocks into three main groups. Lithological properties of soils (grain sizes, grain shape, grain type, grain size distribution, amount of compaction, amount of consolidation and cementation), physical properties of soils (porosity, permeability, density, degree of saturation, pressure, and temperature), and elastic properties of soils (shear modulus (G), bulk modulus (K), Young modulus (E), Poisson's ratio (ν) and Lamé constant (λ)). All these factors are interrelated and affect the seismic velocity of soils. Therefore, analyzing 2D velocity distribution tomograms obtained from seismic refraction surveys provides valuable information on the integrity of the subsurface of dams and levees (Kim et. al., 2011, Bedrosian et. al., 2012, Moustafa et. al., 2012). In Particular, we expect that subsurface zones with higher permeability will have lower p-wave velocity. An area of seepage with fines washed out will have a high resistivity area if it is not fully saturated.

Electrical resistivity is a physical material property that represents the material's ability to oppose the flow of electrical current. The resistivity of a given soil (sand/clay) can have a wide range values due to differing porosity (ϕ), saturation (S_w), pore fluid resistivity (ρ_w), and the presence of clay content. This makes electrical resistivity an ideal method in the early detection of subsurface seepage through dams and levees (Cho et. al., 2007, Sjödahl et. al, 2008, Chinedu et al., 2013 Lin et. al., 2014, Al-Fares, 2014). Case (2012) applied the electrical resistivity method to a model embankment dam where resistivity tomograms are used to infer the subsurface conditions and assist in the resolution of zones susceptible to preferential flow.

SURVEY SETUPS AND PROCESSING

The data acquisition for seismic refraction surveying requires placing a line of multiple geophones on the ground surface and creating seismic waves using an impact source at a shot point location. The geophones record direct and refracted energies which are stored as waveform using a seismograph. The first arrival time is the relevant information required from the data. The first arrival time is the time it takes for the first seismic energy to travel from the source to a geophone. These first arrival times are determined for all geophones of the spread and are used to determine the velocity of seismic waves in the subsurface.

For the P-wave seismic refraction surveys, 48 vertical component 10 Hz geophones with 2 m spacing were used. The whole length of each survey line is covered using a 24-geophone roll-along. Data were collected with a sample interval of 0.125 msec and a record length of 2 sec. Shot records were collected 1 m offset from the first and last geophones and in between all geophones.

Depending on the quality of the data, multiple shot records might be obtained at one location and added together to increase the signal to noise ratio. An 8 lbs sledgehammer was used as a seismic source. Rayfract^{TM}, commercially available software, was used for the inversion of all seismic refraction data. Surfer^{TM}, commercially available imaging software, was used to build the tomograms after processing with Rayfract^{TM}. After first arrival times are picked, an inversion technique is implemented and a 2-D velocity tomogram is obtained which is a station location (distance) versus depth image showing the velocity distribution in the subsurface. The velocity tomogram is plotted using color scales depending on the value of the velocity obtained for each grid after processing the first arrival times. In addition to the velocity tomogram, a ray coverage tomogram, a plot showing the number of rays passing through the grids used to obtain the velocity tomogram is obtained. A high number of ray coverage is an indication that more rays traveled through that area of the subsurface. Low ray coverage on the other hand is an indication that the rays avoided to travel through that location and took a preferred high velocity path in the surrounding subsurface.

In this study, the electrical resistivity method is used to study the distribution of electrical properties in the subsurface by injecting electrical current and measuring the induced potential at various locations along the ground surface. The final product is a 2D distance versus depth electrical resistivity distribution tomogram. Electrical resistivity surveys were conducted using 112 electrodes with 1 m spacing. Dipole-dipole electrode configuration was chosen. Case (2012) showed that the dipole-dipole electrode configuration has a higher sensitivity to horizontal changes, depth of investigation, and horizontal data coverage. The whole length of each survey line is covered using a 56-electrodes roll-along. EarthImager 2D, a commercially available inversion software, was used for the inversion and imaging of all the electrical resistivity data.

RESULTS

Both the P-wave seismic refraction and electrical resistivity surveys were conducted along three 478 m long lines. Figure 3(a) shows the location of the three survey lines and the sand boils. Survey line 1 is on the water side of the levee, survey line 2 is on the berm of the levee and between the levee and the first sand boil, survey line 3 is on the landside of the levee and between the first sand boil and the two sets of sand boils. Each survey line starts at the northern end and progresses southward parallel to the levee.

To cover the entire 478 m length of each survey line, eight roll-along spreads for the seismic refraction and six roll-along spreads of electrical resistivity surveys were conducted. In this paper, results from three locations (rolls) along each line will be presented. The three selected locations are shown in Figure 3(b). These locations are chosen because they show anomalies that might be associated with a pathway for seepage responsible for the formation of the three sand boils on the land side of the levee.

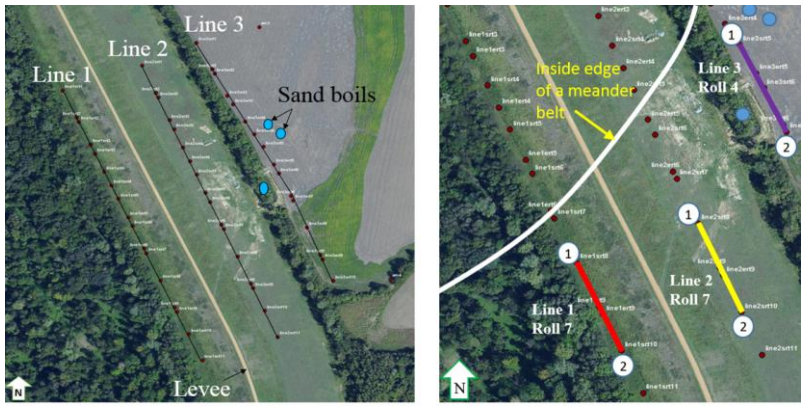

Figure 3 (a) Location of P-wave seismic refraction and electrical resistivity survey lines, (b) Seismic refraction and electrical resistivity survey lines

The white line in Figure 3(b) represents the inside edge of a meander belt from an old river channel composed of complex deposits and sedimentary structures. Figure 4(a) represents a typical cross-section of a meander belt (Saucier, 1994). The cross section shows that the old river channel is filled with vertical structures of medium-course sand and gravel at the bottom, fine-medium grained sand in the middle, and a very fine grained silt and sand at the top. There is a ridge and swale formation in the top silt and sand layer with swale fill clays. There are also clay drapes in between each vertical structure. Measuring from the edge of the natural levee the ridge and swale formation ranges from 6m to 9m of depth. The depth from the bottom of the ridge and swale formation to the bottom of the old river channel is site specific and ranges from 18m to 24m.

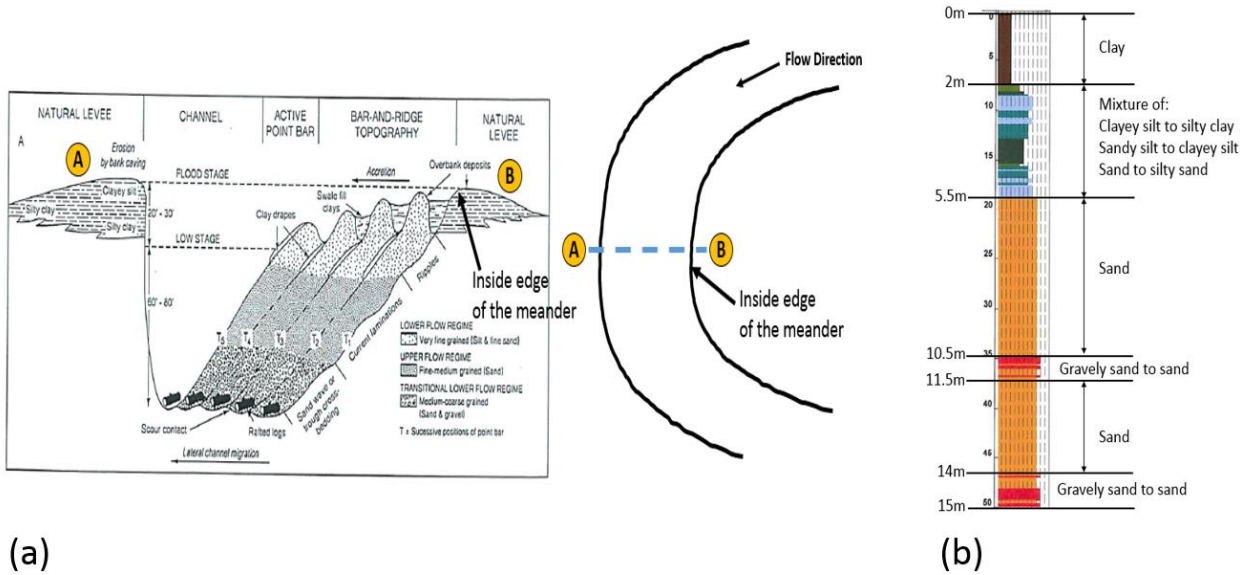

Figure 4 (a) Cross-section of a typical meander belt (Saucier, 1994), (b) An example of borehole information, modified from Brackett (2012)

An example of borehole information close to the three survey lines and inside the meander belt is shown in Figure 4(b). The borehole goes to a depth of 15m (50ft). Considering the 2m clay layer on the top is natural soil deposit after the ridge and swale formation, the bottom of the borehole lies just below the ridge and swale formation and inside the fine-medium grained sand layer in the middle.

After the 2011 flood event, the U.S. Army Corps of Engineers (USACE) mitigated the problem with an installation of water relief wells on the landside of the levee at the end of the apron (berm). Ground water elevation readings from all the relief wells were measured alongside geophysical measurements. Figure 5 shows the average ground water elevation based on the well readings and the above sea level (ASL) elevations of the three survey lines. Based on the ground water elevation shown in Figure 5 and the borehole information in Figure 4(b), the sand layer is fully saturated.

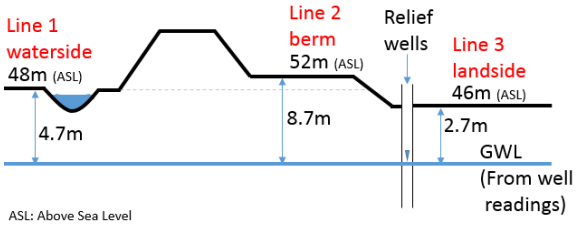

Figure 5 Ground water elevations from well readings

P-wave seismic refraction data was processed using a travel (arrival) time plot analysis for the survey on the water side. Water saturated soils commonly have p-wave seismic velocity of 1500m/s or higher. Based on the travel time plot analysis shown in Figure 6, the subsurface is interpreted to be a two-layer structure. The depth of the water saturated soil with a P-wave velocity of 1667m/s is at a depth of about 8m. The saturated zone predicted from the seismic data is much deeper than one on predicated based on the ground water elevation from the well readings.

	front shot	end shot	average
Vp1 (m/s)	312.5	344.83	328.665
Vp2 (m/s)	1666.67	1666.67	1666.67
Z1 (m)	7.69	7.94	7.815

Figure 6 Travel time plot analysis for survey line 1 (336m to 430m)

Based on the depth of the 2nd layer obtained from the travel time analysis, an initial model for tomography processing is produced with the 1666m/s is close to 8m (Figure 7). The resulting P-wave velocity tomogram in meters/second is shown on the right of Figure 7. There are two velocity anomalies with lower velocity between 15m and 25m of depth annotated with the box.

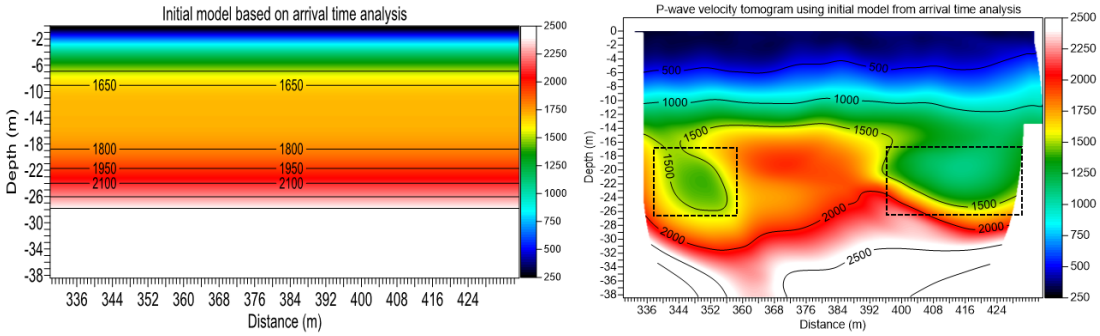

Figure 7 Initial model based on arrival time plot and associated velocity tomogram.

The same survey location in Figure 7 (336m – 430m) is processed again using the 1D-gradient smooth initial model obtained from Rayfract™. Figure 8 shows the Rayfract™ initial model on the top and the associated velocity tomogram on the bottom left and the ray coverage on the bottom right. The velocity tomogram shows similar features to the velocity tomogram in Figure 7 except for the less pronounced anomaly on the left. This indicates that the tomography results are not controlled by the initial model. RayfractTM generated initial models are therefore used for all refraction processing.

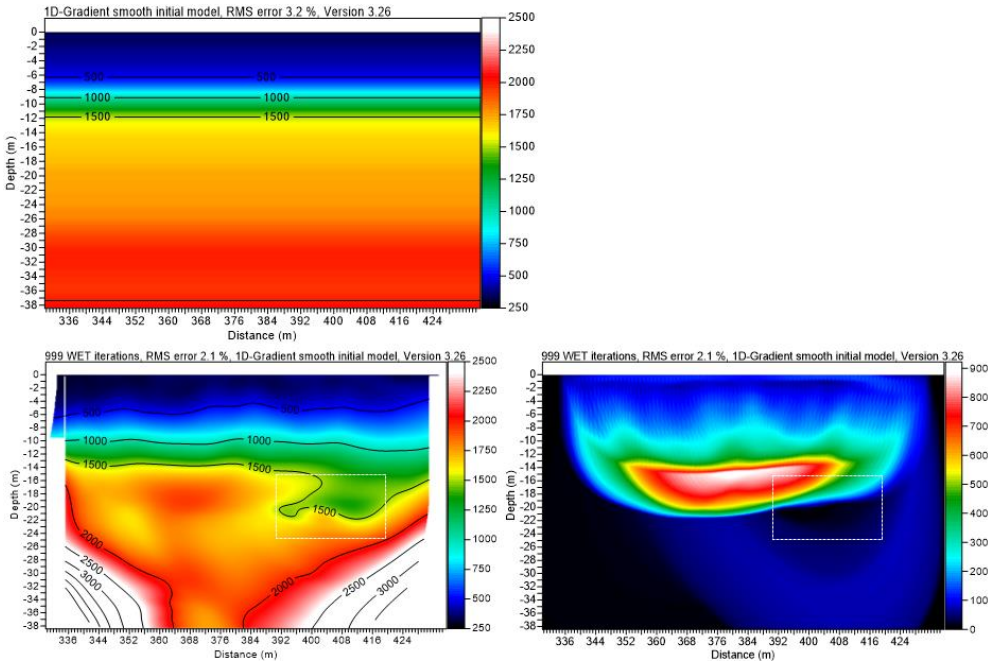

Figure 8 Rayfract™ initial model and inversion results

The velocity tomogram in Figure 8, indicates a P-wave velocity ranging from 350 m/s near the surface to 3000 m/s at 34 m below the surface. Comparing to the borehole information, suggest that the soil between the surface and the 500 m/s contour is clay at the top overlying a mixture of clayey silt to silty sand. Below the 500m/s contour line it is mostly sand. The 1500-1800 m/s P-wave velocity is usually used as indicator of ground water level, because the speed of sound in water is close to 1500 m/s. Seismic interpretation based on the velocity tomogram indicates that the saturated zone is at a depth of around 14m for the first half of the survey line. This depth is in much deeper to what would be predicted from the well readings.

With increasing depth, elastic properties such as bulk modulus will increase due to the added compaction of the overburden pressure (effective stress). An increase in bulk modulus with depth will cause an increase in P-wave velocity with depth. However, lithology can have an effect. Unsaturated sand is expected to have a lower P-wave velocity compared to clay due to high porosity and low bulk modulus. There is a pull down in the 1500 m/s velocity contour annotated with the white box in Figure 8. This location has a lower velocity compared to adjacent material at the same depth. The same location is indicated on the ray coverage tomogram (shown on the bottom right of Figure 8) with an area of low ray coverage. A combination of low P-wave velocity and low ray coverage is an indication of weak compaction or possible void formation due to an internal erosion (washing out of fines) caused by seepage. Seismic waves travel through a preferred path of high P-wave velocity, which can be associated with good compaction (high bulk modulus). When seismic waves encounter low velocity zones, they travel through surrounding areas with higher velocity zones and do not go through the low velocity zones which leads to the formation of localized low ray coverage areas as shown in Figure 8. Another possible reason for the low velocity area could be a zone of high pore pressure causing a decrease in the effective stress of the area and therefore dropping the velocity.

The results for the seismic surveying on the berm of the levee are shown in Figure 9. The P-wave velocity tomogram is on the left and the ray coverage tomogram on the right for. The above sea level elevation of the berm (line 2) is 4 m higher than the elevation on the waterside (line 1). This is due to the 4 m sand layer used for the construction of the berm. The water table indicated by the 1500 m/s contour line is at a deeper depth of 20m which is located 2m shallower on survey line 1. There is an anomaly of low velocity and low ray coverage indicated within the white box. The depth of the anomaly is too shallow to be seepage path associated with the sand boil formation.

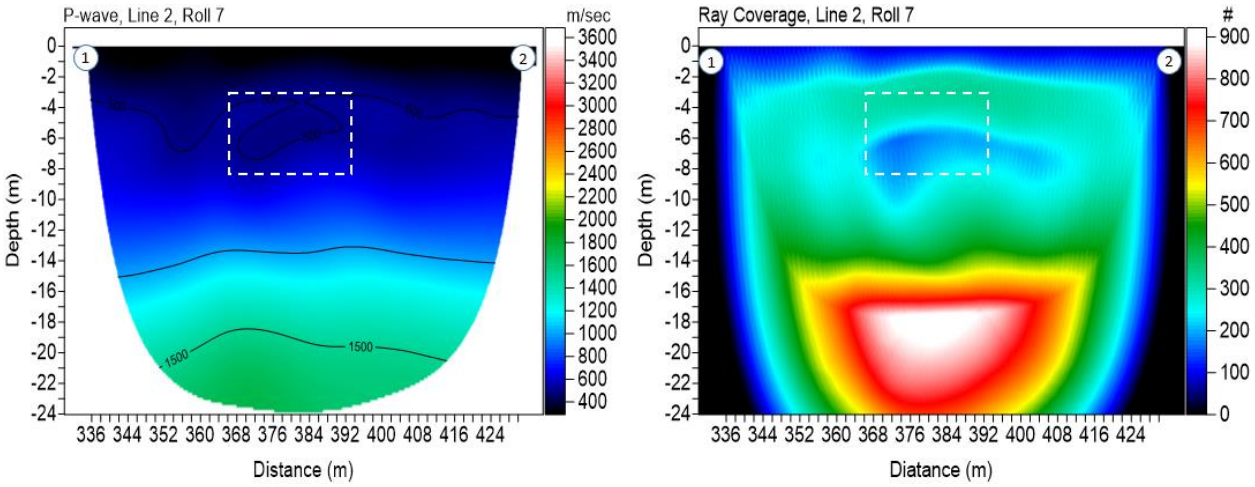

Figure 9 P-wave velocity (left) and ray coverage tomogram (right) for Line 2 (336m – 430m)

The results of the p-wave seismic refraction survey on the landside of the levee, line 3 (192m – 286m), is shown in Figure 10. The p-wave velocity tomogram is on the left and the ray coverage tomogram on the right. Surface elevation of survey line 3 is 2m below survey line 1 and 6m below survey line 2. The ground water table (1500 m/s contour line) is located at a depth of 13 m which is consistent with the observation on the other seismic surveys. The white box indicates an anomaly with a low P-wave velocity and low ray coverage which we interpret as an indication of a weak zone in the subsurface.

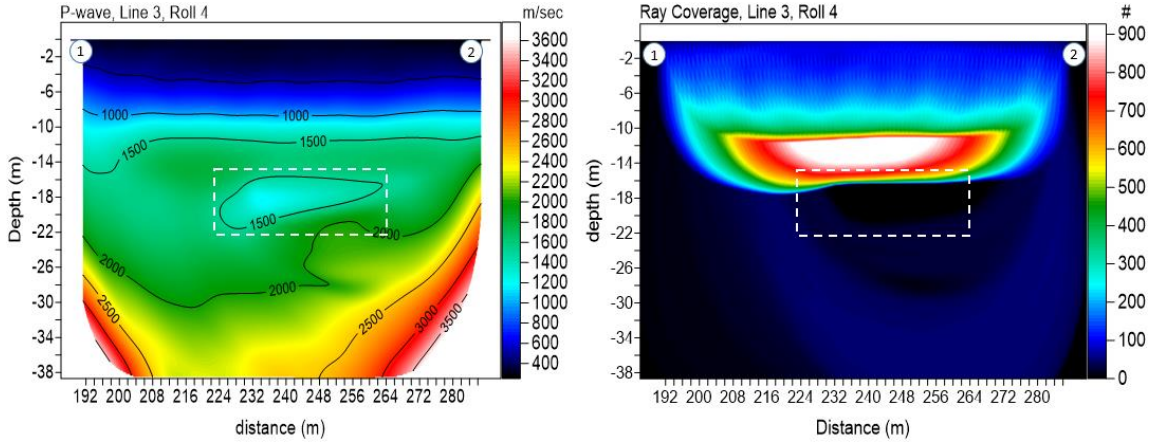

Figure 10 P-wave velocity (left) and ray coverage tomogram (right) for Line 3 (192m - 286m)

The electrical resistivity tomogram for Line 1 (336m - 430m) is shown in Figure 11. The electrical resistivity values are given in Ohm-m. Borehole information is added on the left of Figure 11 to aid with the interpretation of the result. The broken lines on the figure indicate different layers that are observed based on resistivity values.

In Figure 11, the low resistivity region between the top surface and the first broken line is an indication of the clay and silty sand layer. The same location is indicated in Figure 8 between the surface and the 500m/s contour line. Mavok, Mukerji, and Dvorkin (1998) showed that clays have lower resistivity (higher conductivity) than sands due to their high cation exchange capacity. In sands, electrical conductivity is solely based on the conductivity of the pore fluid; whereas in clays, in addition to the pore fluid electrical conductivity takes place through the charged and interconnected surface of the clays.

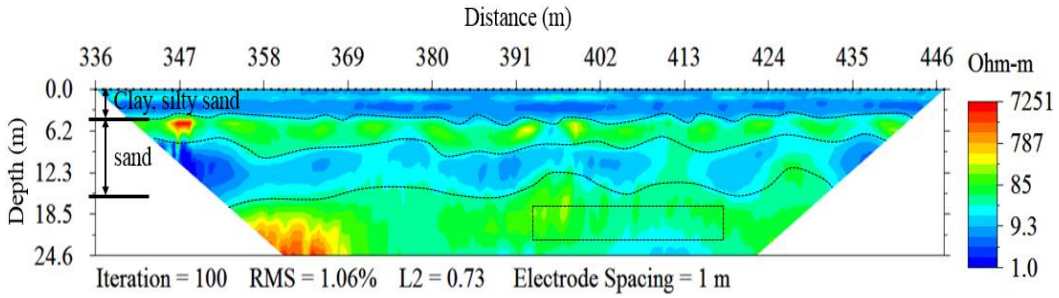

Figure 11 Electrical resistivity tomogram for Line 1 (336 m - 448 m)

The borehole indicates sand at depths greater than 5m. The resistivity data shows a layer between 4m and 8m consistent with sand. However, there is a drop in resistivity to 5-10 Ohm-m within the sand zone at a depth of 8m. Calculation using Archie's first law was made to check if such a low velocity in the sand layer can be achieved by a fully saturated clean sand. Using an electrical resistivity of 15 Ohm-m for the pore fluid and cementation factor for sand between 1.8 and 2, it requires unrealistic porosity to achieve a resistivity lower than 10 Ohm-m for clean sand only due to saturated water. This suggests that there must be a mixture of clay in the sand layer not indicated in the borehole information. The low resistivity structure may be due to the swale fill clays in the vertical structure of the meander geomorphology. The black broken box in the resistivity tomogram indicates the location of the seismic anomaly shown in Figure 8. There is no anomaly at that location indicating a possible location of seepage.

The electrical resistivity survey on the berm of the levee did not yield usable information due to high noise in the data. This problem is due to the high contact resistance of the top dry sand layer. Electrical resistivity survey works when there is good contact between the electrodes and the ground. Attempts were made to reduce the contact resistance by pouring salt water around the electrodes but only slight reduction around the electrodes was observed which did not improve the overall quality of the data.

SUMMARY

Multiple geophysical methods were conducted at the Francis Levee site. In this paper, part of seismic refraction tomography and electrical resistivity tomography results that focus on identifying seepage paths responsible for sand boil formations were presented.

Although electrical resistivity surveys are not completed as planned, results from seismic refraction tomography show an indication of a possible seepage path that can be associated with the three sand boil formations. The location of low P-wave velocity and low ray coverage anomalies observed in the seismic refraction results are shown with the green circles in Figure 12. A possible seepage path is drawn by connecting these anomalies. The three sand boils indicated with the blue circles are in close proximity to the estimates seepage path. It should be noted that the seepage path is perpendicular to the levee and follows the trend of the meander belt. Flow path parallel to the meander is expected because the soil deposit inside the meander has low compaction and high permeability compared to the native ground. Water can flow through the highly permeable sand and gravely sand and cause sand boil formations at locations where the overburden clay layer is thin.

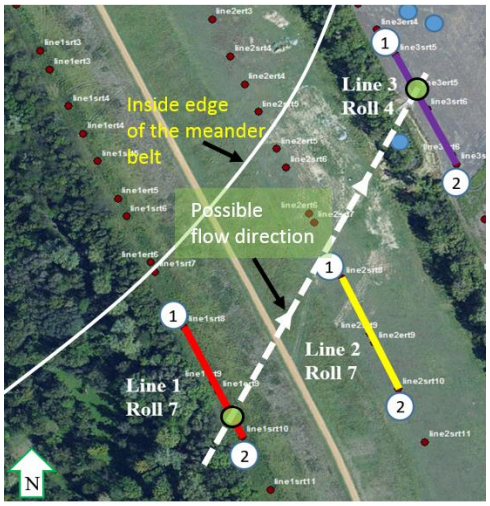

Figure 12 Possible seepage path

It is possible that water flows from the waterside to the landside through the path shown in Figure 12. At places where the overburden clay layer is thin above the seepage path, water can flow to the surface causing sand boil formations.

A SIMPLIFIED BATHYMETRIC SURVEY SYSTEM USING A MODIFIED SOUNDER GPS

Theodore L. Huscher, P.G., Geologist and David Griffith, Water Quality Specialist, USDA-Natural Resources Conservation Service, Lincoln, NE

Abstract

Nebraska NRCS improved the accuracy of bathymetric reservoir surveys and simplified field data collection and data analysis used to calculate sedimentation rates and stage storage determinations for dam rehabilitation work, using a sonar-based depth finder GPS unit with 3-D recording/mapping capability. Portability of the unit and set-up time was improved by mounting the unit's monitor and external antennae onto the lid of a standard 5-gallon bucket. The bucket provides cable storage and protection until used. The unit and battery were modified to use vehicle power adapters, resulting in a readily chargeable and transportable system that is easily set up for field use by a two-person field crew, rather than previous method requiring three or four persons, adding efficiency of operation. With proper software, data are translated into an up-to-date survey of reservoir bathymetry. Data must be corrected for the depth of transducer below water level, the measured reservoir water level, and errant shallows readings caused by minimal depths or false shallow readings due to signal reflection off vegetation. Shallows, vegetation, and other non-germane features are visually confirmed in the field before data synthesis in the office. Technical aspects of system set up, and advantageous features, use of the equipment, helpful suggestions and cautions are highlighted, presenting optimal utilization of this system.

PRACTICE AND PROCEDURES

The Nebraska USDA-Natural Resources Conservation Service (NRCS) adapted a Garmin GPSmap 536s[1] sounder/depth finder system to a standard 5-gallon bucket lid-mount for quicker, more efficient bathymetric survey data collection (Figure 1). This system provides for ease of transport, set up and storage (Figure 2), and needs only a boat and two people to operate (Figure 3). Utilizing a high sensitivity global positioning system (GPS) receiver and dual-beam transducer (sonar transponder) (Figure 4) to plot location and water depth, the system transfers stored data using a Secure Digital (SD) card for rapid download to a computer. Data processing involves opening the *.adm file extension, and loading it into the MapSource® software program, transferring it and saving the data as a text file.

[1] The use of trade names of all commercial products mentioned in this paper shall not be construed as endorsements by the USDA-NRCS of these products. They are presented for informational purposes only.

Figure 2 Depth finder system components: Garmin GSPmap 536s sounder/depth finder, dome antennae (both mounted on bucket lid), battery charger with vehicle adapter plug, 12V battery with vehicle adapter socket, and transducer clipped to bucket rim. Top of transom mount visible at lower right. The Garmin monitor cover shown removed at lower middle.

Figure 3 Manual depth readings are used to verify depth finder readings. This is done to confirm depth finder accuracy and/or determine the need for a correction factor.

Figure 4 Transducer (lower left) shown where it is to be bolted to the bottom of the transom mount and depth adjusted on site. External GPS antennae shown mounted to bucket lid.

The text file is cut and pasted into an Excel spreadsheet, processed and saved as a *.csv file extension format for import into the ESRI ArcMap GIS program. ESRI ArcMap is used to analyze the data and display the map. The shoreline is digitized from the National Agricultural Imagery Program (NAIP) imagery. The *.csv file can be imported and overlaid onto the imagery. The 3D Analyst routine in ArcMap is used to create a Triangular Irregular Network (TIN) of the data points and the shoreline (Figure 5). The TIN creates bathymetric contours and enables calculation of reservoir volume. Surveyed benchmarks and the inlet riser structure elevation serve as points of known reference. Shoreline points serve as the zero contour to tie bathymetric data to the surrounding ground topography (Figure 6). The distance of the transducer below the water surface is measured (Figure 3) to provide a plotting correction factor for the data processing phase of the survey.

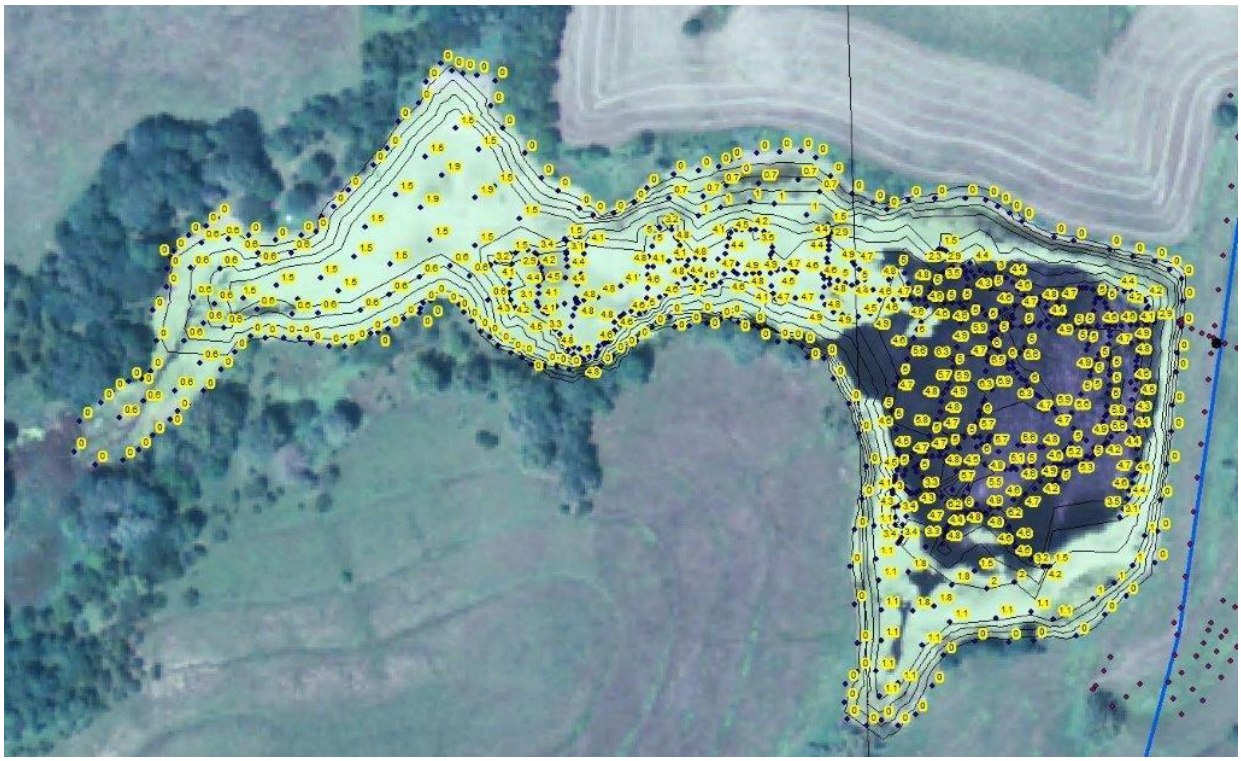

Figure 5 Map of plotted waypoints with extrapolated bathymetric depths, contours and surveyed zero elevation shoreline overlain on current aerial image.

Optionally, a measured keel depth, or a tape measurement of the (negative) distance from the transducer to the water line, can be entered allowing the unit to correct the transducer depth directly for that survey. Errant shallow depths, below the instrumentation sensitivity threshold, and the occurrence of vegetation that may obscure or influence bottom depth readings are corrected during the data rendering (smoothing) phase of the survey plotting. These corrective measurements should be confirmed during the survey by measuring the water depth to reservoir bottom, and top of vegetation, from water level using a range pole, survey rod or survey grade GPS, recorded, and compared to the depth measurement displayed on the unit (Figures 3 and 7).

Figure 6 Shoreline survey using survey grade GPS system provides a zero depth for bathymetric survey.

Figure 7 Wadable lake bottom surveyed with GPS, extending to depth/shoreline. This is the preferred way to confirm location and depth to adjust and correct depth finder readings if necessary.

The system allows for use of two people in the field; a boat driver and bathymetric survey equipment operator. Using two people provides for safety, increased speed, accuracy, and efficiency in conducting a bathymetric survey, as opposed to using a smaller or larger team. The team coordinates to prepare the boat for launch, system set up, adjusting the transducer to a transom mount assuring a proper and equipment safe reading depth, and connecting the transducer cable to power (Figures 8 through 13). Once powered up the unit requires a short time to acquire a satellite signal. A calm weather day on the water is preferred for more accurate data collection as well as general boating safety.

Figure 8 On-shore preparations. Transducer connected to transom mount (lying on its side on back seat of boat) with cable electrical running to depth finder mounted to bucket lid. Survey rod, used to confirm depth against finder reading, is shown at boat's starboard side.

After the transducer is in place, the desired chart/sonar split-screen readout is selected to simultaneously show geographic location and depth to bottom (Figure 14). A pre-loaded (or integrated) U.S. inland lakes map can be used to indicate nearby features and landmarks. However, shoreline accuracy is questionable and should be monitored visually. Signal reception is greatly enhanced with the use of the external GPS antennae, with the bucket lid serving as a convenient location for mounting (Figures 2, 4, 8 and 12). Heading and north arrow are also displayed and, once moving, boat speed by GPS as well. A minimum depth warning signal can also be programmed into the system.

Figure 9 Transom mounted transducer about to be lowered into water.

Figure 10 Close-up of transducer mounted to transom mount, about to be lowered into water and then depth adjusted.

Figure 11 Transom mount screw clamp being tightened and transducer adjusted to proper reading depth. The transducer depth is then measured from the water surface (and recorded as a correction factor).

Figure 12 Cable connection from depth finder (right) to transducer cable (left).

Figure 13 Power cable connection from depth finder plug (right) to 12V battery socket (middle).

When operating the system on the water, the forward facing boat driver watches for hazards, steering the boat for complete coverage of the reservoir pool using landmarks where possible. The backward facing unit operator collects depth data by marking waypoints with the unit, checks for measurements coverage and data gap filling via the unit's map display, calls out displayed depths to let the driver know when shallows approach and monitors areas behind the boat. This arrangement allows for ready communication between boat driver and unit operator to coordinate efforts and concerns.

There are many advantages to this system. The chart/sonar split-screen display allows for real-time situational monitoring in three dimensions and improves overall reservoir bathymetry coverage (Figure 14). The recording of depth measurement points or waypoints is simplified by toggling back to split-screen depth and map view to observe the locations of recorded waypoints. This process simultaneously facilitates selection of the next waypoint while monitoring depth to avoid shallows. The real time read out also allows the unit operator to readily see where the boat is located and to notify the boat driver which direction to drive the boat to complete coverage of the area while the boat driver watches for visible hazards such as potential emergent structures, vegetation, trees, stumps or known or suspected shallows. Waypoints can be collected as frequently as desired without requiring the boat to stop. Map scale can be adjusted for fine-tuned gap filling by zooming in and out. A scale bar and distance display show the current map scale setting.

Figure 14 Dual display depth finder monitor readings of location, heading (top) and depth (bottom).

Shallow depths of approximately one foot or less should be avoided because they are insufficient for signal rebound and accurate reading by the transducer. Shallow water causes the unit to repeat the most recent shallowest depth, alerting the unit operator by blinking a continuous single depth reading, e.g., 0.9 foot, and the unit's depth recording capability is thus frozen. Waypoint recording should be halted and the depth noted so the erroneous data can be adjusted later. To return the unit to normal operation, the system is then taken to water deep enough to provide signal reception to clear the sonar. Generally water depths approaching four feet will suffice to auto reset the unit. Waypoint recording may then resume. Mud-churned waters may also cause the signal to be interrupted or to erroneously read as too shallow. These errant depth readings and time it takes to reset the unit can greatly increase the time needed to conduct a bathymetric survey in the field and data correction back at the office.

If a shallow water alarm depth is not programmed into the unit prior to commencement of the field work, attention must be paid when the depth reading begins to blink on the display. Calculating a reasonable warning depth alarm-level may take some trial and error through exploring shallower areas to determine the minimum depth resulting in the sonar fouling. By adding an additional "cushion value" to the established minimum depth for an accurate measurement, more time is available to maneuver away from the shallows when the shallow

water alarm is activated as the system alerts the crew to the hazard. This results in minimizing unnecessary delays and maximizing field time productivity.

Monitoring current depth read outs is critical to look for drop offs, channels, and to avoid shallows, the latter of which can cause problems for the boat motor propeller and sonar system. The display scrolls the "bottom" surface across the screen while reading depths and adjusting the scale when greater depths are encountered. An alert team is one that monitors shallows both visually from the boat and by watching the unit's depth display. Hazards are thus avoided and the survey will proceed in an overall safer and more time-efficient manner.

If sonar reflects off benthic aquatic vegetation rather than the bottom, an erroneous (too shallow) depth reading may result. Conducting periodic soundings with a measured weighted line or survey rod can help validate bottom depths while measurements from the water surface to the top of the plants can help determine an average height of subaqueous vegetation (Figures 3 and 7). A correction factor can be calculated accordingly where depth measurements appear to be too shallow due to vegetation reflection readings. This correction factor must be added later into the bathymetric survey plot with special attention to areas with vegetation that are visually confirmed and noted, as previously discussed.

The internal storage capacity of the lidded 5-gallon bucket allows for a convenient, mostly buoyant place to store cables, the 12 volt dry cell battery, operator's manual, tape measure and charger (removed before taking into boat) (Figure 2). The lid-mounting of the system monitor and external GPS antennae (Figures 1 and 2) provides a ready-made recording station for the seated unit operator. The 12-volt dry cell battery can be wired to a vehicle power outlet (socket or "female") adapter (Photo 13). Some commercially available 12-volt battery chargers come with a versatile quick connect harness adapter for use with a vehicle power adapter "male" plug. The depth finder unit's power wiring harness can be wired to terminate as a vehicle power adapter plug. This battery adapter system provides for greater versatility for charging the battery in the office, on the road or in the field from a vehicle's power outlet. It also enables quick connection to the depth finder unit.

RESULTS

Nebraska NRCS bathymetric surveys were previously conducted by a three person boat crew consisting of; a boat driver, a technician to type depth measurements into a survey grade GPS rover unit as soundings were called out by a third person using a survey rod to sound the bottom. Often a fourth person was needed onshore to set up and guard a GPS base station reception unit to prevent tampering or theft. The previous system also required a near or complete stop of the drifting boat to obtain an accurate depth sounding measurement and GPS fix to establish location, all of which added time to complete the field survey data acquisition.

The changes implemented simplify how Nebraska NRCS conducts its bathymetric reservoir surveys. The time required conducting surveys, and the number of necessary personnel is dramatically reduced. The streamlining of data collection, and utilization of state-of-the-practice sonar equipment result in a significant increase in time efficiency, improve personnel safety in the field, and more precise bathymetric mapping.

SUBSURFACE HYDROLOGIC EFFECTS ON SEDIMENT DEPOSITION

Zhaoxia Li, Huazhong Agricultural University, Wuhan, CHINA, zxli@mail.hzau.edu.cn

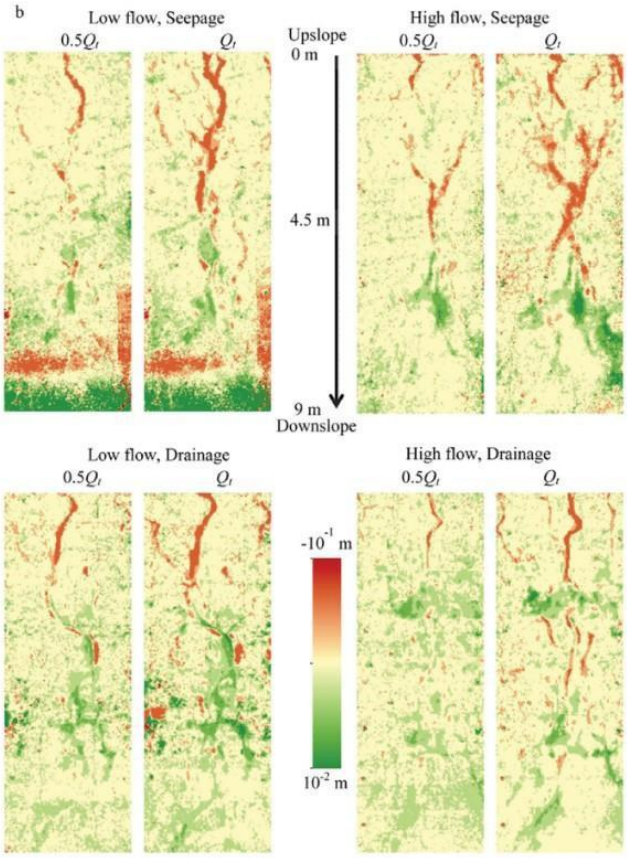
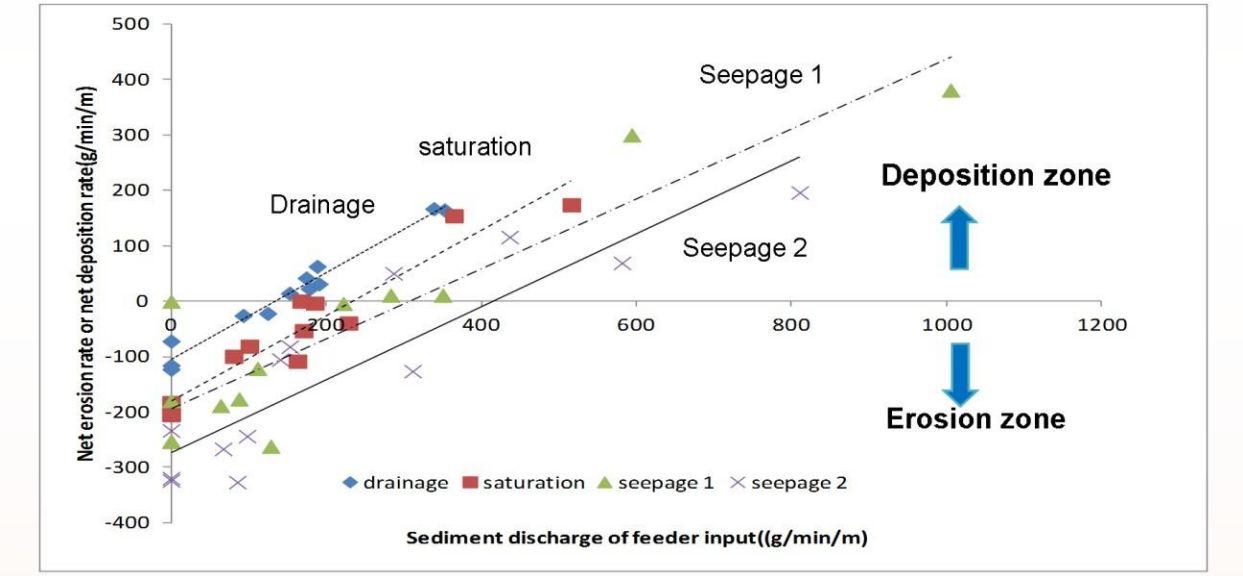
EXTENDED ABSTRACT

Quantification of soil erosion processes has been traditionally focused on soil detachment and sediment transport while efforts in quantifying sediment deposition process are relatively minor. Although soil erosion has been considered as a surface hydrologic process governed by the mechanics and hydraulics of the rainfall and surface flow, there are increasing numbers of literature evidences showing effects of subsurface hydrology on soil erosion processes, some recent examples: Fox et al., 2007; Chu-Agor et al., 2008; Nouwakpo et al., 2010. There are many components of the sub-surface hydrology that may or may not have any impacts on soil erosion. The specific component we are interested in is the near-surface hydraulic gradient which controls whether surface water flows into, i.e., downward drainage, or out of the soil surface (upward seepage). These findings show that as the near-surface hydraulic gradient is shifted from a natural gravity drainage condition to an upward seepage (artesian) condition, soil erosion is greatly enhanced. The question is whether the change in the near-surface hydraulic gradient affects the sediment deposition process.

In a recently published paper from a rainfall simulation study conducted in a laboratory 3.7-m (w) by 9.7-m (l) soil box, we observed the further advancement of the deposition zone when the soil box was free drained as compared to when the box was set to seepage (Nouwakpo and Huang, 2012). This is illustrated here where the deposition areas, shown in green, appeared further into the upper edge of the soil box under drainage (lower graphs) vs. under seepage (upper graphs) (reference here). This graph also shows deeper and more pronounced rills (darker red color) under the seepage condition. The net sediment delivery measured at box outlet supported prior findings of a higher sediment delivery under the seepage condition. Although we have visual evidences of soil profile drainage may have enhanced the development of sediment deposition areas, we need quantitative results to support this observation.



We designed another soil box system specifically to quantify sediment deposition. The box system contains a sediment source box that feeds runoff into a 5-m long rill channel which has water table control to set the rill channel to free drainage, saturation or seepage. The sediment source box and the rill channel have their own programmable rainfall simulator such that the amount of runoff from source box and the study channel can be separately controlled. By regulating the amount of sediment from the source box, the rill channel can have net erosion when the feed sediment at the top of the rill channel is less than the discharged sediment at the outflow end of the channel. Net deposition in the rill channel occurs when the inflow feed sediment is greater than the outflow sediment. For the results shown in this presentation, the rainfall intensities for the feeder box and rill channel were kept constant while the subsurface hydrology of the rill channel was set to one of the following: free drainage, saturation, low seepage (240 ml/m2/min) and high seepage (480 ml/m2/min). For each hydrologic treatment, the amount of feed sediment was varied, by varying the fraction of the feeder box surface covered by a furnace filter, from zero to a maximum rate that the feeder box could generate. Hence, the rill channel went through a transition from net erosion with low sediment feed to net deposition with high sediment feed.



The graph shows the sediment feed rate (x-axis) and net erosion or deposition (y-axis), which is the difference between the feeder input to the rill channel and the rill channel output. As the subsurface hydrology of the rill channel is shifted from drainage, to saturation and seepage, the results show increased erosion and decreased deposition. In other words, soil drainage not only reduces soil erosion, it also enhances sediment deposition. Conversely, saturation and seepage conditions will enhance soil erosion and hinder sediment deposition.

Our results present some challenges in the current thinking of soil erosion processes. If we define the equilibrium sediment discharge as the crossing point from net erosion to net deposition, then this amount increases as the rill channel is shifted from drainage to seepage regime. In our case, the erosion-deposition crossing varies from ~130 to 410 g/m^2/min when the subsurface hydrology changes from drainage to seepage.

In the current erosion model concept, the equilibrium sediment discharge, when neither erosion nor deposition occurs, can be considered the sediment transport capacity, or Tc. However, current concept of Tc is solely based on surface hydraulics and sediment characteristics. In this study, the same soil was used in the feeder box and rill channel, and the same rainfall rate was maintained, hence surface hydraulics and sediment properties were invariant. The challenging question is what is Tc?

The second challenge in current erosion modeling concept is the calculation of sediment deposition. Currently, sediment deposition is based on surface flow hydraulics, sediment characteristics (mainly, size distribution) and sediment concentration. Again, in our research, the sediment property and surface flow hydraulics are somewhat constant. But we show the seepage condition has much greater sediment concentration but much less sediment deposition. Again, this is a deficiency in current sediment deposition equation.

In summary, we have quantified sediment deposition in a rill channel and found the amount of deposition is highly dependent on the subsurface hydrology. Our results show that current process-based erosion modeling concept where erosion and deposition equations based solely on surface flow hydraulics and sediment properties is deficient. It requires a major rethinking on how to incorporate the surface hydrology to properly quantify erosion, deposition, and sediment transport processes on the landscape.

REPRESENTATIVENESS OF SOIL SAMPLES COLLECTED TO ASSESS MINING-RELATED CONTAMINATION OF FLOOD PLAINS IN SOUTHEAST KANSAS

Kyle Juracek, Research Hydrologist, U.S. Geological Survey, Lawrence, Kansas, kjuracek@usgs.gov

INTRODUCTION

Historical lead and zinc mining in the Tri-State Mining District (TSMD), located in parts of southeast Kansas, southwest Missouri, and northeast Oklahoma, has resulted in a substantial ongoing input of lead and zinc to the environment (Juracek, 2006; Juracek and Becker, 2009). In response to concern about the mining-related contamination, southeast Cherokee County, Kansas, was listed on the U.S. Environmental Protection Agency's (USEPA) National Priority List as a Superfund hazardous waste site (fig. 1). To provide some of the information needed to support remediation efforts in the Cherokee County Superfund site, a study was begun in 2009 by the U.S. Geological Survey (USGS) that was requested and funded by USEPA. As part of the study, surficial-soil sampling was used to investigate the extent and magnitude of mining-related lead and zinc contamination in the flood plains of the Spring River and several tributaries within the Superfund site. In mining-affected areas, flood-plain soils had lead and zinc concentrations that far exceeded background levels as well as probable-effects guidelines for toxic aquatic biological effects (Juracek, 2013). Lead- and zinc-contaminated flood plains are a concern, in part, because they represent a long-term source of contamination to the fluvial environment.

An important issue is the within-site representativeness of the surficial-soil samples collected. Specifically, the question is whether or not the samples collected provide an acceptable representation of the lead and zinc concentrations at each site for the purpose of characterizing and comparing sites. The distribution of mining-contaminated sediment on flood plains is determined by several factors including the size and density of the contaminated particles, flood-plain width and topography, flood characteristics (frequency, magnitude, duration), and fluvial geomorphic processes. To evaluate within-site representativeness, additional samples were simultaneously collected to assess within-site variability. In this paper, the specific objectives were to:

(1) Describe the collection and analysis of surficial-soil samples using a 5-point sampling technique;
(2) Describe the collection and analysis of additional surficial-soil samples to assess within-site variability; and
(3) Evaluate the within-site representativeness of the original 5-point samples for assessing mining-related contamination.

DESCRIPTION OF STUDY AREA

The Cherokee County Superfund site is a 115 square mile area located within the TSMD (fig. 1). For about 100 years (1850-1950), the TSMD was one of the primary sources of lead and zinc ore in the world (Brosius and Sawin, 2001). Mining activity in the TSMD ended in the 1970s. Background sediment concentrations of lead and zinc in the Superfund site were estimated by Pope (2005) to be 20 and 100 milligrams per kilogram, respectively.

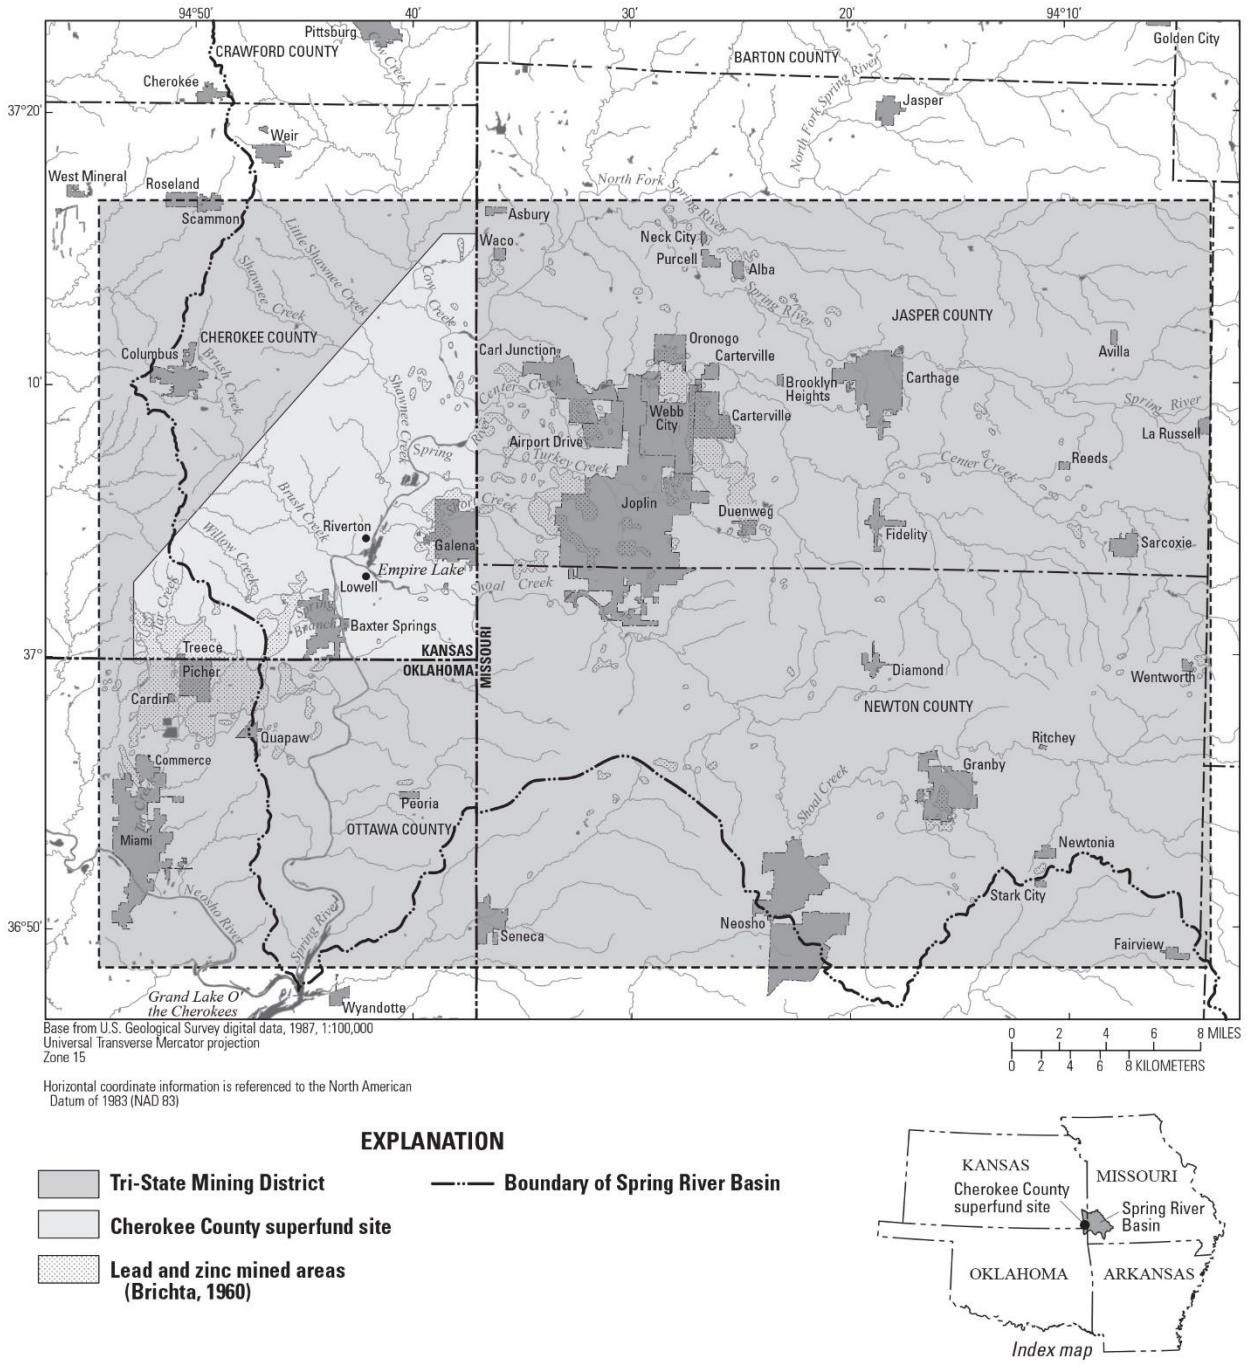

Figure 1. Location of the Spring River and its tributaries, the Cherokee County Superfund site, and lead- and zinc-mined areas in the Tri-State Mining District, Kansas, Missouri, and Oklahoma.

The Superfund site is drained by the Spring River, its tributaries, and Tar Creek. Principal tributaries to the Spring River in Cherokee County include Brush Creek, Cow Creek, Center Creek, Shawnee Creek, Shoal Creek, Short Creek, Turkey Creek, and Willow Creek. Several of the tributaries, as well as Tar Creek, drain areas that were substantially affected by historical lead and

zinc mining (fig. 1). On average, the width of the Spring River flood plain in the Superfund site is about 1 to 1.5 miles. The width of the tributary and Tar Creek flood plains generally is about 0.5 mile or less.

METHODS

As part of a study to assess the extent and magnitude of mining-related lead and zinc contamination (Juracek, 2013), information was obtained through an analysis of surficial-soil samples collected from the Spring River flood plain, tributary flood plains, and the Tar Creek flood plain in the Superfund site. Sampling sites for the Spring River flood plain, as compared to the other flood plains, were selected using different schemes as described below.

Sampling site selection: The selection of surficial-soil sampling sites for the Spring River flood plain involved several steps. First, all one-square-mile sections that were located mostly (that is, at least 50 percent) or completely in the Spring River flood plain were identified using USGS 1:24,000-scale topographic quadrangle maps. Second, the selected sections were divided into quadrants. Third, for each section, a quadrant was randomly selected for sampling. The random-selection process involved the use of coin flips to determine if the quadrant was north or south and east or west. Using this process, either the northwest, northeast, southwest, or southeast quadrant was selected for each section. If the randomly selected quadrant for a section was unusable, either because it was located mostly out of the flood plain or because access permission from the land owner was not granted, the next quadrant was selected using a clockwise rotation. A total of 30 Spring River flood-plain surficial-soil sampling sites were selected. Typically, the flood-plain soil was sampled at the center of each randomly selected quadrant.

Tributary streams for which flood-plain surficial soils were sampled included Brush Creek, Cow Creek, Shawnee Creek, Shoal Creek, Short Creek, Spring Branch, Tar Creek, Turkey Creek, and Willow Creek (fig. 1). Tar Creek is not a direct tributary of the Spring River. It flows into the Neosho River, which subsequently joins the Spring River at Grand Lake O' the Cherokees in Oklahoma. Tar Creek was included because it drains a part of Cherokee County that was substantially affected by historical lead and zinc mining activity (fig. 1). Along each stream, one to three transects were established for the purpose of sampling. Each transect extended perpendicularly away from the channel on one or both sides as dictated by the location of the flood plain and site accessibility. Twenty transects were established. Along each transect, two to four flood-plain sampling sites were selected. The distance between successive sampling sites (when two or more sites were sampled on the same side of the channel) ranged from about 10 to about 300 feet depending on flood-plain width, number of sites, and site conditions. A total of 59 tributary flood-plain surficial-soil sampling sites were selected.

Sample Collection and Preparation: The Spring River flood-plain surficial-soil samples were collected in the fall of 2009. The tributary flood-plain surficial-soil samples (including Tar Creek) were collected in the spring of 2011. All flood-plain surficial-soil samples were collected to a depth of about 1 inch. At each Spring River flood-plain site, the soil was sampled at the selected center location and typically at a distance (hereafter referred to as the sampling radius) of 100 feet north, south, east, and west of the center. This sampling method is referred to as the 5-point sampling technique (fig. 2). For the tributary flood-plain sites, the 5-point technique was used with

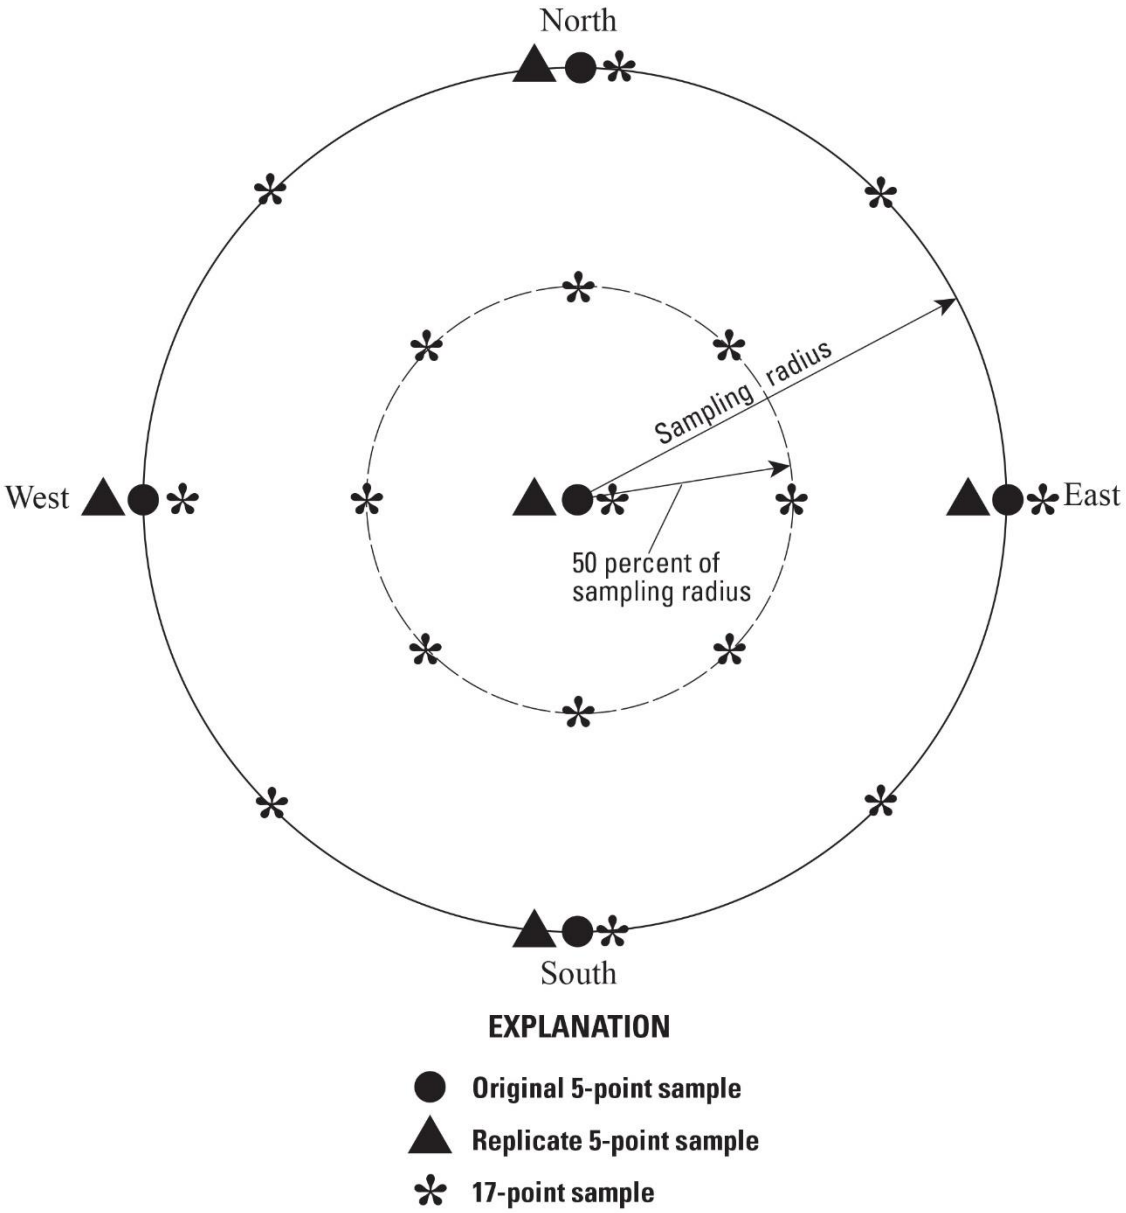

Figure 2. Diagram showing the 5- and 17-point sampling techniques.

a sampling radius that ranged from 5 to 50 feet depending on the width of flood plain available for sampling and the number of sampling sites per transect. Along each transect, samples collected using the 5-point technique were non-overlapping.

At each sampling site, an equal volume of soil was collected at the five locations using a 5-inch long section of cellulose acetate butyrate transparent tubing (2.6-inch inside diameter) that was pushed by hand into the soil. The tubing was thoroughly cleaned with a clean paper towel prior to each reuse. For each site, the soil from the five locations was combined in a plastic bag and transported back to the USGS laboratory in Lawrence, Kansas, for subsequent sample preparation.

Following air drying, each bulk sample was spread out on a clean plastic sheet and all visible organics (for example, plant fragments, seed pods, and roots) were removed using stainless steel tweezers. Each sample was disaggregated using a rubber-tipped pestle until the entire sample passed through a 4-millimeter stainless steel sieve. Then, each disaggregated sample was placed in a glass bowl and homogenized using a plastic spoon to provide a composite sample for each site. All utensils used in sample preparation were thoroughly cleaned with deionized water and wiped dry with a clean paper towel before each reuse.

Sample Collection to Assess Representativeness: To evaluate the within-site representativeness of the 5-point samples collected, two additional sets of samples (each set representing about 10 percent of the total samples collected) were simultaneously collected to assess within-site variability. First, replicate 5-point samples were collected in juxtaposition with the original 5-point samples (fig. 2) at three Spring River and six tributary flood-plain sampling sites. Second, 17-point samples were collected at three Spring River and five tributary flood-plain sampling sites. In the 17-point technique, the soil was sampled at the center and at 100 and 50 percent of the selected sampling radius north, northeast, east, southeast, south, southwest, west, and northwest from the center (fig. 2). Following collection, these additional samples were prepared for analysis in the same manner as the original samples.

Chemical Analyses: The flood-plain surficial-soil samples were analyzed for lead and zinc concentration at USEPA facilities using x-ray fluorescence (XRF) (U.S. Environmental Protection Agency, 2007). All samples were analyzed as bulk samples. The samples collected from the Spring River flood plain were analyzed using a handheld XRF instrument. The samples collected from the tributary flood plains were analyzed using a stationary XRF instrument.

XRF analytical variability was assessed by the triplicate analysis of multiple samples to determine the deviation from the mean concentration. For the Spring River flood-plain samples, the analytical variability for lead ranged from $\pm$2 to $\pm$38 percent with a mean variability of $\pm$17 percent (9 samples). For zinc, the analytical variability ranged from $\pm$2 to $\pm$33 percent with a mean variability of $\pm$11 percent (10 samples). For the tributary flood-plain samples, the analytical variability for lead ranged from $\pm$1 to $\pm$12 percent with a mean variability of $\pm$4 percent (70 samples). The analytical variability for zinc ranged from 0 to $\pm$12 percent with a mean variability of $\pm$3 percent (70 samples). The larger variability for the Spring River flood-plain samples likely was caused, in part, by the use of a handheld XRF instrument.

To assess the comparability of the XRF analyses with another method, split-replicate samples from three Spring River and six tributary flood-plain surficial-soil sampling sites were analyzed at a USGS laboratory for lead and zinc concentration using spectroscopic methods (Fishman and Friedman, 1989; Arbogast, 1996; Briggs and Meier, 1999). For each site, the composite sample was split to provide the original and split-replicate samples. The spectroscopic methods used provided total (at least 95 percent of the element present) rather than total-recoverable concentrations. Analytical variability for the spectroscopic methods was about 10 percent or less (Juracek, 2013).

Overall, including the results for both the Spring River and tributary flood plains, lead and zinc concentrations determined by spectroscopic methods typically were larger. Lead and zinc concentrations for the three Spring River split-replicate samples averaged 55 and 28 percent larger, respectively. Lead concentrations for the six tributary split-replicate samples ranged from 56 percent smaller to 94 percent larger. Zinc concentrations for the six tributary split-replicate samples ranged from 3 to 70 percent larger.

RESULTS AND DISCUSSION

Within-site representativeness of the original 5-point surficial-soil samples was evaluated using two additional sets of samples that were simultaneously collected. On average, lead and zinc concentrations in the replicate 5-point samples collected from the Spring River flood plain were within about $\pm$11 and $\pm$15 percent of the concentrations in the original 5-point samples, respectively (table 1). For lead, the average variability for the replicate samples was computed using only two of the three sampling sites because the lead concentration was less than the XRF limit of detection for one of the original samples. On average, lead and zinc concentrations in the replicate 5-point samples collected from the tributary flood plains were within about $\pm$8 and $\pm$4 percent, respectively (table 1). The larger variability measured for the Spring River samples possibly was caused, in part, by the use of a handheld (as opposed to stationary) XRF instrument for the chemical analyses.

Lead and zinc concentrations in the 17-point samples collected from the Spring River flood plain were, on average, within about $\pm$27 and $\pm$23 percent of the concentrations in the original 5-point samples, respectively (table 1). Lead and zinc concentrations in the 17-point samples collected from the tributary flood plains were, on average, within about $\pm$11 and $\pm$14 percent, respectively (table 1). The larger variability documented for the Spring River 17-point samples may be indicative of greater spatial variability associated with the use of a larger sampling radius. Also, the larger variability for the Spring River samples possibly was caused, in part, by the use of a handheld XRF instrument for the chemical analyses. Finally, the larger variability measured for the 17-point samples, compared to the replicate 5-point samples, may be indicative of the fact that more spatial complexity in flood-plain lead and zinc concentrations is being captured by the 17-point samples.

SUMMARY AND CONCLUSIONS

To assess the within-site representativeness of flood-plain surficial-soil samples collected using a 5-point sampling technique to characterize the extent and magnitude of mining-related lead and zinc contamination in the Cherokee County (Kansas) Superfund site, additional 5- and 17-point samples were simultaneously collected and analyzed. On the basis of the similarity of the chemical results obtained, it was concluded that, for the flood-plain sampling sites selected, the 5-point samples provided representative data for the purpose of assessing lead and zinc contamination.

MORPHOLOGICAL EVOLUTION OF FLUVIAL AND ESTUARINE SEGMENT FLOWS

Geraldo Wilson Júnior, Docteur d'Etat, COPPE/Federal University of Rio de Janeiro-UFRJ, Rio de Janeiro, Brazil, jrwilsong@gmail.com;
Mario Grüne de Souza e Silva, M.Sc., COPPE/UFRJ, Rio de Janeiro, Brazil, mariosilva@poli.ufrj.br

Abstract: Fluvial sedimentological equilibrium is reached when the sediment load discharging into a longitudinal segment equals the solid phase leaving that stretch. In such segments, natural and anthropogenic phenomena may occur as, for example, the formation of sand banks and beaches, erosion, mud slumps, silting, formation of meanders, oxbows and riverbed configurations, with expressive ecosystem interferences. In this paper, the following are shown: (i) qualitative and quantitative descriptions of the hydrodynamic, sedimentological, morphological and phytosociologic processes within fluvial and estuarine systems; (ii) validation and modernization of the methodology for hydrosedimentologic studies developed in Brazil; (iii) the importance of land, bathymetric, remote sensing surveying and (iv) application and validation of this methodology in Brazilian open channels systems. Qualitative and quantitative cases are outlined: (1) Sedimentological and morphological aspects of the *Paraguay* River in the *Pantanal of Mato Grosso* State. (2) *Morro Grande* bathymetry estimate of the *Preto* River Reservoir, in the state of *Rio de Janeiro*, using Remote Sensing analysis. (3) Hydrodynamic, sedimentological and morphological aspects of a *São Francisco* River stretch, and (4) the phytosociologic problems carried out by the diversion of the *Macacu* River into the *Guapimirim* River, which cross one of the few remnant mangrove areas in the *Rio de Janeiro* State. Results showed that the periodic land, bathymetric and Remote Sensing surveys are indispensable tools for the qualitative and quantitative descriptions of the sediment movements in open channel flows methodology.

INTRODUCTION

In open channel flows two phases move: a liquid, governed by the laws of Fluid Mechanics and a solid, composed of sediment particles, which moves in contact with the river bed, or in suspension in the middle of the turbulent flow (Wilson-Jr., 2009). When the mass of sediment that penetrates some stretch is equal to the mass that flows out of it in a period of time, it is said that the sedimentological equilibrium was achieved. The size of the stretch and the period of time that characterize this equilibrium define the scales - spatial and temporal - of the morphological process in the stream. In fluvial flows, the equilibrium time scale is a multiple of a hydrological year. The mean longitudinal profile of a river stretch, for example, remains stable during this period of time. However, in the equilibrium segments, natural morphological phenomena of disequilibrium may occur during a hydrological year, as: meandering, sand banks, erosion, mud slumps, cut-off, silting, and others. Sub-stretches of sedimentological disequilibrium appear and advance along the stretch their analysis depending on the spatial scale of observation.

Anthropogenic interferences in the river's bed and on the watershed add up to these phenomena, and must be detached and controlled, because they are capable of modifying the equilibrium conditions of the stretch, with severe consequences to the environment, engineering projects, and specifically to the phytosociological processes.

OBJECTIVES AND STUDIED CASES

The main objectives of this paper are: (i) To consider the concatenation of hydrodynamic, sedimentologic, morphologic and phytosociological processes within fluvial and estuarine systems; (ii) To present a Brazilian methodology for hydrosedimentologic studies in watersheds, (iii) To emphasize the importance of land, bathymetric and Remote Sensing surveys as special measurements to calibrate these studies, and (iv) To apply this methodology in fluvial systems.

Four Brazilian cases were outlined: (1) Sedimentologic and morphological aspects of the *Paraguay* River in the *Pantanal Matogrossense*, MS; (2) *Morro Grande* Reservoir bathymetric estimate using Remote Sensing, RJ; (3) Morphological aspects of a *São Francisco* River stretch, BA, and (4) Phytosociological problems carried out by the diversion of a river into a remnant mangrove area in the *Rio de Janeiro* State.

METHODOLOGY OF SEDIMENTOLOGICAL AND MORPHOLOGICAL PROCESSES

Sediments are placed in motion or have their movement changed by the natural elements' action, e.g. rain, currents, winds, waves, tides; and by human interventions in the river bed and the watershed basin, that sum out with the natural ones, as: dams, navigation, dredging, mining, waste, deforestation, irrigation, sport, leisure and touristic activities (Figure 1). In other words, the sediments are placed in motion or have their movement changed, every time the river bed and watershed suffer an alteration. Then, two types of solid movement can occur in fluvial streams: (i) Movement of sediments from the river bed that either move in contact with the bed most of the time, or in suspension; (ii) Movement of sediments from the watershed basin, mostly carried out by the rain, generating the wash-load. These sediments are finer than the bed load material and are transported in suspension, by the river, through long distances.

Depending on the case, a non-linear relationship between the liquid flow and the bed sediment discharge is possible:

$$q_b = a\, q^{n_s} \tag{1}$$

where q_b = the solid discharge per unit width, in mass, force or volume per time; q = liquid flow, that can be expressed in the same units. a and $n_s > 1$, are positive constants, that depend on the hydrosedimentological characteristics of the river stretch.

However, the wash load movement, which corresponds to the quickest response of the river to the fluvial basin modification, relates directly to the soil loss in the watershed. Thereby, to estimate the solid discharge of river stretches, it is essential to distinguish and to know the sources of sediments that are being transported and spread over the studied reach.

For some decades, Wilson-Jr. (2009) has dedicated himself, through tests in laboratory channels, creeks, brooks, rivers and estuaries, to developing a methodology to characterize sediment motion in open channel flows. This methodology allows the simultaneous application of bathymetric, hydrometric and sedimentometric measurements, the use of tracers (radioactive, chemicals and fluorescent), Remote Sensing and GIS.

According to this methodology, for the sediment motion description in water streams, three steps are necessary (Figure 2) (Wilson-Jr., 1999, 2009): (i) Knowledge of the watershed; (ii) *In-situ* measurements of the solid motion, in a representative reach of the flow, and during these measurements' period; (iii) Determination of the hydrodynamic, sedimentologic and hydrometeorological characteristics of the representative watershed segment.

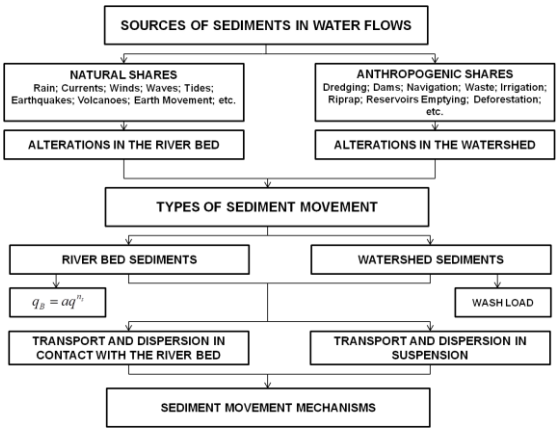

Figure 1. Sources and types of sediment movements (Wilson-Jr., 2009)

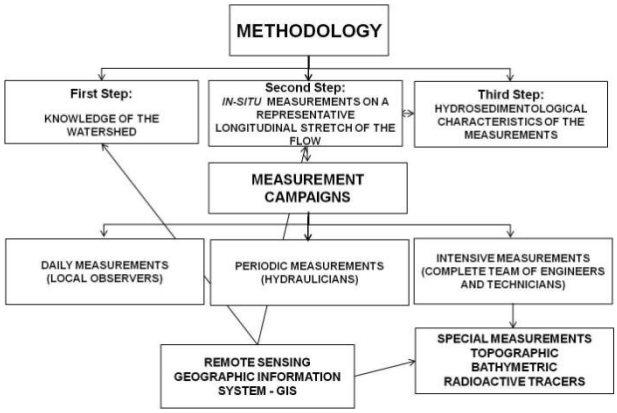

Figure 2. Methodology for sedimentological and morphological studies in open channel flows (Wilson-Jr., 1999, 2009)

First step: Knowledge of the watershed basin

The knowledge of the watershed delimited by the project involves the understanding of their geographic, geologic, hydro-meteorological, sedimentologic, socio-economic and historical characteristics, among others. Knowledge of these characteristics comes from office and field works, and involves the interaction of specialists in these specific fields. In this step, the aerial photography, satellite images and GIS techniques are very useful. They allow identifying fixed (topographic, pedology) and varying (forest cover and soil type) characteristics of the basin, which condition the water and sediment contributions.

Second step: *In-situ* measurements campaigns

It is recommended that the hydrosedimentological measurements in the river be conducted in a stretch of uniform flow and that its hydrodynamic and morphological characteristics be representative of a great extension of the flow. However, in many cases, the studied river stretch is determined by the project: the erosion downstream of a dam, the aggradation of a hydroelectric power plant reservoir and a complex navigational stream due to its sediment banks are some examples. For the quantification of the sediment movement in this representative river stretch, three superposed measurements campaigns are necessary: daily, periodic and intensive.

Daily measurements campaign

This consists of the water level record and the water sample collection to determine the concentration and granulometry of the suspended sediment. These daily values, along with the pluviometric and evaporation data, characterize the hydrologic cycle considered.

Periodic measurements campaign

They must be performed as a function of the hydrometeorological conditions, as a complement to the daily observations. They consist of, e.g. velocity measurements and liquid discharge calculations; watershed erosion and aggradation monitoring; detailed sample of the bed sediments; bathymetric survey, including the measurement of the waterline and bed slopes, flood levels, bed forms records, water flow and watershed basin morphological characteristics.

Intensive measurements campaign

Performed in well defined hydrological conditions, generally during the rainy seasons, when there is a larger sediment production, or during the average discharge period, when there is a sediment

motion representative of the bed forming discharges. Intensive measurements are performed at the same time as the ones of the previous campaigns and include: longitudinal bathymetry of the stretch, bed forms records and special measurements of the bed sediment discharges.

Third step: Hydrometeorologic characteristics during the *in-situ* measurements

The information obtained during the measurements campaign, especially those obtained during the Intensive Measurements Campaign, are limited in time and to defined hydrometeorological conditions, which need to be well known, so the data can be extrapolated.

Special measurements of the sediment movement

The periodic observations campaign results enable the definition of analytical relations between hydrodynamic and sedimentological quantities for the representative river stretch. The daily campaign allows those relations to be extended to hydrological cycle(s). However, the special measurements results are the ones that enable the **calibration** and **validation** of the analytical expression and models obtained. This methodology was developed in Brazil with the use of radioactive tracers and bathymetric surveys as special measurements. It was successfully applied in the *Ivai* River's watershed, in *Paraná* State (Wilson-Jr. *et al.*, 1980). The radioisotopes technique has been very efficient as a selective criterion of bed load formulas. In the *Ivai* River, the methodology enabled the selection of classic sediment motion formulas and their validation through comparison with data obtained by labeled sediments with radioisotopes. The use of tracer techniques enables the determination of kinematic and dynamic characteristics of the flow and sediment. They provide accurate data of the amount transported; sediment trajectories and velocities; residence time in the water flow; liquids and solid circulation; dispersion of liquid pollutants and of those fixed on sediments.

However, as the usage of radioisotopes in open channel flow is restricted to the Nuclear Energy Institutes, other methods are being considered for the direct measurement of sediment motion. In this paper, the usage of Remote Sensing technique and GIS as special measurements is considered, along with bathymetric surveys, for models calibration and validation. This technique is also being used for the knowledge of the watershed basin, as schematized in Figure 2. Following, four Brazilian cases were selected to illustrate the use of special measurements to calibrate and validate the descriptive models of sediment in open channel flows. The regions were the studies took place were outlined in the Figure 3.

Figure 3. Regions where studies were realized

SEDIMENTOLOGICAL BALANCE OF THE FERRADURA ISLAND STRETCH OF THE *PARAGUAY* RIVER (CASE I)

The morphological evolution with time, of a bed stretch of the *Paraguay* River was performed through comparisons between the topobathymetric measures taken in different occasions by the Brazilian Navy and published in 1:10,000 scales. The considered stretch, in which it was possible

to count on two measurements, was that of *Ferradura* Island, in Km 1255 of the *Pantanal* International Waterway. The bathymetries of the Figures 4 and 5 were made in 1974 and 1994, respectively, allowing for the stretch's morphological comparison in this 20-years period. Erosion and sedimentation rates were determined through the calculation of liquid and solid volume variations between the limits established for the stretch. Three methods were used: Contour Lines, Cross Sections Methods and Software Surfer® 7.0's use (Wilson-Jr. and Andrade, 2000).

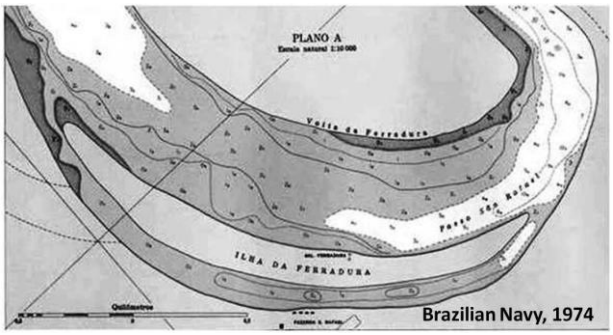

Figure 4. Topobathymetric measures on the *Ferradura* Island Region of the *Paraguay* River at 1974

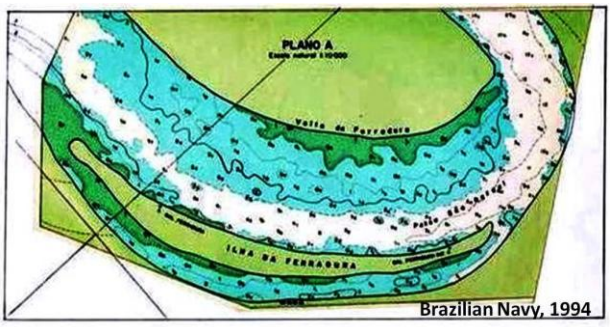

Figure 5. Topobathymetric measures on the *Ferradura* Island Region of the *Paraguay* River at 1994

The **Contour Lines Method** is based on the determination of the areas corresponding to each water level. For a better visualization of the area to be determined, a plane cutting the river segment in the desirable level is considered. The superior flooded areas also contain the interior levels' areas. Thus, obtaining the values of the areas corresponding to each level, a graph of flooded areas as a function of the water level can be constructed, and through the resulting curve, the final reach volume calculated. The increase in flooded areas can be seen for all levels in Figure 6. The volumes were: $V_{1974} = 4.04 \times 10^{-3}$ km^3 and $V_{1994} = 4.61 \times 10^{-3}$ km^3, with a volumetric increase of 0.57×10^{-3} km^3, i.e. an erosion rate 28,500 m^3/year.

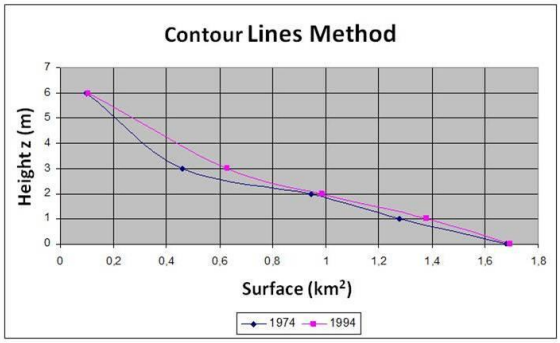

Figure 6. Flooded areas as function of water level

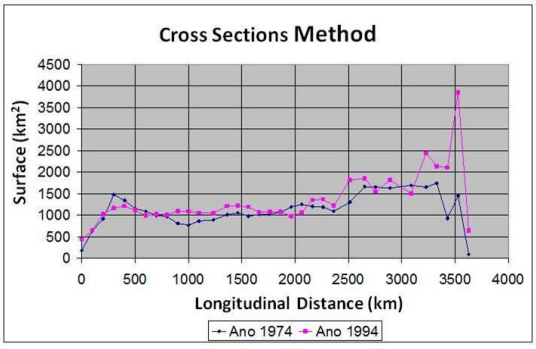

Figure 7. Longitudinal profile in the *Ferradura* Island reach

The **Cross Sections Method** consists in dividing the river stretch in sections whose areas can be determined. Afterward, the studied stretch's volume is calculated. Since it is a curved stretch, it was decided to consider four rectilinear sections of the longitudinal axis, from which were traced perpendicular lines spaced 100.0 m of terrain, considered such as not to intercept within the river channel. Results of this application are presented in Figure 7, where the segments of erosion and sediment deposition can be distinguished along the twenty years. The water volumes were: $V_{1974} = 4.15 \times 10^{-3}$ km^3 and $V_{1994} = 4.99 \times 10^{-3}$ km^3, presenting a volumetric increase of 0.84×10^{-3} km^3, that is, an erosion rate 42,000 m^3/year.

The **Surfer Software** makes the volume determination very fast, besides generating several graphical outputs, among which 3D drawings, as shown in Figures 8 and 9. Results obtained with Surfer® were: $V_{1974} = 4.38 \times 10^{-3}$ km^3 and $V_{1994} = 4.96 \times 10^{-3}$ km^3, presenting a volumetric increase of 0.58×10^{-3} km^3, that is, an erosion rate 29,000 m^3/year.

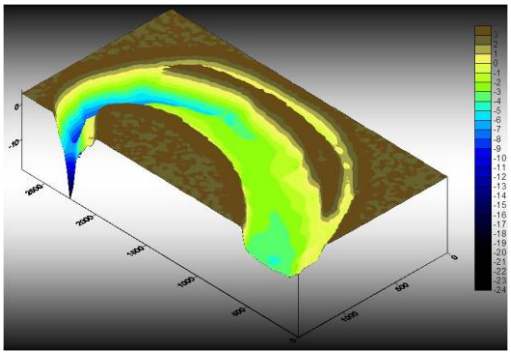

Figure 8. 3D representation of the *Ferradura* Island stretch of the *Paraguay* River in 1974

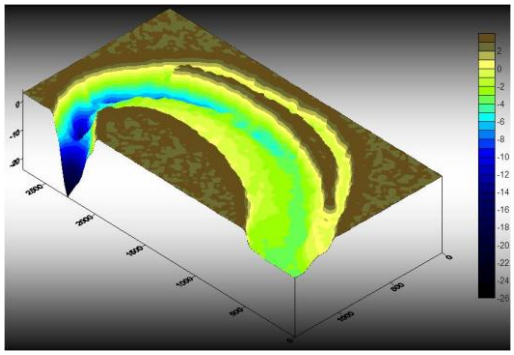

Figure 9. 3D representation of the *Ferradura* Island stretch of the *Paraguay* River in 1994

For the final erosion rates determination, the mean of the values obtained by the Contour Lines Method and the Surfer® application was calculated, obtaining an erosion rate 28,750 m^3/year. Results obtained with the Cross Sections Method presented an erosion rate larger than those obtained by the other ones. This may be due to the distance between cross sections. The larger is the distance between sections, the larger is the interpolation error between the sections' areas. This method is not recommended for very sinuous and irregular reaches.

From the analysis of the Figures 4 to 9, it is observed that along with the deepening of the riverbed that occurs, mainly in the downstream stretch, there is a sandbanks' increase at the upstream entrance of the river's right arm that goes around the *Ferradura* Island. This makes navigation harder through this arm, and also, in the convex part of the left margin, in the center of the segment. The sandbanks' volumes calculated in the years 1974 and 1994, are the following: $V_{Sb1974} = 1.06 \times 10^5$ m^3 and $V_{Sb1994} = 2.52 \times 10^5$ m^3, with a volumetric sandbanks' increase of 1.46×10^5 m^3, i.e., an aggradation rate equal 7.300 m^3/year during these 20 years.

Comparing all these values, it can be concluded that in the study period, the segment presented a sedimentological disequilibrium with predominantly erosive process. However, it has to be mentioned that the aggradation consequences at the entrance of the right arm of the *Ferradura* Island were serious, making navigation and access to the farms located in these margins difficult.

MORRO GRANDE RESERVOIR BATHYMETRIC ESTIMATE USING REMOTE SENSING ANALYSIS (CASE II)

Borges (2004) and Borges *et al*. (2007) used Remote Sensing to study the aggradation in the *Morro Grande*'s reservoir, *Rio de Janeiro* State, Brazil, using a high IKONOS resolution image and some bathymetric survey data, related by Bayesian Kriging method. They investigated the spatial variability in the ground-truth bathymetric dataset and the spatial variability in the image.

The geostatistical analysis showed that a similar behavior and correlation structure is present in both data sets (ground-truth and image) as well as a relationship does exist between the ground and the image. Indeed, the results showed a good correlation between the IKONOS image and the bathymetric measurements, where the Kriging method improved the estimates obtained by the common methods of statistical regression.

The data analysis was recommend for : (i) the estimation and monitoring of reservoirs and rivers aggradation, and (ii) for dredging management and maintenance of navigation channels, once the best correlation between imagery and bathymetric data are obtained for stretches with low depth, i.e., the most aggradated or shallow stretches.

Figure 10 (Borges *et al.*, 2007) shows the IKONOS image and, superposed, the estimated bathymetric through the image, which was adjusted with field data. Continuing this work, Wilson-Jr. (2009) proposed the study of the temporal evolution of sediment banks and river reaches morphology, assisted by Remote Sensing and GIS, for the calibration and validation of sediment transport models.

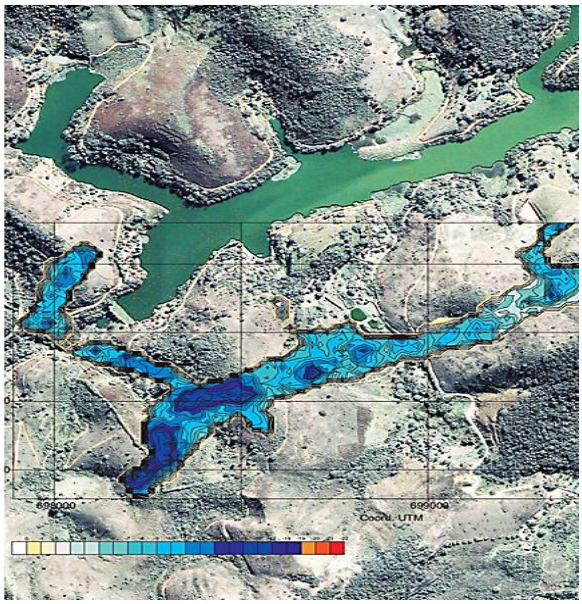

Figure 10. IKONOS image and estimated bathymetry of the Morro Grande Reservoir (Borges et al., 2007)

MORPHOLOGICAL CHARACTERIZATION OF A STRETCH OF THE *SÃO FRANCISCO* RIVER (CASE III)

São Francisco headwater is located in *Minas Gerais* State – Brazil, in *Serra da Canastra*. Until its mouth, in the Atlantic Ocean, on the border of *Sergipe* and *Alagoas* States, it travels 2,830 km, draining areas of seven states. Approximately 2,000 km are (or were!) navigable, so this river is also responsible for the flux of Brazil's Southeast, Midwest and Northeast regions' productions.

***Iuiú* Irrigation Project**

The *Iuiú* Basic Irrigation Project was elaborated in the year 2000 and intended for the agricultural development of an area of 500 km^2, located Southwest of *Bahia* State (Figures 11 and 12), on the border of *Minas Gerais* State, near the *Verde Grande* River mouth. The expected liquid flow for the *Iuiú* Project was 29.7 m^3/s of water captured from the *São Francisco* River. The river stretch of the project is located between two hydrosedimentological stations: *Manga* 30.0 km upstream, in *Minas Gerais* State, and *Carinhanha* 20.0 km downstream, in *Bahia* State.

Figure 12 highlights the river stretch that is being studied for the *Iuiú* Irrigation Project, the location of the hydrosedimentological stations, the alternatives for water intake and the sediment banks that were analyzed during the period of 1985 to 2011. In the drought period, when the hydrosedimentological survey was made by Wilson-Jr. (2000), the measured liquid flow was 1,045 m^3/s. It corresponds to 3.0 % of the minimum flow rate of the *São Francisco* River.

Hydrosedimentological and morphological aspects of the *Iuiú* Irrigation Project stretch

The Water Intake Project in the *São Francisco* River represents an anthropogenic interference in a river stretch whose sediment dynamics have special qualitative and quantitative characteristics. As this stretch is 10.0 km long, the sedimentological and morphological processes assume local importance, and must be addressed on a medium (≤ 30.0 m) and high resolution scale (≤ 2.0 m).

For the water intake alternative selection and for future hydrosedimentological studies, Wilson-Jr. (2000) proposed the methodology presented on Figure 2, in which parts of the first and second steps were completed. Concerning the first step, called Watershed Basin Knowledge, beyond the studies of reports, a field visit was made to the *São Francisco* River Watershed, on the segment between *Manga* (MG) and *Carinhanha* (BA), on the downstream stretches of the *Verde Grande* and *Carinhanha* Rivers and on the port regions of *Malhada*, *Carinhanha* and *Manga*. As the representative stretch of the *São Francisco* River was imposed by the project and it is delimited by *Manga*'s and *Carinhanha*'s stations, a special measurement campaign involving hydro-sedimentological, morphological and bathymetric surveys was conducted on the alternative stretch and was described in Wilson-Jr. (2000).

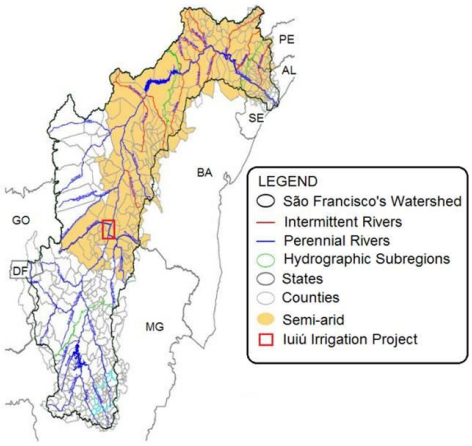

Figure 11. Semi-arid region of the *São Francisco* River watershed (Souza e Silva, 2013)

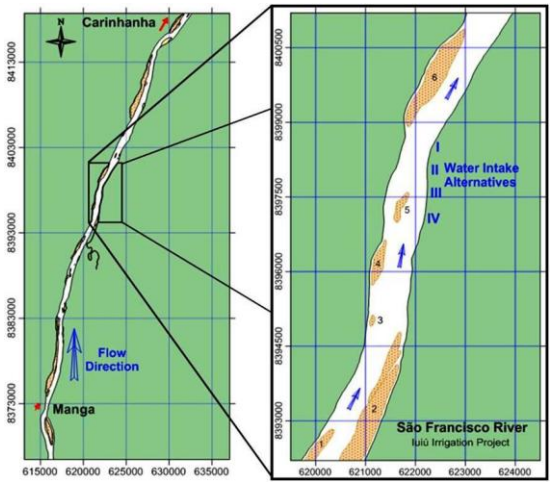

Figure 12. *Iuiú*'s irrigation project stretch water intakes alternatives and sediment banks localization

Movable sediment banks

The *São Francisco* River stretch on the site of the water intakes alternatives is not rectilinear (Figure 12). Its cross sections are asymmetric and because of the liquid flow variations during the hydrological cycle ($Q_{min} \cong 1{,}000$; $Q_{max} \cong 12{,}000\ m^3/s$), varied bed forms, islands and sediment deposits can be observed *in-situ* and on the satellite images. During the drought periods, the sediment deposits emerge, enabling the development of subsistence farming by the riverside population. With the arrival of the rainy season, the water level of the river rises, floods and washes most of the plantations, modifies the banks and islands, removes and deposits sediments, fertilizes the soil, sculpts the margins, the river bed, the movable banks, alters old bed forms and create new ones. During the field visit of July 2000, three sediment banks were observed: Banks 2, 4 and 6 (Figure 12). In this paper, assisted by Remote Sensing techniques during the period of 1985 to 2011, three other sediment banks were noted: Banks 1, 3 and 5. The temporal evolution analysis of these six banks is one of the main objectives of this work.

Remote Sensing Techniques Usage

The morphological evolution study of the *São Francisco* River stretch started with the use of LANDSAT-5 TM satellite images that were immediately provided by INPE (National Institute of Spatial Research) at no cost and extended for a period of 27 years. The first objective of this step was to verify that the LANDSAT-5 image has sufficient resolution to reproduce the borders of the river and sediment banks in the *São Francisco* River stretch, on the *Iuiú* Project area.

This step was called LANDSAT-5 TM Image Validation, and it is shown in Figure 13. Three softwares were used to manipulate the satellite images: ENVI®, Surfer® and AutoCAD®. The first one to manipulate the images and digitize the river stretch and sediment banks' borders; Surfer® to draw the maps, calculate the geometries and evaluate the morphological characteristics of the stretch, and AutoCAD® to adjust the map dimensions obtained in the field and satellite images. The forms and borders of the margins and banks determined by the LANDSAT-5 images and the field topographic and bathymetric survey were compared, as shown in the Figure 13. The image used was from 07/11/2000, because it was the closest to the period when the field survey was made: 07/06 to 07/09/2000 (Wilson-Jr., 2000). The field's survey calibration was made through the determination, with a GPS (Global Positioning System), of known polygons areas on the ground.

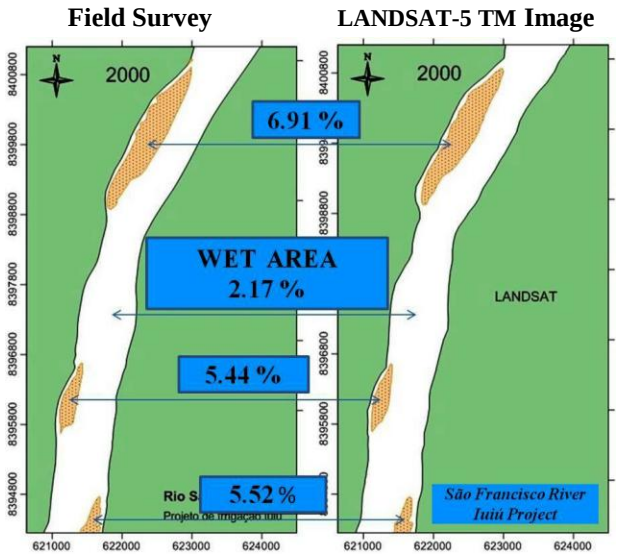

Figure 13. LANDSAT-5 TM image validation

The points' coordinates precision obtained in the field varied from 1.0 to a maximum of 3.0 m, which is inferior to the LANDSAT-5 image resolution. The Image Validation was made by comparing the dry and wet areas seen by satellite on the *São Francisco* River stretch, to the field data, as shown in Figure 13. The maximum discrepancy between the field survey areas and the ones determined with the satellite image was approximately 7.0 %. This value was considered acceptable, and it was concluded that the LANDSAT-5 TM images can be used for the temporal evolution study of the morphological variations of the *São Francisco* River stretch.

Morphological evolution of sediment banks

To evaluate the morphological evolution of the *Iuiú* Project region, 26 satellite images that represented the dry season ($Q \cong 1{,}000\ m^3/s$) and the years of 1985 to 2011, were used. Only the year 2002 was not considered, because an adequate LANDSAT-5 image was not available for the dry season. Afterward the initial images treatments phases, i.e. the georeferencing, resizing and borders' digitations, the banks and islands forms were analyzed, covering these 27 years.

The sum of the emerged areas of the six sediment banks on each image, named Dry Area; and the complement of this sum in relation to the delimited domain of the *São Francisco* River stretch, named Wet Area, were used to estimate the sedimentological behavior of the stretch. The results are shown in Figure 14, hereafter. One realizes that there was an increase of the Dry Area, and consequently, a decrease of the Wet Area, throughout the first 17 years (1985-2001). This finding indicates that the *Iuiú*'s Irrigation Project stretch was not in sedimentological equilibrium and showed a tendency to aggradation. The estimated aggradation value was around 7.70 % in relation to the recorded area values of 1985. Nevertheless, from 2003 to 2011, the dry and wet areas oscillate around constant values, indicating that the *São Francisco* River stretch reached a sedimentological equilibrium during this more recent period.

The aggradation of the *São Francisco* River stretch becomes even more evident when the temporal variations of the dry area of each sediment bank are analyzed. Figure 15 shows the annual variations of dry area of the six banks. The presentation of the banks was made in

ascending order of dry area values in relation to the total area of the studied stretch, so the highest values would stay on the back of the figure and would not hide the value of the smaller banks.

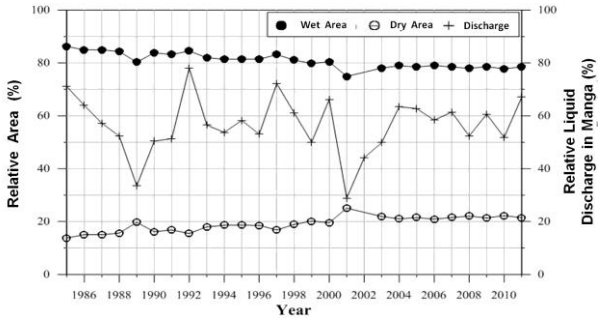

Figure 14. Annual evolutions of the relative dry and wet areas of the *Iuiú* Project in the *São Francisco* River

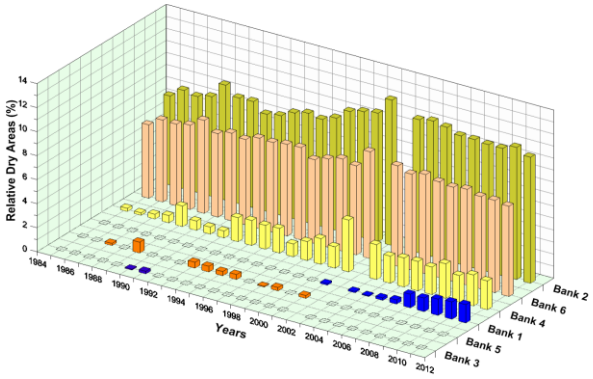

Figure 15. Morphological evolution of the *São Francisco's* sediment banks, from 1985 to 2011

The analysis of the annual images showed that some of the sediment banks are intermittent, while others are permanent. It also showed that some banks migrate downstream, while others remained stationary but had annual morphological modifications. Banks 2, 4 and 6 of Figures 12 and 15 are permanent and present in all of the 26 analyzed images. Bank 1 can also be considered permanent, although it has only reached the *Iuiú*' area in 2001. Before then, the bank fell outside the map's limits, but as Bank 2 it later extended itself downstream.

Banks 3 and 5 represent intermittent movable deposits, common on some Brazilian rivers of the *Amazonas* and *Prata* Basins, which arise during some years, generally after flood seasons, but are gradually eroded on the subsequent periods, with lower water levels. Bank 3 was only present in 1990 and 1991, while Bank 5 emerged in 1987, 1989, of 1993 to 1996, and again in 1998, 1999 and 2001. A great challenge, and, consequently a great motivation to continue the morphodynamic studies on the *São Francisco* River, consists in explaining analytically the formation and disappearances of these movable banks. Certainly, the application of the methodology sketched in Figure 2 will allow the progress in this direction.

PHYTOSOCIOLOGIC PROBLEMS CARRIED OUT IN THE *GUAPI* ESTUARY, *RIO DE JANEIRO* STATE (CASE IV)

The *Guapi* River crosses one of the few remnant mangrove areas in the *Rio de Janeiro* State. This estuarine flow was formed by the *Guapimirim* River, after receiving the *Macacu* River. It crosses the *Atlântica* Forest (an ecosystem of altitude fields, riparian forest, marshes and mangroves).

The *Macacu* River has its sources in the *Órgãos* Mountains, *Rio de Janeiro* State. It covers 74.0 km until joining *Guapi* River and more 20.0 km from this point to *Guanabara* Bay. The *Macacu* and *Guapi* Rivers watershed drainage surface is 1,640 km^2 (Figures 16 and 17).

Originally, *Guapimirim* and *Macacu* Rivers did not have any connection each other, and flowed independently into the *Guanabara* Bay. At the end of 40 decade, the National Works and Sanitation Department – DNOS, carried out several works in this region including the rectification of meanders; the opening of drainage channels; the buildings of dykes and floodwalls (Pires, 2010). A particular work was the *Imunana* Channel construction, which connected the *Macacu* with the *Guapimirim* River, an estuarine region that until this work remained flooded. Subsequently, a water intake system was installed into this channel to supply neighboring cities

and a submerged dam was built to elevate the water level and restrain the salt-water intrusion. The downstream flow was called *Guapi* River.

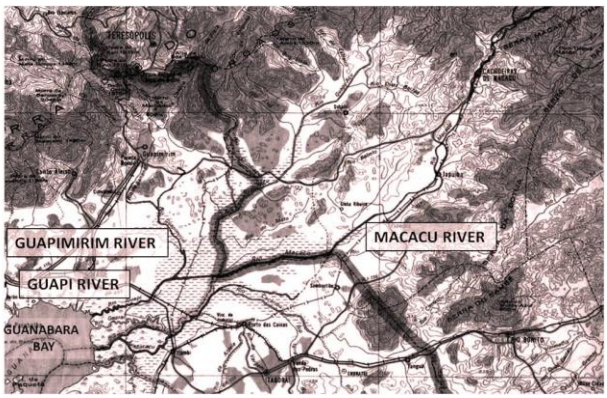

Figure 16. Macacu, Guapimirim and Guapi Rivers

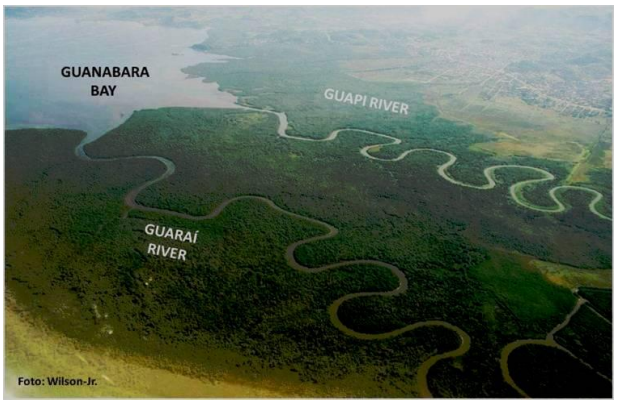

Figure 17. Guaraí and Guapi estuaries

Nowadays, the soil predominant usage is rural: agriculture and castle-raising. The vegetation presents some fragments from the *Atlântica* Forest and a considerable industrial development due to the *Rio de Janeiro* Petrochemical Complex – COMPERJ installation is predictable.

In spite of its environmental conservation organizations: (i) fluvial – *Órgãos* Mountain National Park; Environmental Protection Areas (*APA*) of *Petropólis* Municipality and of *Macacu* River watershed; and (ii) estuarine – *Guapimirim APA* and *Guanabara* Ecological Station; this region has been still submissive to the same former anthropogenic interventions. The vegetation suppression has been intensively practiced, for obtaining new sugar-cane and coffee cultivation areas; and the mangrove wood has been used to feed the brick-works industry. With the fluvial water discharge increase from the *Macacu* River, the *Guapimirim* River bordering forest, which was mainly composed of *Rhizophora* mangle *Linnaeus* (red mangrove), of *Laguncularia racemosa* (*L.) Gaertn f.* (white mangrove) and of *Avicennia schaueriana Stapf & Leechman* (black mangrove), was partially extinguished.

At 1984, when the *Guapimirim APA* was conceived, the mangrove vegetation cutting was forbidden. Nevertheless, in spite of the high resilience power of this ecosystem, the mangrove area that had already been cut did not return to its original conditions, on account of the salt-wedge regression that occurred after the *DNOS* interferences. With the salinity decrease and the hydro corium dispersion of riparian vegetation fragments from upstream, the degraded mangrove areas were gradually replaced by the *Tabebuia cassinoides ecosystem* or *caxetal* ecosystem in Portuguese. As well as the sand banks, shoals and mangrove systems, the *caxetal* system is a littoral marshland ecosystem, which is subject to a fluvial influence (Ziller, 1992). Its species, mainly the *Tabebuia cassinoides* (*Lam.*) *DC* is very resistant to an almost continuous flooding.

So, with the hydrodynamic process changes in the *Guapimirim* fluvial-estuarine system, the phytosociological process also changes, and, it is now affecting local sedimentological and morphological processes, modifying, in particular, the riparian vegetation and the sedimentological equilibrium of the flow segments.

CONCLUSIONS AND RECOMMENDATIONS

The use of topobathymetric measurements and of Remote Sensing and GIS are essential for calibration and validation studies on Sedimentological and Morphological Processes.

The morphological variations of the *Paraguay* River, in the *Ferradura* Island segment, were determined by comparing the topobathymetric curves taken in a 20-years period. Results showed that the segment presented a sedimentological disequilibrium with predominantly erosive process, estimated equal 28,750 m^3/year. However, the aggradation rate equal 7,300 m^3/year was at the entrance of a riparian farm, making the navigation and the farm's access impracticable.

Borges (2004) used high resolution IKONOS images to reproduce the bathymetric of the *Morro Grande* Reservoir in *Rio de Janeiro* State. The adopted treatment showed a great potential to be applied: (i) in the estimate and monitoring of sediments deposits in reservoirs and water streams with depths less than 10.0 m and (ii) on the management of dredging operations and maintenance of navigation channels, once the best results were obtained for aggradated shallow stretches.

It was also showed that LANDSAT-5 TM Satellite Images can be used for the morphological study of a river stretch. These images were used to describe the temporal evolution, during 27 years, of sediment banks and margins of a 10.0 km stretch in the *São Francisco* River. It is recommended that these Remote Sensing, GIS techniques and the topobathymetric measurements be introduced on the Sediment Movement Study Methodology steps, as suggested in Figure 1 of this paper, that is: (i) on the Watershed Basin Knowledge, and (ii) as special measurement of the Sedimentological and Morphological Processes. They enable the calibration and validation of qualitative and quantitative sediment transport models and the understanding of correlated phenomena, as the Phytosociological Process, e.g. the mangrove changes which are taking place on the *Guapi* Estuary borders, in *Rio de Janeiro* State.

Instead of an instantaneous vision of the measurements stations, these tools provide the observer with a wide and detailed vision of the watershed basin, the river stretch and even the bed changes.

ACKNOWLEDGEMENTS

The authors express their sincere gratitude to PENO/COPPE/UFRJ, CAPES, FAPERJ and CNPq for the institutional support received, without which, the realization of this work would not have been possible.

FLOW ENERGY AND BEDLOAD-TRANSPORT EFFICIENCY: THE FROUDE NUMBER AS A METRIC FOR BEDLOAD TRANSPORT RATES

Andrew Simon, Cardno, Senior Consultant, P.O. Box 1236, Oxford, Mississippi 38655 USA; andrew.simon@cardno.com; and Michael Singer, Department of Earth and Environmental Sciences, University of St. Andrews, St Andrews, KY16 9AL, UK; and Earth Research Institute, University of California Santa Barbara, Santa Barbara, California 91306, USA; bliss@eri.ucsb.edu

INTRODUCTION

The study reported in this short paper is preliminary in nature. The ideas and impetus behind this work stem from decades of research on unstable channels and was initiated in the 1990's as part of studies on channel evolution of the Toutle River System in the aftermath of the 1980 eruptions of Mount St Helens (Simon, 1992; 1999). This earlier work included a strong focus on trends of non-linear decay in flow energy and the processes (Graf, 1977) responsible for minimizing energy in an adjusting alluvial stream (Simon and Thorne, 1996). Applied to the suite of extremal hypotheses published in the 1970's and 1980's and placed within the framework of open systems theory with its references to minimizing entropy in landscapes, the associated theory that conditions at critical flow represent the most efficient means for channels to transmit water (Blench, 1966) and sediment (Kirkby, 1977) is considered. If this is to be realized, then maximum sediment transport should occur at hydraulic conditions representing minimum energy for that discharge (ie. critical flow; Froude number equals 1.0). To test this hypothesis, unit bedload transport data and associated hydraulic data were required, which span subcritical and super-critical flow regimes.

Geomorphically we can describe these adjustments in terms of measureable changes in geometry, its effects on boundary roughness and associated hydraulic conditions. Channel widening, particularly when associated with degradation, was found to be the most effective process in reducing flow energy, as all three components of total mechanical energy are reduced (ie. datum [elevation], hydraulic depth, and velocity) (Simon, 1992; Simon and Thorne, 1996). Further, energy slope represents the dissipation of energy over the reach. At Mount St. Helens with its braided channels, plentiful sediment supply, and cohesionless banks and terrace slopes, channel widening is and will remain (assuming no additional disturbances), the dominant process on the North Fork Toutle River for the next century (Simon and Klimetz, 2012). Channel widening of hundreds of meters has resulted in extremely shallow flow depths and frequent observations of critical-flow conditions (standing waves). Similar observations are common on braided streams. Over the course of adjustment, wide, shallow channels form where some peak flows oscillate between sub-critical and super-critical flow regimes (Simon, 1992) trending towards critical. The results further allow for an energy-based explanation for the hierarchy of channel-adjustment processes, their role in minimizing flow energy, and the importance of both bed and bank erosion in channel evolution (Simon and Thorne, 1996).

Sediment transport in rivers and streams is typically predicted as a function of shear-stress based theory, which when applied to bulk properties of channelized streamflow, places a large importance on the depth of flow and water surface (or energy) slope. This theory is based on the Law of the Wall, a logarithmic velocity gradient with increasing velocity with distance above the bed, with a corresponding decrease in boundary shear stress. It is these conditions that are responsible for rotating sediment grains out of pockets on the bed surface. Accordingly, a larger flow depth for a given slope produces a higher integral of shear stress applied to a bed particle and, therefore, a higher sediment flux rate. Such theory and its inclusion in sediment transport equations may not accurately represent observed sediment transport rates in a range of natural environments including sandy beach shorelines, alluvial fans, river bars, and floodplains, where flow is characteristically shallow, bed slopes are steep (≥1%), and beds are generally smooth with larger particles sparsely accumulated over a finer substrate. In such environments, vertical velocity and shear stress gradients may not be relevant at the scale of particles on the bed surface and sediment may be entrained in flows that are near the length scale of particles on the bed.

NEED FOR NEW SEDIMENT-TRANSPORT THEORY

Shear stress based theory tends to predict zero transport under such conditions because the critical flow depth has not been reached, yet particles in these environments typically move at high rates over smooth beds (Laronne and Reid, 1993) in rapid, shallow flows approaching or exceeding the critical value (Froude number ≥ 1):

$$F_r = \frac{u}{\sqrt{gh}} \tag{1}$$

Where u = downstream flow velocity, in m/s; g = acceleration of gravity, in m/s^2; and h = flow depth in m.

We hypothesize that in such rapid, shallow flows the processes by which sediment moves are not well characterized by theory designed for particle rotation out of pockets. Rather, they are more reasonably responsive to a square wave of flow pushing along the stoss particle boundary. In these shallow, rapid flow regimes, sediment particles on the bed are typically not encumbered by clast support, so transport only requires a flow force large enough to push particles with median diameters far greater than the bed roughness scale (e.g., mean friction angle (Buffington et al., 1992; Kirchner et al., 1990)), and do not rotate out of pockets. Once entrained, these relatively coarse particles may continue to move as long as this flow force is maintained and the bed surface remains smooth (preventing grain to grain interactions that would slow them to a halt).

Shear stress approaches are typically very sensitive to empirically defined values of critical shear stress for entrainment, which are known to vary dramatically for non-uniform sediment mixtures (Wiberg and Smith, 1987; Buffington and Montgomery, 1997). Based on the understanding that entrainment is sensitive to bed material grain-size distribution, critical shear stress is typically

computed as a power law of the ratio of particle sizes subject to movement to median bed-grain sizes (Andrews, 1983; Egiazaroff, 1965) or more recently, by sand fraction in the bed (Wilcock and Crowe, 2003), both of which are assumed to account for the effects of relative grain protrusion/hiding and pocket angle rotation on entrainment.

In cases of rapid shallow flow over smooth beds, these calculations of critical (or reference) shear stress yield values near zero, suggesting that any positive value of flow will move sediment particles on the bed surface (i.e., there are no frictional forces to overcome associated with clast support). Even assuming near zero critical shear stress, surface based equations that were designed for gravel-bed rivers (e.g., (Parker, 1990; Wilcock and Crowe, 2003)) still may not perform well under shallow rapid flow regimes over smooth, unarmored beds lacking developed bar morphology (Hassan, 2005; Laronne et al., 1994; Singer and Michaelides, 2014). Consequently, re-calibration of these equations has been undertaken to overcome the limitations in these approaches and to more accurately hindcast high observed flux rates (e.g., ephemeral dryland sediment flux in Nahal Eshtemoa, Israel (Powell et al., 2003)). However, these empirical tweaks to existing equations do not yield new insight into transport processes within shallow, rapid flow regimes. Thus, we in the sediment transport community continue to grapple with the process controls on flux rates and morphologic development in many such fluvial environments. Here, we re-investigate published sediment flux rates for controlled conditions within a range of field and flume datasets and the corresponding hydraulics to develop new insight into sediment transport under rapid, shallow flow regimes.

FLOW-ENERGY BASED HYPOTHESIS

Controversial theories of minimum stream power and rate of energy dissipation were developed in the late 1970's and early 1980's as a means of describing the equilibrium shape of alluvial channels (Yang, 1976; Chang, 1979; Yang and Song, 1979; Chang, 1980; Yang et al., 1981). These theories were the subject of extensive debate in the geomorphic and engineering literature. Chorley (1962) describes channel adjustment in terms of open systems theory "*...wherein the import and export of energy and material are equated by means of an adjustment of the form, or geometry, of the system itself*." (Chorley, 1962, p. B3). Simon (1992) reported that the theories were applicable to the adjustment of alluvial streams, noting that channel widening and reduction in flow depths was a critically important process in minimizing flow energy. This work further showed that equilibrium geometries for the North Fork Toutle River tended towards a minimum specific energy, representing a maximum unit discharge, critical flow and a Froude number of 1.0 (Simon and Thorne, 1996). Blench (1966) and Ergenzinger (1987) also indicate that gravel-bounded streams with no lateral constraints such as cohesive materials or root reinforcement and are controlled only by hydraulic, excess shear stress conditions adjust to a Froude number near 1.0.

An associated theory of maximum sediment-transport efficiency (Kirkby, 1977) was also developed at this time using the corollary that the dissipation of minimum energy by the flow

signified maximum efficiency of bedload transport. If these parallel theories are to be substantiated with bedload-transport data, it holds that maximum, unit bedload transport should occur at a minimum specific energy, which equates to a Froude number of 1.0 (critical flow). The Froude number, representing the ratio between inertial to gravitational forces is an easily measurable metric obtained from discharge measurements.

Based on the parallel theories of minimization of energy and maximization of sediment-transport efficiency, the following hypothesis, can be stated and tested using bedload-transport and associated hydraulic data. That is "unit bedload-transport rates should peak at a Froude number close to 1.0, representing the maximum amount of bedload transport (per unit wdith) that can occur per unit of energy expended."

SUMMARY OF FINDINGS

The hydraulic and sediment transport data used in this study come from about two decades of collecting and collating reports from the US Geological Survey and other agencies. Laboratory bedload-transport and hydraulic data were obtained from unpublished sources at the USDA-ARS, National Sedimentation Laboratory, and Colorado State University, as well as from the literature (ie. Gilbert, 1914; Stein, 1965; Foley, 1975; Nordin, 1976; and others). Field data were obtained from unpublished sources at the USGS Cascades Volcano Observatory, and from the literature. Sampling locations include the North Fork Toutle and Toutle Rivers, Washington (Dinehart, 1998); the Tanana River, Alaska (Burrows et al., 1979; Harrold and Burrows, 1983); the Jordan River, Israel (Inbar and Schick, 1979); and the East Fork River, Wyoming (Emmett, et al., 1982). The transport data cover sand- and gravel-sized bed material with median diameters ranging from 0.19 to 300 mm over Froude numbers ranging from 0.2 to greater than 3.0. All data were normalized by unit width to obtain unit-bedload transport rates (q_s) in kg/m/s and, by particle size (where d_{50} of the material was available) to test the utility of predicting dimensionless unit bedload transport (q^*) across the range of sizes:

$$q^* = q_s \sqrt{\left(\frac{\rho_s - \rho}{\rho}\right) g d_{50}{}^3} \qquad (2)$$

where q^* = dimensionless bedload transport rate; q_s = unit bedload transport rate, in kg/m/s; ρ_s = sediment density, assuming 2.65 kg/m^3; ρ= density of water, assuming 1.0 kg/m^3; d_{50} = median size of sediment, in m.

The various datasets indicate a reasonably tight relation (in semi-log space) between unit bedload transport rate and Froude number, with a peak transport rate occurring in the region of a Froude number of 1.0 (Figure 1). Transport rates increase sharply through the sub-critical regime, reach a flat peak at about 1.0 and then decrease slightly through the supercritical regime. This relation and its general form holds for the combined flume and field data over sand- and gravel-size ranges, and indicates that unit bedload-transport rates can be predicted with only measurements

of flow velocity and depth. Further study is required to determine the nature of the increased scatter in the vicinity of F_r = 1.0 and whether this is due to experimental and/or sampling issues.

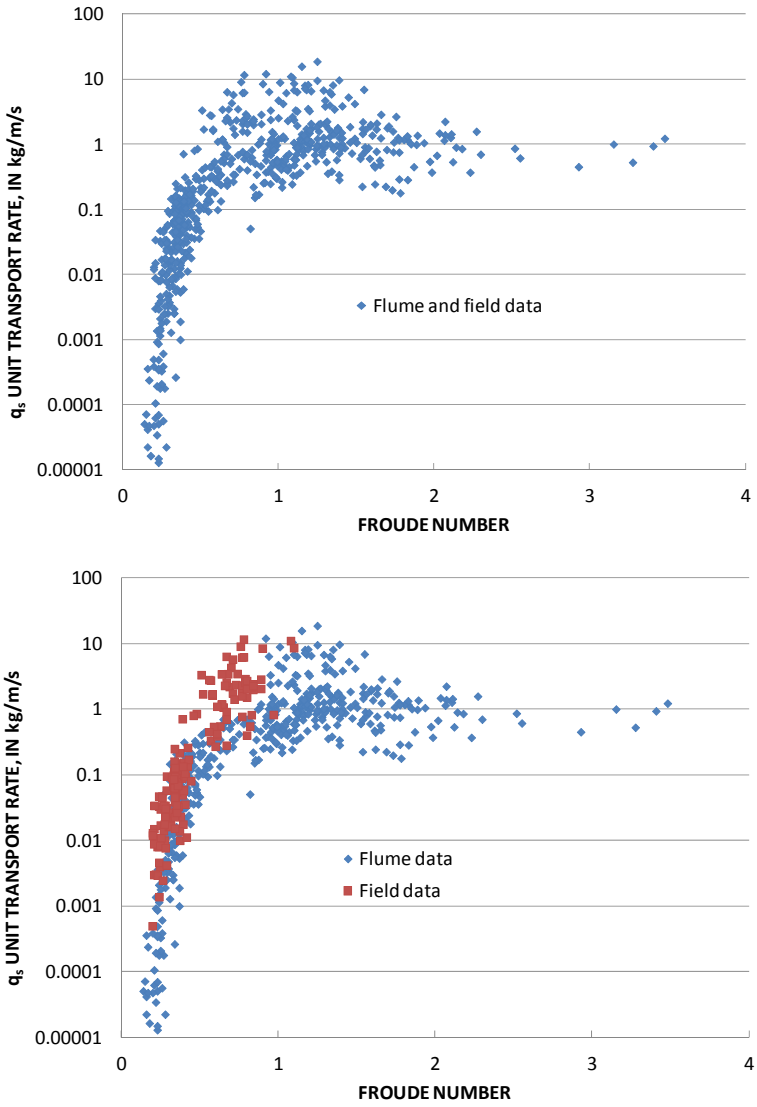

Figure 1 Unit bedload-transport rate (per unit width) and Froude number

To check the consistency of the relation over the range of particle sizes represented by the data, the transport data are converted to the non-dimensional form by dividing by particle size. The resulting relation between q^* (equation 2) and the Froude number is shown in Figure 2. Again we see a sharp increase in transport rates with increasing Froude number through the sub-critical flow regime, reaching a peak value in the region near F_r = 1.0. This plot predominantly includes the flume data. Particle size was missing from some of the extensive field datasets and will be incorporated in future analyses and publications.

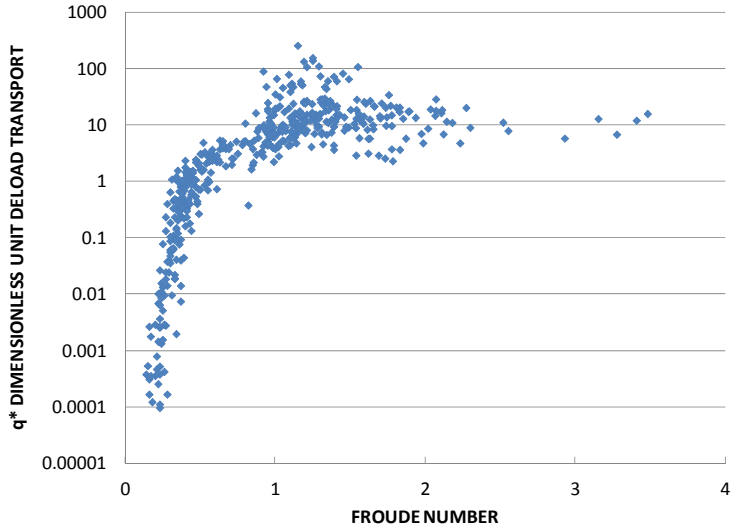

Figure 2 Variation in dimensionless unit bedload transport (q^*) with Froude number

The preliminary results from our analysis presented here support the hypothesis that the Froude number, i.e., a dimensionless relation between inertial and gravitational forces, has marked influence over unit bedload-transport rates, and that maximum rates occur at or near critical flow. This is an interesting development that could have great implications for sediment-transport theory and provide for a more simplified approach to estimating bedload-transport rates. Extension of this result from mechanistic sediment-transport theory to geomorphic-systems theory is also compelling. This work is still in progress. We are currently investigating the consistency of this relation across these and additional datasets after correcting for the effects of flume side walls and using dimensionless particle sizes rather than absolute values of grain size. We believe these steps will improve the resolution of this relation and that we can create a new, simplified sediment transport equation based on Froude number.

Abstract The evolution of barforms from a bed of uniform sediment and changes in sediment storage were measured in a laboratory flume and simulated numerically. Flume experiments were conducted with several upstream sediment supplies and flow conditions. For the sediment supply rates (no upstream supply, equilibrium supply, and 133, 166, and 200 percent of the equilibrium supply) and flow rates examined, the plane bed tended to evolve into mid-channel bars early in the runs ~15 minutes. As the flume experiments progressed, the bed transitioned to a lower mode configuration of alternate bars or a single-thread meandering thalweg. Increasing the upstream sediment supply to 133 percent or more of the equilibrium rate, increased the height and volume of deposited sediment relative to experiments conducted at the equilibrium rate and those experiments without sediment supply. Experiments conducted at flow rates of 0.5 and 1.0 L/s without sediment supply demonstrated that an increase in flow corresponded to a greater volume of erosion. A coupled two-dimensional flow and sediment transport model, Nays2DH, was used to simulate the evolution of bed topography for three sediment supply rates. We compared the morphodynamics and sediment storage predicted by Nays2DH for two initial bed conditions: one set of calculations used a plane bed with a small upstream perturbation as the initial bed condition, and the other set used the bed topography measured 15 minutes after the start of the flume run. Whereas initializing the model with measured flume topography provided a somewhat better analog to the final evolved morphology, predictions of sedimentation were not substantially improved over simulations using the plane bed as the initial condition.

INTRODUCTION

Flow and sediment management have been identified as tools to rehabilitate river corridors impaired by upstream regulation (National Research Council, 1999; U.S Department of Interior, 2006). Management strategies may be directed toward increasing the height of fine-grained deposits along channel margins or increasing barform heights for the preservation or enhancement of in-channel habitat. A number of adaptive management programs are in place in the United States that have objectives related to geomorphic change. A few examples of these programs are the Colorado River in Grand Canyon, the Trinity River in California, and the Platte River in Nebraska. In the case of the Platte River, the Bureau of Reclamation and U.S. Fish and Wildlife Service have identified short duration near-bankfull flows from 1 to 3 days in duration to test the ability of these flows to scour vegetation and build ephemeral sandbars to benefit

nesting species of concern (the least tern and the piping plover, U.S. Department of the Interior, 2006). Sediment augmentation has been recently used in the Platte River to offset reduction in sediment supply created by a clear water return from an upstream hydropower canal. The Platte River Recovery Implementation Program (PRRIP) initiated a pilot study aimed at adding 100,000 tons of sediment to the Platte River (PRRIP, 2014). Due to the magnitude and cost of adaptive management programs, predicting the outcome of management actions becomes an important means to design strategies to achieve the desired goals economically and effectively.

Predicting river response to different physical stimuli can be a difficult task. One of the tools available to river scientists is numerical models that can simulate morphologic change in rivers resulting from various management scenarios, including hydrograph change and sediment input. However, the detailed field information required to run, calibrate, and verify these models may be unavailable, potentially incomplete, or difficult to collect. Specifically, river bed topography before, during, and after flow manipulation may be lacking, as might information regarding the sediment supply rate during the management activities. Additionally, it is not always clear if a model has a range of applicability that encompasses the physical settings of the problem at hand.

Flume experiments have been used by researchers as a means to understand and observe channel evolution processes (Fujita and Muramoto, 1985; Fujita, 1989; Germanoski and Schumm, 1993; Marti and Bezzola, 2006; Madej et al., 2009). Flume experiments can also provide the data necessary for input, calibration, and verification of morphodynamic models (Jang and Shimizu, 2005; Takebayashi and Okabe, 2009). Combining numerical and physical modeling, therefore, offers a more comprehensive approach to predicting the outcomes of river management actions for at least two reasons. It can identify and provide a means to assess conditions that drive model predictions and provide a better understanding of the physical processes involved.

The intent of this paper is twofold. First, we discuss a series of flume experiments designed to explore the effect of upstream sediment supply and discharge alterations on erosion and deposition patterns in a straight channel with an initial plane bed. Second, we applied a coupled flow and sediment transport model to simulate and predict the morphologic changes observed in the flume. The flume experiments were conducted to address how the magnitude of upstream sediment supplied influenced the spatial and temporal patterns of erosion and deposition in a straight channel. In addition, we wanted to understand the effect of flow rate on the deposition and erosion patterns in a coarse, bedload dominated system. These effects are related to many types of management actions and, in particular, are directly relevant to those actions that involve manipulating flow and sediment supply to achieve bar formation. The numerical experiments were conducted for model testing and validation, and to gain an understanding of the influence of boundary conditions (input sediment load and initial topography) on predictions of channel evolution.

METHODS

Flume Experiments Over 30 flume experiments were conducted at the U.S. Geological Survey's Geomorphology and Sediment Transport Laboratory in Golden, CO using a 7-m long and 1.2-m wide tilting and recirculating flume. The flume slope was set to 1.25 percent. Vertical plywood walls were attached to the flume bed to restrict the width of the test channel to 0.50 m and the flow in the flume was adjusted with a computer controlled valve. The sediment used in the experiments was a well-sorted sand d_{50} = 0.6 mm, $\sigma = \sqrt{D_{84}/D_{16}}$ = 1.2. Sediment was introduced at the upstream end of the flume using a motorized sediment feeder. Higher sediment supply rates were achieved by augmenting the feeder supply by manually distributing sand evenly across the upstream end of the flume. We determined the sediment transport rate for a given flow by trapping sediment at the downstream end of the flume at that flow over a set time interval and weighing the dried material. The mean equilibrium transport rate measured for a 1L/s flow was approximately 3.3 $x10^{-3}$ kg/s. The bed of the test channel was screeded at the beginning of each experiment and the initial plane bed topography of the test channel was surveyed. Topographic surveys were repeated at 15-minute intervals over the duration of each experiment. We used a topographic measurement system that included a motorized traverse that spanned the width and length of the flume, a laser mounted to the traverse with its long axis pointing perpendicular to the flume bed, and a video camera oriented to capture an oblique image of the laser spot on the sand. Details of the mapping system are presented in Kinzel and others (2010). During the experiments it was necessary to drain the flume before the bed was surveyed. This was because the refraction of the laser through a small depth of water (< 0.01 m) could not be compensated for accurately, due to the inability to resolve distinct water surface and bed reflections in the images. An ultrasonic sensor was integrated to detect the water surface. The water-surface elevation was measured with the ultrasonic sensor at the end of each flume run.

A series of flume runs was conducted to evaluate channel response to varying sediment loads at a similar discharge. A discharge of 1.0 L/s was used for each of these experiments and with sediment supply rates equal to 0, 100, 133, 166 and 200 percent of the equilibrium transport rate. Each experiment lasted 2 hours to allow sufficient time for the sediment to move through the test section located between 2 and 4 m downstream of the most upstream transect measured. A series of flume runs was also conducted at 0.5 and 1.0 L/s without sediment supply to examine the change in morphology and sedimentation from clear-water flow alteration.

Plots of volumetric change as a function of the vertical deviation from the initial plane bed were made by determining the volume in 1-mm elevation bins within the test section of the flume. The test section was positioned to minimize the effect of the flume boundaries (upstream entrance and downstream tailgate) on the erosion and deposition patterns in the flume.

Numerical Modeling We used a two-dimensional, depth averaged, unsteady, coupled flow and sediment transport model, Nays2DH Version 1.0, to try to reproduce the spatial and temporal evolution of barforms observed in the flume experiments and the concomitant changes in sediment storage. Nays2DH is based on the numerical solution of the shallow water equations in a curvilinear orthogonal, structured grid and is a combination of two models: Nays2D and Morpho2D (iRIC Project, 2014). Nays2D is described in Shimizu (2002) and Morpho2D in Takebayashi (2005) and Takebayashi and Okabe (2009). Nays2DH is one of the models in the

international River Interface Cooperative (iRIC) software, described by Nelson and others (2010). The software is available at no cost and can be downloaded from http://i-ric.org/en/introduction. A general curvilinear coordinate system is used in Nays2DH. For our straight channel simulations we used a numerical grid with 0.02 m x 0.05 m grid cells in the stream-normal and stream-wise directions. Model inputs included the initial bed topography of the flume, downstream water-surface elevation, flow rate, and hydraulic roughness in the form of Manning's n. Nays2DH assumes a non-slip condition along the side-wall boundary.

Nays2DH supports both bedload and suspended sediment transport, and can perform calculations on uniform and mixed-grain sediment beds. The sediment bed in the flume was modeled with a uniform grain diameter of 0.6 mm. Nays2DH uses either the Meyer-Peter Müller (1948) or Ashida and Michiue (1972) equation to compute bed load transport. In our simulations, the Ashida and Michiue equation was used. The bedload transport vector was calculated using the Watanabe formula (Watanabe et al., 2001).

Two sets of model simulations were carried out. In the first set, a common technique to perturb the numerical calculation and stimulate the development of bar morphology from the initially plane bed was used. This technique uses a plane bed topography for the initial condition, and places a rectangular region with a slightly higher bed elevation (bump) at the upstream end of the model domain (Jang and Shimizu, 2005). In the second set of simulations, the flume topography measured after 15 minutes into the run was used directly as the initial condition for the bed topography.

Other modeling experiments were performed to examine the influence of secondary flows on the morphodynamics. Secondary (helical) flows can be treated in Nays2DH by using one of two approaches. One option involves solving an equation for depth-averaged vorticity in the streamwise direction. The other option allows the user to directly specify the strength of secondary flows. This parameter controls the near bed velocity and the direction of bedload transport:

$$\tilde{u}_b^n = \tilde{u}_b^s N^* \frac{h}{r_s} \quad (1)$$

Where: $\tilde{u}_b^n$ = the near-bed velocity in the transverse direction

$\tilde{u}_b^s$ = the near-bed velocity in the stream-wise direction

N^* = the strength of secondary flows, =7 per Engelund (1974))

$\frac{h}{r_s}$ = the ratio of the depth to the radius of streamline curvature

RESULTS

Sediment Experiments Our first experiments demonstrated, albeit somewhat intuitively, that if we supplied sediment at the equilibrium transport rate, the flume channel would degrade less and build bars to higher elevations than without sediment supply. Subsequent experiments demonstrated it was necessary to increase sediment supply 133 percent or more of the equilibrium transport rate for bars to be built to higher elevations than those built with the equilibrium rate. The change in elevation from the initially plane bed for three sediment supply rates and sedimentation after 2 hours with a flow of 1 L/s are shown in figure 1.

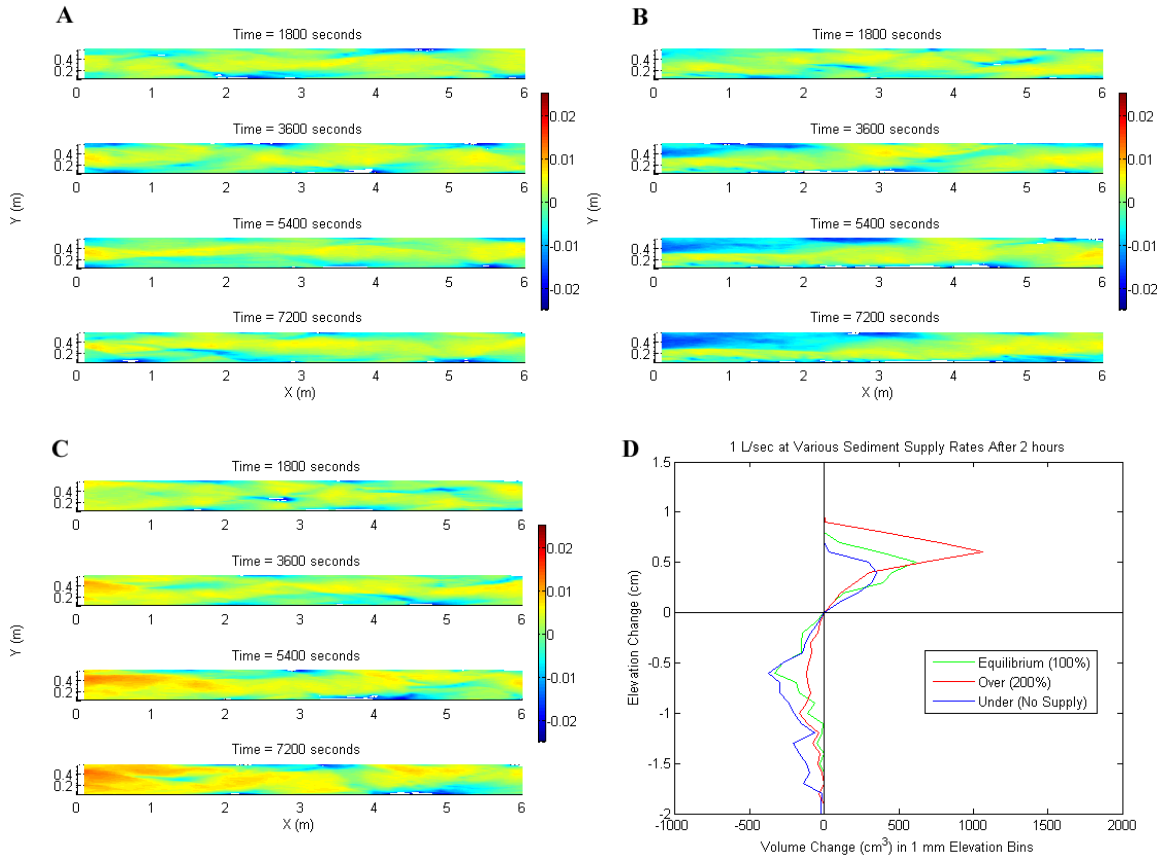

Figure 1 Changes in the bed elevation of the flume, in meters, measured over 2 hours with a flow of 1.0 L/s and sediment supplied at (A) the equilibrium transport rate (B) no upstream supply and (C) double the equilibrium transport rate. Plot showing erosion and deposition volumes measured in the test section as a function of elevation for the various supply rates after 120 minutes (D).

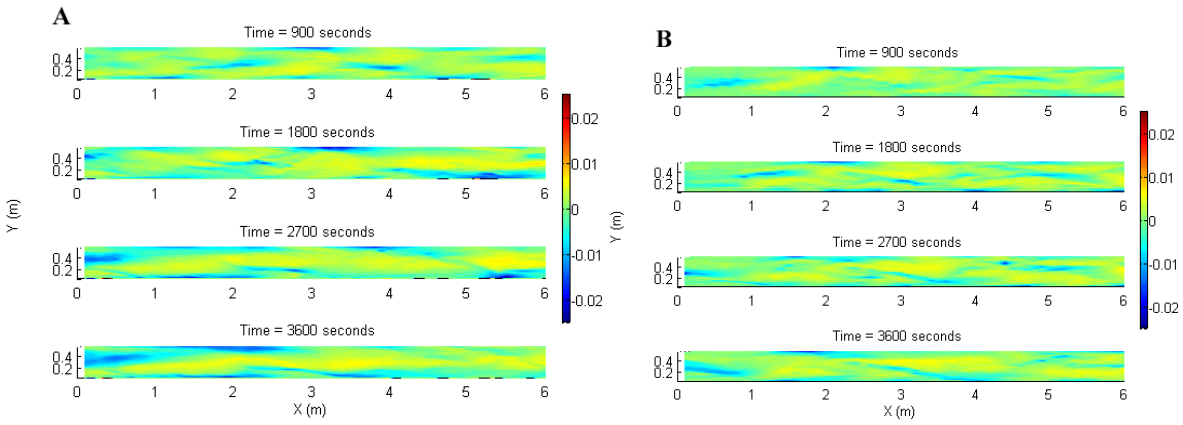
The differences between the supply rates are most discernable in the upper portion of the flume. For the flume run conducted with the equilibrium transport rate (Fig. 1A), the net change in the volume of the test section was a relatively small gain of 358 cm^3. The undersupply run (Fig. 1B) was dominated by erosion in this section and the net change in sediment volume in the test section was a loss of 1768 cm^3. The run with twice the equilibrium transport rate (Fig. 1C) resulted in a delta at the upstream end of the flume that continued to propagate downstream as

the experiment progressed, resulting in a net increase in sediment volume of 2273 cm^3 in the test section.

The morphology of the runs shown in figure 1 could be classified as alternate bars with deeper regions periodically forming along opposing channel walls. A volumetric change plot, which is computed over the inner third of the flume (test section) also highlights differences between the 3 sediment supply rates (Fig. 1D). The volume and height of deposition is highest for double the equilibrium supply rate, whereas the volume of erosion is highest when sediment is not supplied. Not surprisingly, supplying sediment at the equilibrium transport rate shows more equivalent volumes of erosion and deposition.

Flow Experiments A series of experiments was conducted to simulate the effect of flow regulation on channel morphology. These experiments are analogous to river reaches that have experienced alterations in flow due to dams or diversions. Two discharges were examined in detail, 0.5 and 1 L/s. Multiple runs were conducted for each discharge without upstream sediment supply and each lasting a duration of 1 hour.

Figures 2A and 2B illustrate the topographic changes that were measured for Run 3 (1 L/s) and Run 9 (0.5 L/s). The experiments conducted at 1.0 L/s displayed a similar pattern of channel evolution. Typically the channel formed higher mode bars during the initial 15 minutes of the experiment (Fig 2A). Following the 15-minute survey, when flow in the flume resumed, the channel evolved to have a more meandering pattern in which the main thalweg was found along alternating sides of the flume. The experiments conducted at 0.5 L/s (Fig. 2B) initiated bed forms in the first 15 minutes that, based on visual inspection, were less symmetric and of lower relief than the higher mode bars that developed early in the 1.0 L/s experiments. The initiation and progression of upstream erosion during the 1-hour flume run was also less clearly defined for the lower 0.5 L/s flow. Volumetric plots of the elevation changes after 1 hour for each run at 0.5 and 1.0 L/s show variability among each flow rate (Fig. 2C).



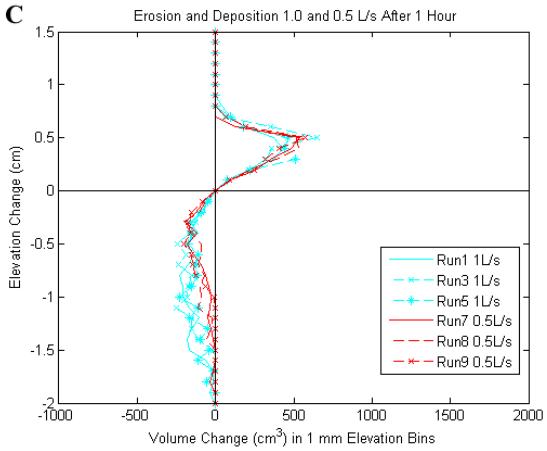


Figure 2 Changes in the bed elevation of the flume, in meters, measured over 1 hour for two flow rates (A) Run 3 at 1 L/s and (B) Run 9 at 0.5 L/s. Plot showing the erosion and deposition measured in the test section for various flow rates after 1 hour (C).

The greatest disparity in sedimentation between the flow rates was observed in the amount of erosion; the height of bar forms were rather consistent. The higher discharge caused more total erosion and erosion to lower elevations. This morphologic response is akin to that of a flushing event wherein water devoid of sediment is released into a channel from a dam or hydropower return canal.

Nays2DH Simulations The roughness value used in Nays2DH was determined by calibrating the water-surface elevation measured at 2 hours into the flume run with the model predicted water surface. This water-surface elevation was influenced by drag from bedforms created during the flume run, but acknowledging that drag changed because of bed evolution we reasoned this profile was most appropriate for calibration. The best calibration (root mean square error of 0.001 meter between measured and modeled water-surface elevations) was found using a Manning's n of 0.03. While Nays2DH can accept varying sediment supplies at the upstream end by specifying the ratio of supplied sediment transport to the equilibrium rate, there is presently no ability to input a transport rate to exactly match observations. We found better agreement in transport rate with our observations using the Ashida Michiue equation (~2.0 $x10^{-3}$ kg/s, i.e., 60.6 percent of the measured transport rate of the flume experiments) rather than the Meyer-Peter Müller equation (~2.0 $x10^{-2}$ kg/s, an order of magnitude greater than Ashida Michiue), which is expected as the latter was developed for fine gravel. Modeling experiments were conducted to compare two approaches for inducing bed instability and initiating bar development in a straight channel. Model results using an initial plane bed with a small bump placed immediately upstream as input are shown in figure 3. Figure 4 shows the outcome from using the flume topography measured at 15 minutes as the initial bed condition.

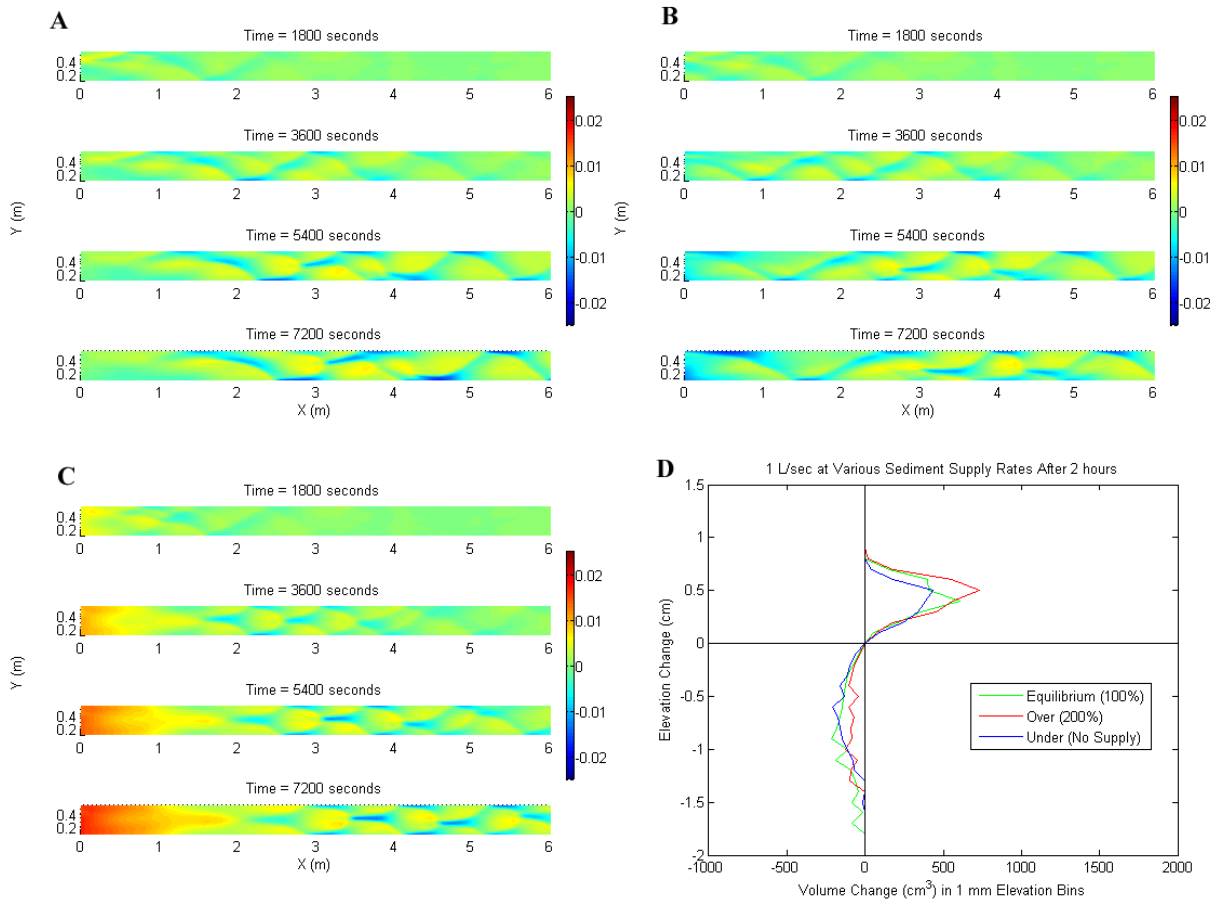

Figure 3 Changes in bed elevation predicted by Nays2DH using a plane bed with upstream perturbation as input and sediment supplied at (A) the equilibrium rate, (B) 0 percent of the equilibrium rate, and (C) 200 percent of the equilibrium rate. Plot showing erosion and deposition volumes predicted by Nays2DH in the test section as a function of elevation for the various supply rates after 2 hours (D).

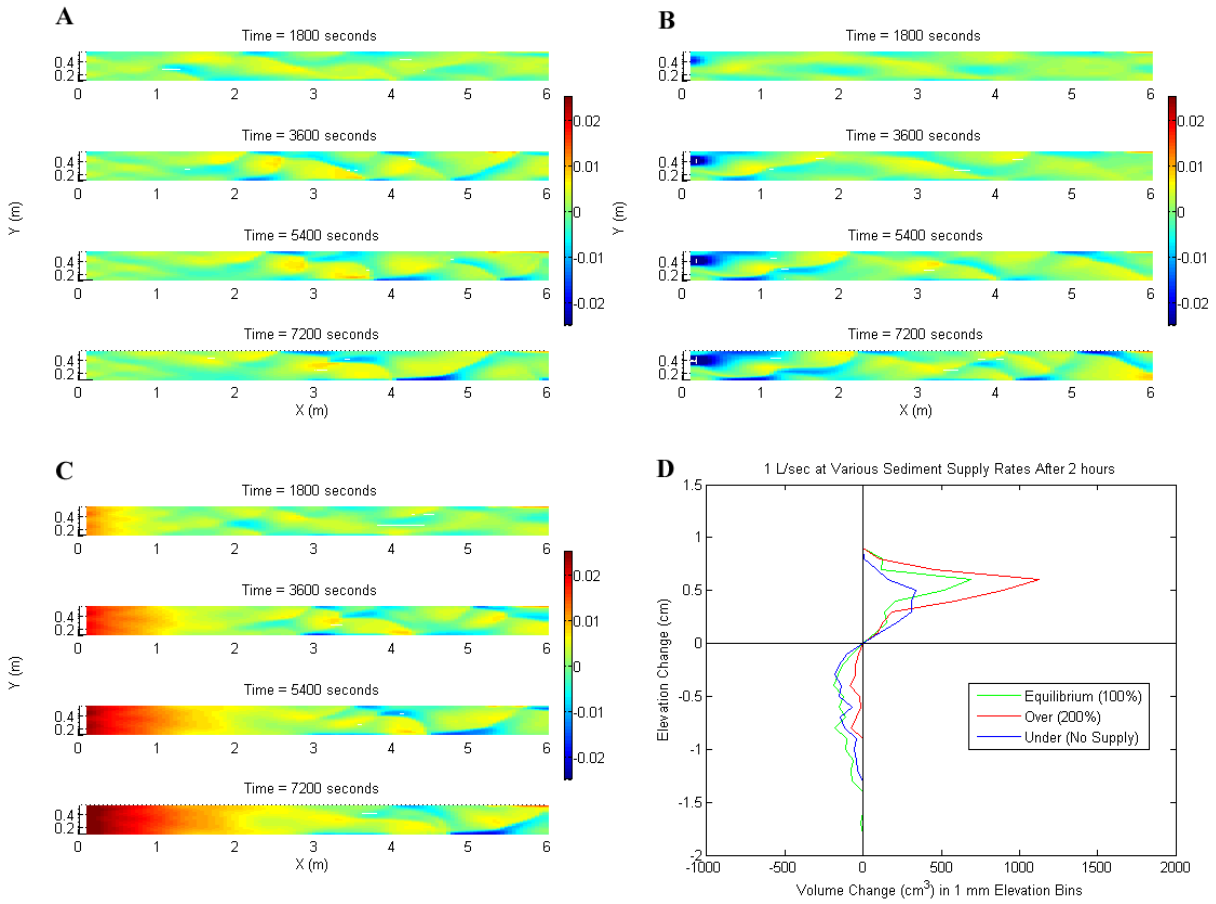

Figure 4 Changes in bed elevation predicted by Nays2DH using the antecedent bed topography in the flume measured at 15 minutes as input and sediment supplied at (A) the equilibrium rate, (B) 0 percent of the equilibrium rate and (C) 200 percent of the equilibrium rate. Plot showing erosion and deposition volumes predicted by Nays2DH in the test section as a function of elevation for the various supply rates after 2 hours (D).

Including secondary flows by computing the depth-averaged vorticity in the streamwise direction resulted in excessively weak alternate bar formation that did not match experimental results. Using the second option and increasing the strength of the secondary flow parameter N^*, from the default value of zero, was shown to induce more substantial variations in bed morphology and sediment storage. However, because we were simulating flow in a straight flume channel, we reasoned that adjusting this parameter was somewhat subjective and more justifiable for stronger meander bends, therefore the results are not discussed here. Nays2DH also is able to simulate periodic boundary conditions. If periodic boundary conditions are used, the sediment and hydraulic conditions calculated at the downstream end of the model domain are applied to the upstream end. However, in the present version of Nays2DH if periodic boundary conditions are enabled the supply of sediment at the upstream boundary cannot be changed from the equilibrium condition. Therefore, to ensure consistency among all supply rates modeled, we disabled this boundary condition for all runs.

DISCUSSION AND CONCLUSIONS

Two sets of flume experiments were carried out: one set with increasing sediment supply, the other with clear-water inflow at different flow rates. In conjunction these two sets of runs show the separate effects of flow rate and sediment supply changes on the morphologic evolution of a plane-bed channel. These experiments were conducted to illustrate and explore basic morphologic responses and serve as simple analogs to river management activities. The sediment supply experiments (Fig. 1) indicated that it was necessary to increase the supply at or above 133 percent of the equilibrium rate to appreciably increase bar heights. Although all runs showed both degradation and bar formation, the height of the bedforms was greater and degradation was smaller for the higher sediment supply rate (Fig. 1D), highlighting the role of sediment transport in bar formation and maintenance. In the clear-water flow experiments without upstream sediment supply, greater flow rates induced increased bed degradation, but did not contribute to the creation of bed forms with higher elevation (Fig. 2). This observation corroborates the idea that increased transport capacity (i.e., higher flow rates) must be accompanied by increased sediment availability in order to create and maintain higher bars and topographic relief.

The Nays2DH numerical model was used to simulate the conditions employed in the laboratory flume. The principal difficulties in the modeling effort were to accurately compute the sediment transport rates and to determine the ideal starting bed conditions for the onset of plane bed instability. Therefore, the primary causes for the differences between the physical flume experiments (Fig. 1) and the numerical simulations (Figs. 3 and 4) may be attributed to the boundary conditions supplied to the model. The initiation of morphologic evolution using an initially plane bed with an artificial perturbation produced higher mode bars at the end of the simulations than did predictions using the natural perturbations present in an antecedent flume topography, which more closely resembled the alternate bar or single-thread meandering morphology observed in the flume.

The initiation and progression of the scour under the no supply case was more pronounced using the antecedent bed condition over the plane bed topography but did not advance downstream to the extent of the flume observations. In addition, the delta predicted at the upstream end of the flume for each modeled over supply case was higher than observed in the flume. These observations indicate the transport rate calculated by the model was not sufficient in either input condition to advance these features, and it may be a direct consequence of the use of the Ashida and Michiue transport equation, which was shown to underestimate the equilibrium transport rate of the experimental conditions by over 39 percent.

The erosion and deposition volumes predicted by either input bed condition were about the same for the equilibrium supply case. For the under supply case, both models over predicted aggradation and under predicted degradation. Turning to the over supplied case, the plane bed input condition under predicted aggradation, whereas using the antecedent topography as input under predicted the degradation. Thus, it can be concluded that although using a natural perturbation produced a morphology that was more analogous to the final evolved flume topography, the transport rates predicted by the model were not sufficient to match the sedimentation observed in the test section. As above, the likely explanation is that the transport

rate computed by the model was less than that of the experiments. Unfortunately, Nays2DH does not at present offer a means to scale existing transport equations to match the observed conditions.

Future work will include comparing the flume experiments and, ultimately, morphologies from river management experiments with predictions from other models in iRIC. These models offer different approaches to sediment transport modeling, such as other transport equations, and can account for three-dimensional flow effects. While resulting in somewhat more computationally expensive models, inclusion of additional boundary conditions (e.g. side wall friction) and three-dimensional simulation of the flow structure and its influence on sediment transport can provide more accurate representation of the dynamics of channel evolution.

INTRODUCTION

The magnitude and pfattern of streamflow and sediment supply of the Colorado River in Grand Canyon (Figure 1) has been affected by the existence and operations of Glen Canyon Dam since filling of Lake Powell Reservoir began in March 1963. In the subsequent 30 years, fine sediment was scoured from the downstream channel (Topping et al., 2000; Grams et al., 2007), resulting in a decline in the number and size of sandbars in the eastern half of Grand Canyon National Park (Wright et al., 2005; Schmidt et al., 2004). The Glen Canyon Dam Adaptive Management Program (GCDAMP) administered by the U.S. Department of Interior oversees efforts to manage the Colorado River ecosystem downstream from Glen Canyon Dam. One of the goals of the GCDAMP is to maintain and increase the number and size of sandbars in this context of a limited sand supply. Management actions to benefit sandbars have included curtailment of daily streamflow fluctuations, which occur for hydropower generation, and implementation of controlled floods, also called high-flow experiments.

Studies of controlled floods, defined as intentional releases that exceed the maximum discharge capacity of the Glen Canyon Dam powerplant, implemented between 1996 and 2008, have demonstrated that these events cause increases in sandbar size throughout Marble and Grand Canyons (Hazel et al., 2010; Schmidt and Grams, 2011; Mueller et al., 2014), although the magnitude of response is spatially variable (Hazel et al., 1999; 2010). Controlled floods may build some sandbars at the expense of erosion of sand from other, upstream, sandbars (Schmidt, 1999). To increase the frequency and effectiveness of sandbar building, the U.S. Department of Interior adopted a "high-flow experimental protocol" to implement controlled floods regularly under conditions of enriched sand supply (U.S. Department of Interior, 2012). Because the supply of sand available to build sandbars has been substantially reduced by Glen Canyon Dam (Topping et al., 2000) and depends entirely on infrequent tributary floods, monitoring of both sandbars and gross sand storage (the sand budget) is required to evaluate whether the high-flow protocol is having the intended effect of increasing sandbar size without progressively depleting sand from the system.

There are many challenges associated with monitoring sand storage and active sand deposits in a river system as large and complex as the 450-km segment of the Colorado River between Glen Canyon Dam and Lake Mead. Previous studies have demonstrated the temporal variation in sand storage associated with sand-supply limitation (Topping et al., 2000) and the spatial variability in the amount of sand stored in eddies and the channel associated with channel hydraulics (Grams et al., 2013). In this study, we report on companion measurements of sand flux and morphologic change to quantify, for the first time, the relation between changes in sand mass balance, changes

in within-channel sand storage, and changes in sandbars comprehensively for a 50-km river segment of the Colorado River in lower Marble Canyon within Grand Canyon National Park.

We show that, when measured over the scale of a 50-km river segment, these complementary measurements of the sand budget agree within measurement uncertainty and provide a rare opportunity to integrate the temporally rich sand-flux record with the spatially rich morphologic measurements. Both methods show that sediment was evacuated from lower Marble Canyon over the 3-year study period. The flux-based budget shows the timing of changes in storage relative to dam-release patterns, while the morphologic measurements depict the spatial distribution of erosion and deposition among different depositional settings.

Figure 1 Map of Colorado River between Lake Powell and Lake Mead. Marble Canyon is the river segment between Lees Ferry and the Little Colorado River confluence. The focus of this study is lower Marble Canyon, which is the 50-km segment of Marble Canyon that begins 50 km downstream from the mouth of the Paria River. Grand Canyon is the segment of the Colorado River from the Little Colorado River confluence to Lake Mead.

METHODS

Flux-based Sand Budget: Streamflow and suspended sediment transport are monitored continuously (15-minute intervals) at the upstream and downstream ends of lower Marble Canyon (Figure 1). Streamflow is gaged by standard gaging methods (Rantz et al., 1982) and sediment concentration is monitored with acoustic instruments that are calibrated to conventional suspended-sediment samples (Griffiths et al., 2012; Topping et al., 2015). These data are used to compute 15-minute sediment loads separately for mud (silt and clay) and sand. The instantaneous values for discharge and concentration from each gage and sand budgets computed

for any time interval between 2002 and present are available at www.gcmrc.gov/discharge_qw_sediment/.

Morphologic-based Sand Budget: Riverbed and sandbar topography were measured by surveys with total stations, singlebeam sonar, and multibeam sonar during separate two-week field campaigns in May 2009 and May 2012. Multibeam sonar was used to map the river channel in all locations with sufficient depth, generally 2 m or deeper. Singlebeam sonar was primarily used to map shallower depths along the channel margins. Some reaches were mapped entirely with singlebeam sonar. Total stations were used to survey sand deposits along and above the water's edge. Gravel bars, talus slopes, and debris fans were not typically surveyed. Areas of the channel where upstream navigation was not possible and areas of the banks dominated by established woody riparian vegetation also were not surveyed. Thus, most of the area of the channel not surveyed consists of immobile or rarely mobile gravel and boulders; most of the area on the channel margins not surveyed has been stabilized by vegetation. Details on the methods of data collection, processing, construction of digital elevation models (DEMs), and analysis of uncertainty are described in Hazel et al. (2008) and Kaplinski et al. (2009; 2014).

The difference between the 2009 and 2012 DEMs was computed for each 1-m grid cell and uncertainty was assigned based on the method of data collection (Kaplinski et al., 2014). Volumes of erosion, deposition, and net change were tabulated by geomorphic unit. The primary geomorphic units are eddy, channel adjacent to eddy, other channel, onshore sandbar, and sandbar above reference stage (Figure 2). Eddies were defined as regions of recirculating flow based on water-surface streamflow paterns at 8,000 ft^3/s. The channel adjacent to the eddy is the entire width of downstream-directed current in the channel adjacent to the length of an eddy. The onshore sandbar category is comprised of all the morphologic types of sandbars described by Schmidt (1990) that occur in eddies. The geomorphic units were mapped in a geographic information system (GIS) with May 2009 digital ortho-rectified imagery as a base and subsequently checked in the field for accuracy. For the purposes of volumetric calculations, onshore sandbars are the portions of the sand deposits in eddies that are above the subhorizontal plane (defined by water surface) associated with a discharge of 8,000 ft^3/s. Thus, changes in the onshore sandbars represent changes in sand volume above the 8,000 ft^3/s stage. The "other channel" category includes all portions of the channel not included in the categories described above.

Uncertainty in the estimate of morphologic change is based on the method of data collection, potential changes in storage for the 30% of the reach that was not mapped, and the potential that some topographic change comprised sediment other than sand. For areas mapped by multibeam sonar and singlebeam sonar, we estimate the uncertainty to be ±0.06 m and ±0.12 m, respectively, based on analysis of repeat maps over stable areas reported by Kaplinski et al. (2014). We estimate uncertainty for areas mapped by total station to be ±0.04 m. These values were multiplied by the area mapped by each method, using the method with greatest uncertainty for areas mapped by different methods in each year. The potential change for the portion of the reach not mapped was estimated based on the mean change in each map unit for the portion of the reach that was mapped. Determining the proportion of morphologic change that involved sand is challenging, because bed texture measured before or after the topographic change is not necessarily indicative of the texture of the material that was eroded or deposited. A comprehensive analysis considering both the direction and magnitude of topographic change and

textural changes is ongoing. In this analysis, we make the conservative estimate that as much as 30% of the morphologic change involved sediment other than sand. We assume each of the sources of uncertainty to be independent and, therefore, the uncertainties are summed in quadrature to arrive at an estimate of gross uncertainty for lower Marble Canyon.

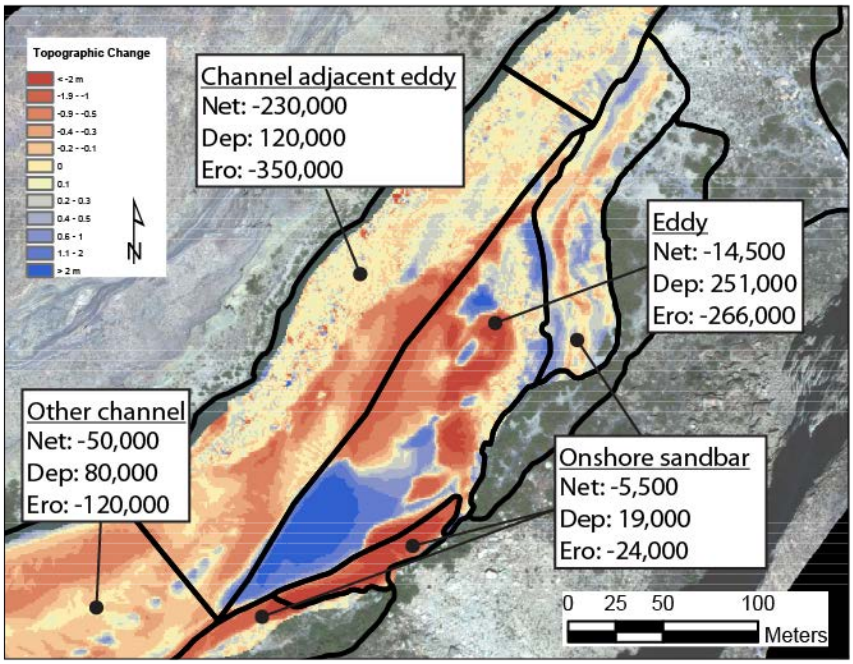

Figure 2 Illustration of sediment storage environments in lower Marble Canyon. Values indicate the volumes, in cubic meters, of net sand storage change, deposition, and erosion summed by indicated map unit for all areas mapped in lower Marble Canyon. Line separating onshore sandbars from eddy is water edge at 8,000 ft^3/s in May 2009. This example location is 71 km downstream from Lees Ferry. Streamflow is from upper right to lower left. All values are in cubic meters.

RESULTS

Comparison of Flux-based and Morphologic-based Sand Budgets: The sand budget computed by measurements of sand flux, and the sand budget computed as the difference between the two topographic surveys, agree within measurement uncertainty. Between May 1, 2009, and May 1, 2012, approximately 2.49 x 10^6 metric tons (Mg) of sand entered lower Marble Canyon at gage 9383050 (Figure 1) and approximately 3.06 x 10^6 Mg of sand was exported past gage 9383100. Ungaged tributaries added an estimated 20,000 Mg of additional sand to the reach. With uncertainty, this results in a flux-based sand budget of -550,000 ± 300,000 Mg (Figure 3). Based on a particle density of 2650 kg/m^3 and 35% porosity, that is equivalent to 320,000 ± 70,000 m^3 of net sand loss in the reach. Over the same time period, the repeat topographic measurements indicate approximately 770,000 m^3 of erosion and 470,000 m^3 of deposition resulting in a net change of -300,000 ± 250,000 m^3.

Most of the net changes in sand storage occurred in the areas of channel adjacent to eddies (Figure 2). However, net change in storage may not be the best metric to evaluate the relative

capacity of each storage environment. Although the net change in storage in eddies was relatively small, eddies were actually the most active storage environments in terms of gross storage change. Gross storage change is defined as the sum of the absolute values of erosion and deposition. For this period of net sand loss from lower Marble Canyon, there was widespread erosion in both the eddy and channel storage environments. However, erosion in eddies was compensated by an almost equally large volume of deposition. Relatively little deposition occurred in the channel. Thus, despite the relatively small net change, eddies were the most active storage environment. This new observation regarding the relative role of the eddy and channel storage environments likely has implications for the processes by which sand accumulates and evacuates from the river.

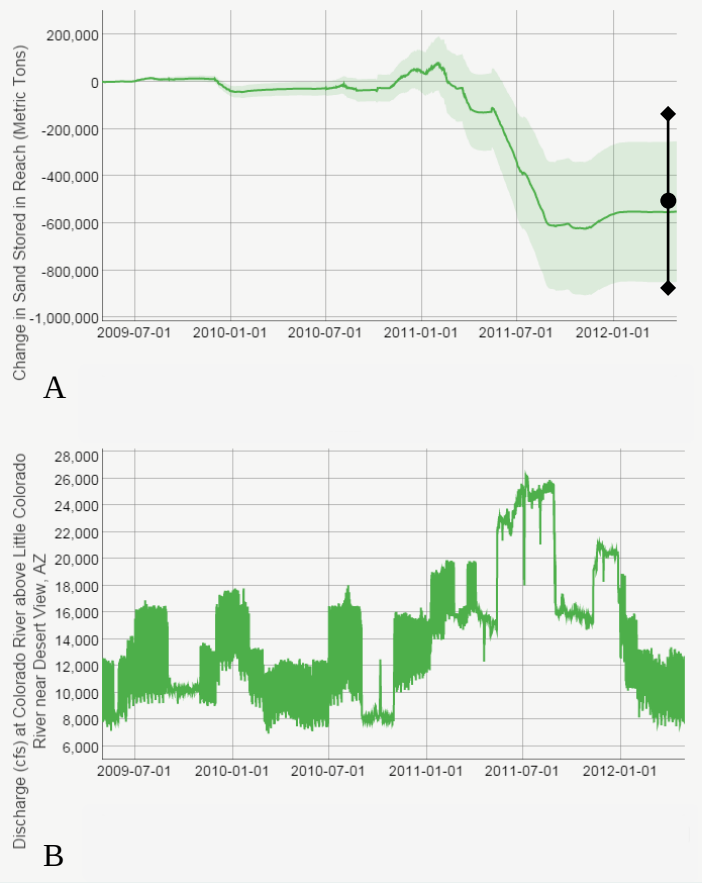

Figure 3 (A) Cumulative change in sand storage for lower Marble Canyon from May 1, 2009 to May 1, 2012. The solid line shows the zero-bias estimate; the shaded region shows the uncertainty band, which increases with time. The point with error bars shows the morphologic-based sand budget for the same period converted to units of mass, with uncertainty. (B) Discharge of the Colorado River at the upstream end of lower Marble Canyon (U.S. Geological Survey gage 9383050). Plot generated Nov. 6, 2014 at www.gcmrc.gov/discharge_qw_sediment/.

Spatial Variability in Sandbar Erosion and Deposition: The parts of sandbars that are exposed above the water surface and available for use by river runners as campsites are of the greatest management interest. Those areas, however, comprise a small proportion of the total

sediment budget. Both the net and gross changes in onshore sandbars were small fractions of the gross changes in other storage environments (Figure 2). Only 2% of the 300,000 m^3 of net storage change in lower Marble Canyon occurred in onshore sandbars above the elevation associated with a discharge of 8,000 ft^3/s, despite the fact that flows exceeded 8,000 ft^3/s over 95% of the time.

While changes in the channel, eddy, and sandbar storage environments are related on some relatively large spatial scale, changes in onshore sandbars and the adjacent eddy and channel appear to be poorly correlated. Over some spatial scale, when sand is depleted from the channel and eddies, more sandbars decrease in size than increase in size. This is shown in a plot of the cumulative changes in each geomorphic unit (Figure 4). Although the cumulative changes do not track precisely, there is consistency between loss of sand from the channel and eddies and decreases in the volume of sand in sandbars. Although this correspondence in the general direction of change exists, the changes are not well correlated at the scale of individual eddies (Figure 5). It is therefore not possible to predict the response of individual sandbars based on the response of the adjacent channel. Correspondingly, responses for individual sandbars cannot be inferred to be representative of the status of sand storage in the adjacent eddy and channel. Based on the data shown in Figures 4 and 5, it appears that there is correlation between onshore sandbar response and eddy/channel response at scales of a few km. However, the spatial scale of this coupling is likely to depend on many factors, including the length of the time interval analyzed, streamflow during the interval, the amount of sand-storage change, and the sand grain size. Thus, further investigation considering these and other factors is required.

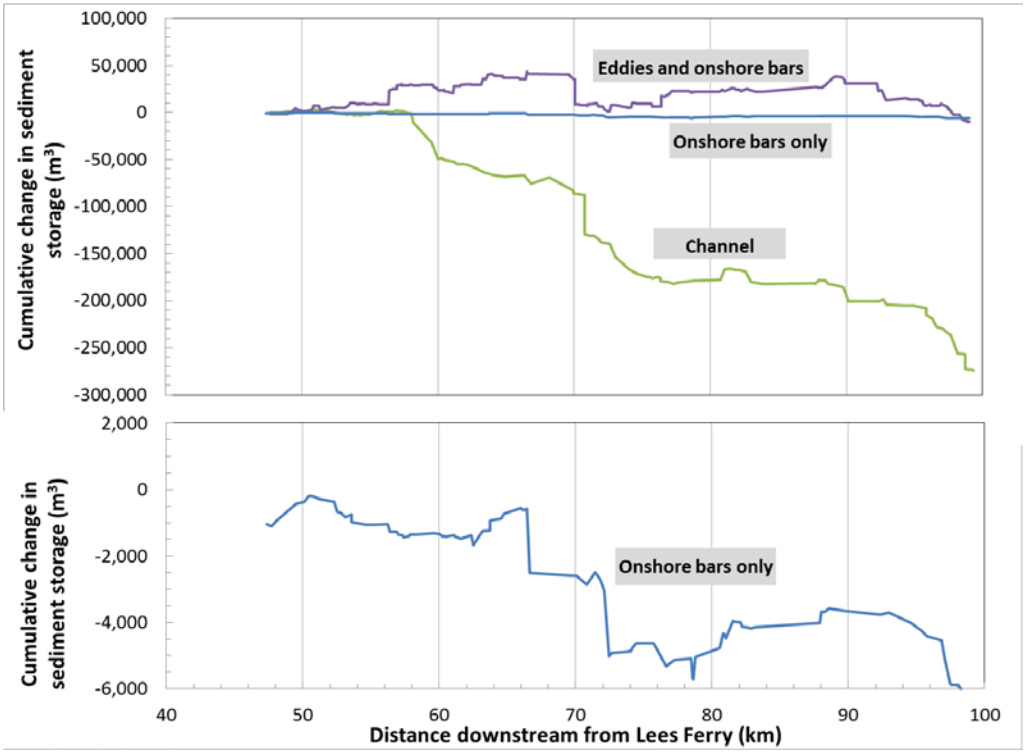

Figure 4 Cumulative downstream change in net sediment storage in lower Marble Canyon by depositional setting. Top panel shows all depositional settings, bottom panel shows the same data for onshore bars only at increased vertical scale.

Evaluation of Sandbar Sampling Design: Comprehensive measurements of onshore sandbar change made throughout lower Marble Canyon between 2009 and 2012 provide the opportunity to evaluate the sampling design for site-based sandbar monitoring that has been in place since 1990. Changes in sandbar topography have been monitored annually since 1990 at study sites throughout Marble and Grand Canyons (Hazel et al., 2010). In lower Marble Canyon, topographic changes of 18 sandbars in 14 different eddies are monitored above the 8,000 ft^3/s reference stage (Hazel et al., 2010). The success or failure of management actions, such as controlled floods, to cause net increases in sandbar size is based largely on the changes in sandbar volume measured at these sites. The maps of geomorphic units described above show that lower Marble Canyon contains 176 eddies larger than 1000 m^2 (combined area of eddy and onshore sand deposits), 84 of which had onshore sandbars larger than 100 m^2 and were mapped in both 2009 and 2012. Thus, the 18 sandbars that are monitored annually comprise a relatively small sample of the total number of large sandbars. Below, we compare topographic changes at the 18 sandbars that are monitored annually with changes that occurred at all 84 sandbars mapped in 2009 and 2012.

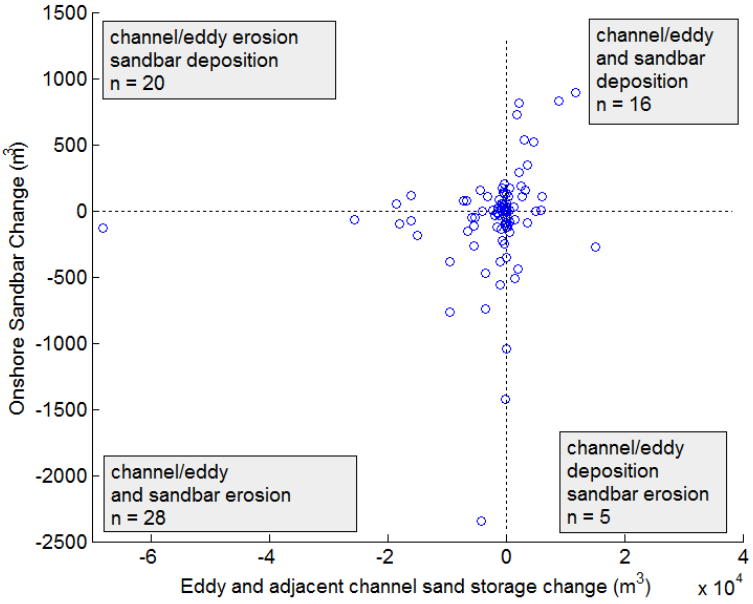

Figure 5 Change in onshore sandbar volume as function of change in channel and eddy storage for the corresponding eddy. This shows that changes in onshore sandbars are not well-correlated with sediment storage change in the same eddy and adjacent channel.

The mean change in sandbar thickness (volume normalized by area) between 2009 and 2012 for these sites (-0.06 m ± 0.06 m standard error), is consistent with the mean change among the much larger sample of 84 sandbars mapped throughout lower Marble Canyon (-0.10 m ± 0.06 m standard error) (Figure 6A). While the mean responses among the two sample sizes are similar for this period, they do not necessarily reflect the full range of sandbar responses, in particular those sites with large gains or large losses. The variance of sand thickness change between 2009 and 2012 among all sandbars in lower Marble Canyon (σ^2=0.12) is double the variance among the 18 monitoring sites (σ^2=0.06), showing that for this period, the monitoring sites had smaller-

magnitude changes than was observed among all sandbars. This suggests that while the set of long-term monitoring sites may adequately represent mean sandbar condition, it fails to capture the full extent of variability in sandbar condition. A bootstrap analysis using all 84 sites surveyed in 2009 and 2012 in lower Marble Canyon indicates that a random sampling of fewer than the current number of monitoring sites would be unlikely to capture mean bar condition better than the current configuration of monitoring sites. The standard error on the mean sandbar thickness as a function of sample size (Figure 6B) suggests that the 18 sites regularly surveyed would capture the trend in the mean sandbar thickness to within approximately 10 cm. While this is a marginally acceptable uncertainty, Figure 6B suggests that one would expect an exponential increase in this uncertainty with decreasing sample size, which is an important consideration for sampling design elsewhere in the canyon.

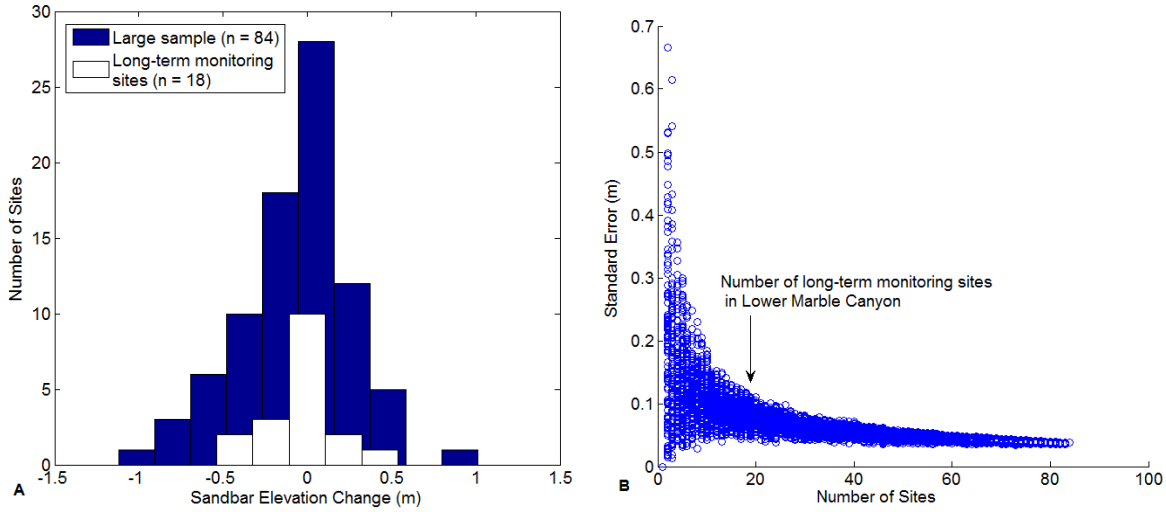

Figure 6 (A) Histograms showing frequency distribution of changes in sandbar elevation for the 84 onshore sandbars measured in lower Marble Canyon (blue) and the 18 of those that are also long-term monitoring sites (white). (B) Bootstrap simulation of expected standard error for estimates of sandbar thickness change as a function of sample size. Measurements of thickness change for 84 sandbars in lower Marble Canyon were sampled randomly using increasing sample size (1 to 84). For each sample size, 100 random selections of (1 – 84) sites were made from among the 84 sites, and the standard error calculated and plotted.

DISCUSSION AND CONCLUSIONS

The goals of resource managers on the Colorado River in Grand Canyon National Park include maintaining and improving the condition of alluvial sandbars in a system that has been perturbed into severe fine-sediment deficit by an upstream dam (Schmidt and Wilcock, 2008). While controlled floods are the most cost-effective management tool that is currently available to achieve that goal, it is uncertain whether sand supply is sufficient to support repeated sandbar building in the context of other dam operations, which also export fine sediment (Wright and others, 2008; Wright and Grams, 2010). The data reported here span a 3-year period that did not include controlled floods but did include over 3 months of steady dam releases that greatly exceeded the range of normal dam operations (Figure 3). The measurements of sand flux and the

measurements of sediment storage change both indicate that these releases evacuated on the order of 300,000 m^3 (500,000 Mg) of sediment from lower Marble Canyon.

Previous attempts to construct a closed sand budget for lower Marble Canyon based on measurements of morphologic change for short monitoring reaches were unsuccessful, because large spatial variability in erosion and deposition resulted in the inability to extrapolate measurements from short reaches to the entire 50-km segment (Grams et al., 2013). In this case, mapping morphologic change in approximately 70% of the same segment resulted in good agreement between the flux-based and morphologic-based budgets. This greatly increases confidence in both the measurements of flux and morphologic change. The results further demonstrate the challenge associated with using morphologic measurements to infer a sediment budget at a scale larger than the reach measured. Although a 10-km study reach might often be considered to be of sufficient length to be representative of a longer river segment, it is clear that in lower Marble Canyon, there are significant differences in the magnitude of sand-storage change between adjacent 10-km reaches (Figure 4). Therefore, without detailed knowledge about the behavior of all major sand-storage locations, it would not be possible to construct an accurate morphologic-based sediment budget for a long river segment like lower Marble Canyon based on a sub-sample of the segment.

The measurements of flux show that nearly all of the sand evacuation occurred during the high releases of summer 2011 (Figure 3). The maps of channel topographic change reveal the locations of that sediment evacuation. Previous studies concluded that most sand-storage changes in Marble and Grand Canyons occurred within zones of recirculating flow – eddies (Hazel et al., 2006). Our findings support that conclusion with some qualification. Between 2009 and 2012 in lower Marble Canyon, eddies were the most active sediment storage environment, but exhibited very little net change in sediment storage. Most net change in sediment storage occurred in the main channel adjacent to eddies. The Hazel et al. (2006) study was conducted over a period that that followed relatively high dam-release volumes and focused on changes that occurred over a short period during a controlled flood. In contrast, we studied changes over a three-year period following relatively low dam-release volumes. This illustrates that the behavior of different storage environments can vary widely depending on the period examined. Because both eddy and channel storage environments are very large and either may dominate the signal of net change in sand storage, both must be measured to compute an accurate sediment budget.

The observations also demonstrate that the entire debris-fan eddy complex (Schmidt and Rubin, 1995) is the dominant storage environment, not just the recirculation zone. The channel adjacent to the eddy includes a scour hole and pool exit slope, both of which accumulate and evacuate sediment. While the channel adjacent to eddies was the dominant location of net change in this period of scour, it is possible that the relative proportions of change between the eddies and channel could reverse in other periods.

This period of sand evacuation followed a period of large tributary inputs and sand accumulation from 2004 through 2010 (Topping et al., 2010). Repeat topographic maps of short reaches within lower Marble Canyon from 2002, 2004, and 2009 also indicate that 2009 was a period of enriched sand storage. We speculate that both channel and eddy sand-storage locations were relatively full at the beginning of the high dam releases in 2011. During the elevated sand concentrations that occurred as sand was exported from the reach, it is likely that eddies were

locations of substantial mixing between the bed and suspension, while sand was simply scoured from other storage locations. In this way, the eddies behave as a buffer for sand evacuation. If all of the sand mobilized in the 2009-2011 interval had been eroded (i.e. the sand deposited in eddies was instead exported), the net loss of sand could have been nearly twice as large as actually occurred. At least 250,000 m^3 of easily mobilized sand remained in storage within the eddies. Thus, if the 2011 high releases continued for a longer period of time, we would expect that sand evacuation would have continued at a high rate for much longer. This is consistent with the measurements of sand flux, which do not indicate a decline in the rate of evacuation during 2011 (Figure 3).

On the scale of the entire 50-km segment of lower Marble Canyon, the changes in onshore sandbars tracked with the overall decline in sand storage. There was net loss of sand from the river channel and net decrease in the volume of sand in onshore sandbars. Previous studies have shown that for short time periods (e.g. the several day span of a controlled flood), there can be widespread deposition on the onshore sandbars while there is net sand loss from the deeper parts of eddies and the main channel (Schmidt, 1999; Hazel et al., 2010; Wright and Kaplinski, 2011). The findings from this comprehensive sand budget for lower Marble Canyon suggest that over the time scale of a few years (e.g. the 3-year period of this study) or longer, onshore sandbars generally increase in size when the sand budget is positive and decrease in size when the sand budget is negative.

There is not, however, a direct correlation in the response between the combined channel/eddy storage environment and the adjacent onshore sandbar. The change in onshore sandbars can be muted or amplified relative to the change in the adjacent eddy and channel. In some cases, the change in the onshore sandbar is the opposite sign of the change in the channel and eddy. This means that in order to monitor both the status of the sand budget and the status of onshore sandbars, it is necessary to monitor both, even though the net changes in the onshore sandbars are small relative to the overall sand budget. Further investigation is required to better describe the spatial scale at which channel, eddy, and onshore sandbar response are coupled. Sandbar sampling design is further informed by an examination of the change in sandbar elevation for the onshore sandbars mapped in lower Marble Canyon. This analysis indicates that the 18 sites currently monitored in the 50-km reach is likely a minimum sample size to reasonably represent the mean response exhibited in the larger set of 84 sandbars.

PREDICTING AND COMPARING MEASURED BULKING AND PEAK DISCHARGE USING MULTIPLE METHODS FOR POST FIRE HYDROLOGIC AND SEDIMENTATION ANALYSIS ON THE DUMP FIRE IN SARATOGA SPRINGS

Nathaniel Todea, USDA Natural Resources Conservation Service Hydraulic Engineer, 125 South State Street Room 4010, Salt Lake City, Utah 84106, 801.524.4573, Nathaniel.Todea@ut.usda.gov

Abstract: As part of the 2012 Utah fire season, analysis of the Dump Fire was conducted to design sediment basins. The event was estimated to be a 1.25-inch storm that lasted 25 minutes and dropped an estimated bedload of 70,000 tons of material, which damaged houses, inundated basements, and overtopped a small basin. The event is comparable to two times the 100-year (1% chance event) flow. The Dump Fire was analyzed as a part of the United States Department of Agriculture Natural Resources Conservation Service Emergency Watershed Protection Program.

The Dump Fire watershed is located near Saratoga Springs, Utah, which is on the eastern edge of the Basin and Range physiographic region. It was analyzed using the United State Department of Agriculture Agricultural Research Service Automated Geospatial Watershed Assessment Tool (USDA-ARS AGWA). The runoff curve number (CN) and derived hydrologic characteristics were calibrated using local stream gage networks, regression equations (USGS StreamStats), National Oceanic and Atmospheric Administration (NOAA), National Weather Service NOAA Atlas 14 rainfall distribution, and modified cumulative Kirpich time of concentration methods for the pre-fire condition.

Furthermore, specific papers and their methods were analyzed and compared for modifications to CN based on burn severity and reduction of cover, changes to lag time, and other basin characteristics. Peak discharge and area of basin burned based on lithology and peak discharge was considered. Lag times were changed due to relative increases in CN. Fire related debris flow volumes from the Western U.S. regression model were used to compare final results.

Of the 70,000 tons of bedload material, about 15% made it to a housing development downstream. Typically, the ratio of sands and colloidal to bedload was estimated at 10:1 or 3:1 ratios. Since the AGWA value was within reason for the total sediment and sands as a percentage (i.e. 10%), it was assumed to be comparable to total bedload in this case. Overall, AGWA was found to be a reliable to tool for sedimentation / bulking values in this situation.

BACKGROUND

In late June 2012 wildfire burned the watershed above the Utah communities of Saratoga Springs and Eagle Mountain, about 40 miles south of Salt Lake City. Reported to have been sparked by target shooters, the fire burned approximately 6,000 acres and required the evacuation of an estimated 9,000 residents. No serious injuries or damages were reported as a result of the event, which became known at the Dump Fire. Local residents protested the name, which came about because the fire was started near an old dump. This case study will refer to the event as the Saratoga Springs Fire. See Figure 1 for location.

The wildfire prompted the City of Saratoga Springs to request assistance from the NRCS through the Emergency Watershed Protection Program (EWP). Storm damages following an early September rainfall event (only about a month after the fire) occurred before counter-measures could be installed. NRCS performed a post-fire hydrologic analysis in support of the design of a sediment basin to protect residents from the accelerated erosion and sedimentation caused by the fire. Figures 2 and 3 illustrate the burning watershed from the point of view of the community of Eagle Mountain.

The storm of 1 September 2012 was centered over an unnamed tributary and Israel Canyon, which drain into Saratoga Springs. Local officials reported that the rainfall was 1.25 inches over a 25-minute duration. NRCS engineers estimated that the subsequent runoff deposited a bedload estimated at 70,000 tons. The mud slurry damaged houses, inundated basements, and filled and overtopped a small debris basin. The event was comparable to two times the 100-year (1% chance event) flow. The flow direction into the residential areas of Saratoga Springs is shown in Figure 4. The drainages discharge onto an alluvial fan that slopes into residential development where mud slurry, small boulders, cobbles, and gravel were deposited during the storm (Figures 5 and 6). This debris

damage was caused by the vulnerability of the watershed immediately following the fire, which increased erosion and mudflows in the steep gradient alluvial fan.

METHODS

As part of the post-fire hydrologic analysis for the Saratoga Springs fire, a number of computer programs were used. Runoff hydrographs were determined using the NRCS hydrology program WinTR-20 (USDA-NRCS(a) 2004). The model Automated Geospatial Watershed Assessment Tool, or AGWA, (Goodrich et al. 2006 and USDA-ARS 2014) was used to determine sedimentation rates. AGWA was created by the USDA Agricultural Research Service, Southwest Watershed Research Center in Tuscon AZ. It combines previously existing models KINEROS2 (Smith et al. 1995, Woolhiser et al. 1990) and SWAT (Arnold et al. 2012).

The runoff curve number (CN) and derived hydrologic characteristics from local stream gage networks and regression equations (USGS StreamStats) were used to determine the logical pre-fire inputs. NOAA Atlas 14 rainfall distribution and modified cumulative Kirpich time of concentration methods were also used.

Changes to the time of concentration, T_c, and CN inputs into WinTR-20 and AGWA were based on past studies for post-fire analysis. Goodrich et al., (2005) provides support for modification of CN values, given reduction of cover and burn severity. McLin et al. (2001) provides a method to estimate change in lag time associated to relative increases in CN.

Two methods were used to analyze the viability of derived post-fire peaks and debris flow volumes. These include the Cannon and Gartner (2005) regression equations for estimating peak debris flow, given burn area and lithology of burn area, basin gradient, and storm rainfall; and the Gartner et al. (2008) regression equations for estimation of debris flow volumes.

Typically, the ratio of sands and colloidal grain sizes to bedload is estimated at 10:1 or 3:1 ratios. Since the AGWA value was within reason for the total sediment and sands as a percentage (i.e. 10%), it was assumed to be comparable to total bedload in this case.

For the hydrologic analysis of the burned watershed above Saratoga Springs, the entire watershed was assumed to have experienced moderate burn severity.

An initial estimate of pre-fire sedimentation conditions was made using the map of Bridges (1973) which shows estimated yearly sediment yield and a breakdown between sheet and rill erosion versus channel and gully erosion. For the Saratoga watershed, pre-fire sediment yield is estimated to range between 0.1-0.2 acre-feet per square mile per year. with sources being 60% sheet and rill and 40% channel and gully.

Pre-fire Flow Ranges The first step in estimating the pre-fire watershed condition was to review existing gages in the area to determine reasonable pre-fire flows for the 25-, 50-, and 100-year (4%-, 2%- and 1%-chance) events.

After this was completed, WinTR-20 was used with NOAA Atlas distributions and a modified cumulative Kirpich equation. Runoff curve numbers were modified between ground cover conditions and used USDA – NRCS National Engineering Handbook, Part 630, Hydrology, Chapter 9, Hydrologic Soil-Cover Complexes (USDA NRCS(b), 2004), the United States Geologic Survey (USGS) National Land Cover Database (NLCD) (Fry et al, 2011), and the NRCS SSURGO database (USDA-NRCS(c), 2012).

Stream Gages Six nearby stream gages were analyzed to help estimate peak flows for the pre-fire watershed above Saratoga Springs. The stream gages are listed in Table 1 and are shown on the Figure 7 map. Their statistics were taken from the StreamStats report appendix (Kenney et al. 2007). Discharge per unit area (cubic feet per second / square mile, CSM) was computed for each probability and graphed (Figure 8).

Table 1. Six stream gages near Saratoga Springs, UT

# on fig. CS5-8	USGS #	Drainage (sq. mi.)	gage name
1	10172790	5.77	Settlement Canyon nr Tooele UT
2	10172805	5.38	N. Willow Creek nr Grantsville UT
3	10172800	4.19	S. Willow Creek nr Grantsville UT
4	10166430	26.5	W. Canyon Creek nr Cedar Fort UT
5	10172765	6.7	Clover Creek abv Big Hollow nr Clover UT
6	10172910	16.8	Settlement Creek abv Resvr nr Tooele UT

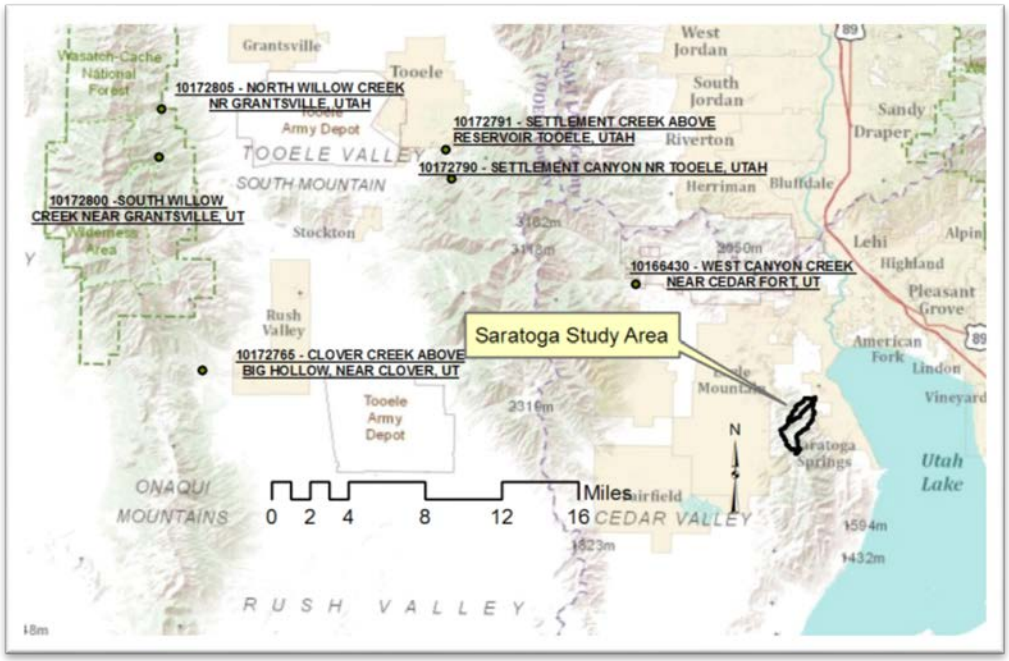

Figure 7. Location of stream gages and study area

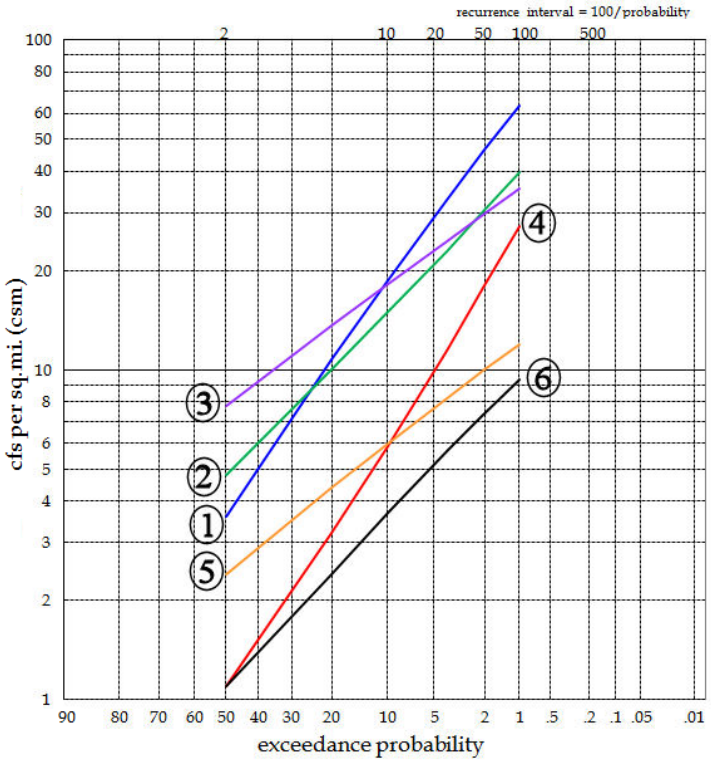

Figure 8. Stream gage regression output converted to discharge per unit area

Of the six nearby gaged watersheds, numbers 1 through 3 (Table 1) are most similar in drainage area, although the modeled watershed area above Saratoga Springs is 2.5 square miles, which is about half the size of three nearby gages. In Figure 8, the graphs of those three gages are the higher ones: blue, green, and violet.

T_c Pre-fire The upper range CSM exceedance probability was used to determine the pre-fire inputs into WinTR-20. The T_c was estimated to be 1 hour, or an average velocity of 6.0 feet per second. The upper elevation of the watershed is 7,500 feet above mean sea level, the watershed outlet is at 4,875 feet above mean sea level, and the longest flow path is 3.8 miles in length.

CN Pre-fire The CN look-up values were adjusted pending NEH, part 630, Chapter 9 ground cover conditions (USDA-NRCS(b), 2004) based on NLCD and SSURGO data. The generated T_c, adjusted CN, and NOAA Atlas 14 rainfall distribution were entered into WinTR-20. The CN was adjusted until the WinTR-20 output and calculated CSM matched the range of CSM of nearby stream gages.

Post Fire Peaks and volumes of sediment The burned watershed above Saratoga Springs has a total drainage area of 4.91 square miles. For WinTR-20 analysis, the burned area was divided into three subareas, as shown in Figure 9. Subareas 1 and 2 converge and provide outlet to the Saratoga Springs residential areas shown in Figures 4 through 6. Subarea 1 is known as Israel Canyon. See Tables 2 and 3 for WinTR-20 basic input related to these subareas, including selected pre-fire and post-fire CN.

Table 2. Burned watershed subarea input to WinTR-20.

subarea	drainage (sq.mi.)	CN (pre-fire)	CN (post-fire)	T_c (hrs, pre-fire)	T_c (hrs, post-fire)
1	1.81	62	74	0.92	0.85
2	0.60	74	80	0.40	0.37
1 + 2	2.50	65	75	1.00	0.92

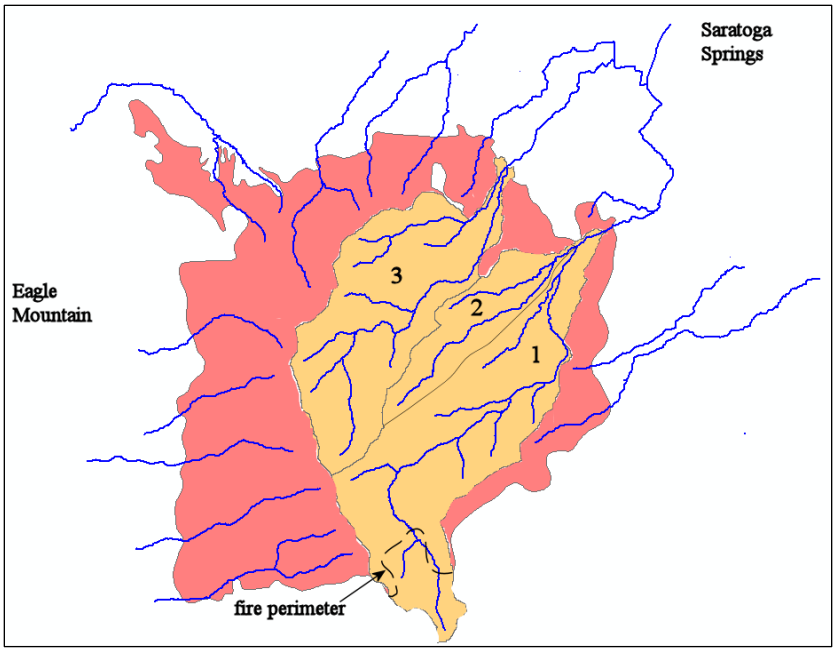

Figure 9. Burned zone (red) and sub-areas upstream of Saratoga Springs.

CN Post-fire Modification Post-fire CN were selected based on Goodrich (et al. 2005), which stated that, "there [is] a 15% reduction in cover for low-severity burns, a 32% reduction for moderate-severity burns, and a 50% reduction for high-severity burns" (Figure 10).

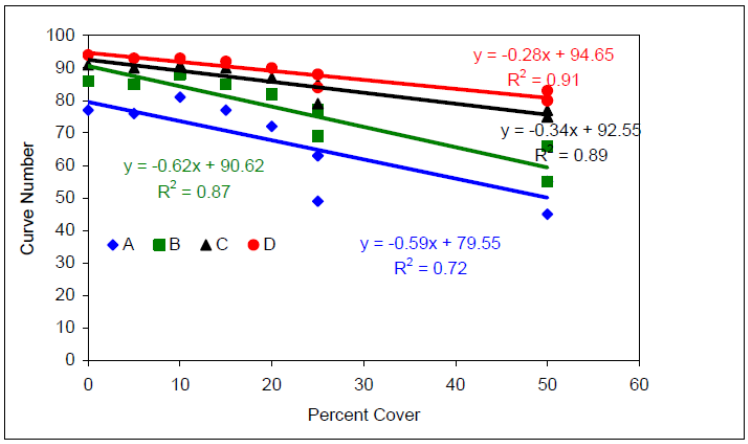

Figure 10. Curve number from cover, for hydrologic soil groups (Goodrich et al. 2005).

Table 3 shows the CN increase from pre-fire to post-fire CN used in this study. The table associates these with the standard National Land Cover Dataset (NLCD) and hydrologic soil groupings (hsg).

Table 3. Increase in runoff curve number from pre-fire to post-fire conditions.

burn severity	NLCD	cover name	hsg A	hsg B	hsg C	hsg D
Low	41	Deciduous Forest	4	5	3	2
	42	Evergreen Forest	4	16	10	8
	43	Mixed Forest	4	5	3	2
	51	Shrubland	2	2	1	1
Moderate	41	Deciduous Forest	10	10	5	5

	42	Evergreen Forest	10	21	12	11
	43	Mixed Forest	10	10	5	5
	51	Shrubland	5	5	3	2
High	41	Deciduous Forest	15	16	8	7
	42	Evergreen Forest	15	27	15	13
	43	Mixed Forest	15	16	8	7
	51	Shrubland	10	11	6	3

Time of Concentration Post-fire Modification T_c was adjusted using McLin et al. (2001), which suggest that lag time decreases from the pre-burn to post-burn condition as a result of increase in CN (Figure 11). Note that this depends on channel blockages caused by the fire, and frequency that the watershed experiences wildfire. Channel blockages can possibly increase lag times. In this case, however, the watershed cover is generally mixed with deciduous forest and low-lying shrubs and no channel blockages were assumed. Furthermore, the roughness of the watershed was assumed to decrease as a result of fire. For this case study, the following rule of thumb was adopted for changes in runoff velocity and associated change in time of concentration: velocity increases 0.5 feet per second for low severity burns, 1.0 feet per second for moderate severity burns, and 1.5 feet per second for high severity burns.

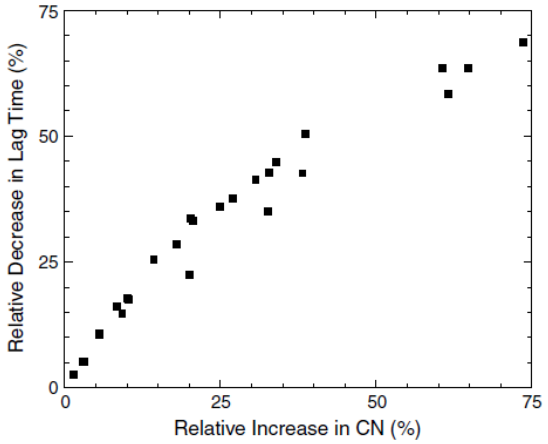

Figure 11. Interdependency of CN and lag time, Cerro Grande Wildfire McLin (et al. 2001)* *Relative change is defined as the sum of pre-fire and post-fire values divided by pre-fire values.

AGWA The AGWA model was used to model sediment rates. AGWA has a GIS interface and uses one of two routines to route runoff using the kinematic wave equation in the sub-model KINEROS2. In AGWA the landscape, including land uses and management practices, are handled by the sub-model SWAT. Table 4 shows output parameters for KINEROS and SWAT. Although AGWA produces both flow hydrographs and sedimentation rates, only the latter was used for the current study.

Table 4. Output Variables Available in AGWA.

KINEROS - ■ Infiltration (mm; m^3/km), ■ Infiltration (in; ac-ft/mi), ■ Runoff (mm), Runoff (m3), ■ Sediment yield (kg/ha), ■ Peak flow (m^3/s), Peak flow (mm/hr), ■ Sediment discharge (kg/s)	SWAT-■ Channel Discharge (m^3/day), ■ ET (mm), ■ Percolation (mm), Surface runoff (mm), ■ Transmission loss (mm), ■ Water yield (mm), ■ Sediment yield (t/ha), ■ Precipitation (mm)

Bulking Another way to estimate sedimentation is to consider typical runoff bulking factors for recently burned watersheds. This was done to further support concentration volumes that were deposited on the alluvial fan. Considering a 20% bulking factor, an event sedimentation volume can be estimated and applied to WinTR-20 post fire results.

Western Regional Equation The empirical Western U.S. regression model to estimate fire-related debris-flow volumes Gartner et al. (2008) was used to estimate post fire sediment. The equation used is presented below (Equation 1). The Western U.S. regression model to estimate fire-related debris-flow volumes Gartner et al. (2008) was taken from the Giraud and Castleton (2009) investigation.

$$lnV = 0.59(lnS) + 0.65B^{1/2} + 0.18R^{1/2} + 7.21 \qquad \text{(eq 1)}$$

V = volume (cubic meters)
S = basin area with slopes greater than or equal to 30% (square kilometers)
B = basin area burned at moderate and high severity (square kilometers), and
R = total storm rainfall (millimeters)

Comparative Analysis to Existing Studies: Figure 12 from McLin et al. (2001) illustrates that the change in peak discharge per unit area caused by wildfire can be quite large, therefore the pre and post fire ranges from Figure 12 were considered.

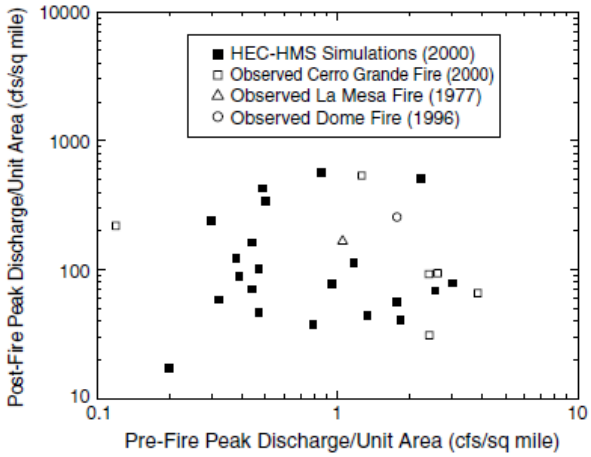

Figure 12. Comparison of observed and simulated pre-and post-fire peak discharges per unit drainage basin area in New Mexico. (McLin et al, 2001)

Regional Equations The regression equations of Cannon and Gartner (2005) were also used to estimate post-fire flow. Since the Saratoga Springs watershed is sedimentary, the regression equation (eq. 2) from Cannon and Gartner (2005) was used to compute an estimated peak discharge. Since the equation units are SI, conversions are required. For the Saratoga Springs watershed, 2.5 square miles converts to 6.47 square kilometers.

$$Q_p = 17A_b^{0.4} \qquad R^2 = 0.42 \qquad \text{(eq. 2)}$$

Bridges Map The Bridges (1973) map entitled "Estimated Sediment Yield Rates for the State of Utah" references many data sources as part of the map, including: 1) Great Basin Upper Colorado and Lower Colorado Regions, Comprehensive Framework Study, Appendices VIII, Water Management, June 1971, Pacific Southwest Inter-Agency Committee/Water Resources Council, 2) Utah State soils map and soil descriptions, 3) Reservoir Surveys by SCS and USBR, 4) suspended load measurements by USGS, USGR and SCS, 5) Watershed studies by SCS, and 6) General knowledge of the state from regular SCS program work. The author notes, "Do not use these rates to determine sediment yields at specific sites. Large variations in sediment rates may occur within the delineated areas".

According to the United States Department of Agriculture, Soil Conservation Service map (Bridges, 1973) the sediment yield for the Saratoga watershed ranges between 0.1-0.2 acre-feet/square mile/year with a 60% sheet and rill erosion and 40% channel and gully erosion.

The range of erosion rates for the Saratoga Springs watershed from the 1973 map are plotted (Figure 13). On the graph, the red squares represent the acre-feet/square mile/year rate that correlates to the tons for 2.5 square miles, pre-burn condition. The blue diamonds on the graph show values assuming a 0.45 acre-feet/square mile/year rate plotted in total tons, a conservative pre-fire condition. Finally, the green triangles represent the breakdown of erosion types (60% sheet / rill erosion, 60% other colloidal material, 40% channel and gully erosion), a post-fire condition.

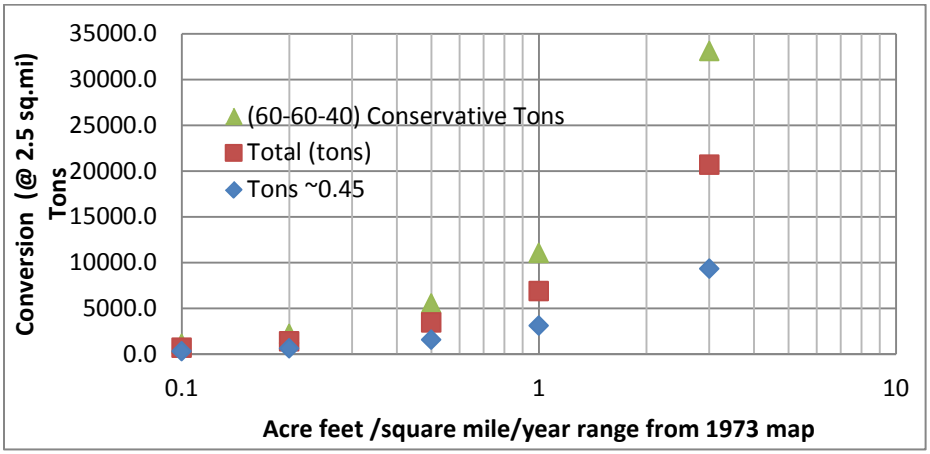

Figure 13. Range of annual erosion rates from Bridges (1973).

RESULTS

WinTR-20 Pre and Post Fire: The WinTR-20 provides pre-fire flow calculations that correlated well to the USGS stream gages CSM provided in Figure 8. Table 5 below illustrates these results. The lower return intervals from WinTR-20 pre-fire results are higher and the higher return intervals are lower than USGS calculated CSM. For estimation purposes, the upper results for the 25 year (4% chance), 50 year (2% chance) and 100 year (1% chance) will be focused on during the rest of the paper. Table 6 reflects the pre and post fire peak discharges.

Table 5. Cubic feet per second per square mile (CSM) from WinTR20 pre-fire results and selected stream gages

	2-year (50% chance) (CSM)	5 year (20% chance) (CSM)	10 year (10% chance) (CSM)	25 year (4% chance) (CSM)	50 year (2% chance) (CSM)	100 year (1% chance) (CSM)
WinTR-20 Pre-fire	0	2.5	6.8	28.4	58	100.8
Observed CSM from Figure 8	~5	12	<20	30	45	60

Table 6. Burned watershed pre-fire and post-fire peak flow output from WinTR-20.

Subarea	2-year (cfs)	5-year (cfs)	10-year (cfs)	25-year (cfs)	50-year (cfs)	100-year (cfs)
1 (pre-fire)	0	0	0	25	65	127
1 (post-fire)	14	57	118	234	359	514
2 (pre-fire)	6	29	62	126	195	280
2 (post-fire)	39	92	149	248	347	466
1+2 (pre-fire)	0	6	17	71	145	252
1+2 (post-fire)	26	92	179	342	516	728

The WinTR-20 output in Figure 14 shows the considerable increase in runoff peaks and volumes due to the fire. The peaks are predicted to more than double, with the 25-year (4% chance) event (red dashed for post-fire versus black dashed for pre-fire) rising from 71 cfs to 342 cfs. The runoff volume (represented by the area under each

curve and in Table 6) is predicted to increase runoff from the pre-fire to post-fire event, 192% to 122% for the 25-year to 100-year events.

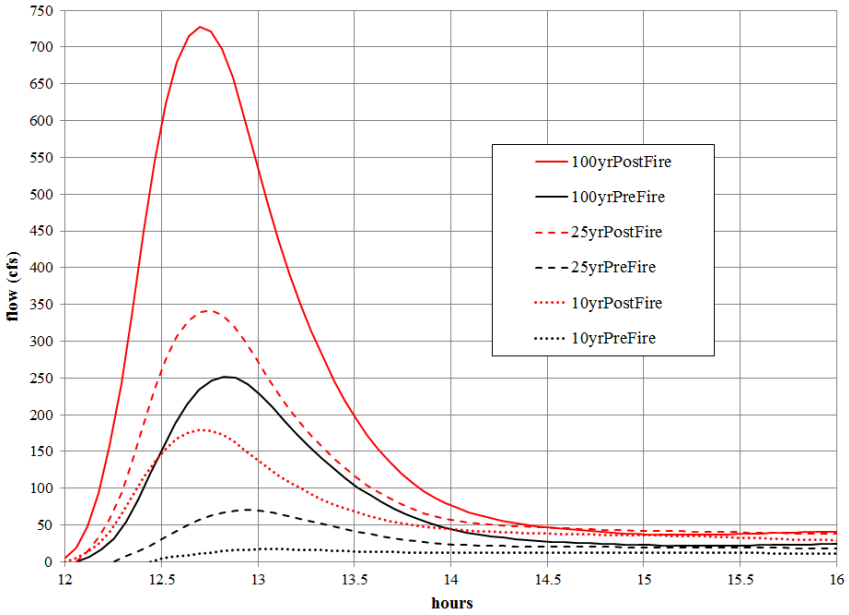

Figure 14. Burned watershed pre-fire and post-fire hydrographs from WinTR-20.

Table 6. Storm totals runoff for various recurrence intervals, input to WinTR-20 and post fire runoff values for Subarea 1+2.

Percent Chance	2-year (50% chance)	5-yr (25% chance	10-yr (10% chance)	25-yr (4% chance)	50-yr (2% chance)	100-yr (1% chance	200-yr (0.5% chance	500-yr (0.2 chance
Pre-Fire runoff (inches) Subarea 1+2	0.01	0.03	0.07	0.13	0.19	0.27	0.35	0.48
Post Fire runoff (inches) Subarea 1+2	0.09	0.17	0.25	0.38	0.48	0.60	0.73	0.92
Pre Fire - Runoff in acre feet over 2.5 sq.mi	1	4	9	17	25	36	47	64
Post Fire - Runoff in acre feet over 2.5 sq.mi	12	23	33	51	64	80	97	123

AGWA The sediment for the 25-year (4% chance) storm was estimated to be 10,303 tons and the 100-year (1% chance event) storm was estimated to be 27,897 tons.

Bulking An event sedimentation volume was estimated considering a 20% bulking factor on the WinTR-20 post fire results. The information in Table 7 was derived by taking the post-fire clear flow hydrographs of Figure 14, from WinTR-20, and considering the event sedimentation rate to be 20% at each time-step. The area under the sedimentation hydrograph provided a volume, which was converted to tons by assuming a sediment unit weight of 108 pounds per cubic foot in Table 7.

Table 7. Burned watershed post-fire event total sediment runoff in tons.

event totals	25-yr (4% chnance) (tons)	50-yr (2% chance) (tons)	100-yr (1% chance) (tons)
sediment	23,705	29,943	37,429

Western U.S. Regression Model The empirical Western U.S. regression model to estimate fire-related debris-flow volumes Gartner et al. (2008) was estimated to be between 34,550 – 51,182 tons for the 2- to 100-year (50% to 1% chance) rainfall events. These numbers are high since the model assumes that watersheds typically have moderate to high severity burns.

Table 8 shows the WinTR-20 pre-fire and post-fire peaks (in cfs per square mile) for comparison with Figure 12. The current case study results would plot generally lower on the figure than the New Mexico watersheds, the WinTR-20 results are considered reasonable.

Table 8. Saratoga Springs burned watershed pre-fire and post-fire peaks (csm) from WinTR-20.

flood	25-year (4% chance)	50-year (2% chance)	100-year (1% chance)
Pre-fire (CSM)	28.4	58	100.8
Post-fire (CSM	136.8	206.4	291.2

Regional Equations The regression equations of Cannon and Gartner (2005) after inserting 6.47 as A_b into the equation results in a Q_p of 35.88 cubic meters per second, or a Q_p of 1267 cfs after converting to English units . This results in 506 CSM; and the WinTR20 post-fire result is 728 cfs or 291 CSM.

CONCLUSIONS

The review of USGS stream gages and making modification to the CN to have both values correlate was an attempt to familiarize one on potential results, pre-fire. Once this was done a post-fire CN was applied and T_c was lowered. This resulted in both higher peaks and bigger volumes of runoff. AGWA, a 20% bulking to WinTR-20 post fire results, and the Western Regional Equation overall correlated well. These results were compared to McLin et al (2001) pre- and post- fire peak discharges per unit drainage basin area and to a range or potential erosion values, Bridges sedimentation map (1973).

Typically, one would think of using the peak discharge of post-fire analysis using WinTR-20, while increasing the CN and decreasing the $_{Tc}$. The peak discharge during the flood event and high water marks were observed as being in range for the post-fire WinTR-20 results. The Cannon and Gartner (2005) estimate of over 1,200 cfs may be reasonable and could be used for preliminary or lower and upper bound limits; the lower limit at 75% of the total, and the upper at 100% of the total.

The range of sediment, bulking and mud slurries were in a range of 10,000 tons to over 50,000 tons for the post-fire 25- to 100-year (4% to 1% chance) events. The AGWA range is between 10,000 and 50,000 tons for the 25- to 100-year (50% to 1% chance) post-fire event. The bulking at 20% is 23,000 to 37,000 tons for the post-fire event. The western regional equation produced a number of 34,600 – 51,200 tons. Between the sand, colloidal, and bedload the percentages can vary. For the sediment, sand and colloidal the numbers above could still be a low estimate. Bedload at either 1:3 or 1:10 ratio could be still be small. However, due to the system being flushed by previous storm events, these ratios may be accurate. A range of 5,000 to 17,000 tons could be accounted for bedload.

STREAM RESTORATION WITHIN A CONFINED SPACE: A CASE STUDY ON THE MIDDLE RIO GRANDE

Jonathan AuBuchon, Hydraulic Engineer, Albuquerque, NM, jaubuchon@usbr.gov; Chi Bui, Hydraulic Engineer, Albuquerque, NM, cbui@usbr.gov

BACKGROUND

The Rio Grande downstream of Cochiti Dam, as described by Happ (1948), Dewey et al. (1979), Lagasse (1980), Salazar (1998), Makar et al. (2006), and Makar and AuBuchon (2012), has seen the frequency of large magnitude floods and the sediment supply decrease over the last few decades. This has decreased the mobility of the medial and point bars and allowed the vegetation to become established, further amplifying the stability of the banks and the channel planform. Since the closure of Cochiti Dam in 1973, the downstream channel has continued to narrow through incision and vegetation encroachment, isolating the main channel from its floodplain. Richard (2001) and Shah et al. (2006) found that Cochiti Dam has had a high trapping efficiency, close to 98%, which as Lagasse (1980), Scurlock (1998), Massong et al. (2008), and Bauer (2009) described has led to the exposure of a dominant gravel fraction in the bed material in the first 30+ miles downstream of Cochiti Dam. Recent analyses by AuBuchon and Bui (2014) showed that within the first 5 miles of the Rio Grande below Cochiti Dam the active channel width has fluctuated around 200 feet and the slope has flattened to about 0.0012 over the last 2-3 decades. In addition, the channel planform has abandoned some of its variability with a decrease in the average number of channels from 2-3 prior to 1962 to about 1-2 since 1972. The sinuosity still fluctuates slightly, although not to the extent that it did prior to 1962, suggesting that there are local areas of instability, amidst the observed stability.

In 2011, the watershed of the Peralta Arroyo was burned by the Las Conchas fire, which has affected the stability of the slopes on the upper watershed. This has resulted in rainfall runoff events moving a significant volume of water and sediment into the lower portions of the Peralta Arroyo watershed. On September 13, 2013, a rainfall runoff event occurred over this watershed and brought enough sediment downstream to the confluence with the Rio Grande that the river was completely blocked (see Figure 1). Collected survey data revealed that about 2–5 feet of sediment was deposited in the Rio Grande from this event, in essence creating a miniature dam on the river. This sediment block created an opportunity for overbanking flows on a terrace that had been isolated from the main channel for decades. The backed up water also created engineering and reservoir operation concerns.

The engineering and reservoir operation concerns included being able to safely release floodwaters stored in Cochiti and minimizing the risk of unconsolidated spoil levee failure, property flooding, and ineffective farm field drainage. For the short term these were addressed by excavating a pilot channel through the sediment block on the main channel. A longer term design was required though to avoid future intervention and allow the natural fluvial and riverine processes to occur with as much freedom as possible while still addressing engineering and reservoir operation concerns.

Figure 1 Sediment deposit at Peralta Arroyo confluence. Photograph taken on 9/17/13.

DESIGN

Key aspects that were used to develop the long term design were 1) observations of the river's response when the channel was blocked, 2) analysis of sediment (channel competency and capacity), 3) addressing the engineering and reservoir operation concerns, and 4) encouraging overbank flows on the eastern terrace.

The first aspect concerns two observations made of the river's response to the sediment block in the river. The first was the observation of incision due to head cutting (see Figure 2) on the southern end of the eastern terrace. As the overbanking flow paths merged together and dropped into an abandoned river channel, enough energy was developed to start carving new channel locations. While the overbank flows only lasted for about 1.5 months, some of the carved new channels extended back a hundred feet or more, incising 1-3 feet. Massong et al. (2010) found that the general governing process for locational changes through this reach of the Rio Grande is lateral migration. Over the years the lateral migration of the banks has decreased through this reach of the Rio Grande, as the coarse fraction in the bed and the dense vegetation growth on the banks helped to minimize further bed and bank erosion. The observation of incision on the eastern terrace reveals that under the right circumstances, and given enough time, a slightly different planform change process may occur in this reach. Since the eastern terrace has significantly less vegetation and more sand than the existing channel banks and bed, respectively, there is less resistance to erosion. As erosion proceeds with time, conditions may set up that cause the Rio Grande to "avulse" from its existing path to a new main channel location on the eastern terrace.

Figure 2 Incision on southern end of eastern terrace. Left: Vertical drop at one of the incision fingers during the overbanking flow. Right: One of the longer incision fingers. Photographs were taken on 9/17/2013 and 10/17/2013 respectively.

The second observation was where and how overbanking occurred on the eastern terrace. Once a pilot channel had been cut through the sediment block on the Rio Grande, flows were increased from Cochiti Dam until a flow of about 2,200 cfs was reached. The observed flow paths at the 2,200 cfs flow rate (orange flow arrows) are shown in Figure 3. While overbank flows were occurring, standing water at the toe of the east side, unconsolidated spoil levee was not observed. On October 21, 2013 releases were made at Cochiti Dam to temporarily increase the flow to 3,500 cfs and then about 5,300 cfs in an effort to assess the current capacity of the system. Figure 3 shows the measurement and observations made that day by AuBuchon and Bui (2013). These observations helped identify some of the features that would be needed in the long term design to address engineering and reservoir operation concerns (discussed later).

The second key aspect considered two basic questions addressing sediment. The first question is whether the flow of a design channel would be competent to move the material found in the eastern terrace. The second question is whether a design channel would have the capacity to transport sediment (both incoming and self-generated through morphological adjustments) at flows between 5,000 and 6,000 cfs. This flow range has been the observed maximum flow releases during the spring snow-melt runoff on the Rio Grande from Cochiti Dam over the last decade.

To address the first question, soil samples were collected at five locations in the eastern terrace. Samples were collected with a hand auger to a depth of about 2.5 feet below the eastern terrace surface. The results of the gradation analysis on the soil samples are summarized in Table 1. The results in Table 1 were used to calculate the critical shear stress for particle mobility using the Shield's approach for incipient motion as described by Yang (1996). A one-dimensional hydraulic model provided the necessary inputs to calculate the normal shear stress according to Brown (1996). The critical and normal shear stress results were then compared to provide an estimate of the initial bed stability (Table 2). From these results it is seen that a design channel would be competent to move the majority of the material in the eastern terrace with sustained

high flows of 5,000 cfs or higher. However, there are larger particles present in the eastern terrace that the channel may not be competent to move, suggesting an armor layer could develop.

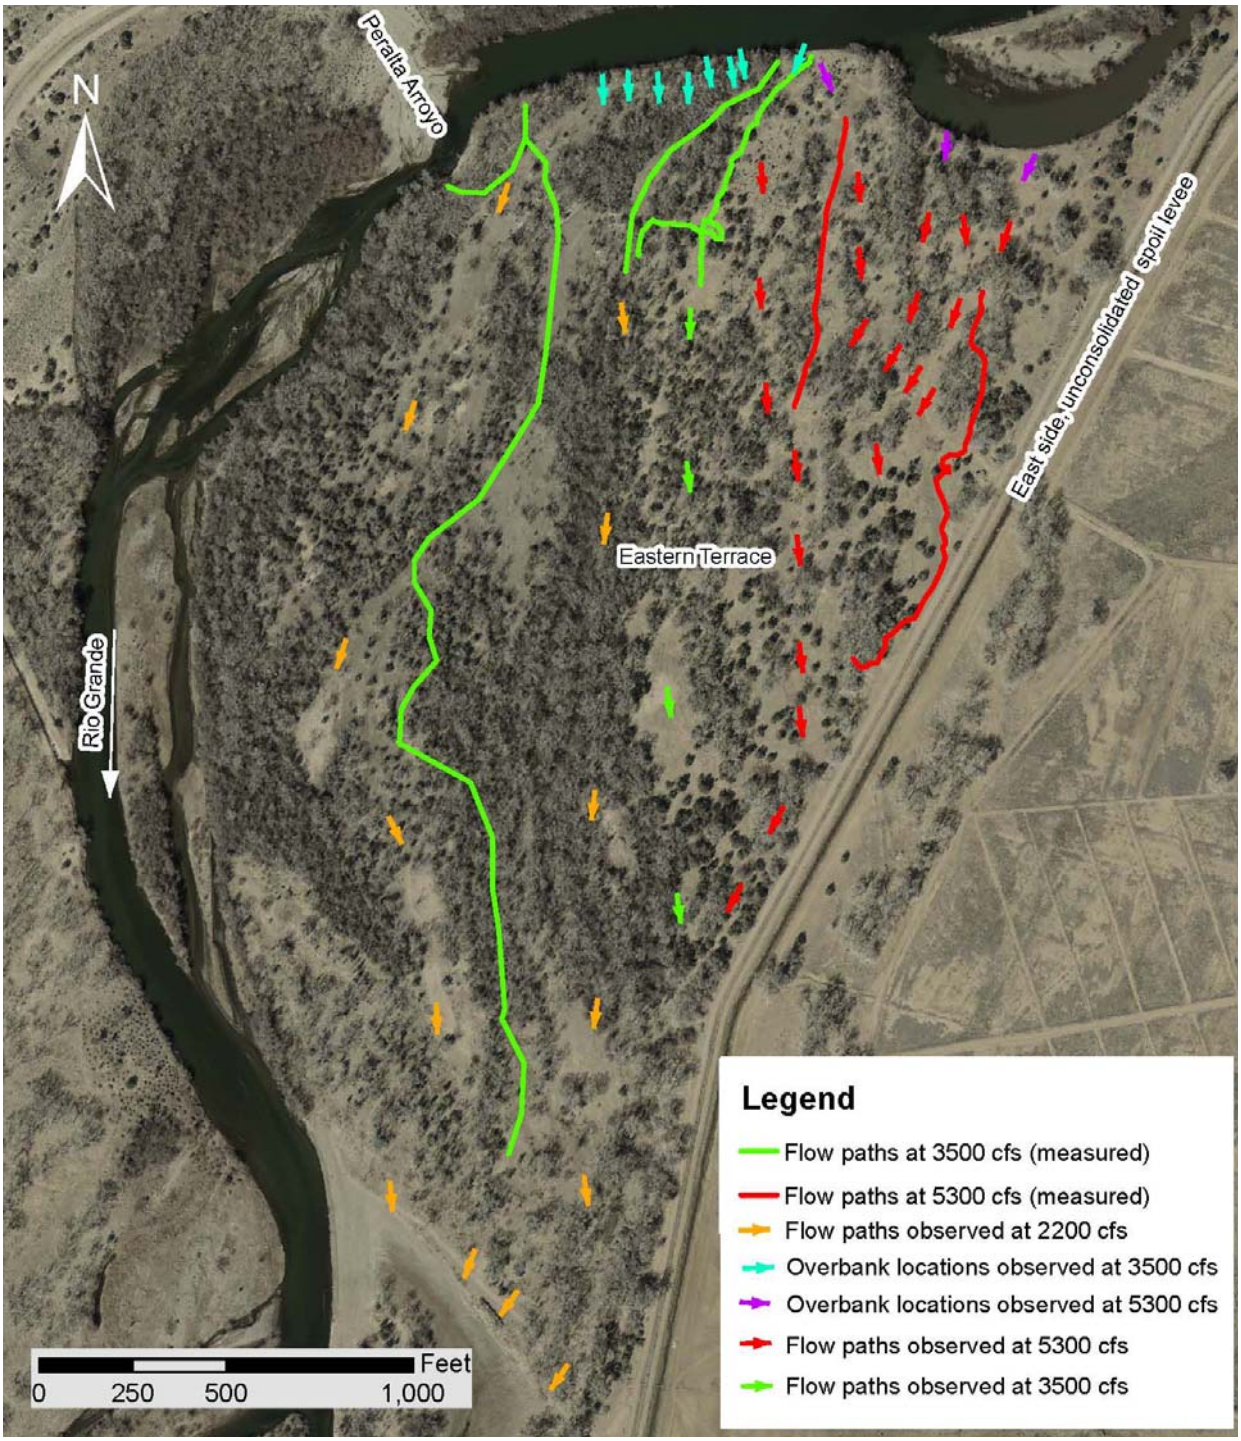

Figure 3 Observed flow paths on the eastern terrace during a short term high flow release in 2013. The background map is from Reclamation's 2012 aerial photography of the Rio Grande.

Table 1 Gradation results (median size – d_{50} and one standard deviation coarser than the median size – d_{84}) of eastern terrace bed material samples. Sample numbers are listed geographically by sample location from upstream to downstream.

Sample #	D_{50} (mm)	Description (D_{50})	D_{84} (mm)	Description (D_{84})
5	0.07	Very fine sand	20	Coarse gravel
1	0.062	Very fine sand	0.31	Medium sand
4	0.084	Very fine sand	10.5	Medium gravel
2	0.0083	Fine silt	14	Coarse gravel
3	14	Medium gravel	100	Small cobbles

Table 2 Critical and normal shear stress results (median size – d_{50} and one standard deviation coarser than the median size – d_{84}) of eastern terrace bed material samples. Sample numbers are listed geographically by sample location from upstream to downstream.

Sample #	D_{50} Critical shear stress (lb/ft^2)	D_{84} Critical shear stress (lb/ft^2)	Normal shear stress at 5,000 cfs (lb/ft^2)	Normal shear stress at 6,000 cfs (lb/ft^2)
5	<0.1	0.3	0.5	0.6
1	<0.1	<0.1	0.5	0.6
4	<0.1	0.2	0.4	0.5
2	<0.1	0.2	0.4	0.5
3	0.2	1.5	0.2	0.3

An additional assessment was also made to look at the competence of a design channel to erode its banks given the information available about the material in the eastern terrace. This assessment was made using the Bank Stability and Toe Erosion Model (BSTEM) described by Simon et al (2000), Simon and Collison (2002), Pollen-Bankhead and Simon (2009), and Simon et al. (2010). The initial channel condition runs with the BSTEM model (no vegetation establishment) projected unstable bank conditions for the design channels, except in the areas where there was a coarser bed material fraction. The presence of coarse particles and the possibility of future vegetation growth (Figure 4) indicate that the banks of a design channel through the eastern terrace may become more stable over time.

To address the second sediment question we first need to understand the available incoming sediment supply. Richard (2001) noted that although the sediment supply on the Rio Grande has been decreasing since the late 1950s, there was a pronounced decrease in the sediment supply immediately below Cochiti Dam after its closure. In the years leading up to the Cochiti Dam closure, the Rio Grande had an annualized average suspended sediment concentration around 2,000 mg/L. This dropped to an annualized average suspended sediment concentration of about 40 mg/L after the closure of Cochiti Dam. An estimate of the incoming sediment supply may be obtained by assuming the annualized average suspended sediment concentration is reflective of the sediment input immediately below the dam and assuming a representative flow rate. The median flow rate (590 cfs) at the USGS gaging station on the Rio Grande below Cochiti Dam, NM (08317400) was used to provide a representation of the flow rate since the closure of Cochiti Dam. The daily incoming sediment supply then for the reach immediately below the dam is roughly 60 tons per day.

Figure 4 First season vegetation growth on bed of design channel near outlet of flow path 2, looking upstream. Photograph was taken on 10/1/2014.

The transport capacity of any channel is very dependent upon slope. The localized slope of the Rio Grande around the Peralta Arroyo confluence is shown in Figure 5 before and after the September 2013 rainfall-runoff event on the Peralta Arroyo. The January 2009 survey data reflects relatively unchanging slope conditions (0.0012) since the early 2000s. The slope increase seen in the 9/20/13 data set (estimated slope of around 0.0038) reflects the large sediment input after the September 2013 event. The third data set reflects conditions on the Rio Grande 2 months after the September 2013 event, and about 1 month after a pilot channel was constructed through the sediment block on the main channel. The slope of the river bed from this data collection effort was found to be around 0.0011. Comparing the localized slope values of the Rio Grande for all three surveys reveals the impact a temporary higher sediment load has on the local river morphology and also the tendency of the river to adjust towards a certain slope value based on average sediment loads.

Based on the previously discussed observations of head cutting on the eastern terrace and the measured slope adjustments around the Peralta Arroyo, an initial slope value of 0.0028 was used for the design channels on the eastern terrace. This steepened slope is not expected to be stable, but was chosen to help induce morphological change. It is expected that the slope of any design channel on the eastern terrace will eventually adjust to around the observed reach tendency, unless the eastern terrace is abandoned as a flow path entirely or the sediment load changes significantly.

Using this initial design slope and the channel hydraulics (derived from a 1-dimensional hydraulic mode) a rough idea of the sediment transport capacity of the design channel at 5,000 cfs was estimated. The estimation approach used a Monte Carlo error analysis assuming hydraulic relations for wide, steady, uniform flow as described by Wilcox et al. (2009). Using this approach, the transport capacity of the initial design channel at 5,000 cfs is calculated to be almost a 100x greater than the estimate of incoming sediment supply discussed previously. The transport capacity of the design channel with an adjusted slope near the reach tendency is estimated to drop to almost a third of this value. This would indicate that the initial channel design has the capacity to transport the incoming sediment load and sediment eroded from the bed and banks as morphological adjustments occur. It also indicates that as adjustments occur, especially along the longitudinal profile, the transport capacity would also decrease with time.

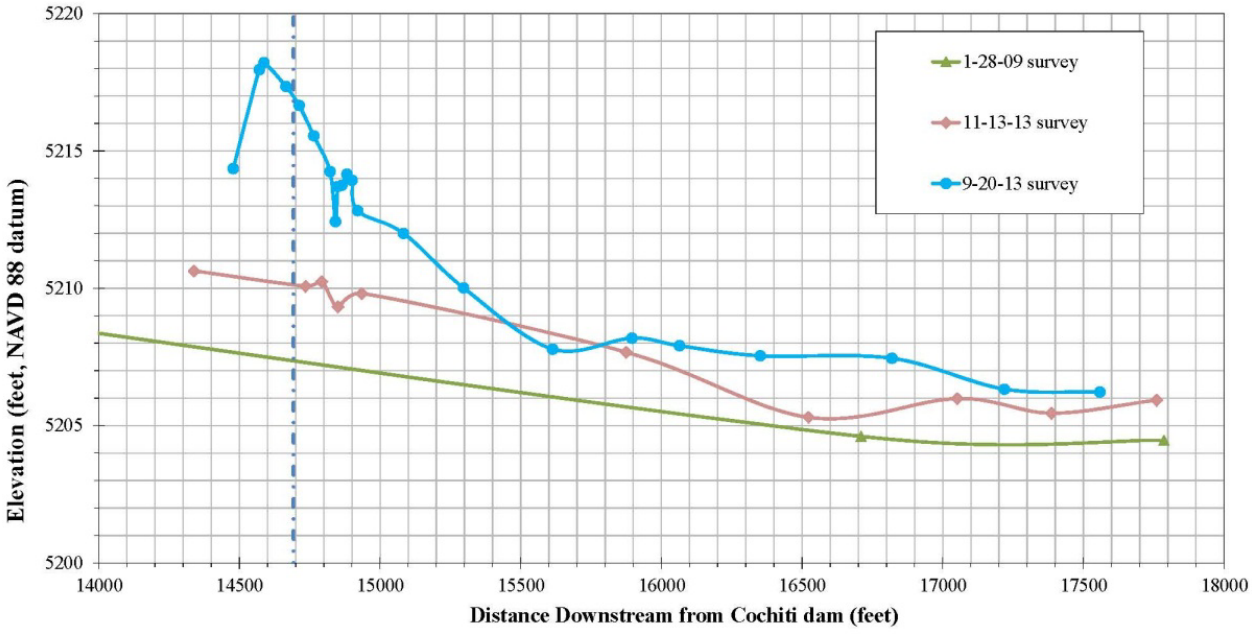

Figure 5 Rio Grande Profile between ~ 200 feet upstream and ~0.5 miles downstream of Peralta Arroyo.

The third key aspect of the long term design was addressing the engineering and reservoir operation concerns. From a reservoir operation perspective the primary concern with a potential sediment block is being able to safely evacuate stored floodwater in Cochiti Dam in a timely manner. Within a week of the September 13, 2014 event, upstream rainfall events had brought in almost 30,000 acre-feet of water to Cochiti Dam. Because of the sediment block at Peralta Arroyo, this water could not be safely released. While the construction of a pilot channel through the sediment block resolved this concern, it was desirable to solve this concern in the future without requiring the intrusion of construction equipment into the river. To mitigate this future risk for the long term design, multiple design channels with different inlets were designed in the eastern terrace. This provided redundancy to bypass the Peralta Arroyo confluence in case a similar event occurred in the future.

Engineering concerns also arose due to the flooding that occurred as a result of the sediment block. The three primary engineering concerns were unconsolidated spoil levee failure due to seepage, property flooding, and ineffective farm field drainage. The concern with the unconsolidated spoil levee failure is associated with pooling of this water at the toe which created seepage on the landward side, as shown in Figure 6. This issue was addressed by placing design features on the eastern terrace to intercept and redirect overbanking flows. Observations of the overbank flow paths, as shown in Figure 3, were directly used to strategically place design features to intercept and redirect flow heading to the unconsolidated spoil levee. The property flooding risk is directly related to the failure of the unconsolidated spoil levee, since the soil levee separates the river from the nearby agricultural land and nearby communities. Because of this relationship any reduction in the risk of levee failure also reduces the property flooding risk. The elevated water levels associated with the sediment block were the primary concern behind the farm drains not operating as designed. By incorporating multiple pathways in the design for the water to be conveyed downstream, the risk of future sediment blocks creating elevated river water levels is minimized.

Figure 6 Seepage and pooling at the unconsolidated spoil levee. Left: Observed seepage on the landward side of the spoil levee. Right: Water pooled on the river side of the spoil levee. Photographs were taken on 9/26/2013 and 10/21/2013 respectively.

The fourth and final aspect of the long term design involved encouraging opportunities for overbank flows to help increase the morphological diversity of the channel. The observations of the overbank flow paths shown in Figure 3 were used to help identify locations where overbanking flows occurred and did not pose a risk to the unconsolidated spoil levee. A temporary spoil levee was then constructed to help contain higher flows within this area. This allowed overbanking flows, such as seen in Figure 7, access to slightly over half of the area observed to be flooding at a flow of 3,500 cfs, and about a third of the flow at 5,000 cfs.

Figure 7 Overbanking flows on the eastern terrace at 3,500 cfs. Photograph was taken on 10/21/2013.

The consideration of all 4 key aspects of the long term design led to the final design, as shown in Figure 8. This design included construction of three channels on the terrace (yellow lines) following locations where the main overbanking flow paths were observed. It also included strategically excavating and placing material (red line) to intercept and redirect overbanking flows away from the unconsolidated spoil levee into the constructed channels. A final component of the design was to place excavated material, as a spoil berm (green line), on the east side of the excavated channels. This provides an immediate channel capacity between 5,000 and 6,000 cfs, while still allowing overbank flooding to occur. The inclusion of multiple channels, a redirection berm and ditch, and a spoil berm also provided a level of redundancy that allows for complex system responses without the need for substantial intervention.

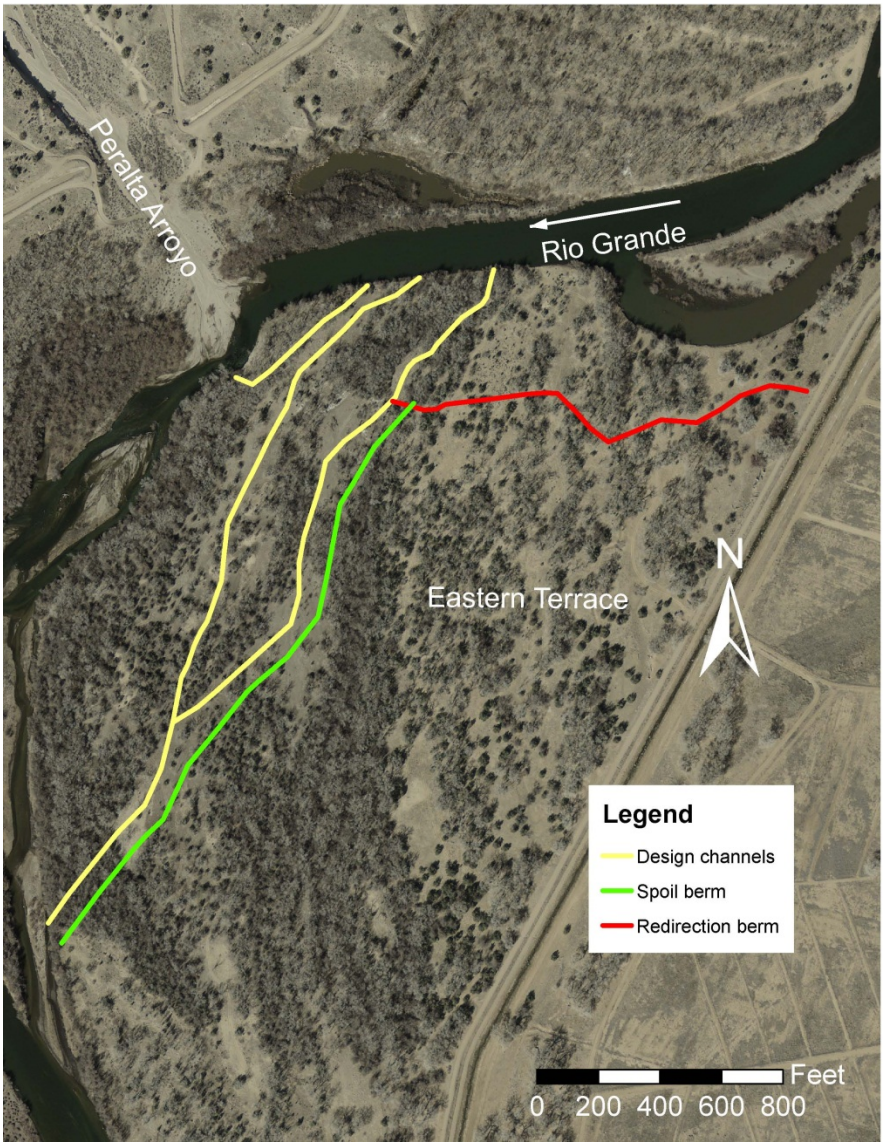

Figure 8 Long term design components for the eastern terrace flow augmentation. The background map is from Reclamation's 2012 aerial photography of the Rio Grande.

EXPECTED RESPONSE

The long term design was constructed in the spring of 2014. In late spring/early summer a small spring snow-melt runoff of slightly less than 2,000 cfs caused a few of the design channels to flow, see Figure 9. While very little morphological change occurred, the channel was visually winnowing finer material, like the sands, and transporting them downstream, as shown in Figure 9. Since the channel banks and bed are expected to adjust, the presence of large trees left at the edges of the construction footprint will hopefully also provide local conditions, as the trees fall into the river, where complex flow patterns will develop. These flow patterns may aid in the formation of channel complexity and create greater diversity in the morphology of the channels.

Figure 9 Looking downstream on one of the constructed channels. Left: Channel during spring runoff flows. Right: Channel after the spring runoff flows. Note the presence of sand deposits from upstream winnowing in the channel. Photographs were taken on 5/9/14 and 10/1/14, respectively.

A long term design that allows for dynamic change within a restrained system was facilitated by considering 4 key aspects. These aspects included observing the river's response to a disturbance event, analyzing the sediment (channel competency and capacity), addressing the engineering and reservoir operation concerns, and encouraging the continuation of overbank flows. This design process allowed the Rio Grande within this confined river reach more freedom to self-adjust, creating opportunities for diverse morphological features to develop on a previously abandoned floodplain terrace.

ACKNOWLEDGEMENTS

Kai-t Blue-sky, Jacob Pecos and other staff/consultants of the Pueblo de Cochiti have assisted with the coordination, selection, and design of this work. Vincent Benoit, Suzanne Devergie, and Nathan Holste have participated in data collection and field reconnaissance trips at this site. Jason Casuga, Victor Chavez, Carolyn Donnelly, and Robert Padilla have also provided valuable insight and ideas throughout the project development process.

THE APPLICATION OF *WARSSS* FOR A WATERSHED-BASED SEDIMENT BUDGET AND POST-FIRE STREAM RESTORATION: THE HAYMAN FIRE, TRAIL CREEK WATERSHED, COLORADO

Dave Rosgen, Ph.D., Professional Hydrologist, Wildland Hydrology, Fort Collins, CO, Dave@wildlandhydrology.com; Darcie Frantila Geenen, Wildland Hydrology, Fort Collins, CO, Darcie@wildlandhydrology.com; Brandon Rosgen, Hydrologist, Wildland Hydrology, Fort Collins, CO, Brandon@wildlandhydrology.com

INTRODUCTION

The Hayman Fire started on June 8th, 2002, and burned over 138,000 acres and 133 homes. The burn area involved a large portion of the 186 mi^2 Horse Creek Watershed on the Pike National Forest, Colorado. Eight years following the fire, disproportionate sediment yields and river impairment were still prominent in the burn area. Thus a watershed assessment was conducted in 2010 and 2011 to ascertain erosional and depositional processes to identify the causes of impairment by specific location. The results of the watershed assessment were used to develop a master restoration plan to reduce the accelerated sediment yields in the areas affected by the burn.

The watershed assessment utilized the *Watershed Assessment of River Stability and Sediment Supply (WARSSS)* methodology (Rosgen, 2006b). *WARSSS* is a three-phase approach that assesses large watersheds with a practical, rapid screening component that integrates hillslope, hydrologic, and channel processes. It is designed to identify the location, nature, extent, and consequences of various past, existing, and proposed, land use impacts.

The initial two phases of *WARSSS* involving the *Reconnaissance Level Assessment (RLA)* and the *Rapid Resource Inventory for Sediment and Stability Consequence (RRISSC)* levels were conducted on the 186 mi^2 Horse Creek Watershed (Rosgen and Rosgen, 2010). The *RLA* and the *RRISSC* assessments identified the Trail Creek Watershed within the Horse Creek Watershed as *High Risk* for disproportionate sediment supply and river impairment. Based on the results of *RLA* and *RRISSC*, the Trail Creek Watershed advanced to the third and most detailed phase of *WARSSS*, the *Prediction Level Assessment (PLA)*. The *PLA* phase was directed to:

1. Identify the erosional and depositional processes that are disproportionately contributing sediment to Trail Creek
2. Quantify sediment loading by location, process, and land use
3. Develop a master plan for watershed restoration

The *PLA* methodology and results are summarized in this paper. These results were used to prioritize the locations within the Trail Creek Watershed for mitigation and restoration based on the magnitude of sediment sources for a variety of land uses. This paper also discusses design solutions for the identified areas with disproportionately high sediment yields throughout the watershed. The designs address typical sediment yield processes for hillslope and channel processes at representative or typical impaired stream type and landscape type locations.

THE *WARSSS* METHODOOGY: THE *PLA* RESULTS

The majority of the Trail Creek Watershed was burned during the Hayman Fire. The watershed involves nearly *16 mi^2* of drainage area within the South Platte River drainage in Colorado. The watershed is located in the Granitic geology associated with the Pikes Peak Batholith composed of erosive grussic granite soils. The confluence of Trail Creek is at West Creek near the community of West Creek. Ownership within the watershed is predominantly USDA Forest Service, Pike National Forest, with some private land inholdings in the upper watershed. The Trail Creek Watershed was delineated into 58 sub-watersheds, each given a unique number ID.

The *PLA* analysis identified and quantified annual sediment yields from hillslope, hydrology, and channel processes (Figure 1). Hillslope processes included assessments of the introduced sediment from surface erosion and roads and trails. Flow-related sediment was analyzed from a change in hydrology due to the fire. The assessment of channel processes included streambank erosion, degradation (bed erosion) due to headcuts and incising channels, and the combined sediment yield of the 58 sub-watersheds and the mainstem Trail Creek.

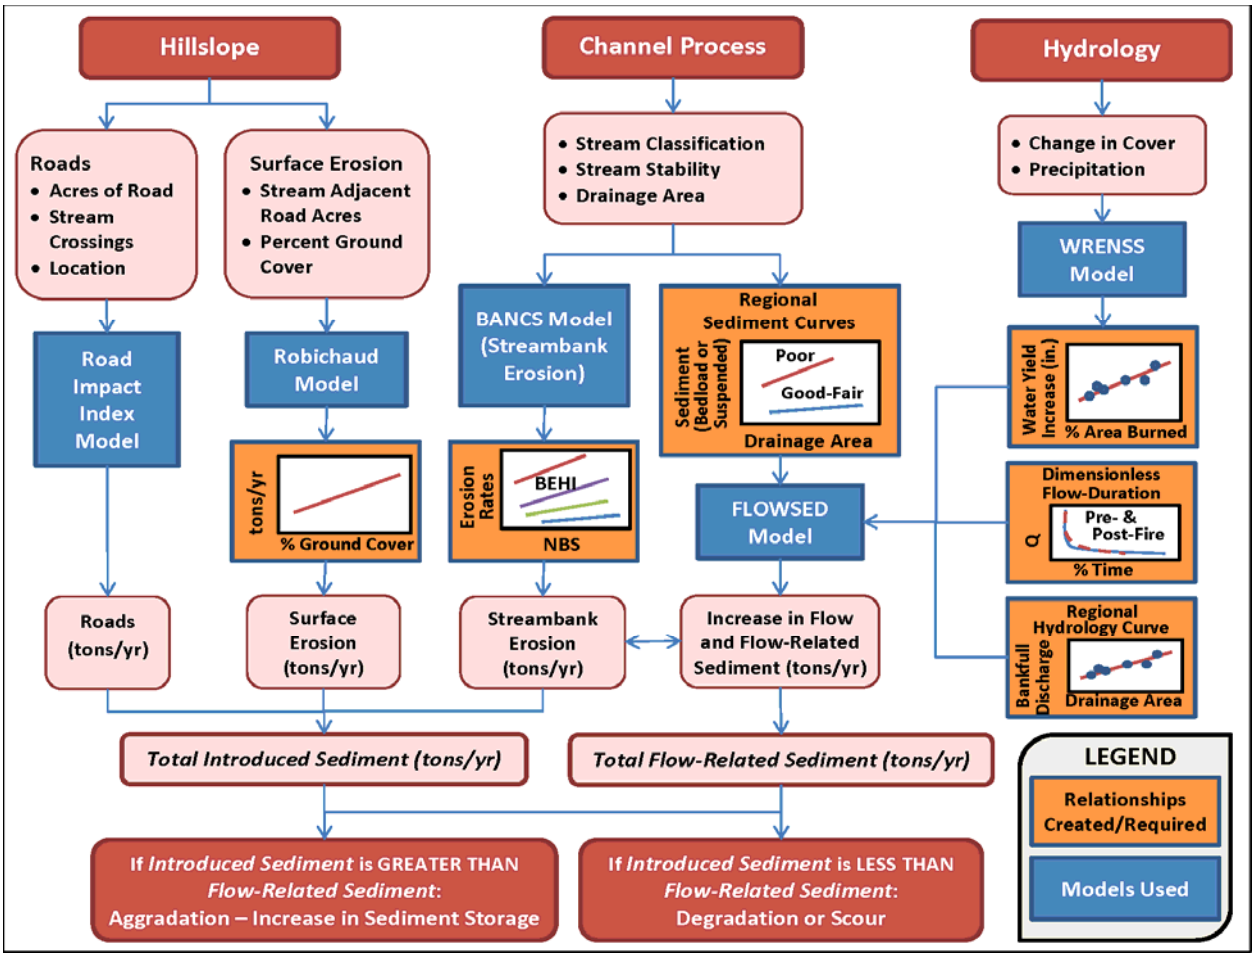

Figure 1 The procedure to quantify the sediment sources by major process (Rosgen, 2011a).

Hydrology

Increases in annual water yield following wildfires, although highly variable, can be expected (DeBano *et al*., 1998; Robichaud *et al*., 2000, 2002, 2003). Intense short duration storms characterized by high rainfall intensity and low volume have been associated with high stream peak flows and significant erosion events after fires (DeBano *et al*., 1998; Neary *et al*., 1999; Moody and Martin, 2001; Robichaud *et al*., 2002). Continued frequent and high magnitude storms will generate excess sediment yields based on flow-related channel response for the Trail Creek Watershed and other tributaries involved in the Hayman fire. According to MacDonald (2009), the Hayman fire will continue to produce sediment from the more extreme storm events because of the limited recovery potential for revegetation to offset evapotranspiration and interception losses. The growing conditions on most of the Hayman fire are very poor due to the coarse-textured soils and low precipitation relative to potential evapotranspiration. Vegetative cover is not expected to increase much beyond the current levels in areas without coniferous trees. If the amount of ground cover is not able to return to pre-fire levels, there will be a continuing susceptibility for a higher than normal streamflow "peak" response to high-intensity summer thunderstorms (MacDonald, 2009).

The hydrologic assessment for Trail Creek and its tributaries involved an application of the WRENSS water yield model (USEPA, 1980), completed by J. Nankervis, 2010, Blue Mountain Consultants. The water yield model simulates the increase in yield based on the percent of the stand that was burned for each sub-watershed to determine the inches of increased annual water yield due to the fire. The increase in flow is reflected in changes in a flow-duration curve, normalized for the flows of each sub-watershed and the mainstem Trail Creek. Changes in pre- and post-fire flow-duration curves were simulated as part of the flow-related sediment yield increase due to the wildfire for each sub-watershed and the entire Trail Creek Watershed.

The pre-fire water yield for the Trail Creek Watershed was predicted at *3,689 acre-ft* and the post-fire water yield at *6,560 acre-ft*. The total water yield increase from pre-fire to post-fire conditions was predicted to be *2,871 acre-ft*, representing a *44%* increase.

Bankfull Discharge

Bankfull discharge is the frequent peak flow that fills the channel to the incipient level of flooding. It often is associated with a return interval of 1 to 2 years and is coincident with the effective discharge or channel forming flows. Bankfull discharge was determined using the continuity equation ($Q = A * \bar{u}$) by estimating velocity ($\bar{u}$) and calculating the bankfull cross-sectional area (A). The calculated bankfull discharge was then compared to a regional curve developed for this project representing bankfull discharge *vs*. drainage area (see Rosgen, 2011b). This regional curve is based on calibrated, field-determined bankfull values at streamgage sites in the same hydro-physiographic province as Trail Creek. Velocity was estimated using a variety of methods, such as flow resistance to relative roughness and Manning's '*n*' by stream type (Rosgen, 1996, 2006b). The bankfull discharge at the mouth of each sub-watershed was determined from the regional curve relation of bankfull discharge *vs*. drainage area.

Flow-Related Sediment Yields

The flow-related sediment yield represents an integration of all introduced sources (including sediment supply from channel and hillslope processes) and the increased flow from flow-duration curves. The FLOWSED model (Rosgen, 2006a, 2006b) was applied to determine flow-related sediment yield increases due to the fire. The model uses dimensionless relations of the flow-duration curves from the WRENSS water yield analysis, along with dimensionless sediment rating curves. The normalization parameter to convert the dimensionless flow-duration curves to dimensional is the bankfull discharge determined from a regional curve of bankfull discharge *vs*. drainage area. Bankfull sediment values are used to convert the dimensionless sediment rating curves to dimensional curves. Flow-related sediment yield is then calculated based on routing the flow increase through sediment rating curves established by stream type and stability categories. This prediction assists in determining individual sub-watersheds that may be disproportionately contributing sediment based on their sediment supply, channel condition, and stream type related to the increases in post-wildfire peak flows and corresponding flow-related sediment.

In the absence of measured bankfull sediment data, similar to the approach used to estimate bankfull discharge, bankfull bedload and suspended sediment data by drainage area can be developed for a given geological region by stability. Regional sediment curves by channel stability were developed for the batholith geology (Pikes Peak, grussic granite geology) for this assessment (see Rosgen, 2011b).

The FLOWSED model was run for each of the 58 sub-watersheds and for the entire Trail Creek Watershed. The flow-related sediment yield from the post-fire, existing condition is compared to the introduced sediment supply from roads, surface erosion, and streambanks. If the combined introduced sediment values exceed the existing annual sediment yield, then excess deposition (increased channel sediment storage) is indicated. If annual flow-related sediment yield values are greater than the combined introduced sediment supply, then channel scour (bed erosion) is indicated.

The flow-related increase in sediment for the Trail Creek Watershed due to changes in the flow-duration curves and the sediment rating curves from the FLOWSED model resulted in an increase from the pre-fire to post-fire total sediment yield of *1,250 tons/yr* to *20,838 tons/yr*, which represents an increase of *19,588 tons/yr*. The total yield is comprised of approximately 26% bedload sediment and 74% suspended sediment. Overall, for a 44% increase in water yield, there is a corresponding 94% increase in total sediment (based on flow-related increases) for the Trail Creek Watershed. The significance of the increased streamflow peaks cannot be overlooked based on the magnitude of the total sediment yield consequence. Annual sediment yields from the introduced supply of roads, trails, surface erosion, and streambank erosion compared to the flow-related sediment yields are helpful in identifying sediment sources to set priorities in restoration and stabilization proposals to reduce sediment.

Hillslope Processes

Surface Erosion

Sediment yields due to surface erosion following fires can decrease by an order of magnitude following the first year, and by seven years, negligible erosion can result (Robichaud and Brown, 1999; Robichaud *et al*., 2002). MacDonald (2009) emphasizes that surface erosion rates are highly dependent on the amount of surface cover. According to the research reported by Robichaud and Wagenbrenner (2009), due to increasing ground cover in the Hayman fire burn area, a major reduction in sediment yield resulted between 2002 to 2008. For slopes in the 15–40% range and for ground cover greater than 50%, limited sediment yields from surface erosion is anticipated based on data six years following the fire. By 2008, although in the presence of high intense rainstorms, sediment yields are greatly reduced from the initial erosion and sedimentation rates. Based on the conducted research, it may be inferred that the highest potential for sediment yields from surface erosion are more likely to occur adjacent to stream systems on very steep slopes with less than 20% ground coverage.

As a result of Robichaud and Wagenbrenner (2009) research, a negative exponential relationship of erosion rate (tons/acre) as a function of ground cover density (%) was developed for this analysis (see Rosgen, 2011b). The sediment delivery data was derived from surface erosion processes for relatively short slope lengths adjacent to ephemeral channels, and for 20–40% slopes based on ground cover density. The erosion rates represent delivered sediment within approximately 100 ft from the surface erosion source. Ground cover densities were determined for each 100 foot zone on both sides of each drainage to obtain the sediment yield from surface erosion in tons/acre/yr. Aerial photo interpretations from ground truth signatures contrasting roads as zero percent ground cover up to 90% were used to obtain ground cover percentage in these 100 foot, stream-adjacent slope zones. These variables were then used to determine the increase in sediment supply from surface erosion processes based on the surface erosion rate multiplied by the total acres for that condition. Although there is evident surface erosion on mid-to-upper slopes, the potential to provide for increased sediment supply is diminished as these locations are far removed from the stream-adjacent slopes. In cases where field observations (ground truthing) indicated lower ground cover than the aerial photo-interpretation, the following procedure was followed to obtain surface erosion contributions for each sub-watershed:

1. Determine the acres of burn intensity within the near-bank zone (100 feet each side of channel) using categories as previously mapped of *High*, *Moderate*, *Low*, and *Unburned* conditions
2. Calculate the percentage of area for each burn intensity condition
3. Determine the percent ground cover for each burn intensity condition using 30% ground cover for *High* intensity, 55% for *Moderate*, 75% for *Low*, and 85% for *Unburned*
4. Calculate the weighted percent ground cover for each burn intensity condition
5. Calculate the ground cover distribution for the sub-watershed
6. Calculate the corresponding erosion rate based on the relationship to the percentage of ground cover

The predictions of sediment yields related to surface erosion resulted in a total of *2,542 tons/yr* from the Trail Creek Watershed. The total surface erosion from individual sub-watersheds is estimated at *1,908 tons/yr*, and the surface erosion adjacent to the mainstem Trail Creek is estimated at *634 tons/yr*. Overall, surface erosion contributes approximately 12% of the total introduced sediment in the sub-watersheds, mainstem Trail Creek, and the Trail Creek Watershed.

Roads and ORV Trails

Over the long-term, studies by Colorado State University indicate that roads and ORV trails generate and deliver as much sediment to the stream channel network as high-severity wildfires (MacDonald, 2009). Sediment from stream encroachment, crossings, cut bank erosion, fill erosion, and poor drainage on the main Trail Creek road results in disproportionate sediment yields. Another source of sediment is from the encroachment of the road system on alluvial fans, which has over-steepened the channels causing headcuts and the routing of sediment from the fans directly into Trail Creek. The Trail Creek road parallels and crosses the stream channel multiple times throughout its length. The majority of the ORV road and trail systems follow in close proximity to the drainageways.

The Road Impact Index (RII) model (Rosgen, 2006b) was used to predict the delivered road erosion sediment from road cuts, surfaces, and fill slopes (RII = road density multiplied by the number of stream crossings). Reasonable

validation agreement of the measured road erosion rates from the Hayman fire research (Libohova, 2004) and the sediment yield prediction from roads using the RII suggests the RII is an appropriate model utilized for this assessment. The acres of road surfaces exposed were broken into three classes based on the type of road or trail, and the typical side-slope gradient. The acres of road divided by the sub-watershed acres multiplied by the number of stream crossings by slope position were used to determine the sediment yield (tons/acre/yr).

The total sediment yield of the Trail Creek Watershed from roads and trails (erosion delivered to stream channels) is *848 tons/yr* based on 8.9 miles of roads and trails. The total sediment from the sub-watersheds, separate from the main Trail Creek road, is *258.1 tons/yr* based on 4x4 and ORV trail systems involving less acres/road length. The main Trail Creek road contributes *589.9 tons/yr* due to its close proximity to the mainstem Trail Creek. Overall, the roads and trails contribute *approximately 11%* of the introduced sediment for the mainstem Trail Creek, *approximately 2%* of the introduced sediment for the sub-watersheds, and *approximately 4%* of the introduced sediment for the Trail Creek Watershed.

Channel Processes

According to MacDonald (2009), most of the sediment due to the fire is coming from rill, gully, and channel erosion rather than hillslopes. Large amounts of sediment are still generated seven years after the fire (MacDonald, 2009). This increase in sediment can be attributed to extreme storms where there is still sufficient surface runoff to cause further channel incision and streambank erosion. Increases in the headward expansion of the drainage network are evident and widespread due to the increased peak flows and decreased flow resistance from destroyed riparian vegetation following the fire. Headcuts result in an over-steepening of the energy slope and corresponding channel bed degradation. Consequently, slope rejuvenation occurs leading to a corresponding accelerated increase in bed and bank erosion rates with increased sediment supply.

River Stability Analysis using Reference & Representative Reaches

Because there are 178 miles of stream channels within the Trail Creek Watershed, it was not practical to traverse each channel length, providing a detailed assessment of each channel. To characterize the major reaches in the watershed, the following procedure was utilized that allows for extrapolation of detailed stream channel process relations to other reaches of similar stream type and condition. Stream impairment and sediment supply are based on:

1. Development of typical, *representative reaches* that represent a range of stability and sediment supply conditions for the various stream types that occur within the Trail Creek Watershed
2. Departure of the representative reaches from the stable, *reference reach* condition for various stream types and landscape types with defined boundary conditions and controlling variables

River stability is evaluated for each reference and representative reach following the procedures in Rosgen (2006b). The evaluation is conducted on the reference reaches to validate a "Good" overall stability, and the data is used in the departure analysis of the representative reaches compared to reference conditions. Estimates of vertical stability, lateral stability, channel enlargement, and sediment supply are assessed, including streambank erosion, channel competence, and transport capacity evaluations. Streambank erosion is assessed using the *Bank Assessment for Non-point source Consequences of Sediment (BANCS)* model (Rosgen, 2001, 2006b). Competence is determined using the revised Shields relation for initiation of motion (Rosgen, 2006b); sediment transport capacity is evaluated using the POWERSED model (Rosgen, 2006a) as programmed in RIVERMorph™. The POWERSED model is also used to determine channel response (aggradation, degradation, or stable) for each representative reach as a departure from the reference condition. The river stability evaluation provides a quantitative expression of the stable form of stream types that may be potentially implemented as part of mitigation or restoration.

Overall, sixteen *representative reaches* and five *reference reaches* were obtained to document a range of stream types and conditions that occur within the Trail Creek Watershed. Data for each stream type and landscape type include the morphological characterization (dimensions, pattern, profile, and channel materials) to determine the departure of each representative reach from the potential, stable stream type (reference reach). If restoration designs are required, the reference reach data is also used to scale the morphological characteristics of the stable form to apply to the restoration reaches that have similar landscape types, boundary conditions, and controlling variables.

The data from the representative reaches were extrapolated to reaches with similar stream types and conditions within the watershed. For example, for the typical "Poor" stability, F4 stream types (entrenched channels with high width/depth ratios and high banks on both sides; see Rosgen, 1994, 1996 for stream type and valley type descriptions), unit erosion rates in tons/yr/ft of streambank erosion were obtained; these rates were extrapolated to other similar "Poor" stability, F4 reaches. The reaches that indicated *moderate* to *very high* sediment supply or channel instability were mapped in detail. Approximately 55 miles (31%) of the streams in the Trail Creek Watershed were traversed obtaining direct observations of stream types and associated stability. The remaining two-thirds of the reaches utilized extrapolated relations due to similar boundary conditions and controlling variables. Based on stable, low sediment supply indicators at the mouth of several small watersheds, values of "Good" were used to predict the potential, flow-related sediment increases. Because of the distinctly evident stable conditions, more detailed site investigations were not warranted; thus these small watersheds were not mapped in the same detail (streambank erosion rates, stream type, and condition) as the "Fair" and "Poor" condition sub-watersheds.

Streambank Erosion

Streambank erosion is accelerated in the presence of aggradation, central bars, channel incision, increased peak flow magnitude and frequency, debris jams, and change in riparian vegetation that decreases frictional resistance. The BANCS model (Rosgen, 2001, 2006b) was used to predict streambank erosion rates on the reference reaches, representative reaches, sub-watersheds, and mainstem Trail Creek. The BANCS model utilizes two tools to predict streambank erosion: 1) The Bank Erosion Hazard Index (BEHI), and 2) Near-Bank Stress (NBS). The BANCS model evaluates the bank characteristics and flow distribution along river reaches and maps BEHI and NBS risk ratings commensurate with streambank and channel changes. Annual erosion rates are estimated using the BEHI and NBS ratings, and then are multiplied by the bank height and corresponding bank length of a similar condition to estimate the tons of sediment per year.

The erosion rates for the reference reaches indicate baseline or geologic rates; whereas the erosion rates from the representative reaches indicate a potential departure from the reference condition, or an acceleration of this process. Stream reaches were mapped in each major sub-watershed and along the mainstem Trail Creek to spatially locate disproportionate accelerated sediment supply from streambank erosion. The total tons of sediment from streambank erosion are weighted by the length and condition for each sub-watershed and the mainstem Trail Creek. This allows the locations with very high sediment contributions to be identified within the sub-watersheds and their relative contribution to total sediment yield. Not all of the sediment, however, that is dislodged or entrained from the banks is routed out of the watershed. Much of the sediment from the streambank erosion process is stored temporarily in the channel. Sediment budgets for each sub-watershed, reference reach, and representative reach include the specific contributions from streambank erosion. Because streambank erosion can be mitigated or reduced through various streambank stabilization methods, this data is used to set priorities for restoration and stabilization recommendations.

Overall, streambank erosion contributes *14,087 tons/yr* of introduced sediment for the sub-watersheds, which represents *87%* of the total introduced sediment. The streambanks along the mainstem Trail Creek contribute *4,031 tons/yr* of introduced sediment, which represents *77%* of the total introduced sediment along the river corridor. Overall, for the entire Trail Creek Watershed, streambank erosion makes up *84%* of the introduced sediment and contributes *18,118 tons/yr* to the post-fire total sediment yield of *20,838 tons/yr*. These values indicate the significant contribution of streambank erosion to the introduced or accelerated sediment supply.

Stream Type Succession

Wildfire-induced changes in the boundary conditions (riparian vegetation and flow resistance) and the flow and sediment regimes promote changes in river morphology and stream type. Typical channel responses to the fire effects are generally increased streambank erosion, channel enlargement, aggradation, degradation, lateral migration, and channel avulsion. The extent, nature, and direction of change is dictated by the landscape type and stream type associated with a given stream reach and its condition prior to the fire. Recognizing disequilibrium or unstable reaches and understanding what the stable form should be is instrumental to this effort on Trail Creek and its tributaries.

Stream type succession is used to interpret and predict the potential stable morphological state. Twelve stream succession scenarios and stream type shifts toward stable end points for each scenario are presented in Rosgen (2006b). These scenarios represent various sequences from actual rivers and are used to assist in predicting a river's

behavior based on documentation of similar response from similar types for imposed conditions. It is important to select the appropriate scenario and current stage of stream succession to assist in selecting the stable, end point stream type for restoration. The use of stream succession in design is dependent on the existing stream type and the stable, potential type based on a landscape type that matches the boundary conditions and the controlling variables. Based on the stream succession scenarios, Table 1 shows the typical, impaired stream types and their respective stable, potential stream types within specific landscape types.

Table 1 Existing, impaired stream types compared to the stable, potential stream types stratified by landscape types for the Trail Creek Watershed.

Existing, Impaired Stream Type	Existing Landscape Type	Stable, Potential Stream Type
A4	Short Alluvial Fan	B4a
A4	Long Alluvial Fan	D4
D4	Terraced Alluvial	C4
F4b	Colluvial	B4
F4b	Terraced Alluvial	B4
F4b	Short Alluvial Fan	B4
F4b	Long Alluvial Fan	D4
F4	Terraced Alluvial	C4
F4	Terraced Alluvial (confined)	B4c
G4	Terraced Alluvial	B4
G4	Short Alluvial Fan	B4
G4	Long Alluvial Fan	D4
B4 “Fair” or “Poor”	Terraced Alluvial	Stable B4
C4 “Fair” or “Poor”	Terraced Alluvial	Stable C4

Summary of Sediment Supply and Sub-Watershed Priorities

The contributions of the total introduced sediment supply to the total post-fire annual sediment yield for the Trail Creek Watershed are shown in Table 2. The total introduced sediment yield is higher than the flow-related annual sediment yield because not all of the sediment is routed out of the basin. Approximately *661 tons/yr* can potentially be related to excess sediment (channel storage) of the total flow-related increased sediment. The stored sediment in the channel is made available during subsequent stormflow runoff events and is reflected as an increase in flow-related channel source sediment.

The contributions of each erosional process for the 58 sub-watersheds are summarized in Rosgen (2011b). Priorities to address the sediment supply for the 58 sub-watershed were established based on a weighted sediment supply by area (see Rosgen, 2011b). The watershed master plan for restoration focuses on the high priority sub-watersheds to reduce the annual sediment supply based on the sediment sources.

Table 2 Relative contributions of erosional or depositional processes to total annual sediment yield for the Trail Creek Watershed.

Erosional or Depositional Processes	Total Annual Sediment Yield (tons/yr)	Percent of Total Introduced Sediment
Surface Erosion	2,542	12%
Roads & Trails	848	4%
Streambanks	18,109	84%
Total Introduced Sediment	21,499	100%
Erosional or Depositional Processes	**Total Annual Sediment Yield (tons/yr)**	**Sediment Deposition/ Increased Channel Storage (tons/yr)**
Post-Fire Flow-related Total Sediment Yield (FLOWSED)	20,838	661

THE WATERSHED MASTER PLAN FOR RESTORATION

The watershed and river restoration plan is based on the Natural Channel Design (NCD) methodology (Rosgen, 2007, 2011a). The watershed restoration master plan and design considers the stated objectives and offers a variety of solutions for a wide range of conditions. The following objectives help define the proposed watershed and river system restoration and sediment reduction plan:

1. Reduce sediment supply from disproportionate sources identified by erosional process, land use, and specific locations within the watershed
2. Quantify the sediment supply reduction by proposed restoration
3. Develop restoration scenarios that address the cause of impairment
4. Improve fish habitat diversity and function
5. Stabilize streambanks and streambeds
6. Utilize a natural channel design methodology that results in a natural appearance
7. Accelerate the recovery processes from the Hayman Fire
8. Re-establish a functional riparian corridor
9. Reduce road and trail maintenance
10. Provide for improved recreational opportunities
11. Provide ecological restoration (including habitats for birds, fish, mammals, and amphibians)
12. Reduce flood stage
13. Accommodate floods and reduce flooding impacts on adjacent road
14. Create cost-effective and low-risk restoration solutions
15. Be complimentary to the central tendency of natural systems
16. Provide a demonstration reach for extrapolation of similar applications
17. Provide an opportunity for research and restoration monitoring

Hydrologic Processes

The increase in peak flows due a reduction in evapo-transpiration will continue until a forested stand is re-established. Decades will be required to reach a full hydrologic utilization. Planting coniferous trees on the burned landscape will help accelerate the re-establishment of a forested stand for the potential long-term condition.

Restoration Plan for Hillslope Processes

Surface Erosion

Surface erosion reduction is planned within the *100 foot buffer* to existing streams because this zone has the highest probability of delivered sediment. The highest priorities are also set adjacent to perennial channels. The annual sediment contribution of approximately *2,542 tons/yr* makes this effort worthwhile. The following recommendations are designed to reduce this sediment source.

Because ground cover density is directly related to erosion rates and sediment supply, any sites with a ground cover density less than *40%* will need treatment. Treatment includes reseeding with a grass hay or straw mulch surface. Adding debris such as small logs, tops, and branches will also help reduce soil loss transport. The highest priorities for treatment are on slopes adjacent to perennial streams. The locations of the lowest ground cover density based on burn intensity for each sub-watershed are also zones of highest priority for surface erosion contributions.

Where sufficient space allows, constructing a bankfull bench against the toe of the slope is also recommended rather than allowing the sediment to be routed directly into the stream channel. The bench is most appropriate adjacent to B and C stream types. The materials for the entire bench width and length are generated from borrow sites. The borrow sites can also be used as a sediment detention basin. It is also necessary to establish vegetation on the bench to add as a potential sediment filter and sediment catch. Native bunchgrasses, such as big mountain brome, are appropriate species for the bench as these sites are not typically in wetland areas. The design requires approximately *89 yds*^{3} of fill per *100 ft* of constructed bench based on a bench width of *12 ft* and a mean depth of *2.0 ft*. Thus the borrow depression would be sufficiently deep and spaced to provide the needed fill. There is a net balance of cut and fill by design.

Overall, it is anticipated that at least *50%*, or *1,270 tons/yr*, can be reduced by increasing ground cover to above *65%* and by installing benches and establishing riparian vegetation on stream-adjacent slopes that are contributing to sediment delivery from surface erosion.

Roads & Trails

The *WARSSS* assessment indicated that the mainstem Trail Creek road contributes approximately *589.9 tons/yr* of delivered sediment compared to the total of *848 tons/yr* from the trails, off-road 4x4 roads systems, and the mainstem Trail Creek road. To reduce the delivered sediment and erosional debris from the Trail Creek road directly into Trail Creek, decreasing the *number* of stream crossings is recommended. Relocating the main Trail Creek road in two major locations will potentially reduce six crossings.

It is also recommended to reduce the fill erosion along many actively eroding road fill sites that are responsible for direct sediment contributions to Trail Creek; the following practices are recommended:

1. Relocate the channel away from the road fill slope to reduce the toe erosion from lateral channel migration
2. Place grass seed and native grass hay mulch or straw mulch over the seed on the fill slopes; native grass hay mulch is preferred as it is not as susceptible to wind transport as straw mulch and provides additional seed source
3. Move the localized road prism farther away from the channel without total relocation at locations where feasible
4. Stabilize channels cut through fills with step–pool grade control structures, side-slope reduction, and seeding and mulching
5. Place woody debris on fill slopes, including limbs, tops, branches and small logs, perpendicular to the slope; seed and mulch the slopes
6. Construct small terraces perpendicular to the slope to reduce rill erosion; seed and mulch the terraces
7. Construct a bankfull bench between the toe of fill slope and the channel where the channel impinges on fill
8. Install the toe wood structure with sod mats and willow transplants (or soil lifts with cuttings) on the bankfull bench to prevent Trail Creek from eroding the fill material

Also, reseeding and grading the road surface to reduce surface rills and maintain drainage features are recommended. Improving the road surface drainage is also advised as follows:

1. Out-slope the road to reduce concentration of water and sediment on the inside ditch line; this avoids the concentration of water from sub-surface interception and disperses the flow instead of concentrating such flows on the road and ditch-line surface
2. Place rolling “Kelly dips” on slope gradients greater than three percent
3. Construct sediment detention depressions at drainage outfalls or at drainage turnouts to encourage infiltration and sediment deposition

Headcut channels intercepted by the road should also be stabilized with step–pool grade control. This will help reduce the current high maintenance of sediment deposition on the road surface and will prevent over-steepening of the channel at the toe of the road.

It is anticipated that the aforementioned recommendations can effectively reduce the existing sediment yield from the Trail Creek road by approximately *413 tons/yr*, representing a *70%* sediment reduction.

In addition to the Trail Creek Road, numerous ORV roads and trails parallel and cross the channels in the Trail Creek Watershed; it is recommended to relocate the majority of these systems that are frequently introducing direct sediment away from the drainage proximities. Based on the immediate proximity of the ORV roads and trails to the adjacent channels and their steepness, it would be extremely difficult with a poor likelihood of success to institute sediment mitigation on these systems. The proposed ridge routes are available and feasible for these trails without changing their origin or destination sites (see Rosgen, 2011c). This recommendation can reduce nearly *200 tons/yr* of delivered sediment to Trail Creek.

Restoration Plan for Channel Processes

Due to high sediment yield results from flow-related increases, stream channel restoration and stabilization can be effective to reduce this accelerated sediment supply. The restoration work includes protecting streambeds and streambanks from the increased flows and re-establishing floodplain connectivity where possible. Creating a functioning riparian corridor is also recommended for the long-term stability of stream channels. Aquatic habitat will also be improved with such river restoration and stabilization work. The proposed restoration of the stream channels to reduce the accelerated sediment supply focuses on converting unstable stream types to stable stream types and reducing the streambank erosion.

Typical Design Scenarios

The *representative reaches* were established, measured, quantified, and evaluated in great detail to develop typical design scenarios that can be extrapolated to other locations in the Trail Creek Watershed where this level of detail was not obtained but is assumed to be similar. The reference reaches were established to provide the stable design criteria to develop the proposed design for the representative reaches. The nine design scenarios shown in Table 3 were developed to represent the range of stream types and stability conditions that require restoration within the Trail Creek Watershed. Each of the design scenarios is related to a specific location within the watershed for demonstration purposes. The appropriate scenario can then be extrapolated to other reaches of the same stream type, landscape type, and stability condition as the representative reach.

Table 3 The nine typical design scenarios developed to extrapolate to other locations in the Trail Creek Watershed for restoration.

Stream Type Conversions		
Existing, Impaired Stream Type	**Proposed Stream Type**	**Landscape Type**
1. D4 Poor	C4 Good	Terraced Alluvial
2. F4 Poor	B4 Good	Terraced Alluvial (confined)
3. G4 Poor	B4 Good	Terraced Alluvial
4. C4 Poor	C4 Good	Terraced Alluvial
5. F4b Poor Tributary	D4	Alluvial Fan
6. F4b Tributary	B4 Good	Alluvial Fan
7. A4a+ Poor	A4a+ Good	Colluvial
8. A4a+ Poor	D4	Alluvial Fan
9. A4a+ Poor	B4a Good	Alluvial Fan (short fan)

Each typical design scenario includes detailed descriptions of 1) General Description and Morphological Data; 2) Bankfull Discharge, Cross-Sectional Area, and Mean Velocity; 3) Plan View Alignment; 4) Cross-Section Dimensions; 5) Longitudinal Profile; 6) Structures; 7) Riparian Vegetation; 8) Cut and Fill Computations; 9) Streambank Erosion; 10) Flow-Related Sediment; and 11) Sediment Competence (see Rosgen, 2011c, for the detailed design scenarios).

The flow-related sediment and potential sediment reductions, including streambank erosion contributions, for the existing and proposed design reaches are documented in Rosgen (2011b). The majority of the design scenarios convert "Poor" condition stream types to "Good" stream types and unit sediment transport reductions are computed. However, the typical design scenarios 5 and 8 in Table 3 convert A4a+ and F4b stream types to the braided, D4 stream type with sediment detention basins and surface storage on alluvial fans. The typical designs for these scenarios store 100% of the sediment yield and are associated with a zero sediment transport to the mainstem Trail Creek.

The sediment reduction potential by implementing the proposed stream restoration design scenarios involving 3,025 ft of stream channels is approximately *1,600 tons/yr* for 7 of the 9 scenario locations. The remaining 2 scenarios associated with creating D4 stream types with sediment detention basins on alluvial fans result in reductions of

approximately *5,468 tons/yr* of sediment. In total, over *7,000 tons/yr* of sediment could be kept out of Trail Creek per year based on the implementation of the nine scenarios presented. This represents approximately *29%* of the total annual sediment yield in the Trail Creek Watershed. Extrapolating and implementing the design scenarios to appropriate locations will result in even greater sediment yield reductions.

Total Potential Sediment Reductions

The potential sediment reductions associated with implementing the nine typical design scenarios and the recommendations for hillslope processes are presented in Table 4. The total potential reduction is approximately *8,853 tons/yr*, representing approximately *37%* of the total annual sediment yield.

Table 4 The potential sediment reductions by implementing the recommendations for hillslope and channel processes.

Total Sediment Contribution Reductions	
Hillslope Processes	
Surface Erosion	*1,270 tons/yr*
Trail Creek Road	*413 tons/yr*
ORV Roads and Trails	*200 tons/yr*
Channel Processes	
The Nine Typical Design Scenarios	*7,000 tons/yr*
Total Potential Reduction	***8,853 tons/yr***

SUMMARY

The Trail Creek Watershed master plan for stream restoration and sediment reduction is the result of a detailed watershed assessment that has directed the proposed restoration to impaired streams. The assessment also identified the source of impairment including hillslope, hydrology, and channel processes. The master plan identified priorities of restoration based on disproportionate sediment supply contributions and the various sources, including streambed and streambank erosion from post-fire related streamflow increases, and direct introduction by surface erosion and roads and trails. These various erosional processes were identified and specific restoration scenarios were proposed to reduce the sediment supply and restore the physical and ecological function.

Each of the 17 specific, multiple objectives for the master restoration design for the Trail Creek Watershed are potentially met with the implementation of the various scenarios and locations proposed. Overall, the various restoration scenarios within the Trail Creek Watershed were developed to extrapolate general hydrology, sedimentological, and morphological relations and to create the dimensions, pattern, and profile of stable stream types scaled for individual reaches.

These subsequent designs are intended to accelerate the recovery of the Trail Creek Watershed from the adverse impacts of the Hayman fire. The proposed design scenarios and subsequent implementation will potentially direct the future of watershed restoration following large wildfires. The procedures can also be used for other watersheds that are currently impaired due to the Hayman fire in the South Platte Basin in a timely manner. Overall, the field assessment for the entire Horse Creek Watershed was completed in eight months and the assessment report and master restoration plan was completed in six months.

An individual 404 permit was issued for the master restoration plan for the entire Trail Creek Watershed to be implemented over 20 years, and project implementation began in 2011. The Forest Service (Pike and San Isabel National Forest) is monitoring the physical and biological response of the WARSSS-based restoration. The research and monitoring will document the benefits of restoration and watershed recovery.

Abt, Ph.D; Senior Research Scientist/Scholar, Colorado State University, sabt@engr.colostate.edu

Abstract: Hybrid hydraulic modeling research, which integrates physical and numerical modeling, is currently being conducted to develop empirical design procedures for river-training structures. Transverse features are rock structures, usually installed in series around a river bend, which can control near-bank flow velocities, increase bank stability, decrease the effect of secondary currents, and promote habitat. An extensive database was developed from physical modeling of transverse features in a native-topography channel. The laboratory database is being used to calibrate and validate computational fluid dynamic (CFD) models, which will be used to approximate flow fields for varying structure designs. Empirical design procedures will then be developed from the resulting numerical-modeling database. The hybrid hydraulic modeling approach is detailed and results are presented from the CFD model calibration and validation to laboratory data.

INTRODUCTION

Hydraulic modeling has historically been grouped into the paradigms of either theoretical or empirical derivation. In essence, theoretical models are derived from conservation fundamentals while purely empirical methods rely on statistical methods to fit observed data. Due to the complex nature of fluid flow, the majority of theoretical models have a degree of associated empiricism; e.g. Manning *n*, viscosity, energy loss coefficients, which must be calibrated using observed hydraulic data. However, the core of the theoretical models is grounded in the Navier-Stokes equations. Empirical models used for hydraulics, such as stage-discharge relationships, scour-depth studies, rip-rap sizing, or stilling basin design, typically implement pertinent design parameters grouped into physically meaningful groups with numerical weights tailored to a collected dataset.

With increasing computational power and efficiency, theoretical models have evolved into robust, three-dimensional computational fluid dynamics (CFD) simulations. Such simulations have been shown effective in the evaluation of complex hydraulic conditions. While validated, the widespread use of CFD has not been realized in the current applied engineering and scientific realms. Theoretical models incorporating assumptions of the behavior of flow are widespread for practitioners, including HEC-RAS one-dimensional and two-dimensional code; however, the assumptions of such models significantly limit accuracy of results in complex flow environments where they are violated. In one-dimensional and two-dimensional theoretical flow simulations, assumptions break down when there are spatially rapidly-varied flow conditions containing a significant vertical flow component. Codified and widely implemented theoretical modeling codes such as HEC-RAS utilize empirical equations to account for the instances where assumptions break down, such as in the instance of a hydraulic jump or encountering an instream structure. The research presented in this proceeding illustrates a novel approach for hydraulic modeling methods by examining the feasibility of the combination of both theoretical and empirical models to develop design procedures for riverine structures. Proposed methods for the development of empirical design guidelines for transverse instream structures using data gathered from three-dimensional CFD simulations are expounded and detailed.

The Middle Rio Grande River between Cochiti Dam and Elephant Butte Reservoir in New Mexico has been the focus of extensive river restoration work since the upstream Cochiti Dam installation in 1975. The dam effectively disconnected the sediment continuity to the downstream reach, resulting in a geomorphic shift from a historically braiding channel to a slightly sinuous, incising system. The United States Bureau of Reclamation (Reclamation), as the responsible party for management of the river, launched an investigative study on the performance of transverse

in-stream structures jointly with Colorado State University (CSU). Research performed by CSU and Reclamation has provided a wealth of physical model hydraulic data surrounding transverse in-stream structures and quantitative design guidelines for structure installation.

Transverse in-stream structures are a type of river-training structure that has the primary goal of halting bank migration in a meandering system. Structures extend from the outer-bank of the channel into the center, diverting flow from the outer-bank to the relocated channel thalweg at the structure tips. Nomenclature for transverse in-stream structures varies dependent upon the crest height and intended flow pattern. Bendway-weirs, spur-dikes, and bank-attached vanes are types of in-stream structures, planimetrically identical, yet different in their cross-sectional geometries and intended hydraulic effects. Planimetric and cross-section schematics of the three identified in-stream structures are provided in Figure 1, which expounds differences between structure classifications in the cross-sectional view. In a general hydraulic sense, bendway weirs redirect conveyance perpendicularly and over the top of the structure crests, spur-dikes shift flows around the structure tip, and bank-attached vanes combine both crest overtopping and shifted flow to redirect conveyance to the channel center.

Design recommendations for transverse in-stream structures are typically anecdotal and do not provide specifics of hydraulic performance based upon alteration of design parameters within recommended ranges. Examples of guidelines include NRCS (2005) for bank-attached vanes, Lagasse et al. (2009) for spur-dikes, and McCullah and Gray (2005) for bendway weirs. Scurlock et al. (2014) presented a quantitative model for estimation of normalized maximum and average velocities at various locations within a channel resulting from structure installations. The general mathematical model presented by Scurlock et al. (2014) is given as Equation 1.

$$MVR, AVR = a_1 + a_2\left(A^*\right)^{a_3}\left(\frac{L_{ARC}}{T_W}\right)^{a_4}\left(\frac{R_C}{T_W}\right)^{a_5}\left(\frac{L_{W-PROJ}}{T_W}\right)^{a_6}\left(\frac{D_B}{D_B-\Delta z}\right)^{a_7}\left(\frac{2\theta}{\pi}\right)^{a_8} \quad (1)$$

where:

MVR = maximum velocity ratio;

AVR = average velocity ratio;

A^* = percentage of baseline cross-sectional area blocked by structure;

$L_{W\text{-}PROJ}$ = projected length of structure into channel [L];

L_{ARC} = arc length between centerline of structures [L];

R_C = radius of curvature of channel bend centerline [L];

T_W = averaged top width of channel measured at baseline in bend [L];

D_B = averaged maximum cross-section baseline flow depth in bend [L];

Δz = elevation difference between water surface and structure crest at the tip [L];

θ = structure plan angle [radians];and

$a_1, \ldots, a_6$ = regression coefficients.

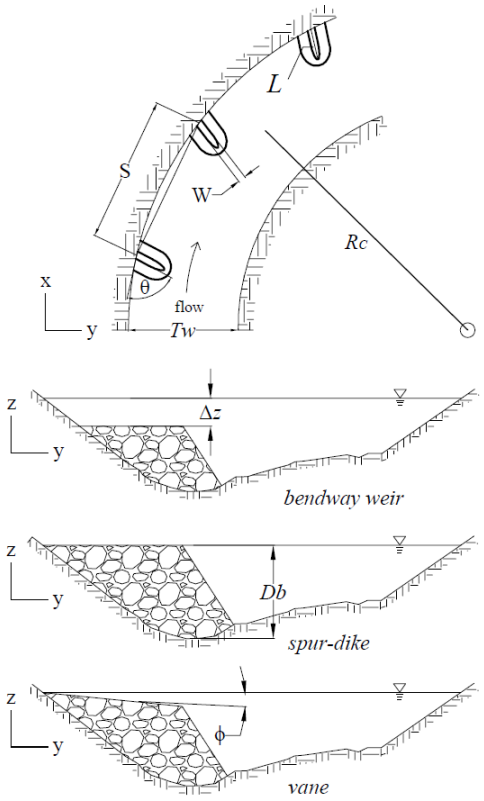

Figure 1 In-stream structure geometric parameter definitions

Heintz (2002), Darrow (2004), and Schmidt (2005) evaluated hydraulic performance of transverse in-stream structures in a physical model at CSU. Using physical model data collected from these studies from a 1:12 Froude scale model of two trapezoidal representations of the prototype Middle Rio Grande River, Equation 1 was optimized to predict normalized velocities at the outer-bank, centerline, and inner-bank of the channel for spur-dike and bank-attached vane installations. A total of 130 independent data points were used for regression analysis, representing a statistically large database for equation development.

Further research was conducted at CSU by Thornton et al. (2011), Scurlock et al. (2014a), and Scurlock et al. (2014b) on spur-dikes, bendway-weirs, and bank-attached vanes installed in a physical model representation of natural channel geometry. Survey data were obtained from two channel bends in the Middle Rio Grande and were constructed within the spatial constraints of the trapezoidal physical model. A total of four bendway-weir configurations, one spur-dike, and one bank-attached vane configuration were evaluated in the natural channel with comprehensive velocity fields realized through data collection with an acoustic Doppler velocimeter (ADV). Data collected in the natural topography physical model elucidated important hydraulic characteristics regarding transverse in-stream structures; however, evaluated configurations do not substantiate regression analysis using the model of Equation 1.

The primary goal of the current research is to investigate methods of compiling a large dataset for the bendway-weir structure type in attempt to develop quantitative design guidelines similar to the model of Equation 1. To facilitate this development, a dataset of significant size would be required, at least one order of magnitude higher than the four physically modeled natural-topography bendway-weir configurations. Physical modeling can be time consuming and resource intensive; factors which can inhibit the compilation of the requisite dataset for design guideline development. Utilizing CFD, it may be possible to take numerically simulated results from modeled bendway-weir configurations and compile a dataset large enough for empirical development. The feasibility of developing bendway-weir design guidelines using CFD is examined using calibration and validation procedures with the physical model data of Scurlock et al. (2014a) and Scurlock et al. (2014b). It is shown that CFD methodologies

present a viable alternative to physical modeling or field data collection for the development of empirical equations, representing a hybrid approach to hydraulic modeling.

NUMERICAL MODEL SELECTION

A proven, reliable, and reproducible model was desired for the completion of numerical evaluation of laboratory data. A balance between desired accuracy and required computational resources must be achieved during numerical modeling. While large-eddy simulations and direct-numerical solutions outperform Reynolds-averaged Navier-Stokes (RANS) models in resolving turbulent and separating flows (Kang and Sotiropoulos, 2012; Constantinescu et al., 2011), the required computational times are substantially greater and unfeasible for the proposed research objectives. A numerical code using a RANS approach with an appropriate turbulence model was investigated. FLOW-3D is a commercial numerical package created by Flow Science which has been proven in open-channel flow applications and in-stream structures (Rodriguez, 2004; Abad et al., 2008; Plymesser, 2014; Kolden, 2013). The model incorporates a Fractional-area-volume-obstacle-representation (FAVOR) method for solid object interfaces and volume-of-fluid (VOF) method for free-surface fluid interfaces. FLOW-3D uses a rectilinear, orthogonal grid system in conjunction with FAVOR and VOF to rapidly develop discretized meshes around complex objects, which is preferable when investigating multiple geometries.

The RNG k-ε turbulence mode, an option incorporated into FLOW-3D model, was found to be an appropriate numerical method of representing overall hydraulic trends while accounting for smaller scales of turbulence than other RANS turbulence closure models. The RNG k-ε model presented by Yakhot et al. (1992) accounts for different scales of turbulent motion influencing the transport of k and ε and may improve RANS model resolution of rotating flows. All simulations were conducted using the RNG k-ε RANS model with the standard turbulent mixing length coefficient of 0.09. Pressure was solved for implicitly and momentum advection was set as a second-order monotonicity preserving explicit scheme akin to the PRIME method of Maliska and Raithby (1983).

Meshing proficiency, graphical display capabilities, ease of user interaction, numerical method flexibility, and application track record led to the selection of FLOW-3D as the model of choice to meet project objectives. With the numerical package selected and specific code aspects of the model determined, the spatial domain of the simulation was then defined in order for the mesh to be generated and the numerical code executed. Representations of the physical model channel and in-stream structures were created to serve as the boundaries for the numerical simulations.

GEOMETRY REPRESENTATION AND MODEL SETUP

Representation of a physical surface as a boundary in a numerical mesh requires surveyed data and a method for interpolation between known data points. The nature of the FAVOR model in FLOW-3D allows for rapid integration of new components to surfaces. This concept works well in the context of the current research. A baseline model was created as an individual surface and in-stream structure configurations were represented as independent surfaces and brought into the model separately.

The creation of the numerical domains utilized high-resolution LiDAR data of approximately 15 million individual points parsed to approximately 6 thousand points for surface generation. Parsed data were imported to AutoCAD Civil 3D and developed into a surface using a triangular-irregular network (TIN) which was then exported to FLOW-3D. The same process was followed with bendway-weir configurations. Figure 2 illustrates a schematic of the bendway-weir configurations installed with a topographic representation interpolated from LiDAR data. FLOW-3D requires that the flume outlet be oriented on an orthogonal axis. The model was rotated and linearly translated to ensure that the outlet was oriented parallel to x = 0 ft. Initial and boundary conditions within FLOW-3D are specified once the surface has been imported to the program. The developed baseline surface was added, the mass-flow outlet was designated, and the domain inlet was defined as a constant mass input. Constant mass input boundary conditions designate the full cross section with a uniform deliverance of volumetric flow and do not initially contain information regarding developed velocity profiles expected in a physical laboratory or field. This entrance effect was mitigated by extending the model input section approximately 10 channel widths upstream allowing uniform cross-section inflow to develop along the channel before it encountered the test area. Downstream boundary conditions were specified at water-surface elevations observed during laboratory testing. Figure 3 provides

an example of the numerical model topography depicting the baseline model (in grey) along with a bendway-weir structure installation (in red).

MODEL CALIBRATION

Numerical models may be calibrated to specific applications through adjustment of spatial grid resolution, maximum permitted time step, surface roughness, turbulence parameters, mass inflow, fluid properties, initial conditions, and boundary conditions. In the case of modeling bendway-weirs using FLOW-3D, grid independence, time step, surface roughness, and mass inflow was adjusted during the calibration process. Initial grid, time step, and mass inflow calibrations were performed on the baseline model and then applied to the bendway-weir configurations. Approximately 3,000 ADV data were used for the baseline calibrations as reported in Scurlock et al. (2012). Total velocity measurement variability from instrumentation thresholds as reported from Scurlock et al. (2012) amounted to ± 4.5% of the measured value. Surface roughness was calibrated to baseline and structure installation configurations.

Numerical grid independence is an evaluation of the level of mesh resolution required for efficient and accurate representation of fluid dynamics throughout the solution domain. Both spatial precision and solution accuracy increase with finer grid resolution up to a threshold at which further reduction of grid size does not warrant computational expense. To prove grid independence, an original Cartesian mesh of size {x,y,z} = {1.5 ft, 1.5 ft, 0.5 ft} was evaluated then split by a factor of two for reevaluation. Global mean absolute difference was computed between the flow velocities for each mesh and a mean absolute percent difference (MAPD) tolerance was established at 5%. *MAPD* was calculated using the grid points from the coarser mesh as comparison locations and used the finer mesh for deviation normalization. Five grid sizes were evaluated and grid independence for the baseline model was established at a spacing {0.1875 ft, 0.1875 ft, 0.0625 ft}. The *MAPD* between the last grid iteration was 2.6% for depth-averaged velocity points and 3.7% for all velocity data, largely centered in small, localized areas at the flow boundaries.

Time-step discretization is another dimensional grid in addition to the spatial mesh which must be specified for numerical model execution. Time-step sizing is not as important as spatial grid resolution for data precision; a smaller time step will generally not provide more information than a larger one. However, the explicit nature of the momentum advection numerical scheme and Courant-Friedrichs-Lewy (CFL) limitations makes the time-step size fundamental for local numerical stability as well as for attenuation of global numerical oscillation perturbations (Courant et al., 1928). Time-step independence was proven by iterating maximum time step size. CFL limitations dictate that the time step must be small enough to reconcile all advective motion within a given grid cell, or that the speed at which the mass travels through a certain distance cannot exceed the numerical computation speed. As such, the time step was automatically reduced if CFL requirements were violated.

Surface roughness affects the frictional resistance on the flow and all hydraulic properties within the channel. Five roughness iterations were carried out to bracket the minimum deviation between numerical and physical results. Flow depths, 60% depth laboratory velocity locations, and the full set of laboratory velocity data collection locations were used for comparison between numerical and physical models. A surface roughness value of 0.07 ft produced the most accurate results at a precision level of ± 0.01 ft.

Using the calibrated mesh size, time step, and roughness value, a full-domain simulation was performed on the baseline model. It was observed that flow depths as well as velocities were greater than those recorded in the physical model, indicating that the volumetric flow rate in the numerical model was in excess of that in the physical model. The physical model surface was not impermeable and an amount of seepage was present during operation. A calibration adjustment of the numerical flow rate to 11.5 ft^3/s produced more accurate results and the discharge reduction of 0.5 ft^3/s, representing 4.7% of the bankfull flow rate, was applied to all subsequent numerical simulations.

The calibrated numerical baseline model was run at 11.5 ft^3/s until a steady-state condition was achieved. Numerical model data were extracted at the physical data-collection locations for comparison. Flow depths throughout the solution domain matched physical values well with mean-absolute deviation of 0.026 ft and *MAPD* of 3.78%. Velocity magnitudes at 60% flow depth were represented well with important regions of flow for the project

objectives resolved. Regions of high and low flow at the respective outer-bank and inner-bank were nearly identical in both models and velocity magnitudes were of approximately the same. The *MAPD* was calculated at 11.67%, the median was 9.00%, and the standard deviation was 12.33%, indicating a strong right-skew. Approximately 55% of the data were represented with less than 10% difference and 84% of data were predicted with 20% difference or less.

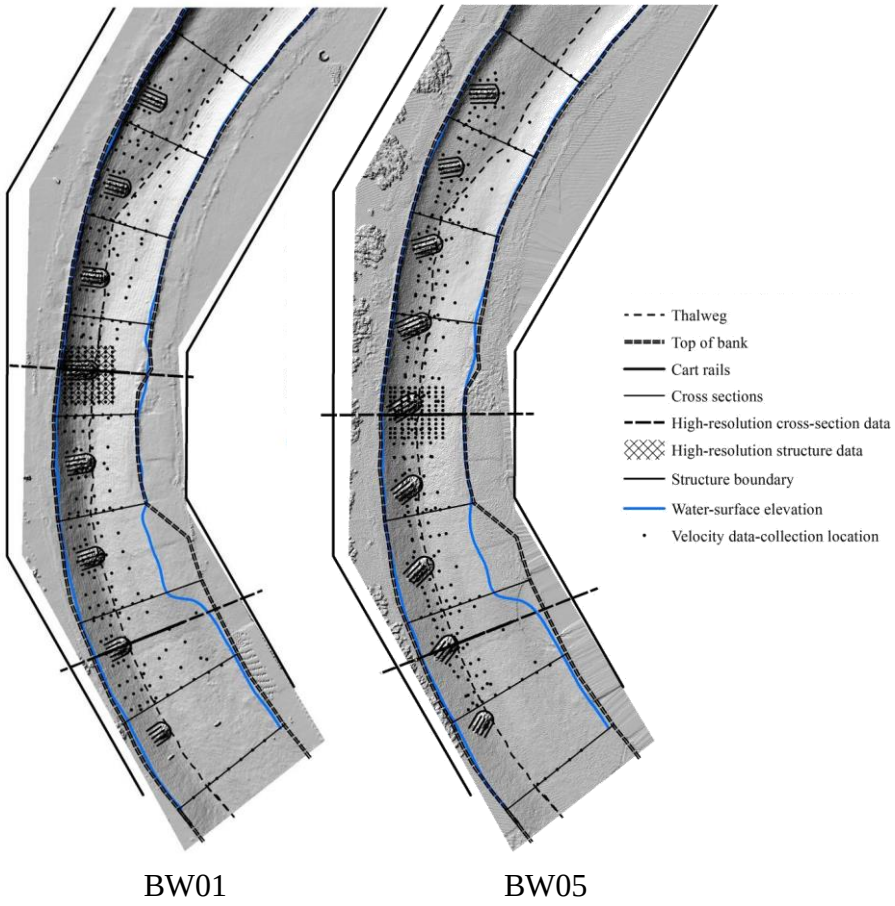

Figure 2 Bendway-weir configurations, flume schematic, and data-collection locations

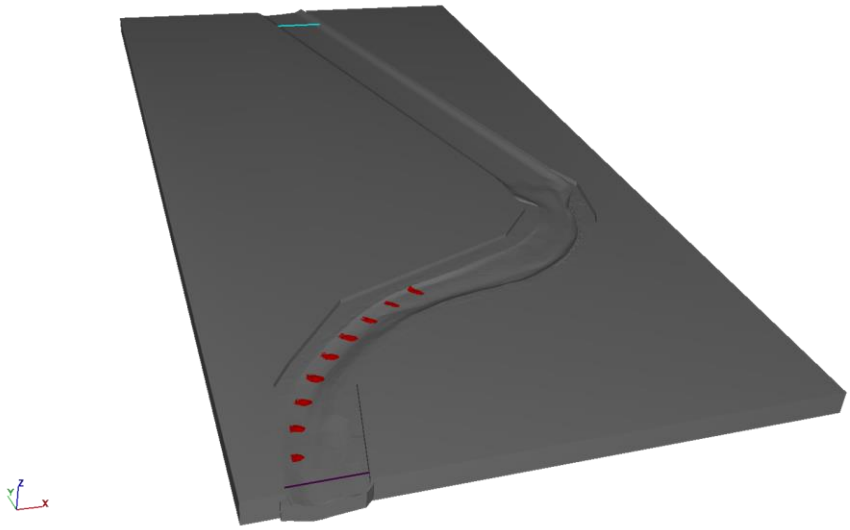

Figure 3 Geometric representation of baseline model (grey) and installed structures (red)

A calibration simulation at 11.5 ft^3/s was performed on the BW05 bendway-weir configuration from Scurlock et al. (2014b) with uniform surface roughness set at R = 0.07 ft and compared to the physical model dataset. Figure 3 illustrates the BW05 structure configuration and velocity data-collection locations. Roughness values for the structures were iterated and deviations between numerical and physical results increased with roughness greater than the bed surface. The structures were then set uniformly at 0.07 ft of surface roughness. Mean-average difference for flow depth was calculated as 0.04 ft and the *MAPD* was found to be 4.61%. Distributions of velocity in the physical and numerical model of the BW05 configuration are presented in Figure 4. The numerical model velocity distribution adheres closely to magnitudes at 60% flow depth in the physical model with shifted conveyance to the channel center, acceleration over structure crests, acceleration around structure tips, and outer-bank velocity increases captured. A notable area of accuracy of the numerical and physical model occurs at the shear layer between the reduced outer-bank velocity zone and increased channel-center velocity zone. The gradient zone was well resolved by the numerical model especially in the downstream regions of the channel. Discrepancies in the velocity distributions were mainly concentrated in the leeward areas of the bendway weirs and at the downstream extent of the model where a planimetric expansion occurred. The RNG κ-ε turbulence model used in the numerical model has limitations in application to highly turbulent flows with strong vorticity components and flow separation (Menter, 1994), such as observed in the areas of higher difference. Overall, 60% velocity magnitudes were predicted with a right-skewed difference distribution with a *MAPD* of 14.30%, median of 9.21%, and standard deviation of 16.53%. Seventy-nine percent of the data were predicted at better than 20% relative difference and 52% were predicted at 10% difference or less.

A high-density data collection cross section for BW05 transected behind the structure crest and passed through the zone of reduced outer-bank velocity. Approximately 300 ADV data collection points were spaced across this cross section. The distributions of velocity magnitudes between the physical and numerical models were similar as illustrated in Figure 5. A high velocity core was centered in the channel due to bendway-weir flow redirection, high velocity was noted above the structure crest, and low velocity zones were located behind the structure and at the inner-bank boundary. The gradient between the high velocity in the channel center and low velocity in the leeward shadow of the structure was represented well by the numerical model. The zone of high velocity in the channel center was slightly larger in size and of higher magnitude for the physical model. The majority of the channel cross-section was predicted with relatively low differences; 54% of the data were below 10% difference and 81% were below 20% difference. The calculated cross-sectional *MAPD* was 12.80%, median difference was 8.99%, and standard deviation was 13.67%

MODELVALIDATION

Numerical model validation consists of application of a calibrated numerical algorithm to an independent, yet similar simulation to which the numerical model was tailored to apply. If a numerical model performs well in describing a validation situation when no parameters are adjusted, then confidence is warranted for interpretation of further simulation extrapolations. The downstream minimum, BW01 configuration from Scurlock et al. (2014a) was used for the validation dataset for the bendway weir structure type. Figure 3 details the structure schematic and data-collection locations overlaid on a LiDAR topographic survey.

Numerical simulations for BW01 were performed at a steady 11.5 ft^3/s flow rate with calibrated parameters and boundary condition water-surface elevations observed in the physical model. Numerical data were extracted at the physical data-collection locations for comparable analysis. Flow depths for BW01 were predicted with an average difference of 0.034 ft and *MAPD* of 4.34%. Planimetric velocity magnitude distributions at 60% flow depth for the physical and numerical model are displayed in Figure 6. The distribution of velocity within the BW01 structure field was complex and varied rapidly between high and low velocity magnitudes. Velocity contours between models matched closely, with high velocities centered off the structure tips, structure-crest acceleration, outer-bank acceleration over the structure crests, and reduced velocity zones in the leeward zone of the structures. Transition gradient zones between regions of high and low velocity were similar between the two datasets and the numerical model represented the overall flow conditions of the physical model with high accuracy. The most flagrant discrepancies in the velocity magnitude distributions occurred at the leeward side of the fifth and sixth structures moving downstream in the structure configuration series. In this leeward zone, the numerical model simulated high velocities on the order of the outer-bank increased zone while the physical model contained data which indicated a region of reduced velocity. The distribution of difference percentage was strongly right-skewed with a *MAPD* of

44.62%, a median of 14.83%, and a standard deviation of 111.47%. The majority of data in the solution domain contained differences much lower than the regions near the fifth and sixth structure. Sixty-two percent of the data had relative difference of less than 20% and 35% of the data were below 10% relative difference. Median difference of 14.83% exceeded the BW05 calibration median difference of 9.21%.

An upstream high-resolution data cross-section transected the majority of the fourth structure crest in the BW01 configuration series. The cross-sectional topography and numerical and physical velocity magnitude distributions are presented in Figure 7. Velocity magnitude distributions between the two models share similar overall patterns. The largest velocities were centered over the tip of the structure crest, a low velocity region existed at the inner-bank, and acceleration over the structure crest was noted. Numerical results also produced higher velocities and less boundary interference near the channel thalweg than observed in the physical model. However, on a cross-sectional scale, results of the two models are visually equivalent. The majority of the cross section was well predicted, with a *MAPD* of 8.92%, median difference of 7.85%, and standard deviation of 6.02%. The median difference for the validation configuration was less than that of the cross-sectional calibration median difference of 8.99%.

SUMMARY AND CONCLUSIONS

Approximation of open-channel hydraulics may be achieved through the theoretical or empirical solutions. Prediction of flow conditions using theoretically grounded CFD methods has been proven to be accurate for in-stream structure hydraulics; however, widespread implementation of three-dimensional numerical modeling has yet to be fully integrated into typical engineering design. Designers typically employ empirical equations to account for scenarios in which typical one-dimensional and two-dimensional models are inaccurate. This study investigated the feasibility of using CFD to compile a large enough database for the development of an empirical model from numerical results, representing a hybrid modeling approach.

A CFD model was chosen and physical models of bendway weirs in a meandering river channel were represented numerically. Grid independence, maximum time-step independence, surface roughness, and seepage losses were calibrated using baseline flow data and one bendway-weir configuration and then validated using a separate bendway-weir configuration. Pursuant to the goals of empirical model development, the velocity magnitudes between the observed physical model data and predicted numerical results were compared. It was found that the numerical model represented observed velocity trends well and the general flow patterns were captured. Median percent differences in velocity magnitudes of comparable datasets were on the order of 10% and right-skewed, indicating a global representation of flow patterns with localized regions where results did not match.

Calibration and validation results accentuate the potential of CFD as a method of compiling a large enough dataset for empirical model development. A series of structure configurations at various geometry parameters will be created and placed within the baseline numerical model and simulations will be performed. Results of this process will provide substantial information about the effects of bendway-weir geometries on resulting flow fields and aid in the development of structure design procedures.

A CYCLIC STREAM EVOLUTION MODEL INTEGRATING HABITAT AND ECOSYSTEM BENEFITS, INCORPORATING SPACE-TIME SUBSTITUTION

Brian Cluer, Regional Geomorphologist, NOAA Fisheries, Santa Rosa, CA 95472 (brian.cluer@noaa.gov); Colin Thorne, ESA Vigil-Agrimis, Portland OR 97214 (cthorne@esassoc.com)

Abstract While channel evolution models (CEM) provide an organizational structure for considering river channels and their complex response to disturbances (for example; changes in base level, channelization, levees, or alterations to the flow and sediment regimes), physically and ecologically streams comprise more than their channel. We present a revised model, updated in light of several decades of research and practical experience, including realization that the single thread, meandering channel form may not represent the natural or pre-disturbed state, or the potential evolutionary end-state, an assumption implicit to CEMs. The new Stream Evolution Model (SEM) includes precursor and successor stages featuring floodplain interactions and multi-threaded channels, and stream evolution as a cyclical phenomenon within which natural channels evolve (Figure 1).

The SEM links habitat and ecosystem benefits to the hydrologic, hydraulic, morphological and vegetative attributes of each evolutionary Stage, highlighting the interactions between physical and biological processes (Figure 2).

Consideration of the links between stream evolution and ecological services leads to improved understanding of the ecological status of modern, managed rivers compared to their unmanaged, natural counterparts. The potential utility of the SEM, with its interpretation of habitat and ecosystem benefits, includes improved river management decision making with respect to future capital investments in river conservation, restoration, and species recovery (Figure 3).

This presentation adds original, new capabilities to the version of the Stream Evolution Model published in 2013 in the Journal *River Research and Applications*. The new version considers space-time substitution to account for the effects of upstream propagation of nickpoints and downstream delivery of excessive sediment loads, together with implications for habitats and ecosystems (and their conservation or restoration).

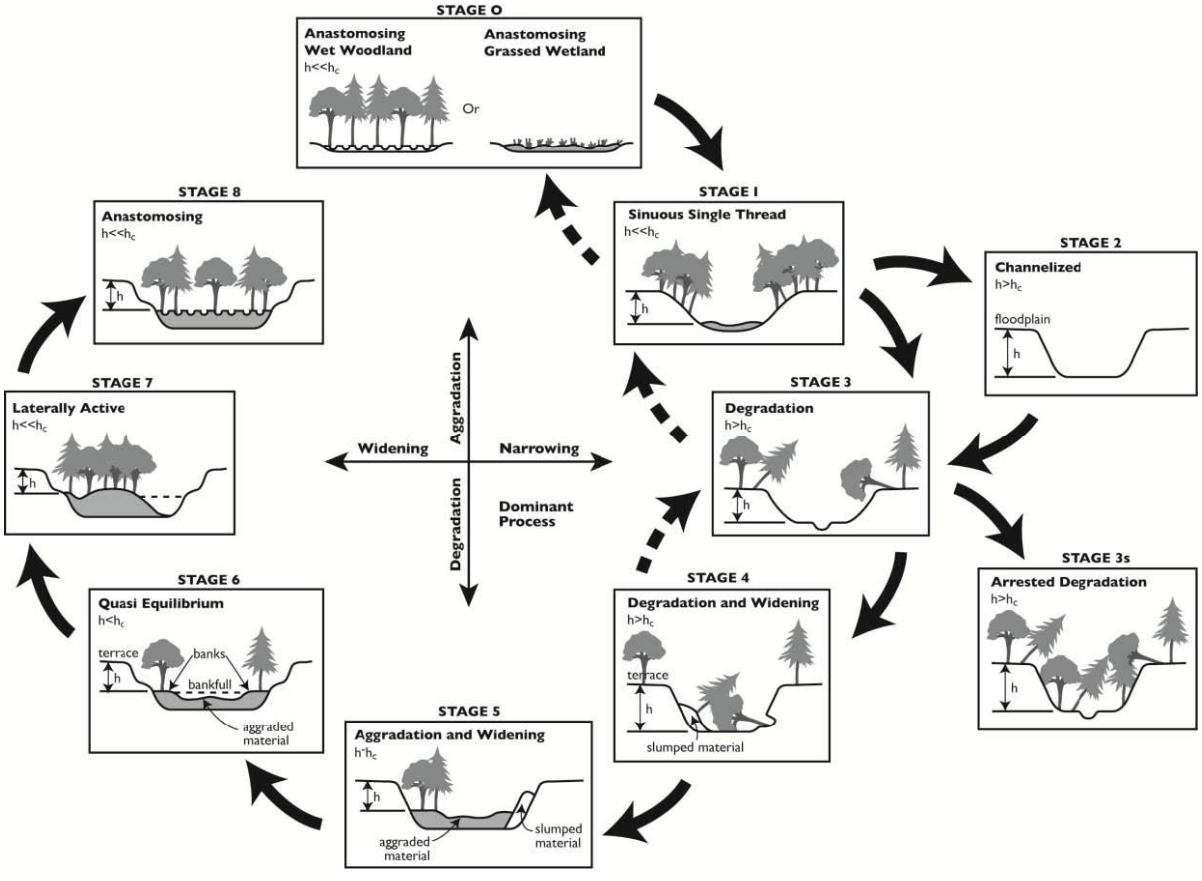

Figure 1 Stream Evolution Model based on: combining the former CEMs (Schumm et al. 1984; Simon and Hupp 1986); inserting a precursor stage (Stage 0) to better represent pre-disturbance conditions; adding two successor stages (Stages 7 and 8) to cover late-stage evolution; and, representing incised channel evolution as a cyclical rather than a linear phenomenon. Dashed arrows indicate 'short-circuits' in the normal progression indicating, for example, that a Stage 0 stream can evolve to Stage 1 but then recover to Stage 0, a Stage 4-3-4 short-circuit which occurs when multiple head cuts migrate through a reach and which may be particularly destructive. Stage 2 is a constructed stage in which the stream is channelised, while Stage 3s is outside the cycle and represents an evolutionary "dead end" where an erosion resistant layer in the local lithology stabilizes the bed and banks on an incised channel.

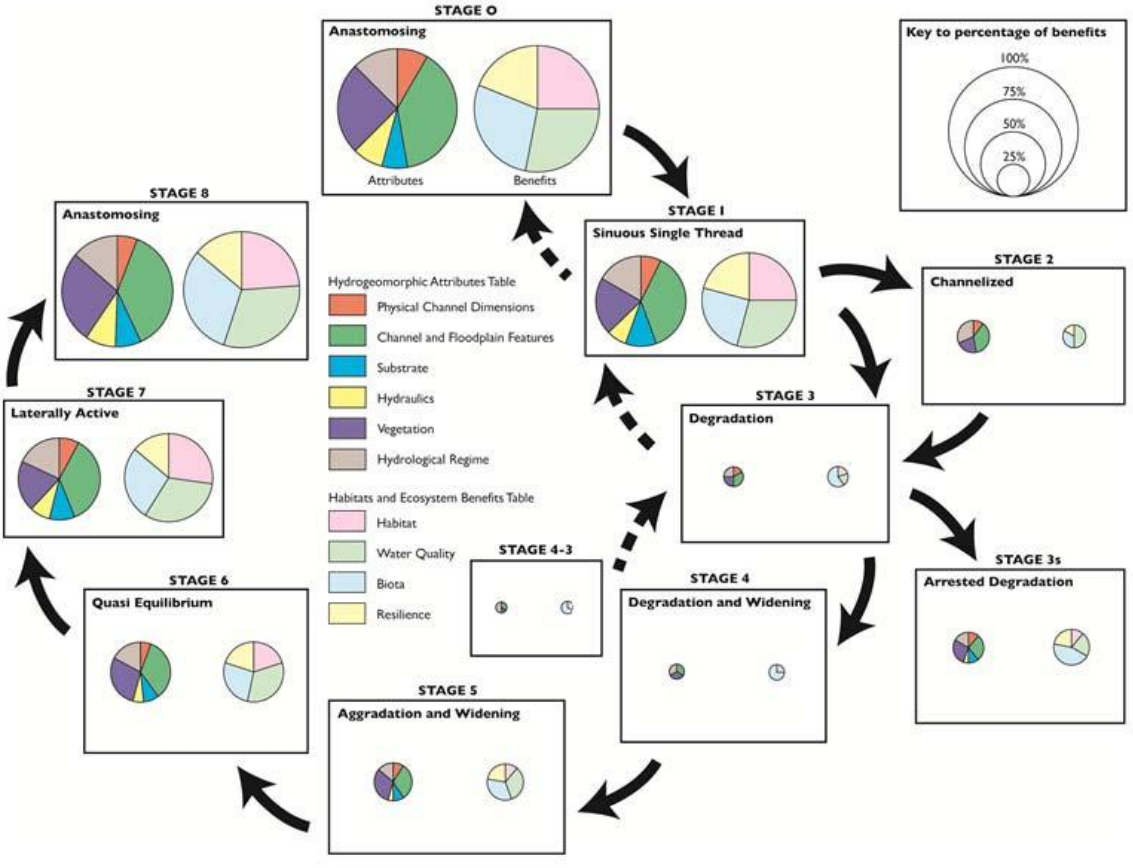

Figure 2 Habitat and ecosystem benefits associated with each SEM stage, set out using the same spatial pattern as Figure 1. Each stage is represented by two pie charts whose diameters indicate the relative percentage of maximum benefits provided by a pristine stream in Stage 0. For each stage, the pie chart on the left summarizes the richness and diversity of the hydromorphic attributes, while the pie chart on the right summarizes the associated habitat and ecosystem benefits.

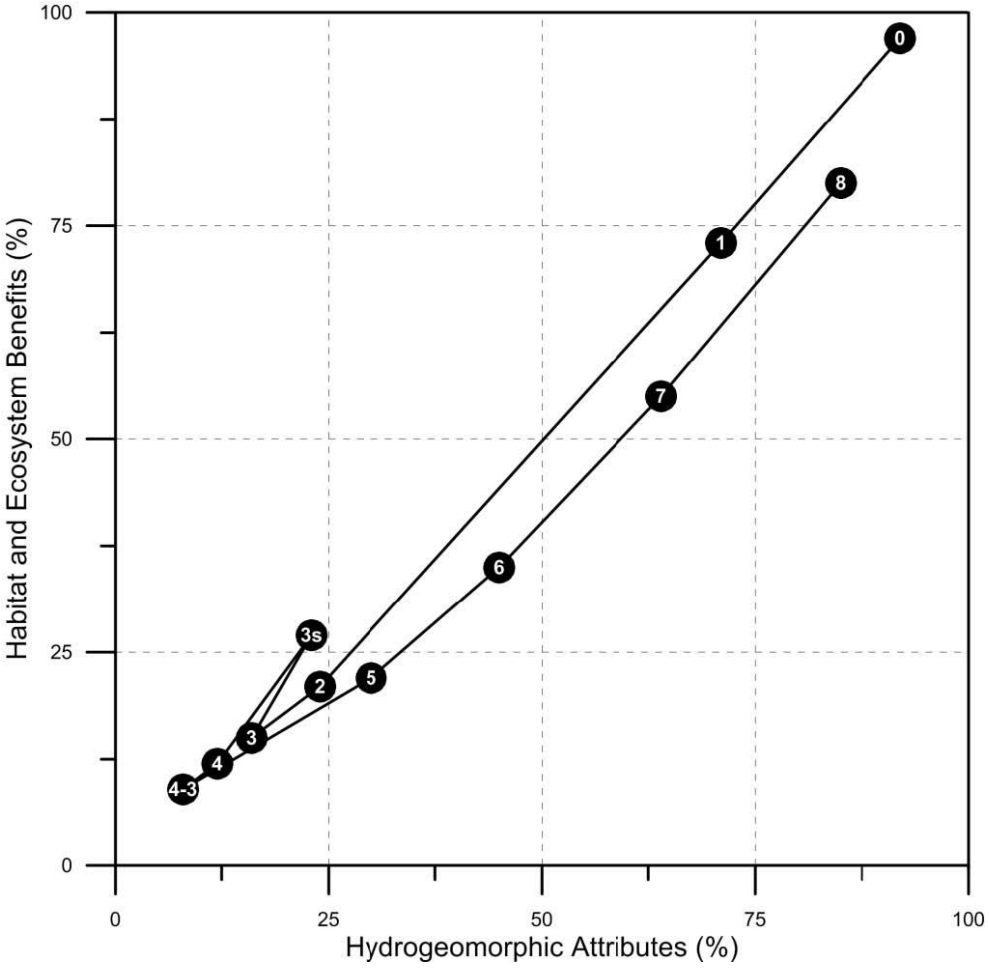

Figure 3 Relationship between hydrogeomorphic attributes and habitat and ecosystem benefits, in proportion to fully functional stream in a Stage 0 condition. There are two main clusters: streams that have greater than 50% of their pristine hydrogeomorphic attributes habitat and ecosystem benefits; and, streams with less than 30%. Stage 6 (Quasi-equilibrium) streams are intermediate. The most abrupt difference between adjacent stages is that from Stage 1 to Stage 2, where scores drop from nearly 75% in a single-thread channel to less than 25% in a channelised stream, due primarily to floodplain disconnection. The existence of a hysteresis loop reveals that habitat and ecosystem benefits recover less quickly and less completely than do the corresponding hydrogeomorphic attributes over long time scales. It is likely that the loop is broader over short times scales.

COMPOSITE MODELING OF THE HALFWAY WASH FISH BARRIER

Mike Sixta, M.S., P.E., Hydraulic Engineer, U.S. Bureau of Reclamation, Denver, CO, msixta@usbr.gov; Kendra Russell, M.S., P.E., Hydraulic Engineer, U.S. Bureau of Reclamation, Washington DC, krussell@usbr.gov; Leslie Hanna, Hydraulic Engineer, U.S. Bureau of Reclamation, Denver, CO, lhanna@usbr.gov

BACKGROUND

The lower Virgin River in Southeast Nevada is home to two native fish species currently listed as endangered. These fish populations are under threat due to the upstream invasion of non-native fish from Lake Mead. The Virgin River Fishes Recovery Plan outlines the steps necessary to recover the endangered fishes, calling for the construction of fish barriers on the river. Fish barriers play a central role in the re-establishment of native fish populations by preventing the current and future upstream migration of invasive, non-native fishes. Once a barrier is constructed, the non-native fish can be eradicated from the river upstream of the barrier and the native populations re-introduced. The barrier then prevents future invasion of non-native species, allowing the native fish populations to rebound.

INTRODUCTION

The Bureau of Reclamation was tasked with designing an effective fish barrier on the lower Virgin River in an area referred to as Halfway Wash; approximately 16 miles upstream of Lake Mead in the northwest corner of Arizona. A project location map is shown in Figure 1. This structure will be the most downstream structure on the lower Virgin River. The barrier is to be located where the river valley consists of a wide, relatively flat floor bounded by steep canyon walls. The valley floor is about 1,600 feet wide with a maximum elevation change of about 10 feet across its width. Only during very large flood events does the river occupy the entire width of the river valley.

A composite set of models, each at varying spatial scales, was utilized to propose a fish barrier design concept that would optimize its use as a deterrent to non-native fish passage while minimizing erosion immediately downstream of the structure. Composite modeling is when numerical models are used in conjunction with physical modeling to obtain more detailed information (Rahmeyer et al., 2011). Each modeling technique has its own sets of uses and limitations. Therefore, the collaborative results from the concurrent use of multiple models allowed for a more accurate and thorough analysis of the proposed barrier.

A geometrically scaled physical model along with two-dimensional (2D) numerical modeling of the local hydraulics and sediment were employed to achieve project goals. The project goals, besides limiting the passage of non-native fish species, were to assess the barrier effectiveness through evaluating local hydraulics at various discharges of interest and structure stability through determining the scour and aggradation effects of the barrier. The physical model was used to optimize the fish barrier design while verifying that design criteria were met and evaluating potential scour immediately downstream of the structure. The Sedimentation and River Hydraulics Two-Dimensional (SRH-2D) numerical model was used to evaluate the overall

effect the structure would have on the surrounding area hydraulics as well as predict the erosion patterns downstream of the structure, which was accomplished through the use of two separate modules; the first being fixed bed hydraulics and the second being mobile bed sediment transport. Together, this suite of modeling techniques allowed for the development and comprehensive evaluation of an effective fish barrier.

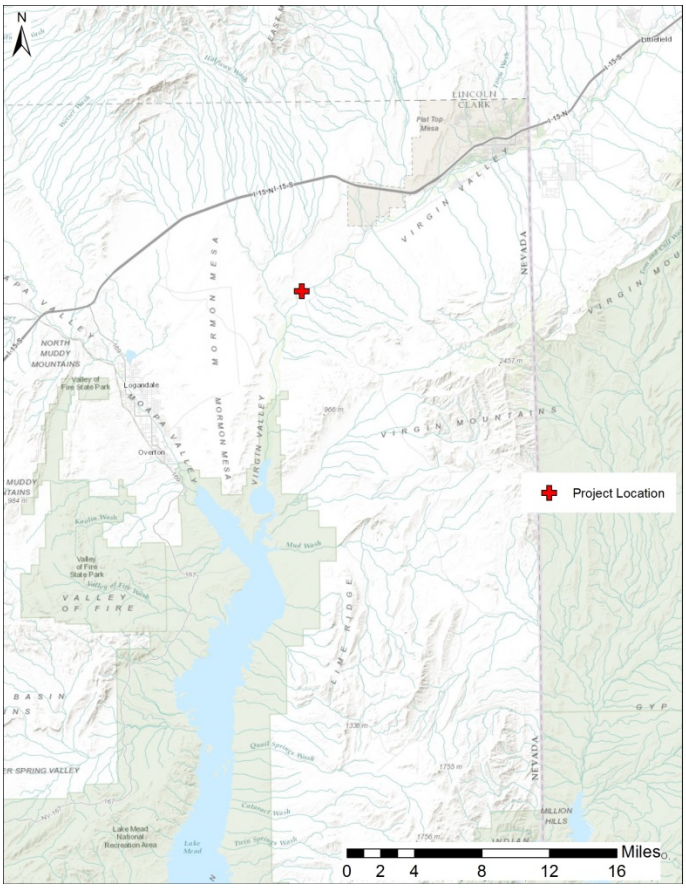

Figure 1 Project location map.

PREFERRED DESIGN ALTERNATIVE

The primary purpose of the fish barrier was to create enough of a vertical discontinuity and increases to in-stream velocities to prevent the upstream passage of invasive, non-native fishes. At low flows, the barrier will create a vertical discontinuity in the stream surface that the fish will not be able to jump over. At high flows, the barrier will be partially submerged and the vertical discontinuity will not develop, but the stream velocity will be above the highest dash speed of the fish. At intermediate flows, the barrier will produce a combination of vertical discontinuity and high stream velocities that will prevent fish passage. The Bureau of Land Management (BLM) provided Reclamation with design requirements that the barrier create a minimum 5 foot tall vertical discontinuity and increase the stream velocities to at least 11.5 ft/s whenever the vertical discontinuity criterion was not met.

The design flow for the structure was given as 45,000 ft^3/s. However, flows in the river are more often in the range of 100-to-5,000 ft^3/s. Therefore, the barrier had to be designed to perform well throughout this full range of flow conditions. An ogee shaped crest is generally considered the most efficient design for passing large flood events and was chosen for the design.

The next question that had to be addressed was how to maximize energy dissipation while also providing an upstream fish deterrent for this range of flow conditions. Past field observations have indicated that a roller bucket design for the barrier energy dissipater may also serve as a good deterrent to upstream fish passage; the roller bucket produces extreme turbulence in the localized area at the toe of the structure where the fish would normally stage to jump over the barrier. The turbulence within the bucket is much more disorganized than would occur in a typical hydraulic jump basin, making it more difficult for fish to stage for a jump at that location.

Utilizing the ogee crest and roller bucket concepts, a physical model study was completed by Reclamation's Hydraulic Investigations & Laboratory Services Group, evaluating several design iterations in ultimately determining the preferred barrier design that was deemed the most effective for meeting all design criteria (Hanna and Lentz, 2012). The outline of the preferred design alternative is shown in Figure 2.

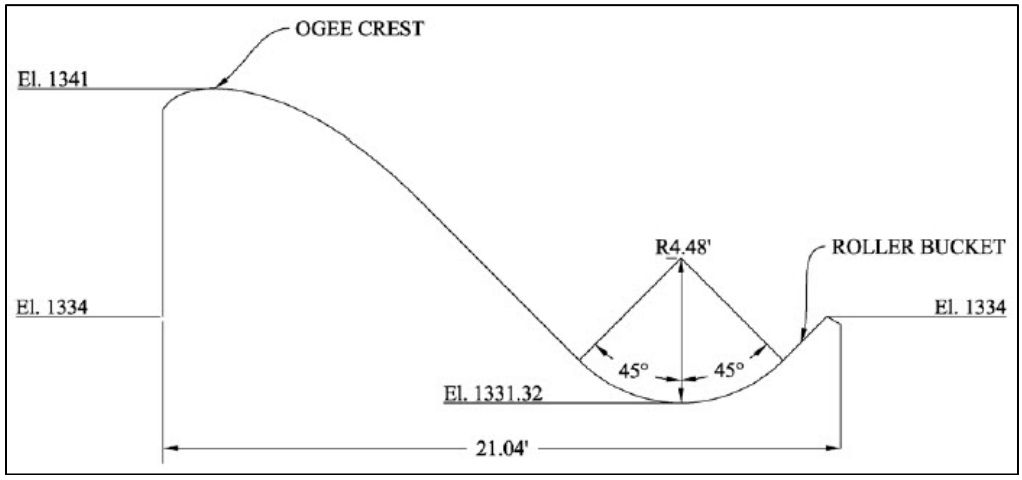

Figure 2 Preferred design alternative of the Virgin River fish barrier (prototype dimensions and elevations).

MODELING METHODOLOGY

All models require simplifying assumptions and thus have limitations. The choice of model is often governed by time and budget constraints, access to and knowledge of existing models, and the ability to develop the model (data availability). It is important to understand the formulation of the selected model, recognize the model limitations, and apply the model in a manner that takes advantage of its strengths. Model predictions will always include some uncertainty because the physical processes being modeled are not completely represented.

A composite suite of models was utilized to evaluate both the stability and predicted effects the proposed fish barrier will have on the river system. A physical model was used to optimize the

fish barrier design while verifying that design criteria were met and evaluating potential scour immediately downstream of the structure (Hanna and Lentz, 2012). A two-Dimensional (2D) numerical hydraulics and sediment transport model was used to evaluate the overall effect the structure would have on the surrounding area hydraulics as well as predict the erosion patterns surrounding the structure and scour downstream of the structure (Russell and Sixta, 2012).

Physical Model: Due to such a large width of the river channel and the wide range of flow conditions to be tested, a 1:5 geometric scale sectional physical model was used to represent the structure (Hanna and Lentz, 2012). The width of the barrier inside a 4-foot wide testing flume represented a 19.75 foot slice of the prototype barrier. Froude similitude was used to establish a kinematic relationship between the model and the prototype. Sand was placed downstream of the barrier to evaluate local scour depths and erosion patterns. This was a qualitative evaluation relative to each subsequent design given that the river channel is made up of silts and sand and not possible to be accurately represented geometrically in the model using Froude similitude. The layout of the physical model is shown in Figure 3.

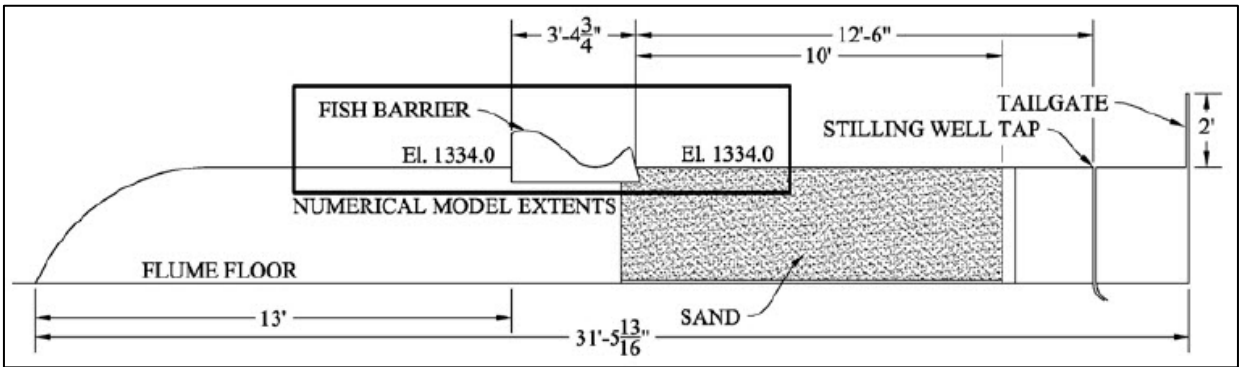

Figure 3 Physical model layout (dimensions in model scale, elevations in prototype scale).

Tailwater depths in the model were set to match depths determined from a one-dimensional HEC-RAS model of the Virgin River. Upstream depths were measured 4 model-feet upstream from the barrier crest. Downstream depths were measured 12.5 model-feet downstream from the roller bucket. Other water surface measurements and velocities were taken along the length of the structure to determine if design criteria were properly met. Model flow rates were measured using calibrated venturi meters.

Two-Dimensional (2D) Numerical Model: SRH-2D is a two-dimensional (2D) hydraulics and sediment transport (mobile-bed) model for river systems developed by Reclamation at the Technical Service Center (Lai, 2008). SRH-2D solves the depth-averaged dynamic wave equations with a depth-averaged parabolic turbulence model using a finite-volume numerical scheme. The model adopts a zonal approach for coupled modeling of channels and floodplains; a river system is broken down into modeling zones (delineated based on natural features such as topography, vegetation, and bed roughness), each with unique parameters such as flow resistance. One of the major features of SRH-2D is the adoption of an unstructured hybrid mixed element mesh, which is based on the arbitrarily shaped element method of Lai (2000) for geometric representation. This meshing strategy is flexible enough to facilitate the implementation of the zonal modeling concept, allowing for greater modeling detail in areas of

interest that ultimately leads to increased modeling efficiency through a compromise between solution accuracy and computing demand.

The SRH-2D modeling was broken up into two distinct efforts (Russell and Sixta, 2012). Fixed bed, hydraulic conditions were first modeled; to determine an appropriate model extent (primarily width), to perform a flow roughness calibration, and to obtain hydraulic model results to address some of the study questions. Modeling of the mobile channel dynamics and sediment transport commenced after a satisfactory hydraulics model was constructed and calibrated.

Due to the increased computational demand for the mobile-bed modeling, separate meshes/model domains were generated using Surface-water Modeling System (SMS) software for the hydraulics and sediment transport modeling. The model domain spanned laterally valley wall-to-valley wall and longitudinally 0.9 river miles upstream and 2.0 (hydraulics) and 0.9 (mobile-bed) river miles downstream of the fish barrier. A total of 56,500 and 21,000 mixed quadrilateral/triangular elements were used to represent the model domain for the hydraulics and sediment transport modeling, respectively. In each mesh, the resolution was denser (~5X; longitudinal spacing) at the fish barrier in order to better capture its geometry as it was a feature of focus.

A combination of several data sets was used to construct the topography of the study area. Ground survey data were collected upstream and downstream of the proposed fish barrier before December, 2010 (exact date is unknown) and on June 20, 2011 and July 5, 2011. These data were mainly used to represent the wetted portion of the channel (bathymetry). To supplement the survey data in the floodplain areas, a Digital Terrain Model (DTM) containing elevations of natural terrain features was obtained. The data making up the DTM was collected using airborne Interferometric Synthetic Aperture Radar (IfSAR) technology. The IfSAR data had a 5-meter posting with a published vertical accuracy of +/- 1 meter. The ground survey and IfSAR data were combined to create a representative topographic surface in ArcGIS using a Triangulated Irregular Network (TIN) methodology that each mesh was solved against.

Four distinct roughness zones were used in the model domain; 1) main channel, 2) vegetated floodplain, 3) cleared floodplain, and 4) fish barrier. Delineation of these zones utilized aerial photography in combination with information from the ground survey data. The corresponding material type roughness values used in the modeling were set through an iterative model calibration process. The resultant roughness values were 0.020 for the main channel, 0.045 for vegetated floodplain, 0.025 for cleared floodplain, and 0.013 for the fish barrier. The same roughness coefficients were used for both the hydraulics and sediment transport modeling and all were held constant for the entire range of discharges modeled.

Bed sediment gradations and sediment supply are needed for sediment transport modeling. For this study, uniform surface and subsurface gradations were applied to the entire model domain. Ten (10) geologic test pits and three (3) drill holes were excavated near the proposed fish barrier site. Sediment data was measured at each location for multiple depths. Based on that information, a change in bed material was detected at 5 feet of depth. Therefore, sediment gradations were averaged for the top surface layer (less than 5 feet) and subsurface layer (greater than 5 feet). A uniform two layer gradation with 5 sediment size classes was used over the entire

model domain due to the small number of samples surveyed. Vertical erosion limits were not set for the subsurface layer. Sediment supply was determined using the Engelund and Hansen (1972) sediment transport formula to calculate capacity, which is the amount of sediment that can be transported while maintaining a stable bed locally.

Seven (7) steady state discharges were simulated in the 2D hydraulics and sediment transport models: 200 ft^3/sec, 600 ft^3/sec, 1,000 ft^3/sec, 5,000 ft^3/sec, 10,000 ft^3/sec, 30,000 ft^3/sec, and 45,000 ft^3/sec. These discharges range from a regularly occurring high flow to a conservative design flow. In addition, three (3) unsteady hydrographs were simulated for the sediment transport modeling. All three hydrographs represented flood flows happening on a less than annual basis. The hydrographs represented the 1995 flood, a high flow flood, and a scaled synthetic design flow flood to peak at 45,000 ft^3/sec. The hydrographs have duration of less than 12 days. For the unsteady flow simulations, the annual peak stream flow and average daily stream flow at the nearest USGS gage (Virgin River at Littlefield, AZ 09415000) were used to determine the magnitude and shape of storm hydrographs for the Virgin River in the project area. The only time flow was above the largest design flow under consideration (45,000 ft^3/sec) was in 1989 when there was a dam break upstream.

MODEL RESULTS DISCUSSION

Physical Model: Three (3) designs were evaluated with the physical model before settling on one that met either the surface drop and/or velocity criteria for all flow conditions tested. For each test condition, depth measurements along the barrier were taken through the flume glass sidewall, perpendicular to the urethane surface at 0.5-to-1.0 foot incremental drops in elevation until the determined tailwater surface was reached. Measured depths were used to calculate average velocities flowing over the barrier at each location. Velocities were also measured using a Swoffer propeller meter at the model centerline when flow depth was adequate. These velocities were not averaged over the full flow depth, so in most cases the readings are higher than the average velocity calculated using the depth measured near the same location.

Surface drop criteria for the preferred alternative design was met for flows up to 1,000 ft^3/sec and velocity criteria was met for flows of 1,000 ft^3/sec and above (Table 1). This overlap in meeting both criteria brings an added level of confidence in achieving acceptable performance throughout the range of flow conditions expected at the barrier.

Table 1 Measured stream surface drop and velocity for preferred alternative design.

Prototype Discharge (ft^3/s)	Stream Surface Drop (ft)	Maximum Calculated Prototype Velocity (ft/s)	Maximum Measured Prototype Velocity (ft/s)
200	6.1	8.0	N/A
600	5.7	11.5	N/A
1,000	5.5	15.4	N/A
5,000	4.5	16.0	N/A
10,000	3.9	15.4	16.3
20,000	3.5	16.0	19.4
30,000	2.9	16.7	19.2
45,000	1.7	18.2	19.2

Although actual scour depths could not be simulated due to scaling issues, the patterns of erosion that would occur could be reasonably represented in the physical model using fine sand. Therefore, erosion measurements were conducted to get qualitative data on resulting erosion patterns relative to each test. The maximum scour depth was measured and documented along with the distance from the barrier (referenced to downstream edge of the roller bucket) where it occurred. Table 2 shows the scour depths and corresponding distance for each flow rate tested for the preferred alternative design. Results show that as flow increases, maximum scour depths increase and move further downstream. For flows up to 1,000 ft^3/sec erosion occurs close to the downstream edge of the barrier. Erosion occurs next to the structure with low discharges because velocities are low, and therefore flow at the end of the roller bucket tends to drop vertically downward over the downstream edge resulting in erosion in close proximity to the barrier, but also not very deep. At flows of 5,000 ft^3/sec and above, the flow pattern appeared to go through a transition. The patterns of erosion indicated that scour produced downstream from the barrier should not endanger that stability of the structure. However, it's important to note that the structural design for the barrier was not determined from this study.

Table 2 Scour depths and corresponding distance for preferred alternative design.

Prototype Discharge (ft^3/s)	Barrier Design #3	
	Sand Depth (ft)	Downstream Distance from Barrier (ft)
200	0.5	0.10
600	0.58	0.31
1,000	0.58	1.46
5,000	1.54	8.21
10,000	2.25	12.10
20,000	3.71	21.50
30,000	5.29	27.0
45,000	7.50	28.0

Two-Dimensional (2D) Numerical Model: As mentioned previously, the 2D numerical modeling was broken into two separate efforts; fixed-bed hydraulics modeling and mobile-bed sediment transport modeling. The main objective of the hydraulics modeling was to quantify differences among the currently existing and proposed conditions over a range of flow conditions. The predicted hydraulic parameters of interest included flow depth, water surface elevation, and velocity magnitude and direction. The spatial distributions of these parameters were examined to determine the location and magnitude of the differences between the existing and proposed conditions, which were used to forecast project impacts. This was accomplished by differencing raster grids representing the specific model hydraulic parameters in ArcGIS.

The spatial distribution of the differences in water depths near/around the fish barrier for the 45,000 ft^3/sec event is shown in Figure 4. Results show an overall increase in depth upstream of the fish barrier and decrease in depth downstream of the barrier. The relative magnitudes of depth decreases downstream of the barrier are small as compared to the depth increases upstream of the barrier; the biggest differences occur within close proximity of the barrier. The results also show the barrier to back water upstream approximately 0.4 miles.

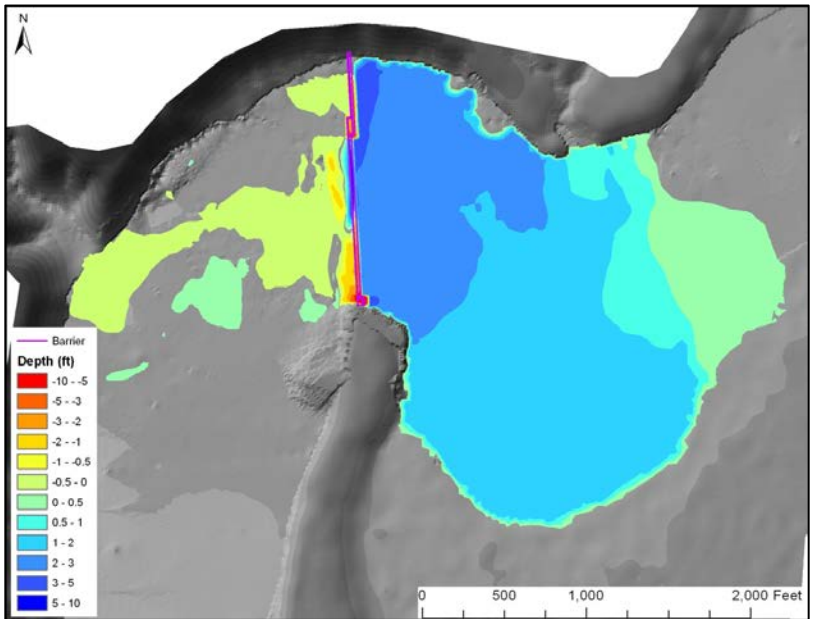

Figure 4 Depth difference (proposed – existing) for the 45,000 ft^3/sec event. (Flow is from right-to-left).

Resultant velocity magnitude and vectors for the 45,000 ft^3/sec event with the proposed barrier showed flow to be distributed along the entire barrier, but not with a consistent magnitude. Velocities were seen to be larger along the southern portion of the barrier. The average velocities for the 45,000 ft^3/sec event just upstream of the barrier ranged from 6-8 ft/sec, while the average velocities just downstream of the barrier ranged from 7-9 ft/sec on the northern half, and 12-18 ft/sec on the southern half. (These velocities can be compared against the design criteria of 11.5 ft/s. However, it's important to keep in mind that they refer to the velocities in the main channel and not on the barrier itself). Furthermore, the velocity vectors showed slower recirculation zones on the northern end of the barrier on both the upstream and downstream sides.

Sediment transport modeling was used to predict the erosion/deposition patterns near/around the structure. The first set of mobile-bed simulations used a constant, steady flow that was carried out for 10 days for both the existing and proposed barrier conditions. The net change in bed elevation, relative to the initial bed at time zero is shown in Figure 5 for the design event (45,000 ft^3/sec). Based on results from all of the steady flow runs, the following conclusions were made:

- At 200 ft^3/sec there is little change to the bed elevation for both the baseline and barrier conditions; flow must be greater than 200 ft^3/sec to move appreciable amounts of sediment within the system.

- For the baseline condition, erosion occurs along the south valley wall. There is potential for the river planform to shift toward the south and straighten under this condition.

- For the proposed condition, erosion will occur downstream of the barrier and it appears likely that the river planform will shift to the south and straighten (similar to the baseline condition). The model does not include the differences in potential erodibility of cleared versus vegetated areas on the banks and floodplain. Although all of the simulations above 10,000 ft^3/sec show this planform change, it may be a slow developing process.

- For the proposed condition, the backwater upstream of the barrier creates a net depositional area. However, there is some local scour in certain places. Most notably a bar develops on the south side of the channel which concentrates the flow in the north portion. Local scour occurs where the flow is concentrated.

- For the proposed condition, it is likely that alternating bars will form upstream until the river is out of the barrier backwater influence. This process will likely develop slowly and will depend on the amount of time and frequency that the river discharge is greater than 200 ft^3/sec.

- In the proposed condition, bank erosion may be an issue where the flow is concentrated upstream of the barrier. The sediment transport model does not include bank erosion, but it is likely that the right bank upstream of the barrier will experience some bank erosion.

- Immediately downstream of the barrier, erosion occurs. However, this erosion does not include plunging scour off of the barrier roller bucket and is potentially under predicted. Further downstream the erosion represents the reach average scour.

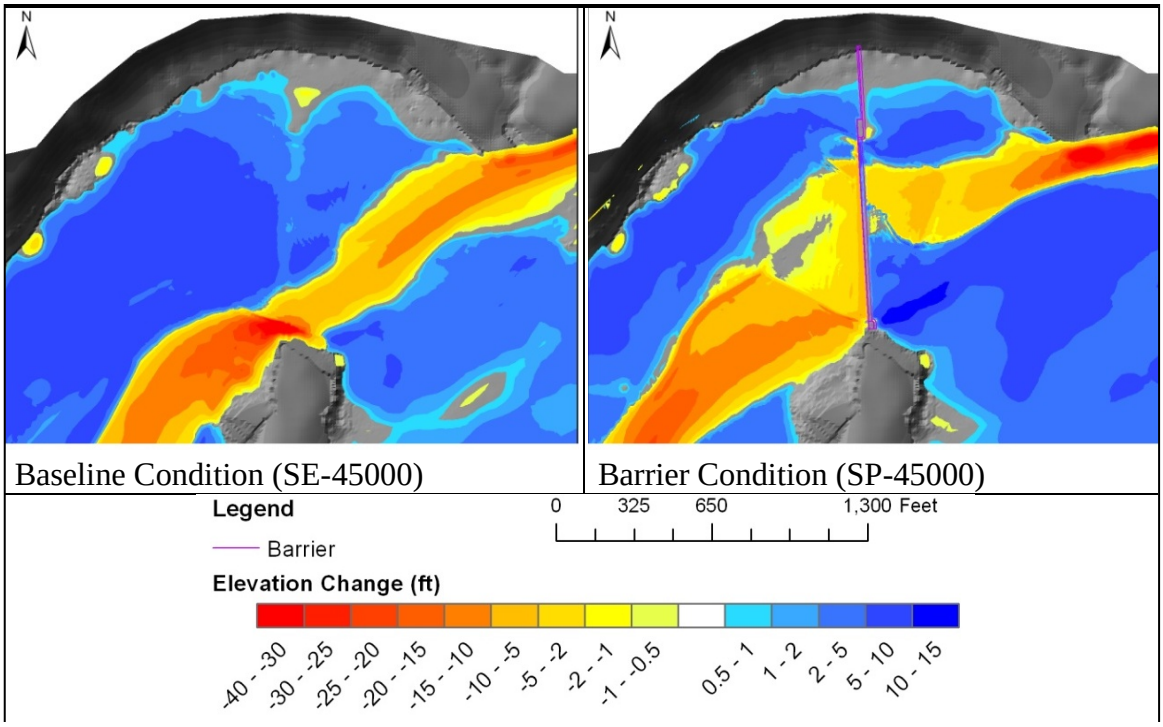

Figure 5 Change in bed elevation for existing and proposed conditions at 45,000 ft^3/sec. (Flow is from right-to-left).

Based on the flow record, high steady flows are unlikely to occur at this location. As a result, the prolonged steady flow simulations were viewed as a conservative estimate of the erosion that will occur in the study reach. Three unsteady hydrographs were simulated to provide a more realistic prediction of the erosion and deposition patterns. The evolution of the bed elevation throughout the simulations were evaluated and seen to produce similar erosion and deposition patterns although the magnitude of bed change varies. Deposition occurs upstream of the barrier in all three scenarios. For the 45,000 ft^3/sec peak hydrograph, a deeper main channel is eroded. This is similar to the steady flow results where the flow was concentrated upstream of the barrier due to bar development.

Downstream of the barrier, there is a pocket of increased erosion that occurs on the north abutment in all three hydrographs. Erosion did occur in this location during the steady flows but the magnitude was less. As expected, further erosion occurs downstream of the barrier. One of the most noticeable differences between the 45,000 ft^3/sec steady flow and the 45,000 ft^3/sec hydrograph is that during the steady flow simulation, deposition occurs downstream of the barrier on the left and right banks; a single thread main channel is clearly defined. However, for the hydrograph simulation, the majority of the downstream valley bottom is degraded. It appears that the channel has started to straighten and shift towards the south. Figure 6 shows the net eroded/deposited depth, relative to the initial bed at time zero for the last time step (t = 11 days) of the 45,000 ft^3/sec simulation. The river channel has started moving towards the planform shown in the steady flow runs, but was unable to completely develop and shift its alignment.

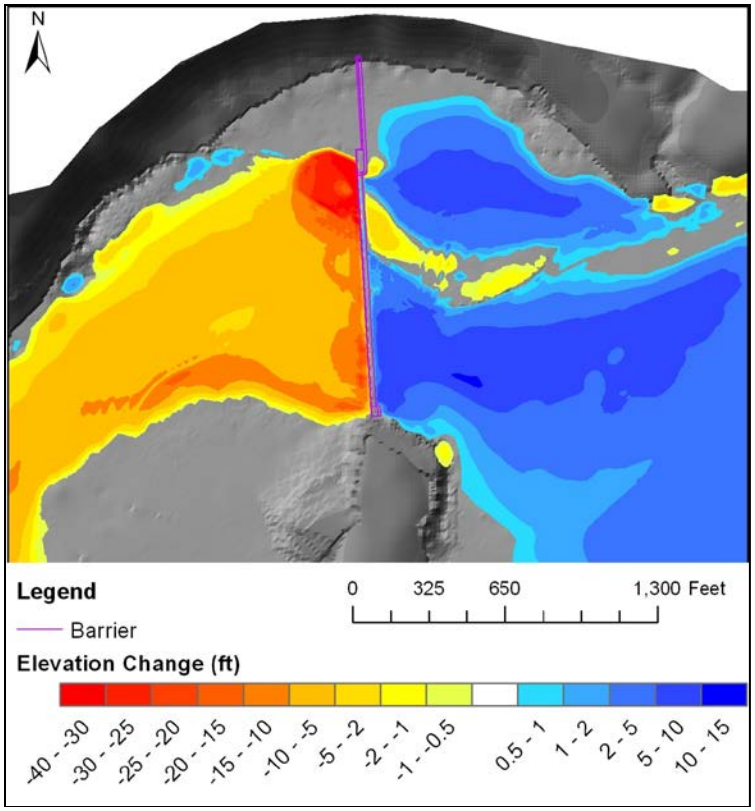

Figure 6 Change in bed elevation for the final time step (t= 11 days) for the synthetic 45,000 ft^3/sec peak hydrograph.

The 2D sediment transport numerical model cannot predict local scour due to the inability of quantifying plunging flow, but it can predict the decrease in river bed elevations due to the reduction in sediment load caused by the structure and larger discharges. Therefore, the 2D model was used to estimate the "reach average" erosion. The reach average erosion is that erosion that occurs over a large spatial scale and is relatively uniform in the streamwise direction. The reach average erosion was approximately 20.5 feet, which was considered the maximum total bed scour that the fish barrier's foundation should be designed around. However, it's also worth keeping in mind the scour findings from the physical modeling showing that as flow increases, maximum scour depths increase, but also move further downstream.

SUMMARY AND CONCLUSIONS

The Bureau of Reclamation was tasked with designing an effective fish barrier on the lower Virgin River in an area that is referred to as Halfway Wash. The barrier is designed to prevent upstream non-native fish passage by creating a vertical discontinuity in the river that fish are unable to jump over as well as increasing the stream velocities above the maximum dash speed of the fish. A composite of models, each at varying spatial scales, was utilized to propose a fish barrier design concept that would optimize its use as a deterrent to fish passage while minimizing erosion immediately downstream of the structure. Each modeling technique has its own sets of uses and limitations. Therefore, the collaborative results from the concurrent use of multiple models allowed for a more accurate and thorough analysis.

Scaled physical modeling along with 2D numerical modeling of local hydraulics and sediment were employed to achieve project goals of preventing fish passage while maintaining structural stability of the feature preventing fish passage. An ogee crest with roller bucket concept was used in the design of the fish barrier. The physical model showed a design that met both drop height and velocity design criteria with an overlap of discharges. Patterns of erosion showed that as flow increases, maximum scour depths increase and move further downstream of the barrier. The 2D hydraulics modeling showed non-uniform velocities upstream and downstream of the barrier, and that the barrier will back water upstream approximately 0.4 miles during the 45,000 ft^3/sec design flow. The 2D sediment modeling showed that flow must be greater than 200 ft^3/sec to move appreciable amounts of sediment within the system. The backwater upstream of the barrier was seen to create a net depositional area with some local scour in areas where the flow is concentrated. Erosion occurs immediately downstream of the barrier. Further downstream the erosion represents the reach average scour, which was approximated to be 20.5 feet. Together, this suite of modeling techniques allowed for the development and comprehensive evaluation of an effective fish barrier.

Abstract

The São Francisco River Basin - located in northeast Brazil - has undergone a significant amount of anthropogenic changes in the last several decades, including agricultural expansion, irrigation activities, mining, and the construction of large dams. Together, these changes have altered the historic sediment budget and have led to an aggradation of sediments in the navigation channel, impacting the ability to efficiently ship commodities to regional ports. In an effort to aid decision makers in future waterway navigation planning, a SWAT model of the 630,000 km^2 São Francisco River basin was developed and used to calculate a basin-wide sediment budget.

The SWAT model of the São Francisco River Basin was calibrated for hydrology and sediment loads. Monthly discharges were calibrated at ten Agência Nacional de Águas (ANA) gages, with NSE values ranging from 0.52 to 0.72 for a six-year simulation. An additional seven ANA gages were used to validate the model, resulting in NSE values between 0.51 and 0.88 for these additional gages. Sediment loads were calibrated to an ANA sediment gage located in the Middle São Francisco River Navigation Channel, with a PBIAS of -12.6. A sediment budget was calculated and approximately 94% of the sediment that is shoaling in the navigation channels originates from overland sources. A total of approximately 23 million tonnes of net sediment is deposited in the bed of the São Francisco River and major tributaries annually. This net deposition has contributed to an impaired navigation channel due to shoaling of sandy sediments in the navigation channel.

Combining a geomorphology study with the SWAT model, conceptual designs for navigation improvements were developed for the São Francisco River navigation channel. A HEC-RAS sediment transport model was built for the navigation channel to predict long-term navigation sustainability using spur dikes and cut-off dikes at the critical shoals. This conceptual design was shown to be a viable long-term alternative to maintaining a sustainable, economically feasible navigation channel when compared to the current practices of maintenance dredging alone.

Keywords: Sediment Budget, Waterway Navigation, Sediment Transport, Sediment Yield

INTRODUCTION

The Companhia de Desenvolvimento dos Vales do São Francisco e do Parnaíba (CODEVASF) and the US Army Corps of Engineers (USACE) engaged in an intergovernmental partnership agreement to support river engineering, navigation improvements, and bank stabilization projects along the São Francisco River in northeast Brazil. The São Francisco River is an important north-south corridor of navigation in Brazil, which links the important agricultural and mining activities that occur in the southern states of Minas Gerais and Bahia to the northeast part of the country. The São Francisco River Basin has undergone significant landuse changes over the previous few decades. Large percentages of the watershed have been converted from native vegetation to either grazing or intense row crop agriculture. In addition, hydropower dams and large-scale irrigation projects have been constructed and the expansion of row crop farming as well as dam and pumping plant construction is expected to continue in the basin. The impacts associated with these watershed changes are currently not well understood, and a numerical watershed yield model and navigation sediment transport model were developed to improve the overall understanding of the sediment dynamics (yield and transport) in the São Francisco River Basin and navigation channel.

The São Francisco River is approximately 2,900 kilometers in length with a watershed area of 630,000 km^2 (see Figure 1). It is the longest river that is entirely contained within Brazil and includes portions of the states of

Alagoas, Bahia, Goiás, Minas Gerais, Pernambuco, Sergipe, and the Federal District. The upstream boundary of the navigation channel begins at a small port city – Pirapora, Minas Gerais. The navigation channel then continues through a low sinuosity alluvial river valley for 1,015 km until it reaches the upstream end of a large reservoir, the Sobradinho reservoir. Navigation continues approximately 200 kilometers through the Sobradinho reservoir (which includes a navigation lock), and then another 42 kilometers downstream of the reservoir through a rock controlled section of river. The navigation channel terminates at the twin port cities of Juazeiro, Bahia, and Petrolina, Pernambuco. The São Francisco River continues downstream of Petrolina/Juazeiro for an additional 675 river kilometers through three large hydropower dam systems (which do not include any navigation locks) to its outlet in the Atlantic Ocean. There is no commercial navigation downstream of Petrolina/Juazeiro.

Figure 1 Location Map and Boundary of the São Francisco River Basin

Approximately 13 million people live in the São Francisco River Basin, with the highest density living in the south (headwaters), especially near the Belo Horizonte metropolitan area. The climate ranges from humid in the headwaters (south) to semi-arid in the Lower São Francisco River (north). Vegetation associated with a cerrado ecosystem is present in the headwaters with a high diversity of mixed forest, and a caatinga ecosystem (sparse and stunted vegetation) is associated with the semi-arid region of the watershed to the north. More information regarding physical characteristics of the São Francisco Basin is found in CODEVASF & ANA (2002) and Biswas et al. (1999), which presents an overview of the site location, weather, vegetation, hydrology, navigation, dams, development, geomorphology, geology, and other watershed feature information.

METHODS

Modeling Framework

A decision support system is necessary for planning the waterway development within the São Francisco River Basin. The primary navigation impedance in the São Francisco River waterway is shoaled alluvial sediment (primarily medium sand), which reduces the navigation draft and prohibits year-round commercial transport of agricultural goods and mining commodities. To address these concerns, a numerical modeling framework to support navigation planning was developed and then applied to the São Francisco River in Northeast Brazil. This modeling framework includes the development of a hydrology and sediment yield model of the São Francisco River Watershed, coupled with a sediment transport model of the navigable waterway. The results of this watershed model were used for determining sub-watersheds that are primary sources of sediment and also used as input values for the sediment transport model. The sediment transport model was developed for the Middle São Francisco River, where the current alluvial navigation channel is defined.

The modeling approach consists of nine steps (graphically presented in Figure 2). First, an understanding of the existing sediment dynamics of the basin is developed using the Soil and Water Assessment Tool (SWAT) as the sediment yield model. Next, this information is used to develop a sediment budget for the watershed, which indicates the primary sediment sources and sinks. The sediment budget allows for decision makers to prioritize sediment mitigation measures (either focusing on upland sediment management, bank stabilization, or other mitigation areas). The sediment mitigation measures then can be applied into a watershed development plan. The future conditions of the watershed plan are then modeled in a future sediment yield model (using SWAT) to understand the future sediment dynamics of the system.

In parallel to the sediment management planning and modeling, an understanding of the fluvial system is necessary for navigation planning purposes. A geomorphology study of the waterway allows for a determination of what types of measures may be suitable for improvement of the shoaling issues. The geomorphology study feeds into a conceptual design of a navigation plan that can consist of dredging, and riverine training structures, such as spur dikes, cutoff dikes, and other navigation structures. The sediment dynamics of the future watershed plan and the conceptual design of the waterway can then be modeled in a sediment transport model to predict the effectiveness of the proposed conceptual designs and to make iterative revisions in order to finalize a proposed navigation plan.

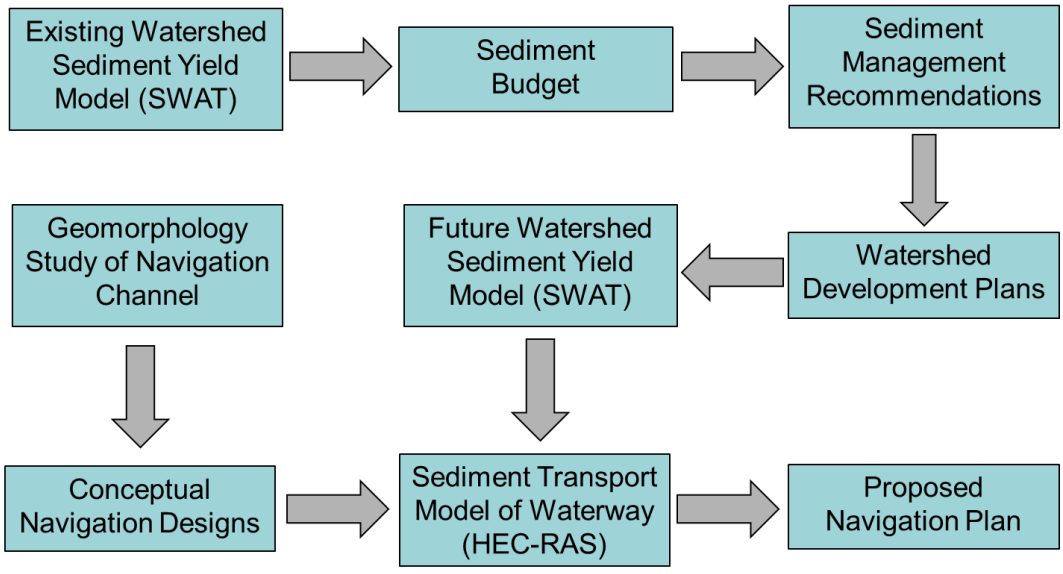

Figure 2 Waterway Modeling and Planning Framework

Hydrology and Sediment Yield Model

The Soil and Water Assessment Tool (SWAT) was the model selected to evaluate the sediment dynamics of the São Francisco River Basin. The primary data that was used to build a hydrology and sediment yield model in SWAT include the following: topography, soils, landuse, reservoirs, irrigation withdrawals, weather (precipitation, temperature, relative humidity, solar radiation, and wind), and river gages (streamflow and sediment gages). The topography, soils, and landuse layers were overlaid in ArcSWAT and were used to create Hydrologic Response Units (HRUs). Areas that have similar slopes, soil classification, and landuse were grouped into a single HRU, with each subwatershed consisting of numerous HRUs.

The topography data were obtained from the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) by NASA (NASA, 2013). This data consists of a 30m Digital Elevation Model (DEM) for the entire basin. The DEM data was divided into three slope classes 1) 0-1%; 2) 1-2%; and 3) Over 2% (see Figure 3a for derived slope classes).

Soils data were obtained from the Empresa Brasileira de Pesquisa Agropecuária (Emprapa, 1981), which had previously been converted to a digital format by the U.S. Geological Survey's EROS Data Center. There are seventy soil groups defined in the overall Brazil Soil Dataset within the São Francisco River watershed. See Figure 3b for a map of the soils in the watershed. Soil physical and chemical property data were not directly available in the Embrapa dataset; therefore, a second soil dataset was used to extract soil property information and was applied directly to the Embrapa soil boundaries. The International Soil Reference and Information Centre (ISRIC) provides a soil data set at a 5 arc-minute resolution for the world, including soil physical and chemical properties (Batjes, 2012).

The GlobCover 2005 (European Space Agency, 2006) was used to assign the landuse to the São Francisco River SWAT model. GlobCover 2005 is a global dataset with 300m x 300m resolution of landcover from the year 2005. Figure 3c includes the landuse data used in the SWAT model.

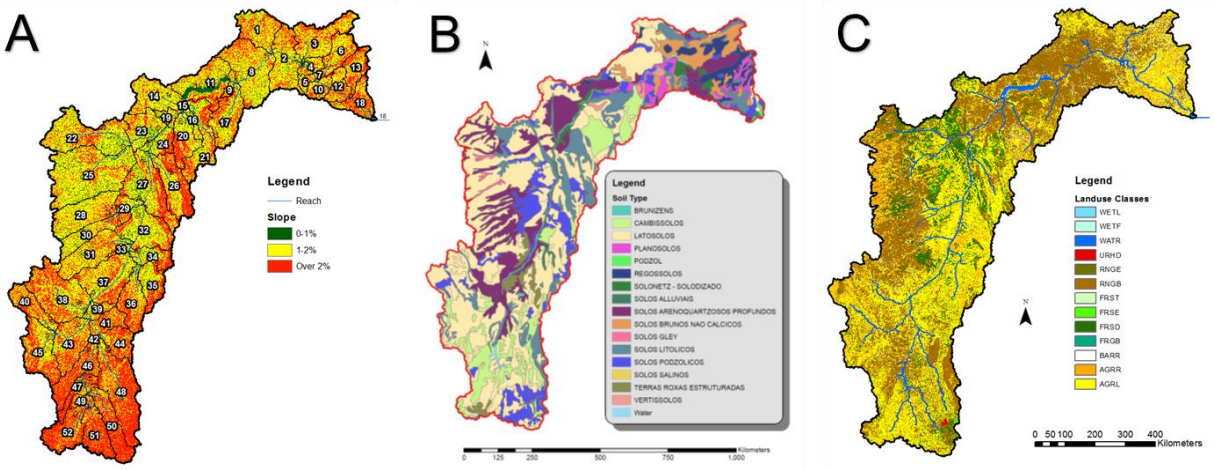

Figure 3 HRUs Built from A – Slope (ASTER, 2013); B – Soils (Embrapa, 1981); and C – Landuse (European Space Agency, 2006)

Five of the largest reservoirs in the São Francisco Basin were added to the model. These reservoirs include the Três Marias, Sobradinho, Luiz Gonzaga, Paulo Afonso and Xingó reservoirs. Irrigation practices were also added to the SWAT model. Irrigation within the basin is permitted throughout the São Francisco River watershed, with most projects owned and constructed by CODEVASF. There are a total of 26 major irrigation sources identified by CODEVASF (2013) and these were input into the SWAT model.

Weather data for the São Francisco River Basin were obtained from the Global Weather Data website http://globalweather.tamu.edu/. These data includes temperature, precipitation, wind, relative humidity, and solar radiation weather. Weather data were collected from 1995 through 2006 at 1,254 locations throughout the basin.

Although the modeling was designed to include daily output from 2001-2006, all data from 1995 through 2006 were collected in order for the model to have a sufficient "hotstart" period (from January 1, 1995 through December 31, 2000). Existing conditions, historic conditions (using pre-European settlement landuse data and the removal of anthropogenic activities such as hydropower and irrigation), as well as future conditions of the hydrology and sediment were modeled using the developed SWAT model.

The Nash Sutcliffe Efficiency (NSE), developed by Nash and Sutcliffe (1970) was the primary hydrological statistical measure to determine if calibration was achieved. The NSE is a measure of how much better a model predicts hydrologic behaviors compared to the mean of the observed data. The calibration of sediment yield for typical SWAT modeling studies is based on a Percent Bias (PBIAS) statistical technique, which was applied to this study. The São Francisco Basin SWAT model was first calibrated to the hydrology of a gage in the Middle São Francisco basin at Morpará (ANA gage 46360000). Monthly flow simulations yielded a NSE = 0.66 and daily flow simulations yielded a NSE = 0.56 for a simulation from 2001-2006 (Figure 4).

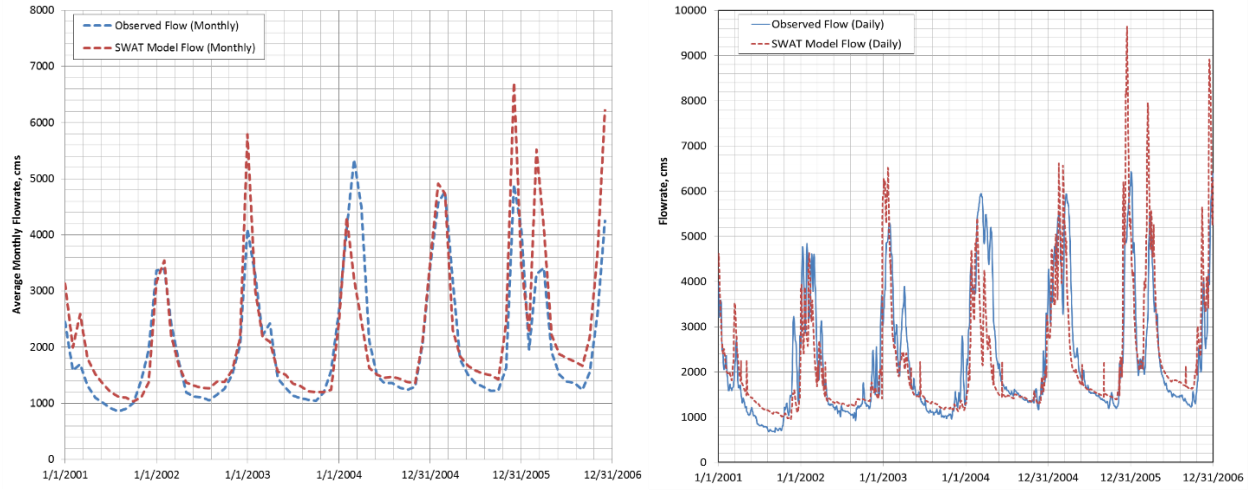

Figure 4 Monthly (left) and Daily (right) Hydrology Calibration at Morpará Gage

The hydrology was calibrated at ten locations throughout the basin and validated at seven additional gages along the São Francisco River's main channel. All calibration and validation yielded a minimum of satisfactory results based on recommended procedures from Moriasi et al (2007), and is presented in Table 1.

The Morpará Gage (ANA Gage 46360000) was selected for the initial basin-wide calibration of the SWAT model for sediment. This gage was selected for the following reasons: 1) the gage includes a long daily flow record (since 1954) and is still an active gage; 2) the gage includes both flow and sediment records; 3) the gage is in the middle São Francisco River (the focus area of navigation impacts); and 4) the gage is not heavily influenced by dams/reservoirs. Suspended sediment data are collected at the Morpará gage four times per year using a USDH-59 sampler, which collects suspended sediment loads. Previous studies have found that the bedload in this reach is approximately 25% of the suspended load (Creech, 2014). These data were compiled into a flow-sediment load rating curve and monthly sediment loads were calculated for the duration of the SWAT simulation (2001-2006). The SWAT output was compared to the observed sediment loads, and a PBIAS of -12.6 was calculated for the length of the simulation (Figure 5). According to Moriasi et al. (2007) this is considered a "Very Good" calibration of monthly sediment loads.

Calibration of the hydrology and sediment for the São Francisco River baseline conditions was achieved by adjusting 15 variables for the hydrology, and 14 additional variables for sediment loads. These variables and the final values of each are listed in Table 2 and 3. Calibration was achieved combining manual methods and utilizing the automated calibration programs SWAT-CUP. All other variables not listed in Table 2 and 3 applied default SWAT values.

Table 1 Hydrology Calibration and Validation within the São Francisco and Major Tributaries

ANA Name	Gage	SWAT Basin	Type	NSE	Description
Rio Pará	40330000	74	Calibration	0.66	Good

Geomorphology Study and Sediment Transport Model

The São Francisco River has a very mild slope (ranging from approximately 0.00006 m/m at the downstream reaches to 0.00013 m/m at the upstream reaches). The width of the river ranges from approximately 200 meters in the upper reaches of the navigation channel to approximately 1 km in the lower reaches (upstream of the Sobradinho Reservoir). Widths can be much larger and in some locations the bank to bank width is over 2 km where islands are present. Depths are on average 2-3 meters deep; however, the navigation channel ranges from 0.3 meters to over 18 meters according to a survey of the navigation channel conducted in 2012 by the Administração da Hidrovia do Rio

Sao Francisco (AHSFRA, 2012). AHSFRA is responsible for the operation and maintenance of the navigable portion of the waterway.

Upon evaluation of the current morphological conditions of the navigation channel a pattern of the plan-form was observed. The São Francisco River within the boundaries of the navigation channel generally consists of a narrow and deep section of the river which is horizontally controlled by a rocky bank, with extremely low bank erosion rates. Downstream of the horizontally controlled section, the river begins to widen and in many cases an island may be present in the wide portions of the river. Navigation is typically impeded most significantly either downstream or upstream of the islands in the wider portions, and where the transport capacity of the river is low. Due to the rocky knick points that control many sections of the river, the river evolutionary rates are extremely low. The slow evolutionary patterns are evidenced by comparing historic 19th century surveys of the river to the present day morphology. In the early 1850s, Henrique Guilherme Fernando Halfeld was commissioned by Dom Pedro II, the Emperor of Brazil, to survey the São Francisco River from Pirapora, Minas Gerais to the Atlantic Ocean (Halfeld, 1860). These detailed Halfeld maps provide significant insight into the conditions of the São Francisco River prior to major development in the basin. After reviewing these maps it was shown that there is very little difference between current widths of the river and the river widths in 1852-1854 when the originally surveys were conducted. See Figure 6 for a comparison of the river morphology near Paratinga, Bahia in 1852 and 1999, which demonstrates that the river has a similar morphology, width, and location of islands between these time periods (although there are some changes to the shape and size of some of the islands). This is a typical result when comparing the majority of the locations of the navigation channel that have not been influenced by reservoirs associated with dams.

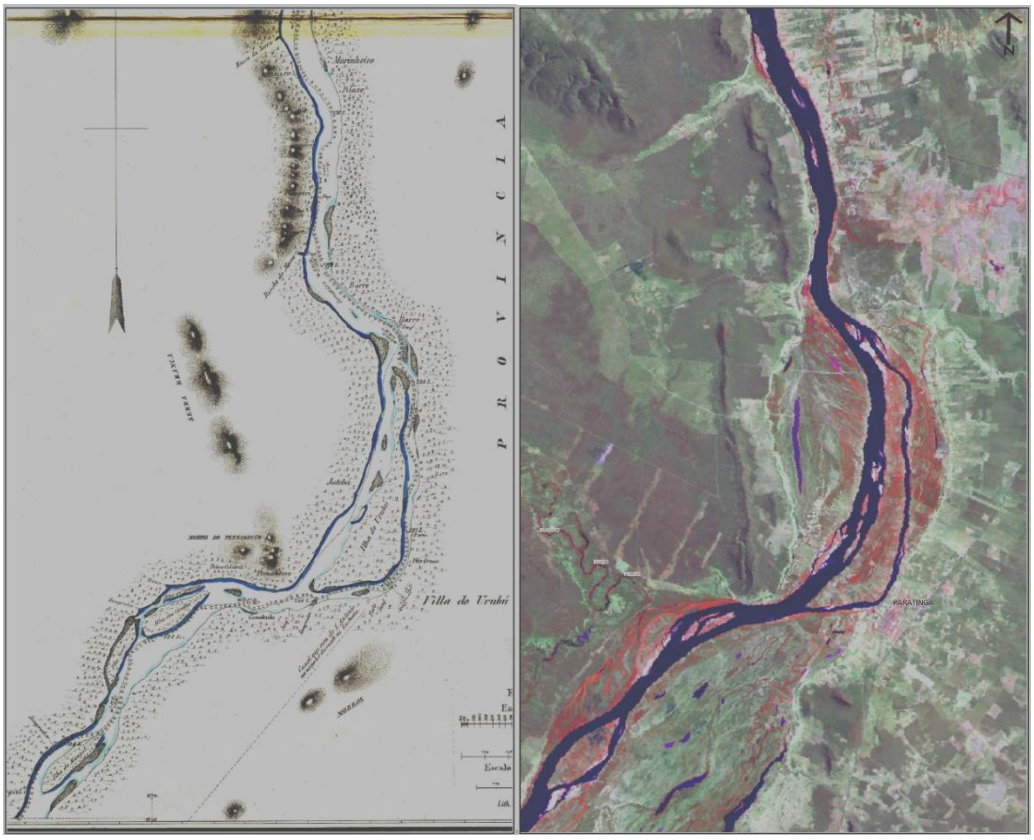

Figure 6 São Francisco River Morphology Surveyed in 1852 (left) and from aerial survey in 1999 (right) at Paratinga, Bahia, Brazil

Prior to the sediment transport modeling, an analysis of the fluvial geomorphology of the river was conducted. The Middle São Francisco River was first divided into sub-reaches based on hydrologic and geomorphic characteristics. The upper and lower limits of each reach are defined at confluences of major tributaries (i.e., where significant increases in flow and sediment exist). Major tributaries contribute a significant load of sediment and flow to the São

Francisco River, leading to potentially differing geomorphic conditions. Between the major tributaries, it was assumed that there is limited hydrologic or geomorphic changes to the slopes, width/depth ratios, sinuosity, etc. The assumption of similar geomorphic characteristics between major tributaries was qualitatively validated by investigating maps of each defined segment. The widths, depths, sinuosity and other dimensionless characteristics were verified to be similar for each defined reach. No major geologic conditions were noted to contribute to a major geomorphic changes in any of the defined reaches. Therefore, the geomorphic reaches are defined based only on the confluences of major tributaries. For each geomorphic reach a specific width of the river is necessary in order to maintain a sustainable self-scouring channel. In locations where the identified width is exceeded navigation shoals may persist. Therefore, a reduction in the effective width (using river training structures) was identified and applied for a conceptual design to be tested and modeled in the HEC-RAS sediment transport model.

RESULTS

SWAT is able to calculate the bank erosion, bed erosion, overland sediment sources, reservoir sedimentation, and net annual sediment loads to the Atlantic Ocean at the watershed scale. Together, these variables make up the São Francisco Basin's sediment budget. The sediment output was evaluated at the average annual scale to determine the sediment sources and sinks for the overall watershed. Each of the net average annual sediment source and sink data are summarized in Figure 7 based on the six-year SWAT simulation. This figure shows that a small percentage of the gross sediment erosion comes from the banks of the São Francisco River and the major tributaries (approximately 6%). The much larger contribution of the net sediment to the shoaling navigation channel is from the upland overland sources and small tributaries (approximately 94% of the net erosion). Most of the sediment that is delivered to the São Francisco River is deposited in the five major reservoirs modeled in the basin (approximately 72%). Only a small percentage is deposited in the São Francisco River floodplain (less than 1%). This may be due to the limited over-bank flooding that occurs due to regulation of the major reservoirs. Overall, the model predicts approximately 23 million tonnes of sediment per year (approximately 25% of the sinks) is deposited within the São Francisco River navigation channel and major tributaries, leading to a net aggradation in the system.

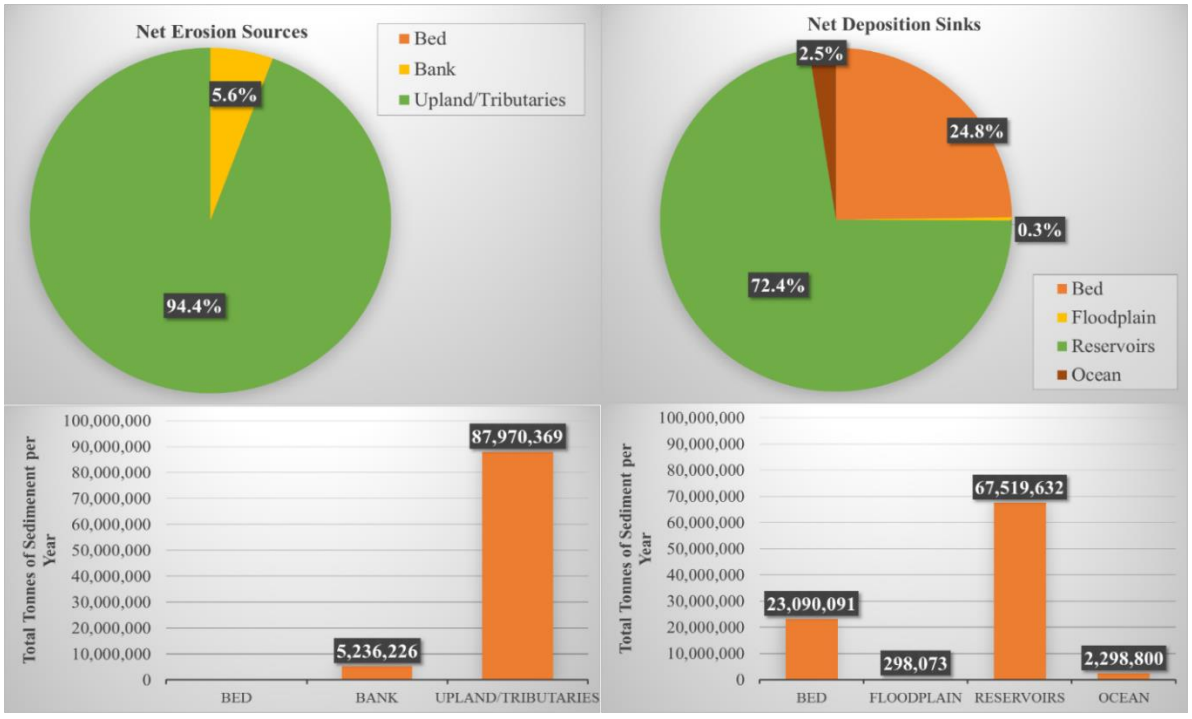

Figure 7 Sediment Budget: Net Sources (Left) and Sinks (Right) of Sediment in the São Francisco River Basin

Approximately 2.5% of the sediment sinks is associated with the delivery of sediment to the Atlantic Ocean at the São Francisco River mouth. Syvitsky and Milliman (2007) developed a predictive model for suspended sediment delivery of major rivers to the oceans using dimensional analysis of the sediment load, area, topographic relief, fluid

density, and gravity. Using this model, Syvitsky and Milliman (2007) calculated that the São Francisco River should deliver approximately 6.4 million tonnes of sediment per year to the Atlantic Ocean (compared to the 2.3 million tonnes that the SWAT model calculated). A suspended sediment gage at Propriá, Sergipe (ANA gage 49705000, located approximately 69 km upstream from the São Francisco River mouth) shows the long-term suspended sediment load (from 1977-1999) is approximately 2.7 million tonnes per year. The Propriá gage is located in the São Francisco River estuary without any major tributaries between Propriá and the São Francisco River mouth, and may be used to represent the sediment load to the Atlantic Ocean. The SWAT model annual average sediment load results are similar to the long-term sediment load at the Propriá gage. The overestimation by Syvitsky and Milliman (2007) may be due to the selected reservoir trapping factor of 0.30 (representing a 70% reservoir trapping efficiency). Due to the three major dams just upstream of the mouth, a trapping efficiency of 85% may be more appropriate, which would bring the Syvitsky and Milliman reservoir trapping factor to 0.15. This would change their prediction of sediment delivery to the Atlantic Ocean from the São Francisco River to 3.2 million tonnes per year; a value closely resembling the observed long-term average at the Propriá gage.

Based on the required reductions in width of the São Francisco River navigation channel for each geomorphic reach, conceptual river training structure designs were developed and analyzed in a sediment transport model. An example of a conceptual design is shown in Figure 8. After the structures were input into the sediment transport model, the results of a six-year simulation were analyzed. The primary analysis consisted of investigating the depths of the thalweg along the navigation channel. This provided confirmation that the proposed design (based on geomorphic characteristics of each reach) would provide a sufficient amount of self-scour along the navigation channel. In several instances the self-scouring goal of 2.0 meters at the low water datum (an economically viable navigation draft) was not achieved, and the structures were revised. After the revised structures were added to the model, the channel was able to maintain a self-scour depth of at least 2.0 meters along the channel for each geomorphic reach. The results of the final navigation depths are shown in Figure 9.

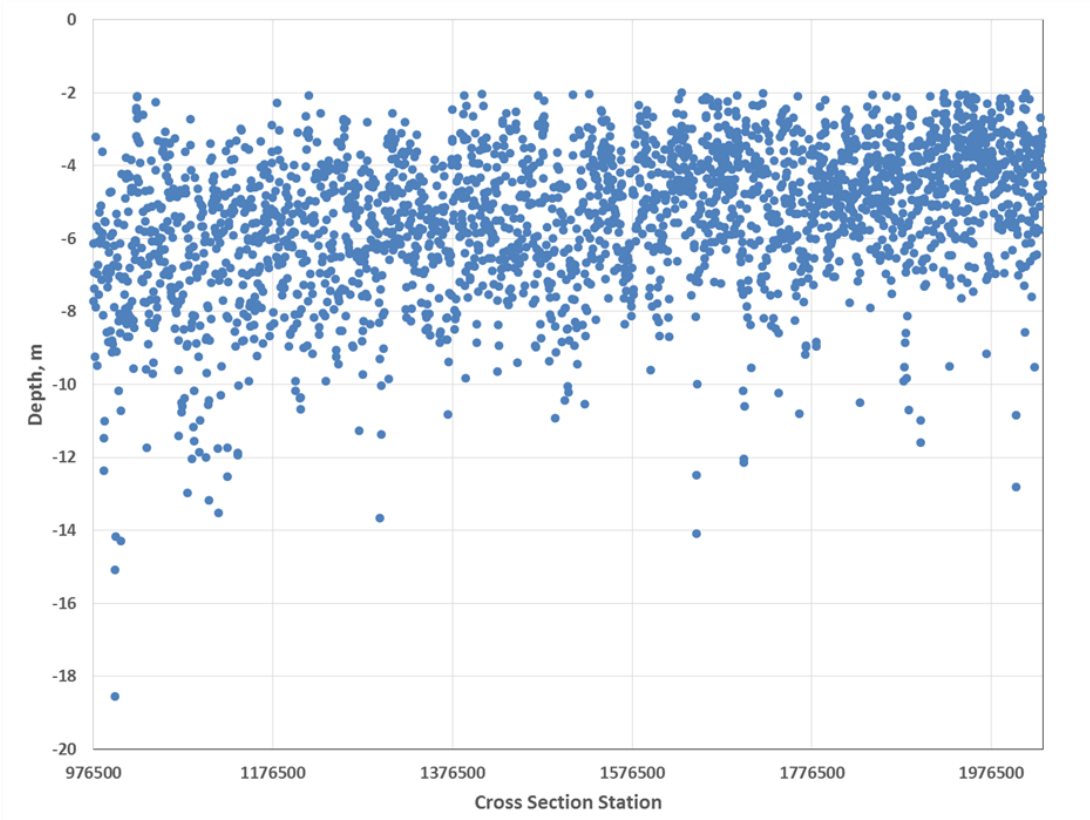

Figure 9 Predicted Navigation Channel Depths following a Six-Year Sediment Transport Simulation

CONCLUSIONS

A SWAT model of the São Francisco Basin was developed to calculate a modern sediment budget for the watershed and to analyze the changes to the sediment budget since Pre-European settlement. Based on the SWAT model results, currently only a small component of the existing sediment budget is due to bank erosion of the São Francisco River. Approximately 5.6% of the sediment that is causing shoals in the São Francisco River may have originated in the banks of the São Francisco River or the banks of the major tributaries. The remaining 94.4% of the sediments that are causing shoals originated from overland sediment sources or sediment erosion occurring in minor tributaries. Due to the high percentage of sediments that originated in the uplands and minor tributaries, bank erosion measures alone will have a negligible effect on the existing shoals in the São Francisco River navigation channel, and an improved navigation channel will only result from minimizing sediment yields at upland sources and by projects designed to improve navigation at the shoal locations.

The sediment transport model confirms the effectiveness of the conceptual layout of self-scouring structures, and the proposed alignments of structures can be used as a guide for planning long-term structural solutions for improving navigation of the Sao Francisco River. The linked sediment yield and sediment transport modeling is a system wide model, which characterizes likely future conditions throughout the entire system, and the modeling demonstrates that the layouts and approaches used will likely not create new navigation hazards. The modeling conducted in this alternative analysis should only be used as a guide for general structure layouts and planning purposes. Any specific project will need to develop a site-specific model or analysis in order to verify the effectiveness of the proposed self-scouring structures. In addition, other concerns such as bank erosion associated with the proposed designs (particularly on the opposite bank) will need to be investigated for any site-specific project that will be developed into a basic or executive design. Therefore, although the model will not support detailed analysis at the site-specific level, the modeling results can be used for general planning purposes such as calculating costs to efficiently develop the Sao Francisco River navigation channel.

Many streams and rivers throughout the U.S. have experienced degraded water quality and declines in both number and diversity of aquatic species. These changes are undesirable consequences of an intensification and expansion of human actions on the landscape combined with climatic trends occurring in the last few decades. The Minnesota River Basin (MRB) is no exception. Changes in agricultural management in the MRB, including installation of tile drainage, have reduced surface runoff and erosion from agricultural fields in recent decades. However, increased drainage has also increased streamflow and therefore amplified erosion of streambanks and bluffs. As a result, no net change in suspended sediment loading has been observed, but rather a drastic shift in sediment sources from upland agricultural fields to near-channel river banks and bluffs (Belmont et al., 2011; Schottler et al., 2014). Targeting management actions to ultimately improve ecosystem health and function requires navigating the cascade of changes from streamflow to sediment to river biology.

In the MRB, the locations and rates of erosion and deposition of major sediment sources and sinks (i.e., bluffs, streambanks/floodplains, agricultural fields, and ravines) have been well documented over millennial and decadal timescales (Belmont et al., 2011; Gran et al., 2011a, 2011b, 2013). But robust modeling of watershed sediment dynamics (i.e., generation, transport, and storage of sediment through the entire river network) requires understanding how these features are arranged within the river network, the "skeleton" of the landscape, and how process-based time delays of input, storage, and transport set the system in motion. We investigate the sediment dynamics of the Le Sueur River Basin, the major sediment-generating subbasin of the MRB, using a sediment budget to inform a modeling framework that incorporates simple reach-scale process dynamics into a river network context (Czuba and Foufoula-Georgiou, 2014, 2015). We seek to better understand how fine and coarse sediment moves through an entire river network over decadal to century time scales, given a heterogeneous distribution of sources, transport pathways set by the river network, and underlying process dynamics. We also extend this understanding to discuss implications for watershed scale sediment management and policy.

The network-based modeling framework of Czuba and Foufoula-Georgiou (2014, 2015) focuses on understanding large-scale system functioning and predicting the emergence of vulnerabilities, "hotspots" of change, and system resilience for guiding effective landscape management decisions. Landscapes are too complex to be modeled with fully distributed deterministic models that consider all the small-scale physics and interactions, due to large and unavoidable uncertainties associated with the myriad of relevant processes. Besides, changes in climate, land use, and water management impose non-stationary conditions and also nonlinearities in the system make it sensitive to small perturbations. Instead, the aim of this framework is to capture the most important interactions and amplifications by exploring the system connectivity and its transport pathways including residence times, threshold behavior, and physical transformations. The framework focuses on understanding network transport by: (1) decomposing the landscape into a connected network of elements including river channels, wetlands, agricultural fields, etc., (2) spatially and temporally distributing inputs of water and sediment, and (3) tracking these inputs through individual landscape elements through process-based time delays.

The application of this framework so far has focused on the dynamics of water and sediment on the landscape. The transport of sediment has been reduced to simple time delays as functions of upstream drainage area and channel slope by combining and reducing equations for uniform flow hydraulics, (at capacity) sediment transport, hydraulic geometry scaling, and intermittent sediment-transporting flows (see Czuba and Foufoula-Georgiou, 2014 for the derivation and limitations of mud, sand, and gravel transport time-delay equations). This framework has successfully answered questions as to likely hotspots of fluvial geomorphic change that have been validated with field observations. Specifically, the framework has been used to identify vulnerable reaches of a river network prone to high rates of channel migration by highlighting where bed-material sediment has a tendency to persist and thereby force channel migration through the bar-push mechanism, i.e, more rapid accretion of the point bar along the inner bank forcing erosion of the outer bank (Czuba and Foufoula-Georgiou, 2015).

We apply and advance this framework to capture the dynamics of sediment-size classes of mud, sand, and gravel in the Le Sueur River Basin. Sediment input to the network is informed based on the locations and erosion or deposition rates of bluffs, streambanks/floodplains, agricultural fields, and ravines as well as physically-based process dynamics of sediment generation. Sediment transport closely follows the approach developed by Czuba and Foufoula-Georgiou (2014). The advancement of the framework is in allowing for feedback between the accumulation of mass, geomorphic properties, and sediment transport (via travel time) within a reach. Thus, we now couple geomorphic properties with density-dependent transport, all within a network context. Furthermore, we explore how floodplain storage (via additional storage delays) affects the system dynamics.

As part of this ongoing research, we are exploring: (1) how the heterogeneity of landscape features affects the spatial distribution of sediment impacts, e.g., confined to select reaches near the sources, (2) timescales of movement of sediment through the system, including floodplain storage, that can better inform legacy effects and hysteresis, and (3) the implications of system dynamics for targeting management actions that will most effectively reduce the detrimental impacts of sediment.

INTRODUCTION

The Rio Grande in the Big Bend region is subject to rapid geomorphic change consisting of channel narrowing during years of low flow, and channel widening during rare, large, long duration floods. Since the 1940s, there have been large declines in mean and peak stream flow, and the channel has progressively narrowed. Large, channel widening floods are infrequent and have failed to widen the channel to widths measured prior to the onset of channel narrowing in the 1940s. Before the most recent channel-widening flood in September 2008, the Rio Grande in the Big Bend was more than 50 percent narrower than measured in the 1940s.

Channel narrowing results in increased flood frequency and flood magnitude due to the loss of channel capacity and flood conveyance (Dean and Schmidt, 2011). Channel narrowing also results in the loss of important aquatic habitats such as backwaters and side-channels, because these habitats accumulate sediment and are converted to floodplains. Environmental managers are attempting to construct an environmental flow program for the purposes of minimizing channel narrowing during low flow years such that channel capacity, flood conveyance, and important aquatic habitats are maintained. Effective mitigation of channel narrowing processes requires an in-depth understanding of the predominant sediment source areas, the quantity of sediment input from those source areas, the parts of the flow regime responsible for the greatest sediment deposition, and the effect of managed flows in ameliorating the sediment loading that occurs within the channel.

Here, we analyze data collected with acoustic instrumentation at high temporal resolution to quantify suspended-sediment transport during a variety of flood types. We also investigate the effect of long duration managed flows in promoting sediment export and minimizing channel narrowing.

STUDY AREA AND BACKGROUND

The Rio Grande in the Big Bend region of the Chihuahuan Desert extends from the confluence with the Rio Conchos 490 km downstream to Amistad Reservoir (Figure 1), and is the international boundary between the United States and Mexico. Prior to the 1940s, the hydrology

of the Rio Grande in the Big Bend region was comprised of a snowmelt flood pulse in late spring and early summer from the upper Rio Grande, followed by a much larger summer flood pulse from the Rio Conchos basin driven by rains of the North American Monsoon and dissipating tropical storms in northern Mexico (Dean and Schmidt, 2011; Dean et al., 2011, Dean and Schmidt, 2013). Dam construction and agricultural diversions on the upper Rio Grande completely eliminated the spring snowmelt pulse from the Rio Grande in the Big Bend by the 1940s (Dean and Schmidt, 2011). Dam construction and water development on the Rio Conchos also contributed to reductions in mean and peak flow on the Rio Grande in the Big Bend region, however, large floods driven by dissipating tropical storms in northern Mexico occasionally still occur on the Rio Conchos when reservoir capacity is exceeded (Dean and Schmidt, 2013).

The current flood hydrology of the Rio Grande is highly variable. The lowest flows occur during the winter and spring, and base flows are commonly less than 1.5 m^3/s. High flows usually begin in May and June and can be generated by localized, convective thunderstorms lasting a few hours or days, or can be caused by longer duration dam releases from Luis L. Leon Dam on the Rio Conchos. Flash floods associated with convective thunderstorms contribute large amounts of sediment to the Rio Grande. Dam release floods from Luis L. Leon Dam are generally of moderate magnitude (40 to 200 m^3/s) and usually last longer than 5 days. Channel reset floods have peak discharges greater than 1,000 m^3/s, and have durations of weeks to months. Floods of this magnitude were common in the early 1900s, but are now rare.

Geomorphic investigations show that the modern Rio Grande in the Big Bend region is a river in geomorphic disequilibrium (Dean and Schmidt, 2011; Dean et al., 2011, Dean and Schmidt, 2013). This disequilibrium is characterized by channel narrowing over decadal timescales, and episodic channel widening during large floods (i.e., channel reset events, >1,000 m^3/s) originating in the Rio Conchos basin. Between channel reset events, the Rio Grande rapidly narrows by oblique and vertical accretion of fine sediment on floodplains and formerly active channel bars. Between 1991 and 2008, the river narrowed between 36 and 52 percent through the accretion of sediment that exceeded three meters in thickness (Dean and Schmidt, 2011; Dean et al., 2011). The most recent channel resetting flood occurred in 2008 and the channel is in a new phase of narrowing (Dean and Schmidt, 2013). The rapid rates of channel narrowing and sediment accumulation in the Rio Grande indicate that the river presently resides in a state of sediment surplus. Although general patterns of sediment surplus have been described, sediment inputs, and sediment-transport processes associated with this surplus condition remain unquantified.

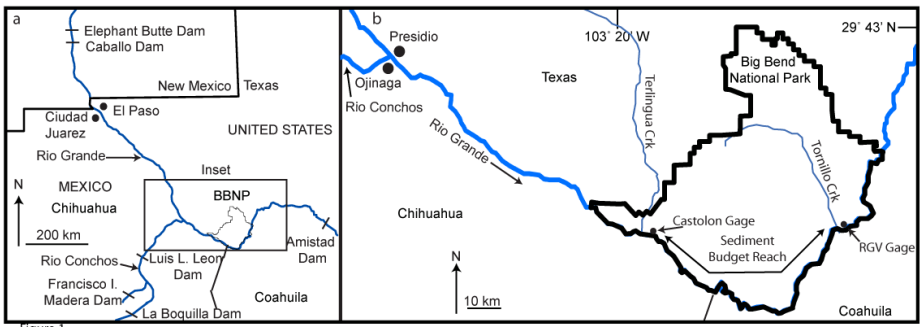

Figure 1 (a) Map of the Big Bend region. (b) Study Area

Little is known of the relative contributions of sediment from various source areas, the ranges in suspended-sediment concentrations and loads associated with different types of floods, the longitudinal trends and continuity of sediment transport along the river corridor, and whether all flood events or only a subset of floods contribute to the sediment surplus condition. We use 15-minute stream-flow and suspended-sediment transport data collected using acoustic instrumentation at discrete locations along the Rio Grande to begin to address these knowledge gaps. Using these data, we analyze suspended-sediment dynamics during two parts of the flood regime, (1) short-duration tributary-derived flash floods, and (2) longer-duration dam release floods from Luis L. Leon Dam on the Rio Conchos. We analyze the degree to which flash floods contribute to sediment accumulation within the channel, and examine the hypothesis that dam releases help to ameliorate sediment surplus conditions.

METHODS

Continuous Acoustic Suspended-Sediment Monitoring: In rivers, the concentrations of some grain-size fractions of suspended sediment are typically controlled or regulated by changes in the upstream supply of those fractions. These supply-driven changes in suspended-sediment concentration can vary somewhat independently of the water discharge (Colby, 1963; Guy, 1970; Dinehart, 1982; Topping et al., 2000a, 2000b). The development of a progressive lag between suspended-sediment concentration and the kinematic discharge wave during a flood may result in poor correlation between water discharge and suspended-sediment concentration (Heidel, 1956; Dinehart, 1982). Increased form drag caused by bedform development during floods may also result in reduced suspended-sediment concentrations for the same discharges (Kleinhans et al., 2007). In the case of the Rio Grande in the Big Bend region, the upstream supplies of water and sediment are at times completely decoupled. Water during low flows is primarily supplied from the dam-regulated Rio Conchos and shallow aquifers, whereas water during high flows may be supplied from the Rio Conchos, any number of ephemeral tributaries within the region, and occasionally from the Rio Grande upstream from the Rio Conchos. Sediment is generally supplied by the Rio Conchos, local tributaries, and during higher discharge, may also be supplied by erosion of the floodplains that have developed in the formerly braided channels of the Rio Grande. Thus, at no time can stable relations between the discharge of water and suspended-sediment concentration be assumed.

Computation of accurate sediment loads in rivers where the transport of suspended sediment is, at least partially, regulated by changes in the upstream sediment supply requires high-resolution measurements of suspended-sediment concentration that are discharge-independent. To make these discharge-independent measurements of suspended-sediment concentration and grain size at high temporal resolution, we use a multi-frequency acoustic method that was developed and tested on the Colorado River in Grand Canyon National Park (Topping et al., 2004; Topping et al., 2007). This method utilizes 15-minute measurements of acoustic attenuation and backscatter using an array of 1 and 2 MHz side-looking acoustic-Doppler profilers (Topping et al., 2015). The basics of this method are as follows: (a) acoustic attenuation is used to calculate the velocity-weighted suspended-silt-and-clay concentration in the river cross section, (b) acoustic backscatter is used to calculate the apparent suspended-sand concentration at each frequency corrected for the backscatter produced by the silt and clay, (c) the apparent suspended-sand concentrations calculated at each acoustic frequency are then used in combination with theory to

calculate an unbiased two-frequency measure of the velocity-weighted suspended-sand concentration and median grain size in the river cross section.

In November 2010, the USGS Grand Canyon Monitoring and Research Center (GCMRC), Utah State University (USU), and the National Park Service (NPS) installed two continuously operating suspended-sediment gaging stations on the Rio Grande near Castolon, Texas, and Rio Grande Village, Texas (Figure 1b). The Castolon sediment gage (Rio Grande above Castolon, Texas, 08374535) was established approximately 1.8 km upstream of the Castolon stream gage (Rio Grande near Castolon, Texas, 08374550), and the RGV sediment gage (Rio Grande above Rio Grande Village, Texas, 08375295) was established approximately 400 m upstream from RGV stream gage (Rio Grande at Rio Grande Village, Big Bend National Park, Texas, 08375300). Each sediment gage consists of a 1 MHz and 2 MHz side-looking acoustic-Doppler profiler, and an ISCO 6712 automatic pump sampler[1]. For ease of communication, the Castolon and RGV sediment and stream gages are referred to as the Castolon and RGV gages.

Acoustic attenuation and backscatter data were calibrated using physical suspended-sediment samples. At high flows, standard depth-integrated samples were collected using a US D-74 sampler (Edwards and Glysson, 1999) using the Equal-Width-Increment (EWI) method (Edwards and Glysson, 1999) at 10 equally spaced verticals across the channel using the additional transits recommended by Topping et al. (2011). At low flows, EWI measurements were made using a US DH-48 sampler and the same numbers of verticals and transits (Edwards and Glysson, 1999). During night-time hours, and when field crews were not available, suspended-sediment samples were collected automatically by the pump sampler. Samples collected by the pump sampler were calibrated to the cross section using paired EWI-pump measurements. These calibrations were developed for silt and clay and for multiple individual size classes of sand, as recommended by Edwards and Glysson (1999). The outcomes of the pump-sampler calibration are calibrated-pump measurements of the velocity weighted suspended-silt-and-clay concentration, suspended-sand concentration, and suspended-sand median grain size (albeit with larger error than the EWI measurements).

Sediment loads were calculated using the calibrated acoustic data, the EWI measurements, and the calibrated-pump measurements using the standard methods described by Porterfield (1972). Calibrated acoustic data at the two sediment gages were combined with discharges measured at the nearby Castolon and RGV stream gages to calculate instantaneous loads of suspended silt and clay and suspended sand. These instantaneous loads were then integrated over the hydrograph to calculate cumulative loads. Calibrated acoustic data include instantaneous concentrations of silt and clay, and sand, and the instantaneous median grain size of the suspended sand. All EWI and calibrated-pump and acoustic data are available on the USGS-GCMRC website, http://www.gcmrc.gov/discharge_qw_sediment/. This website also includes a sediment budget tool that calculates the change in sediment storage between the Castolon and RGV gages (i.e. the sediment budget reach) for any time period of interest. Uncertainty bands calculated using the sediment budget tool include biases in discharge calculations, uncertainty in the quantity of sand bedload (assumed to be 5% of total sand load), small biases in the

suspended-sediment measurements, and uncertainty in the contribution of suspended sediment from ungaged tributaries.

RESULTS

Here, we examine suspended-sediment transport dynamics during two parts of the Rio Grande flow regime. First, we analyze suspended-sediment transport during two periods when flash floods occurred in 2011 and 2013. The periods of flash floods are just two of many that have occurred since installation of the sediment gages, and are discussed here because they are representative of these types of events. Second, we analyze suspended-sediment transport during longer duration dam release floods that occurred in 2011, 2012, and 2013.

Sediment Dynamics During Flash Floods: Flash floods generally cause sediment deposition within the channel. Large suspended-sediment concentrations occur during flash floods, however, discharge and suspended-sediment concentration can attenuate rapidly downstream. This is clearly illustrated during the flash flood that occurred on 6/2/2011 as depicted in Figure 2a-d. This flood was sourced in the Rio Conchos basin and was nearly 200 m^3/s at the confluence of the Rio Conchos and the Rio Grande. At the Castolon gage, over 125 km downstream, discharge attenuated to 80 m^3/s, and was only approximately 20 m^3/s at the RGV gage (see Figure 1 for locations).

Sediment concentrations also significantly attenuated downstream. At the Castolon gage, the peak silt and clay concentration was 14,200 mg/L, and downstream, at the RGV gage, the peak silt and clay concentration was an order of magnitude less at 1,470 mg/L (Figure 2a). The peak sand concentration at the Castolon sediment gage was 260 mg/L, and was less than one mg/L at the RGV sediment gage (Figure 2b). The nearly complete attenuation of flow and sediment resulted in the deposition of more than 96 percent of the silt and clay load, and 100 percent of the sand load between the Castolon and RGV sediment gages during this flood.

For the same supply of sand on the bed, increases in flow will result in increases in the concentration and grain size of suspended sediment (Rubin and Topping, 2001). Thus, if increases in flow cause increases in suspended-sediment concentration and decreases in suspended-sediment grain size, changes in the sediment supply occurred (either from upstream or the floodplains). During the flash flood depicted in Figure 2a-d, silt and clay concentrations were higher on the falling limb of the flood (Figure 2a, c), resulting in a strong counterclockwise hysteresis loop for discharge and silt and clay concentration (Figure 2c). This indicates that a progressive lag developed between the kinematic discharge wave and the suspended silt and clay; the water and sediment both had the same tributary source, but the kinematic discharge wave "outran" the suspended sediment traveling at or below the velocity of the water. Sand concentrations however, was greatest during the largest discharges (Figure 2b), but the largest concentrations had the finest grain sizes (Figure 2d). Thus, silt and clay transport at both gages was primarily controlled by the upstream supply of sediment and the downstream rate of sediment transport relative to the flood wave, and not flow magnitude at the sediment gages. The negative relationship between suspended sand concentration and the grain size of suspended sand whereby the grain sizes of the suspended sand were finer for increasing concentration (Figure 2d) also indicate that sand transport at Castolon was controlled by the upstream supply.

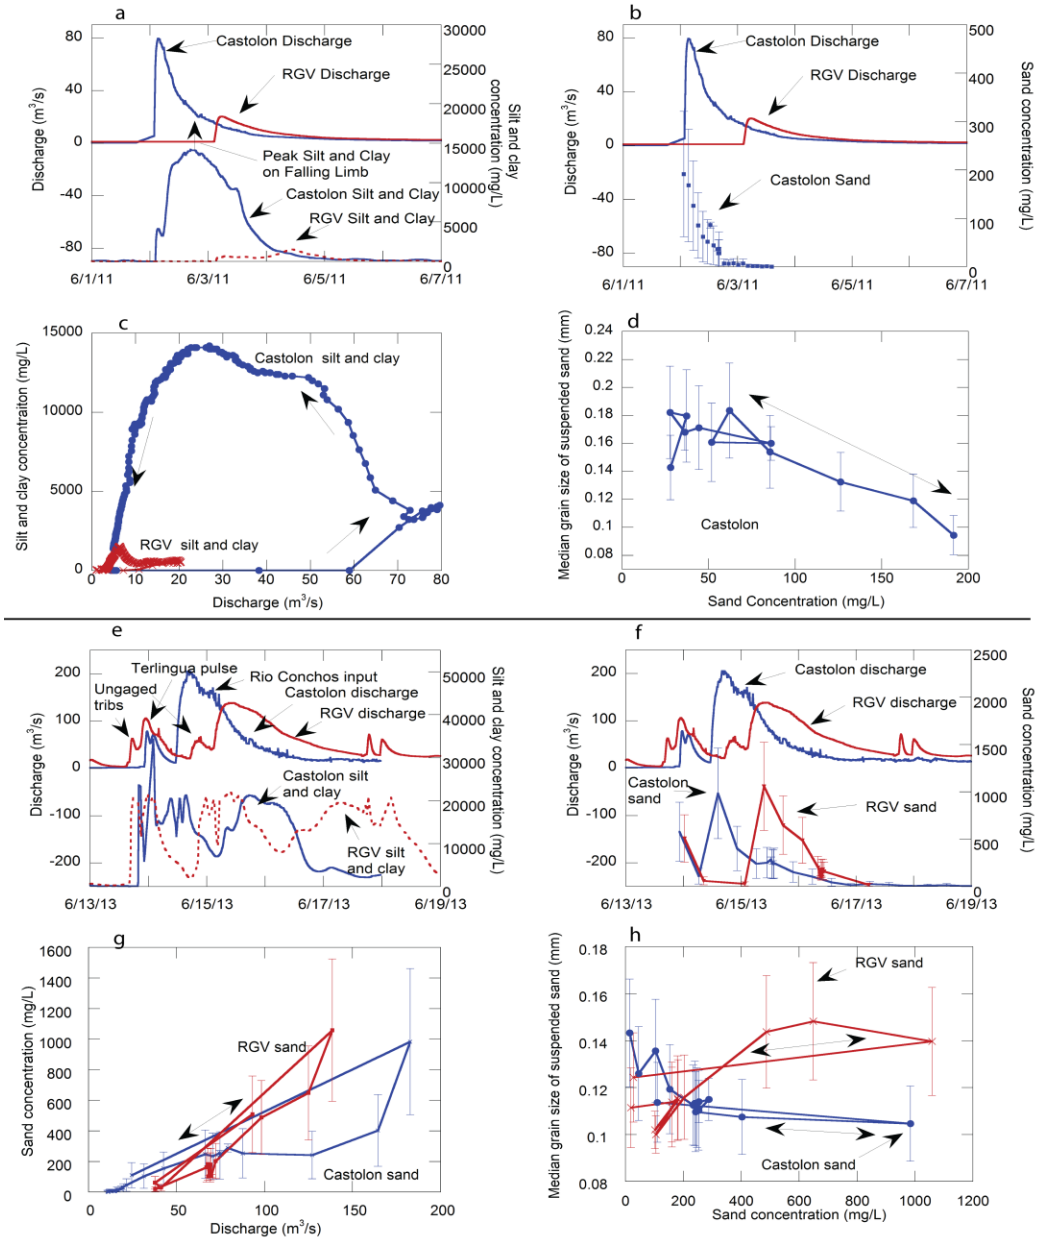

Figure 2 Suspended-sediment dynamics for flash flood between 6/2/2011 and 6/6/2011 (days 244-248)(a-d). Time series of discharge and sediment concentration are shown in (a) and (b). Counterclockwise hysteresis loop between discharge and silt and clay concentration shown in (c), and declines in sand grain size with increasing concentration show in (d). Suspended-sediment dynamics for flash flood event between 6/13/2013 and 6/19/2013 (days 986-992)(e-h). Time series of discharge and sediment concentration are shown in (e) and (f). Relations between discharge and sand concentration shown in (g), and relations between sand concentration and grain size shown in (h). Double-headed arrows show relations that are roughly linear in nature. Time-series are in days since 10/1/2010 because the start of the 2011 water year roughly corresponds to the installation date of the sediment gages. Data in b,d, and f-h show physical measurements only because some short-term biases existed in the acoustic data.

The second period of flash flooding shown here occurred between 6/13/2013 and 6/19/2013 (days 986-992, Figure 2e-h), and consisted of many flash floods from multiple source areas, including: ungaged tributaries both upstream and within the sediment budget reach, Terlingua Creek which is a large tributary approximately 9 km upstream from the Castolon gage, and a much larger pulse of water from the Rio Conchos. Peak flow magnitudes were more than twice as large as the previous flash-flood example.

Suspended-sediment dynamics were much more complex during the 2013 floods compared to in the 2011 flash flood example. The largest spikes in sediment concentration occurred at Castolon and were driven by the flash flood from Terlingua Creek. Silt and clay concentrations were over 34,000 mg/L, and sand concentrations were 877 mg/L at the Castolon sediment gage during this initial spike (Figures 2e-f).

With the exception of the initial flash from Terlingua Creek, concentrations of both silt and clay and sand during the remaining high flows were roughly equal at the two gages (Figure 2e-f). However, there was significant discharge attenuation between the Castolon and RGV gages, and thus, elevated sand concentrations occurred for a shorter period of time at the downstream RGV gage (Figure 2e-f). The attenuation of flow, and the shorter duration of elevated sediment concentrations at the downstream gage, resulted in the deposition of approximately 18,000 metric tons of sand, and over 110,000 metric tons of silt and clay.

Sand concentration at both sites increased relatively linearly with increasing discharge (Figure 2f-g). However, the suspended sand was finest at higher discharges at Castolon (Figure 2h), and the suspended sand was the coarsest at higher discharges at RGV. Thus, suspended-sand transport at Castolon was partially regulated by the upstream supply as evidenced by the fining of the suspended sand at the highest discharges, whereas sand transport was mostly regulated by flow at RGV, because larger discharges always transported more sand, and the median grain sizes of sand coarsened with increasing discharge. Higher sand concentrations, and coarser grain sizes with increasing discharge suggest that transport at RGV was primarily controlled by flow. Thus, sand transport at the two gages was controlled by different mechanisms (i.e. supply vs flow), and this is depicted in the different trends between sand concentration and the median grain size of sand in transport.

Sediment Dynamics During Dam Release Floods: Floods have been released annually from Luis L. Leon Dam since 2011. Here, we discuss some of the basic sediment-transport data from these releases. The first two dam release floods (2011 and 2012) were both of similar magnitude and duration; they were both between 50 and 70 m^3/s, and each lasted approximately 8-10 days (Figure 3a-b). The 2013 dam release flood (Figure 3c) consisted of three distinct pulses over the duration of approximately two and half months. The initial pulse was steady at approximately 180 m^3/s for approximately 15 days. The second pulse lasted approximately 10 days and peaked at 80 m^3/s, and the third pulse was steady at approximately 110 m^3/s for about 10 days. During each of the dam release floods, there were concurrent flash floods, indicated by the abrupt discharge spikes shown in Figure 3. These are not the same flash floods described in the previous section of this paper.

Trends in Suspended-Sediment Concentration and Grain Size During Dam Release Floods: Trends in sediment concentration and grain size for the three dam release floods provide insight into the relative supply of sediment near the sediment gages, and the evolution of the sediment supply over time. During the steady-state parts of each dam release, mean silt and clay concentrations were larger downstream at RGV compared to concentrations at Castolon (Figure 4a). The largest mean silt and clay concentrations occurred in 2012, and this was likely a result of the frequent 2012 flash flood activity that occurred before and during the dam release, thereby increasing the supply of silt and clay within the channel. The lowest mean silt and clay concentrations occurred during the largest and longest duration dam releases in 2013. The smaller silt and clay concentrations in 2013 indicate that the supply of readily-transportable silt and clay within the channel had been depleted over the longer duration of these dam releases.

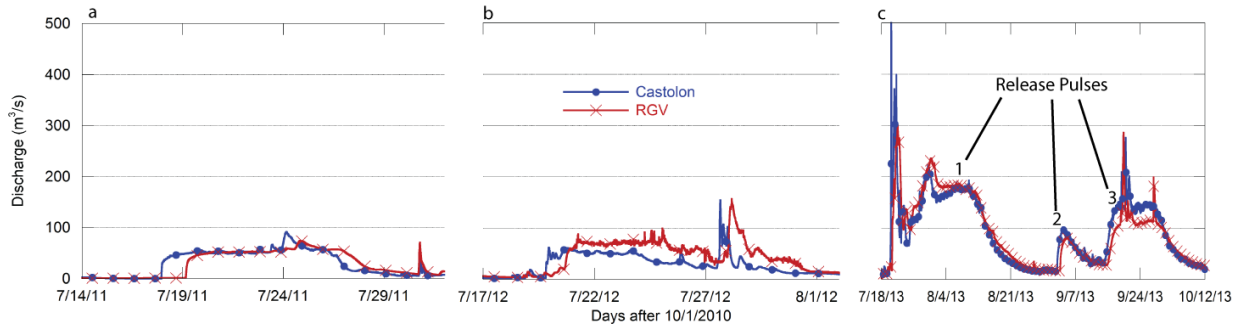

Figure 3 Luis L. Leon Dam releases in 2011 (a), 2012 (b), and 2013 (c).

The trends of sand transport during the dam releases were different than the trends in silt and clay transport. In 2011 and 2012, sand concentrations during the steady-state parts of the releases at the Castolon sediment gage were roughly twice as large as concentrations measured at the RGV sediment gage (Figure 4a). In 2011, the mean sand concentrations were approximately 60 mg/L at the Castolon gage, and 34 mg/L at the RGV gage. In 2012, mean sand concentrations were approximately 230 mg/L at the Castolon sediment gage and 125 mg/L at the RGV sediment gage.

Unlike during the 2011 and 2012 releases, mean sand concentrations during the 2013 release were higher at the RGV gage than at the Castolon gage (Figure 4a). During the steady-state part of pulse 1, mean sand concentrations at the Castolon sediment gage were approximately 550 mg/L, and mean sand concentrations were 650 mg/L at the RGV sediment gage. During pulse 2, mean sand concentrations were 160 mg/L at the Castolon sediment gage, and 175 mg/L at the RGV sediment gage (Figure 4a), and during pulse 3, mean sand concentrations were 257 mg/L at the Castolon sediment gage, and 475 at the RGV sediment gage. Although the error bars overlap in 2011, 2012, and pulses 1 and 2 of 2013, the general shift from higher upstream sand concentrations in 2011 and 2012 to higher downstream sand concentrations in 2013 is important because it provides insight into the evolution of the sand supply near each gage.

The average median grain sizes of suspended sand were generally much coarser at Castolon than at RGV (Figure 4b). Median grain sizes at the two sites were only similar during the 2012 dam release, and during pulse 3 of the 2013 dam release (Figure 4b). The finer median grain sizes at

Castolon in 2012, and during pulse 3 of 2013 may have been influenced by the flash flood activity that occurred coincidently with the releases. Thus, the channel was likely enriched with respect to the finer fractions of sand antecedent to these releases.

In 2011 and 2012, the larger concentrations of sand at Castolon indicate that there was a greater sand supply upstream of the sediment budget reach, and that sand supply was also generally coarser than the sand at the RGV gage (Figure 4). The increase in concentration over time at the RGV sediment gage indicates that the sand supply in the downstream portion of the budget reach became enriched with respect to the sand supply that existed in 2011 and 2012. The increase in downstream sand supply was likely caused by the frequent flash flood activity that occurred between the 2012 and 2013 releases, which would have loaded the channel with sediment prior to the 2013 release.

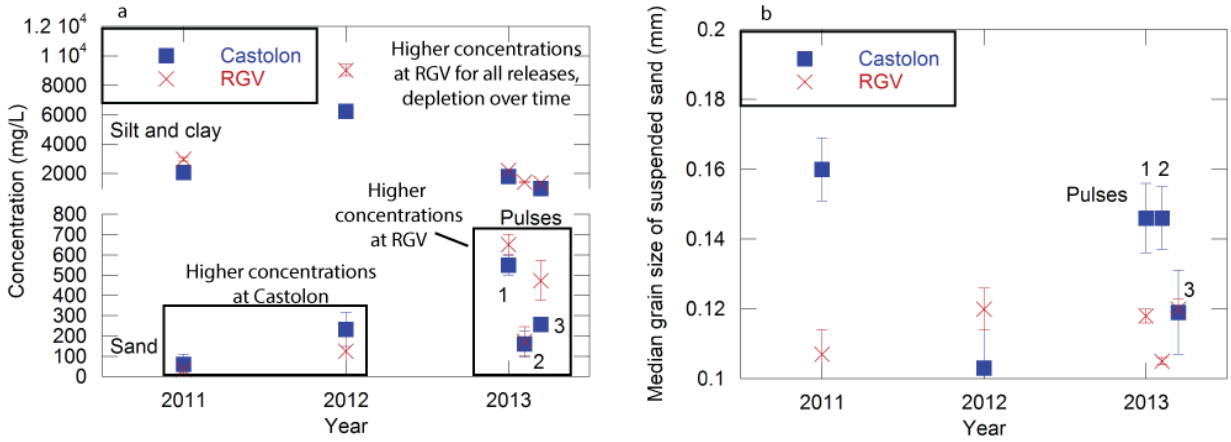

Figure 4 Mean sand concentrations (a) and median sand grain sizes (b) during the steady-state parts of the three dam release floods. Error bars represent 95 percent confidence intervals around the mean. For clarity, mean concentrations and median grain sizes were calculated without including the spikes in concentration during concurrent short-duration flash floods.

The long duration of the 2013 dam releases appears to have resulted in the partial depletion of transportable sand above the Castolon sediment gage. During the second and third pulses of the 2013 release, sand concentrations at the Castolon gage were much lower than concentrations during pulse one, which indicates that the sand supply was becoming depleted above/at the Castolon sediment gage, and erosion was occurring throughout the duration of the release. Sand concentrations during pulse 3 at RGV, however, were nearly as high as pulse 1 which indicates that erosion from upstream reaches was resulting in the enrichment of sand in the downstream parts of the budget reach.

Analyses of the Change in Sediment Storage During Managed Flows: Dam release floods have the potential to export sediment from the budget reach. The amount of export is controlled by the magnitude and duration of the releases, and the amount of sediment supplied from ephemeral tributaries. Analyses of the change in storage during the dam release floods show differing results over the three years; the central estimate of the silt and clay budget in 2011 was negative, while the central estimates of the silt and clay budgets in 2012 and 2013 were positive.

The central estimate of the change in storage for the silt and clay budget in 2011 indicates that 11,000 ± 25,000 metric tons of silt and clay were eroded from the budget reach (Figure 5a). A series of flash floods during the second half of the flood offset some of the export that occurred during the first half, and the uncertainty bands indicate that the silt and clay budget in 2011 was indeterminate (Figure 5a). During the steady-state part of the dam release flood, however, the silt and clay budget was clearly negative, which indicates that erosion was occurring throughout the duration of the release (Figure 5a). The central estimates of the change in the storage of silt and clay for the 2012 and 2013 dam release floods were both positive, yet the uncertainty bands indicate that the silt and clay budgets in these years were also indeterminate. Approximately 56,000 ± 244,000 metric tons of silt and clay accumulated during the 2012 release, and 250,000 ± 850,000 metric tons of silt and clay accumulated during the 2013 releases. Similar to the 2011 release, the estimate of the change in storage during the 'steady-state' parts of these releases do show that silt and clay was being eroded (Figures 5c, e). Flash flood activity during these floods, however, offset these negative changes in the budgets.

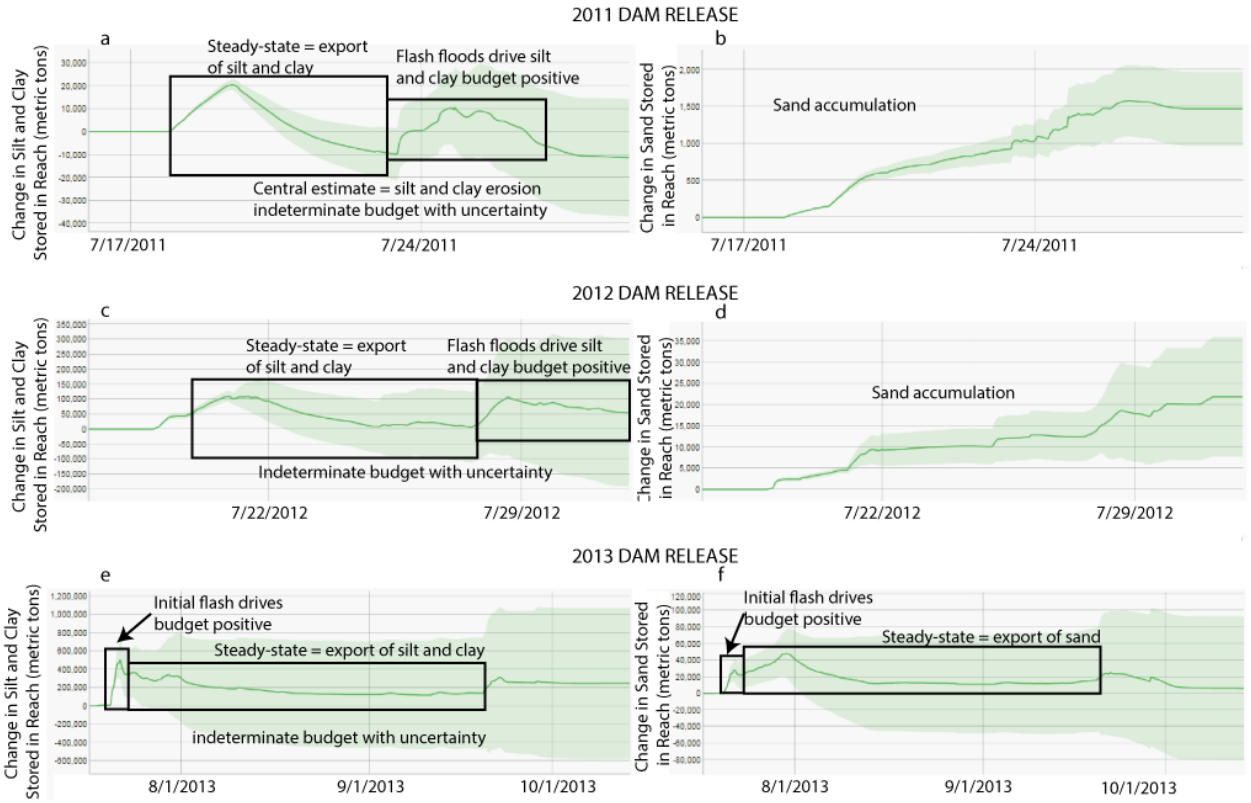

Figure 5 Changes in sediment storage for the 2011(a-b), 2012 (c-d), and 2013 (e-f) dam release floods.

Positive changes in the storage of sand occurred during the 2011 and 2012 dam release floods. In 2011, the budget reach accumulated 1,500 ± 500 metric tons of sand, and in 2012, the budget reach accumulated 21,000 ± 14,000 metric tons of sand. These changes were primarily driven by the much larger suspended-sand concentrations upstream at the Castolon sediment gage, thereby resulting in more sediment being transported into the budget reach than was exported. In 2013, the larger downstream sand supply, and the larger suspended-sand concentrations at RGV

relative to Castolon resulted in a sediment budget that was much less positive compared to 2011 and 2012 (6,400 ± 86,600 metric tons), and the 2013 sand budget was indeterminate. Although many of the sediment-budget predictions were indeterminate during the dam release floods, general trends in the central estimate of the change in storage offer important insights into the erosion and deposition patterns during these releases. Additionally, specific trends in concentration and median grain size obtained from the acoustic data help corroborate these trends.

CONCLUSIONS

The Rio Grande in the Big Bend region is in a stage of channel contraction following the 2008 channel resetting flood. Channel contraction occurs through the accumulation of sediment within the channel, and on bars and floodplains. The sediment responsible for this contraction is largely supplied by tributary-derived flash floods during the summer thunderstorm season. Continuous suspended-sediment monitoring at two sites on the Rio Grande has provided the ability to constrain the sediment contributions during tributary floods, and evaluate the impacts of long-duration dam release floods in alleviating the degree of tributary-sourced sediment loading that occurs.

Although the general sediment conditions on the Rio Grande consist of sediment surplus, periods of sand supply limitation can persist in downstream reaches after channel reset floods until the tributary sediment supply overwhelms the enlarged channel. Sand supply limitation was observed during the dam release floods in 2011 and 2012 whereby sand concentrations were much higher upstream at the Castolon sediment gage compared to the RGV gage downstream. Frequent summer storm activity, and associated flash floods, resulted in increases in the downstream sand supply by 2013. This increase in the downstream sand supply was apparent during the 2013 dam release because suspended-sand concentrations were larger in downstream reaches compared to upstream reaches for the same discharges. Continuous 15-minute sediment transport measurements provided the means for identifying these temporal changes in supply.

Analyses of suspended-sediment transport during long-duration dam releases shows that during the steady-state parts of these releases, sediment is evacuated from the sediment budget reach. This is corroborated by the decrease in sand concentration at the upstream gage for the same discharges during the 2013 dam release, the negative changes in the storage of silt and clay during the steady-state parts of the dam releases, and the decline in suspended sediment concentrations throughout the duration of the 2013 dam release. However, the amount of sediment evacuated during steady-state dam releases may be completely offset by sediment contributions from just a few flash floods. Therefore, larger or longer duration dam releases than those observed during the 2010-2013 period of this study are likely required to result in net sediment evacuation, channel enlargement, and habitat maintenance.

PRELIMINARY ANALYSIS OF SUSPENDED SEDIMENT RATING CURVES FOR THE KALAMAZOO RIVER AND ITS TRIBUTARIES FROM MARSHALL TO KALAMAZOO, MICHIGAN

David T. Soong, USGS, 405 N. Goodwin Ave., Urbana, Illinois, dsoong@usgs.gov; Christopher J. Hoard, USGS, 6520 Mercantile Way, Lansing, Michigan, cjhoard@usgs.gov; Faith A. Fitzpatrick, USGS, 8505 Research Way, Middleton, Wisconsin, fafitzpa@usgs.gov; Ronald B. Zelt, USGS, 5231 S. 19th Street, Lincoln, Nebraska, rbzelt@usgs.gov

ABSTRACT: Suspended sediment concentration (SSC) rating curves for the Kalamazoo River and its tributaries from Marshall to Kalamazoo, Michigan, U.S.A., were developed based on measured data. The slopes of the at-site SSC rating curves were of two general types: either increasing or decreasing with increasing discharges. By examining the basin characteristics and flow patterns, streams with negative SSC rating curve slopes were associated with groundwater-dominated streams and those with positive slope terms were associated with surface-water dominated streams. A panel regression with fixed-effects analysis was applied to the pooled at-site data according to various grouping criteria. The results from the subgroups which considered groundwater and surface-water dominance, seasonality, and dam effects showed better fit than the at-site SSC rating curves did. It was assumed that the rating curve slopes for sites in each subgroup were the same but their intercepts varied from site to site. The groundwater and surface-water dominance division was used as the basis for estimating SSC at ungaged sites. The study was conducted as a component of hydrodynamic modeling under the Enbridge Line 6B pipeline oil-spill recovery activities.

INTRODUCTION

Background: The July 25, 2010 oil spill that occurred near Kalamazoo, Michigan, was one of the largest oil spills into freshwater in North American history. The Enbridge Line 6B pipeline released approximately 843,000 US gallons of dilbit (http://www.epa.gov/enbridgespill/, accessed February, 2013), which is bitumen diluted with natural gas condensate, into a wetland draining to Talmadge Creek and then to the Kalamazoo River downstream from Marshall, Michigan. The spill impacted 38 miles of the waterway. Less than a month after the spill, the dilbit submerged, likely because of mixing and forming aggregates with fine-grained particles of mineral sediment and organic matter (Dollhopf et al., 2014). The large quantity of oil released required the development and implementation of new approaches for detection and recovery of submerged oil and oil-particle aggregates (OPAs) (Dollhopf et al., 2014). Fitzpatrick et al. (this volume) provided a detailed overview of the hydrodynamic modeling work that was done for the spill response. The modeling, which started in 2011 and continued into 2014, helped to answer questions about the fate and transport of the remaining submerged oil in the Kalamazoo River, and whether the oil would be transported out of the Morrow Lake delta and past Morrow Dam. To establish hydrodynamic model boundary conditions suspended sediment samples were collected from the oil-affected reach for analysis of suspended sediment concentrations and loads. This paper describes the challenges encountered in the development of rating curves for estimating the suspended sediment concentrations (SSC) for the hydrodynamic models used to predict the movement of sediment and OPA.

Study Reach: The study reach extended 38 miles from the site of the pipeline spill at Talmadge Creek downstream to the confluence with the Kalamazoo River, and downstream on the Kalamazoo River to Morrow Dam (Fig. 1). Some of the tributaries included in the study are too small to identify in figure 1 but are listed in table 1. Table 1 is a list of study reaches from the upstream to downstream direction together with their drainage areas and streamflow gage status.

Suspended Sediment Rating Curve: A water discharge (Q_w) to suspended sediment concentration (SSC) rating equation is referred to as an SSC rating curve in this paper. An SSC rating curve commonly takes the simple log-linear form as:

$$\log_{10}(SSC) = a + b \times \log_{10}(Q_w) + \varepsilon \quad (1)$$

where:

$\log_{10}(SSC)$ = the $\log_{10}$ transformed SSC, in milligrams per liter (mg/l),
$\log_{10}(Q_w)$ = the $\log_{10}$ transformed Q_w at the time of SSC measurement or estimation, in cubic feet per second (cfs),
a is the intercept and b is the slope of the linear regression, and
ε is an error term.

The SSC rating curve has been widely used for estimating SSCs in rivers at similar flow conditions (Colby, 1956; Porterfield, 1972). However, when applying the ordinary least-squares (OLS) method to estimate the regression equation parameters based on the logarithms of measured SSC and Q_w, the resulting equation may underestimate SSC at high flows (Ferguson, 1986; Singh and Durgunoglu, 1989). Some authors (for example, Asselman, 2000) have proposed using nonlinear least-squares regression to mitigate this potential underestimation. Transforming $\log_{10}$(SSC) back to SSC can introduce a bias and Helsel and Hirsch (1992) recommend addressing the bias by using the Smearing estimator.

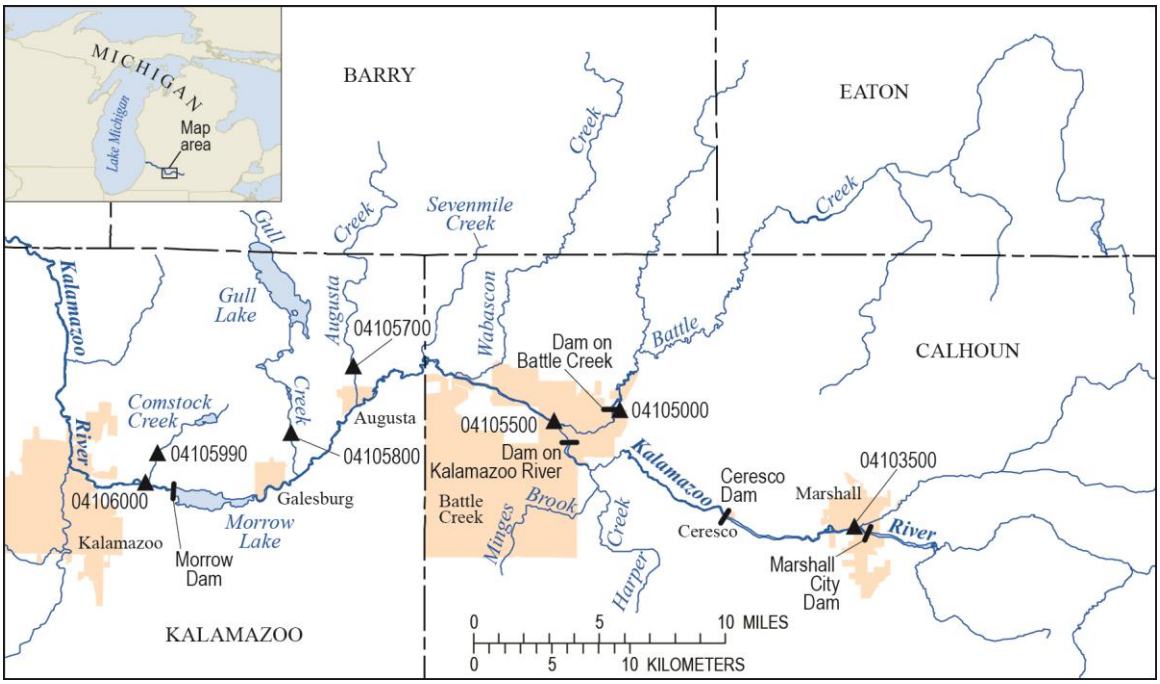

Figure 1 Diagram showing the study reach in the Kalamazoo River Basin.

Developing an SSC rating curve is challenging because SSC samples are typically limited in number and scattered around the rating curve. Scatter contributes to uncertainty of derived rating curves (Porterfield, 1972). Glysson (1987) illustrated many possible causes that could lead to variability in rating curves, such as seasonality and asynchrony of sediment peaks in relation to discharge peaks. Colby (1956) discretized the rating curve with partial-year records when seasonal variations were obvious. Different SSC values could be expected at equivalent Q_w in the rising and falling limbs of a storm hydrograph (hysteresis effect) (Ahanger et al. 2013; Baca, 2008). Considerations for deriving a meaningful at-site SSC rating curve may include (1) the coverage of the ranges of discharge and SSC to be estimated (that is, avoid extrapolation beyond the range of measured data), (2) the amount of measured data at specific flow ranges of interest for an application, and (3) exclusion of extreme sediment-transport rates from mixed populations of sediment-production processes (such extremes might occur after a dredging or dam removal).

Physiography and human activity (such as roads and structures) are common factors in the sediment concentration regimes. With the sediment availability and delivery governed by watershed and channel (hydraulic) characteristics, the parameters a and b (equation 1) are unique at individual sites. There have been

attempts to attribute physical meaning to the parameters *a* and *b*. For example, Morgan (1995) considered that the intercept, *a*, represents an index of erosion severity, and slope parameter *b* indicates the extent to which new sediment sources become available as discharge increases. Based on sediment characteristics in the Lower Yellow River, Mai et al. (1990) interpreted *a* to characterize the boundary conditions, such as the incoming sediment composition, and *b* to characterize the sediment carrying capacity. Asselman (2000) did not find these parameters to have any physical meaning.

Table 1 Rivers included in the study and their drainage areas and streamflow gage status in upstream to downstream order. Drainage areas for ungaged locations are calculated at the confluence with the Kalamazoo River.

Station Number or Ungaged	***Site Name***	***Drainage Area, mi^2***
04103500	Kalamazoo River at Marshall, MI	449
Ungaged	Talmadge Creek, MI	3.3
Ungaged	Bear Creek, MI	14.8
Ungaged	Minges andHarper Creek, MI	54.9
04105000	Battle Creek at Battle Creek, MI	241
04105500	Kalamazoo River near Battle Creek, MI	824
Ungaged	Wabascon Creek, MI	43.1
Ungaged	Sevenmile Creek, MI	16.4
04105700	Augusta Creek near Augusta, MI	38.9
04105800	Gull Creek at 37th Street near Galesburg[1], MI	38.1
04105990	Comstock Creek at E. Main Street near Kalamazoo[2], MI	18.3
04106000	Kalamazoo River at Comstock, MI	1,100

1. Gull Creek at 37th Street near Galesburg (04105800) has daily streamflow records between 10/01/1964 and 02/02/1973.
2. Comstock Creek at E. Main Street near Kalamazoo (04105990) has 28 field discharge measurements between 02/06/1964 and 09/03/2002.

MEASURED DATA AND ASSESSMENT

Data collected during the project: The USGS collected SSC data in August 2012, January through April 2013, and in March 2014. For each round of water samples, SSC samples were collected at five gaged sites (table 2) in the study reach. Samples were not collected at the two historical gage sites on Gull and Comstock Creeks.

Table 2 Description of data collection stations and suspended-sediment data availability

Station Number	***Site Name***	***Number of Project samples***	***Number of Historical samples***
04103500	Kalamazoo River at Marshall, MI	6	0
04105000	Battle Creek near Battle Creek, MI	6	0
04105500	Kalamazoo River near Battle Creek, MI	6	0

04105990	Comstock Creek at E. Main Street near Kalamazoo, MI	0	4
04106000	Kalamazoo River at Comstock, MI	6	4

Historical data: SSC data collected in the mid-1980s from 29 sites covering the main stem and tributaries of the Kalamazoo River were retrieved (C. Hoard, USGS, written communication, February, 2013). Four of the 29 sites are in the study reach and each of the four sites has four samples. Table 2 summarizes the sites and SSC data points available for the study and table 3 lists the data. Hereafter, the gaged sites will be referred to by their station numbers.

Table 3 List of available suspended sedimentation concentrations (milligrams per liter, mg/l) according to the location, date, discharge (in cubic feet per second, cfs), and water temperature (in Celsius). [SSC: suspended sediment concentration]

Station Number	Sample Date	Instantaneous discharge, in cfs	SSC, in mg/l	Water Temperature, in ℃
04103500	8/16/2012	243	20	21.72

Timing of collected data: The SSC data were collected near the storm peaks or slightly afterward during the falling limbs of the hydrograph (Fig. 2). The magnitudes of SSC collected on March 31, 2014 were much lower than those for samples collected previously. As part of the oil-mitigation work, sediment from the channel upstream of the Ceresco Dam, located approximately 3.75 miles downstream from the confluence of Talmadge Creek and the Kalamazoo River, was dredged and removed. Additionally, the channel was shaped to a wide floodplain channel and the Ceresco Dam (near Ceresco in Fig. 1) was notched in October 2013. Because of this dredging and channel alteration, the March 31, 2014 SSC data at sites 04105500 and 04106000 were not included in this analysis.

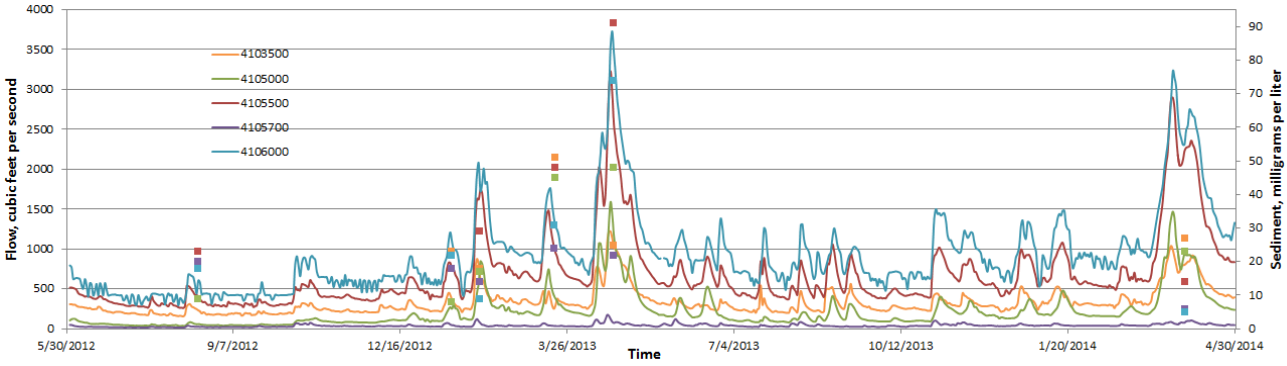

Figure 2 Timing of suspended sediment concentration data collection in relation to flow from June 1, 2012, to April 30, 2014. (Solid lines represent the hydrographs and dots show suspended sediment concentrations.)

Flow regimes of collected data: Both project and historical SSC data are plotted in relation to the flow duration curves (FDCs) to determine how well they represented the full streamflow regime. The FDCs were developed using mean-daily streamflow records from water years (WY) 2001 to 2014. The flow exceedance probability used for plotting the SSC data was computed based on the instantaneous discharge reported with each sample, assuming the differences between mean daily discharge and instantaneous discharge are not appreciable. The SSC data spanned a wide range of flow duration at each site (Fig. 3).

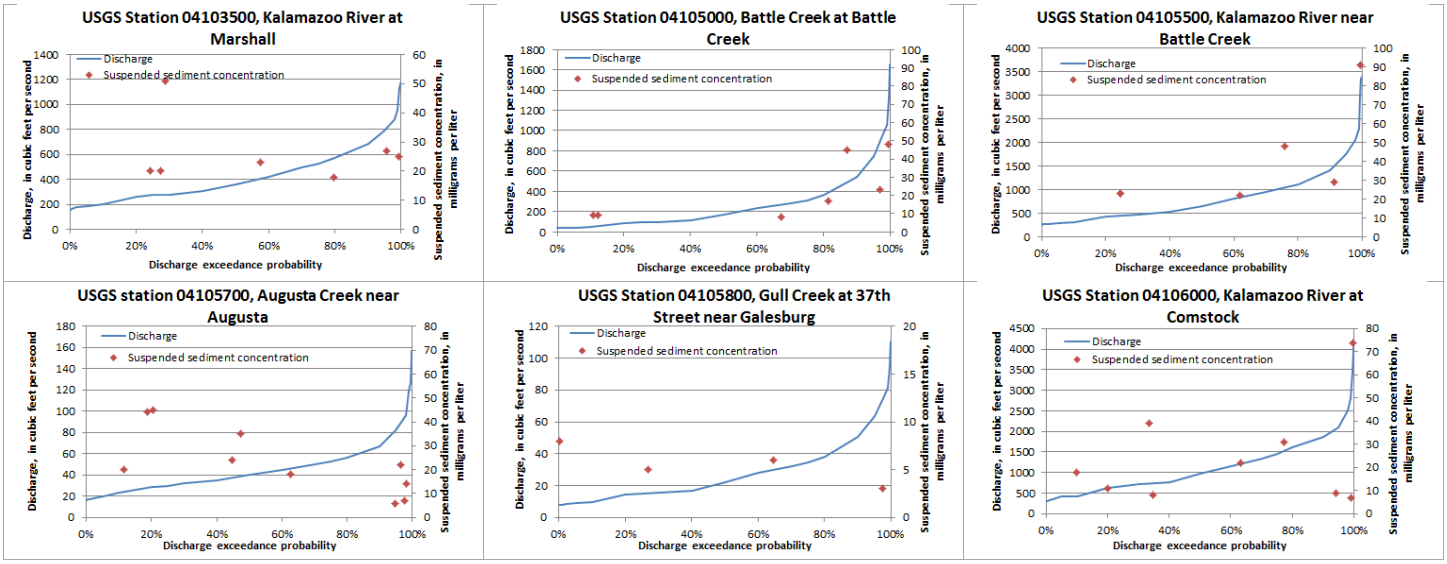

Figure 3 Coverage of suspended sediment concentration data in relation to discharge exceedance probability (flow-duration curve). Note as discussed in the "Timing of Collected Data" section, the March 31, 2014 SSC data at Kalamazoo River near Battle Creek (04105500) and Kalamazoo River at Comstock (04106000) were not included in this analysis.

The FDC for site 04105990 was not developed because the site has only 28 historical miscellaneous streamflow measurements. However, based on the 28 streamflow measurements, the range of flows for Comstock Creek is from 1.76 to 19.5 cfs, and the SSC measurements are considered to have covered the range of flows reasonably well.

AT-SITE SSC RATING CURVES AND SITE CHARACTERISTICS

At-site SSC rating curves: Figure 4 shows log-log plots of Q_w and SSC data for each site, along with the rating curve obtained from OLS regression. All data except for the two samples collected on March 31, 2014 at sites 04105500 and 04106000, were used in developing the at-site rating curves. Each at-site SSC rating curve was obtained from OLS regression between all remaining $\log_{10}(Q_w)$ and $\log_{10}(SSC)$ data pairs. Although the dataset sizes were limited, the trend of the resulting rating curves was considered representative because the sampled SSC data spanned much of the respective FDCs.

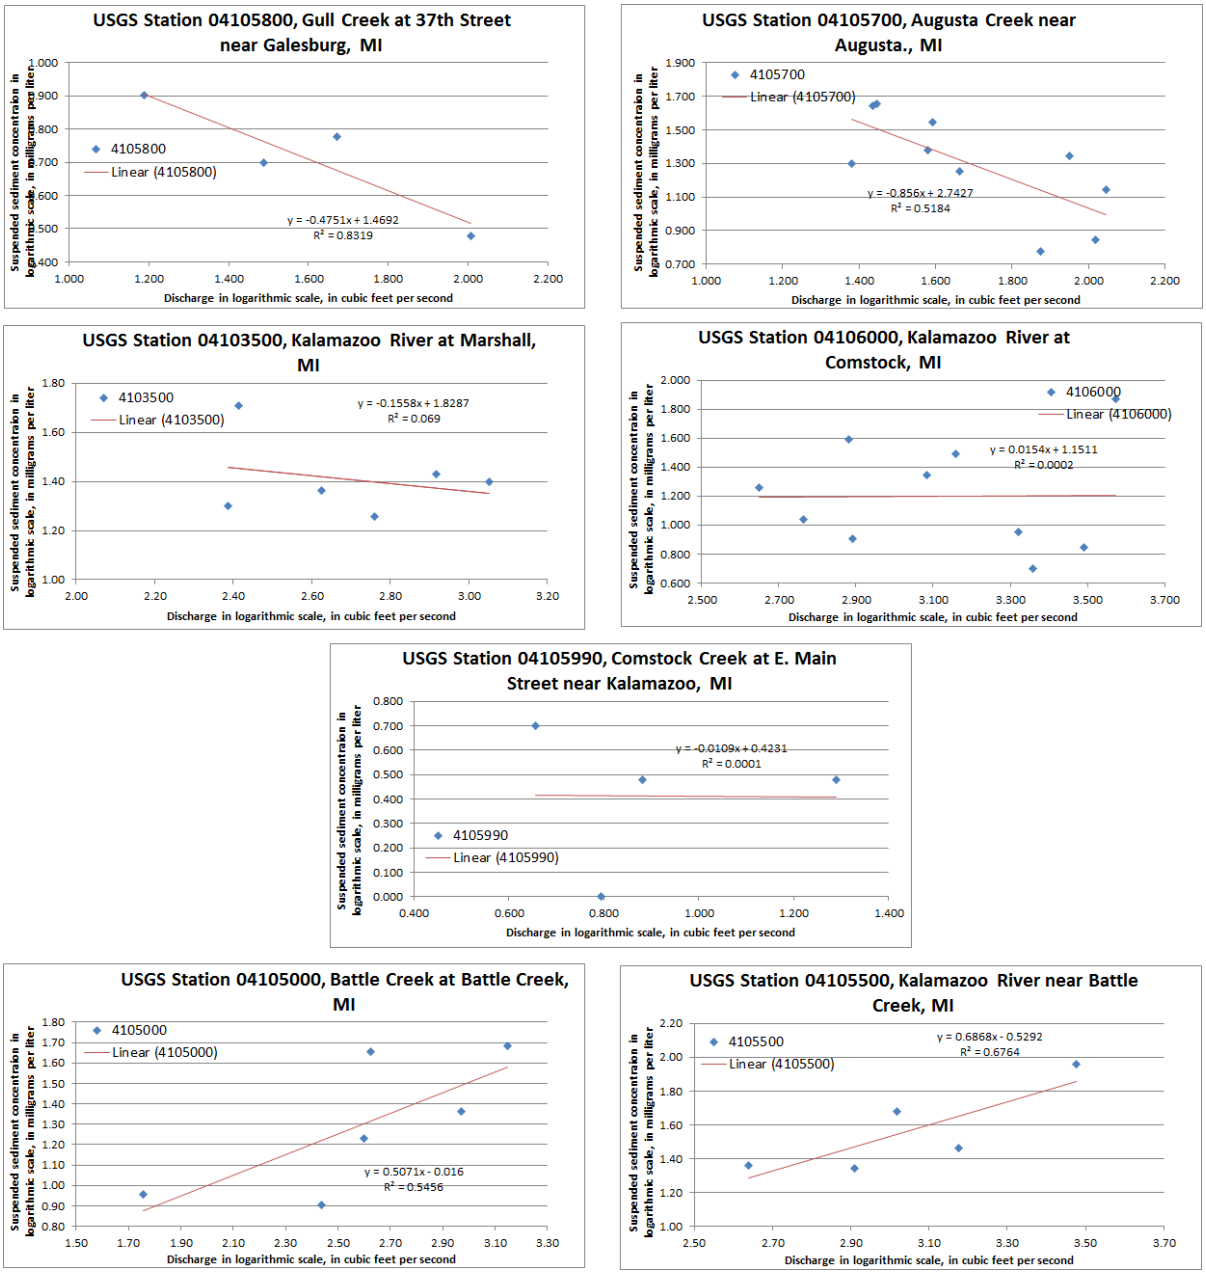

Figure 4 Relations of suspended sediment concentration (SSC) to discharge (Q_w) in logarithmic plots and SSC rating curves developed for seven study sites. [y stands for $\log_{10}$SSC, x stands for $\log_{10}Q_w$, and R^2 is the coefficient of determination]

The regression analysis resulted in negative SSC-rating slope estimates at sites 04105700 and 04105800; and weakly negative slopes at sites 04103500 and 04106000. In contrast, the positive slope estimates at sites 04105000 and 04105500 are more typical, in that SSC increases as Q_w increases (Porterfield, 1972). The SSC-rating slope at site 04105990 is difficult to assess with the scatter in the limited data points. Physically, decreasing SSC at increasing Q_w indicates that either the amount of sediment supply is similar at all flow rates, exhausted after early season flushing, or became supply-limited after the early part of each hydrograph pulse; or the transport of sediment is limited because of hydraulic carrying capacities. To understand whether the sediment transport is supply-limited or transport-limited, additional information on the amount and particle sizes of sediment is needed for analysis. The challenges to resolve for the present study are to: (1) use the available samples to improve the at-site analysis, and (2) use the at-site results to estimate SSC at ungaged locations.

Temperature effect on SSC: Some of the SSC data were collected between January and March at water temperatures between 5°C and 0°C and their values were higher than other samples collected at those sites in warmer weather (table 3). Barton and Albertson (1953) experimentally demonstrated that the depth-averaged SSC increases with a decrease in water temperature, and Colby (1956) documented that for finer sediment in the size range from 0.016 to 0.062 millimeter, there was a 57 percent increase in SSC as temperature dropped from 80 °F (26.7°C) to 40 °F (4.4°C). Plots made of the two subsets of the at-site data--those with water temperature above 5°C, and those with water temperature below 5°C--suggested a seasonal effect may exist in the study area as indicated by the different rating slopes in the two subsets at sites with adequate data.

Dam effects versus free-flowing reaches: There are several transverse (across the river) structures in the study reach including decommissioned dams (upper structure removed), a low-head dam, and hydropower dams. These transverse structures slow current velocity and cause coarse-grained sediment to settle. Depending on the incoming flow and incoming sediment magnitudes and particle sizes, in general the run-of-river conditions in these impoundments will not prevent fine sediment from being transported downstream. Therefore, SSC measured downstream from some of these dams could rise rapidly when streamflow increases from low to high discharges (i.e., a steeper rating-curve slope). In free-flowing channels, sediment deposits along the low-gradient reaches can produce similar effects. At regulated sites, the incoming flows and dam operations at the time of measurements can alter the relation between measured SSC and flow.

Among the gaged sites, the Kalamazoo River at Marshall and the Kalamazoo River at Comstock are located downstream from hydropower dams. Marshall has a small hydropower station by its dam that receives water from the Marshall pool through a side-channel. About 8 miles downstream from Marshall is a decommissioned dam at Ceresco. The operational rules at Morrow Dam are designed to release the amount of discharge flowing into its pool, as estimated from flows reported at the Kalamazoo River near Battle Creek gage, when discharges are above 1,000 cfs. Battle Creek is one of the largest tributaries of the Kalamazoo River, and the gage at Battle Creek at Battle Creek is located about 2.9 miles upstream from a low-head dam. Also, the gage on the Kalamazoo River near Battle Creek is located about 0.35 miles downstream from the low-head dam on Battle Creek.

Monthly hydrographs: Mean monthly streamflow hydrographs for six of the gaged sites are presented in figure 5 using data from water years (WYs) 1987 to 2011 except for the Gull Creek site, which used data from WYs 1964 to 1972. In general, streamflow rises from base flow in October to annual peaks in March or April, and then declines through August and remains low through September. Hydrograph bars in figure 5 are coded with two colors; the orange bars are those whose hydrograph patterns are clear and with low base flows in August to October; the blue ones are those with comparatively higher base-flow magnitudes and with monthly volumes fluctuating in the higher discharge period (signifying greater groundwater and surface water exchange). The hydrographs with blue bars are also associated with sampling sites that have negative SSC-rating-curve slopes. The monthly discharges were graphed using per unit area values, and it was observed that peak magnitudes for those coded with blue generally have lower values than those that are coded with orange.

Watershed and stream characteristics: Watershed characteristics such as the basin relief and geology (soil erodibility and permeability, and sediment delivery and storage), geomorphology of the channel (channel

sinuosity, narrow or floodplain channels, bank and bed erodibility), and land-cover changes are factors affecting sediment yield from a watershed. On a large scale, most of these factors are also affecting streamflow from the watershed. Therefore, the streamflow patterns can serve as a surrogate for analyzing the sediment yields. On this basis, the watershed and stream characteristics that could serve as indictors for explaining SSC rating curves at the gaged sites and help extending the results of gaged sites to ungaged sites were sought.

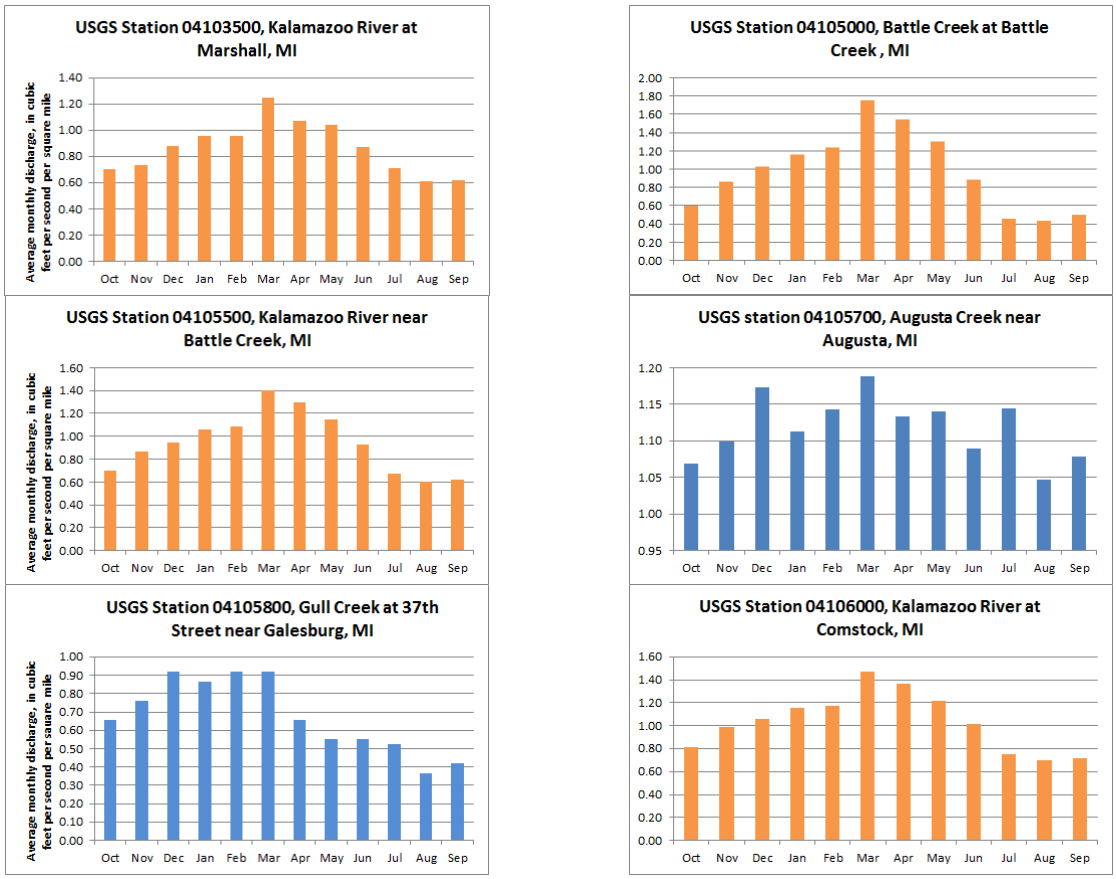

Figure 5 Mean monthly streamflow hydrograph patterns for sites in the study reach that have suspended sediment samples. Hydrographs coded in orange are considered to have clear yearly seasonal rising and falling patterns and with low base flows in August to October; those coded in blue have comparatively higher base-flow magnitudes and large monthly volumes fluctuations in the remaining months. Statistics were computed for water years (WYs) 1987 to 2011 except for the Gull Creek site, which used data from WYs 1964 to 1972.

Wesley (2005) used a "flow stability" index to classify the streamflow patterns of a watershed. A stream with more stable flows is characterized by lower peak flows and higher base flows than a stream with less stable flows. One component of the flow stability index (Wesley 2005) was the ratio of mean high flow to mean low flow. The dominance of stable streams (streams with low flow stability ratios) is mainly due to abundance of permeable surficial soils and geology, which promote groundwater inflow and outflow (Wesley, 2005). Groundwater dominated streams generally have cooler water temperatures than surface-water dominated streams. Surface-water dominated streams generally have relatively warmer water temperatures and higher flow-stability ratios because of faster responses to rainfall or snowmelt than groundwater dominated streams (Wesley, 2005). Less permeable soils, land-use changes (agriculture or development of less pervious surfaces), and channelization contribute to higher stream flow stability ratios. However, wetlands and lakes, wide floodplains that create channel storage also contribute to low flow-stability ratios. Wesley (2005) suggested that a ratio between 1.0-2.0 indicates a typical self-sustaining cold-water trout stream, between 2.1-5.0 indicates warm-

water streams, between 5.1-10.0 indicates somewhat flashy warm-water rivers, and >10.0 represents very flashy warm-water rivers.

Relevant characteristics found in Wesley (2005) for describing the watershed and stream and the flow-stability index of the gaged and ungaged sites in the study reach are presented in table 4. The high urban land cover in the Comstock Creek watershed might have caused the inconsistency in SSC data collected at the Comstock Creek site. For sites where such information is unavailable, the stream temperature class, defined as cold- or warm-water as described in Wesley (2005), is used as the indicator. A cold-water stream (groundwater dominated) has a low flow-stability index and the annual hydrographs are typical of those coded in blue in figure 5; the warm-water streams (surface-water dominated) have more diverse flow-stability indexes and annual flow patterns, most likely due to channel patterns.

Table 4 Watershed and stream characteristics and flow stability index for study sites along the main stem and tributaries used in hydrodynamic modeling work. [GW: groundwater; SW: surface water]

River Reach	***Stability Index***	***Watershed and stream characteristics (Wesley, 2005)***	***Classification***
Marshall pool above the Marshall Dam on the Kalamazoo River at Marshall, MI	4.4	Heavily influenced by inflows from Rice Creek, which is groundwater dominated and comes in from upstream of the Marshall Dam. The measurement site is downstream of Marshall Dam.	Mixed
Talmadge Creek, MI	N/A	A cold-water stream; with gravel and coarse sand substrate.	GW dominated
Bear Creek, MI	N/A	A cold-water stream, having gravel and cobble substrate.	GW dominated
Minges and Harper Creek, MI	N/A	A cold-water stream.	GW dominated
Battle Creek, MI	7.0	A surface-water dominated stream, has channelization near the mouth, drainage includes urban area; located at upstream of Battle Creek Dam.	SW dominated
Kalamazoo River above the junction with Battle Creek, MI	3.4	Located downstream of Battle Creek Dam which is an urban area.	SW dominated
Wabascon Creek, MI	N/A	A warm-water stream. Drains a mixture of moderate-relief plains. Flows through several lakes and swamps.	Mixed
Sevenmile Creek, MI	1.6	A cold-water stream; substrate features gravels overlain by sand.	GW dominated
Augusta Creek, MI	2.2	A cold-water stream; features a series of wetlands and reservoirs. The substrate dominated with gravel and cobbles.	GW dominated
Gull Creek, MI	N/A	A warm-water stream. Gull Lake is located at headwater and Gull Creek flows through several lakes and swamps. Substrate: gravel and cobble.	Mixed
Comstock Creek, MI	N/A	A warm-water stream, drains through a few small lakes. 85 percent is in an urban area.	Mixed
Kalamazoo River near Comstock, MI	2.9	Located downstream of Morrow dam, whose release has been controlled by gates and turbine operations.	Regulated

DEVELOPING SSC RATING CURVES FOR GAGED AND UNGAGED SITES

Supplemental measures to improve the accuracy of at-site SSC rating curves are needed because of the small number of samples collected at each site. Furthermore, the distinctive SSC rating slopes could be caused by effects of water temperature, dam, and watershed and stream characteristics individually or in combination. The modeling challenges include determining the at-site SSC rating curves by incorporating these factors and then estimating SSCs for the ungaged sites.

Panel regression with fixed-effect analysis for gaged sites: The SSC data presented in table 3 were pooled as panel data for regression analysis, and the fixed-effects model was applied to analyze the panel data. Data were grouped in the analysis according to the causative factors: dammed or free-flowing reaches, winter or non-winter seasons, and surface-water or groundwater dominated watersheds. An assumption made was that the slope parameter *b*-the sediment source term-was similar for sites in each of the five subgroups, but the intercept, parameter *a*, varied from site to site. The assumption was based on reasoning that the magnitude of SSC is a function of channel erosive power and conveyance capacity. The following five subgroupings were tested and the goodness of fit between measured and estimated SSC was evaluated using the quantitative statistics presented in table 5.

- Group 1: Results from at-site linear regression analysis; i.e., no groups, no panel regression. This is the baseline condition.
- Group 2: The free-flowing and dammed reaches partition. Sites 04105700, 04105800, and 04105990 belong to the free-flowing reaches, and sites 04103500, 04105000, 04105500, 04106000 belong to the dammed reaches.
- Group 3: The groundwater and surface-water dominated reaches partition. Sites 04105000 and 04105500 belong to the surface-water dominated group, the remaining 5 sites belong to the groundwater-dominated group.
- Group 4: A further partition of Group 3 into winter (January through March) and non-winter months (the rest of the year).
- Group 5: Similar to Group 4, but the at-site SSC rating curve is used for site 04103500 and this site is not used in the panel analysis. An additional constraint is imposed at site 04106000: when Qw <= 1000 cfs (up to four turbines opened) the data are classified under groundwater-dominated stream (the dam effectively traps sediment), and when Qw is larger than 1000 cfs, the data are classified under surface-water dominated streams.

Table 5 Quantitative statistics of estimated suspended sediment concentrations for the five groupings studied. [R^2, coefficient of determination; PBIAS: ratio of deviation of simulated from measured data; NSE: Nash-Sutcliffe efficiency; and RSR: ratio of the root-mean-square error to the standard deviation of measured SSC data. Moriasi et al. (2007) recommended the use of the latter three statistics.]

Parameter	*Group 1*	*Group 2*	*Group 3*	*Group 4*	*Group 5*
R^2	0.77	0.72	0.72	0.76	0.78
PBIAS	-0.11	-0.13	-0.13	-0.11	-0.11
NSE	0.57	0.47	0.49	0.55	0.60
RSR	0.65	0.73	0.71	0.67	0.64

Group 5 results had a better fit and the least variance among the groups; therefore, parameters *a* and *b* (table 6) for that group were used to construct the SSC rating curves at specified gaged locations.

Estimation of parameters *a* and *b* for ungaged sites: For ungaged tributary sites, it was assumed that parameter *a* is a function of basin characteristics and that parameter *b* can be transferred from gaged sites that have similar watershed and channel characteristics.

Parameter *a* for ungaged sites was obtained using the assumption that they can be transferred from gaged sites to ungaged sites based on the criterion of whether the stream is groundwater or surface-water dominated. Table 7 lists the two parameters used for the ungaged study sites.

CONCLUSIONS

Suspended sediment concentration (SSC) rating curves for gaged and ungaged sites in the Kalamazoo River and its tributaries from Marshall to Morrow Dam were developed. Despite the paucity of measured SSC data, the developed rating curves adequately covered the range of flows at each study site. Several sites had negative SSC rating curve slopes, in contrast to the typical SSC rating curve pattern in which SSC increases as streamflow

increases. This variability added an additional challenge to the SSC rating curve analysis for this study. By pooling at-site data as panel data and grouping them according to possible causative factors, a fixed-effects model analysis found classifying study sites according to their groundwater or surface-water dominance yielded better quantitative statistics than other groupings tested. For ungaged sites in the study area, it was assumed the parameters of SSC rating curves could be transferred from gaged sites reasonably well, based on the similarity in watershed and channel characteristics.

Table 6 Parameters *a* and *b* for estimating suspended sediment rating curves at sites with measured data. Winter was designated as January 1 through March 31, and non-winter period was designated as April 1 through December 31.

River Reach	***Season***	***a***	***b***

Sevenmile Creek, MI (tributary)	Non-winter	-0.161	0.603

Tributaries with negative SSC-rating slopes were found to come from watersheds that are characterized by lower stream temperatures and permeable surficial soils and geology indicative of groundwater-flow dominated systems. Such streams generally have low flow stability indices. However, surface-water dominated watersheds can also have a lower flow stability index if the channels have abundant storage. Classification of the watershed and channel characteristics as described in this paper improves the estimation of the SSC-rating curve at both gaged sites and ungaged sites. This identification can be an important consideration for the analysis and modeling of watershed streamflow and sediment.

FROM MOBILE ADCP TO HIGH-RESOLUTION SSC: A CROSS-SECTION CALIBRATION TOOL

Justin A. Boldt, Hydrologist, U.S. Geological Survey,
Kentucky Water Science Center, Louisville, KY, jboldt@usgs.gov

INTRODUCTION

Sediment is a major cause of stream impairment, and improved sediment monitoring is a crucial need. Point samples of suspended-sediment concentration (SSC) are often not enough to provide an understanding to answer critical questions in a changing environment. As technology has improved, there now exists the opportunity to obtain discrete measurements of SSC and flux while providing a spatial scale unmatched by any other device.

Acoustic instruments are ubiquitous in the U.S. Geological Survey (USGS) for making streamflow measurements but when calibrated with physical sediment samples, they may be used for sediment measurements as well. The acoustic backscatter measured by an acoustic Doppler current profiler (ADCP) has long been known to correlate well with suspended sediment, but until recently, it has mainly been qualitative in nature. This new method using acoustic surrogates has great potential to leverage the routine data collection to provide calibrated, quantitative measures of SSC which hold promise to be more accurate, complete, and cost efficient than other methods.

This extended abstract presents a method for the measurement of high spatial and temporal resolution SSC using a down-looking, mobile ADCP from discrete cross-sections. The high-resolution scales of sediment data are a primary advantage and a vast improvement over other discrete methods for measuring SSC. Although acoustic surrogate technology using continuous, fixed-deployment ADCPs (side-looking) is proven, the same methods cannot be used with down-looking ADCPs due to the fact that the SSC and particle-size distribution variation in the vertical profile violates theory and complicates assumptions.

A software tool was developed to assist in using acoustic backscatter from a down-looking, mobile ADCP as a surrogate for SSC. This tool has a simple graphical user interface that loads the data, assists in the calibration procedure, and provides data visualization and output options. This tool is designed to improve ongoing efforts to monitor and predict resource responses to a changing environment. Because ADCPs are used routinely for streamflow measurements, using acoustic backscatter from ADCPs as a surrogate for SSC has the potential to revolutionize sediment measurements by providing rapid measurements of sediment flux and distribution at spatial and temporal scales that are far beyond the capabilities of traditional physical samplers.

CALIBRATION METHOD

The conversion from echo intensity, also known as raw backscatter (RB, in counts), to sediment-corrected backscatter (SCB, in dB) uses the following equation (Gartner, 2004):

$$SCB = K_c * RB + 20 * \log_{10}(\psi R) + 2\alpha_w R + 2\alpha_s R \quad (1)$$

where K_c is the instrument- and beam-specific echo intensity scale factor (dB/count), ψ is the non-dimensional function describing the non-spherical spreading of the backscattered signal in the near field (Downing et al., 1995), R is the range or distance along the beam (m), α_w is the sound absorption coefficient (dB/m) (Schulkin and Marsh, 1962), and α_s is the sediment attenuation coefficient (dB/m) (Wright et al., 2010; Landers, 2010). In Eq. (1), the first term converts the raw backscatter from counts to decibels, the second term corrects for beam spreading, the third term corrects for water absorption, and the fourth term corrects for sediment attenuation.

The sediment attenuation coefficient can either be measured using the slope of the water-corrected backscatter (WCB) profile (Wright et al., 2010) or computed using knowledge of the suspended-sediment characteristics. The first method assumes uniform SSC over the range from which the slope is obtained. Vertical SSC profiles usually are not uniform with depth, but the upper portion of the SSC profile may be nearly uniform, and this assumption may be acceptable in certain environments. The second method requires analysis of the density and particle-size distribution of the sediment, but its application to a real-world environment is complex to say the least. Both of these sediment attenuation estimation methods are the subject of ongoing research.

The SCB to SSC calibration method relies on concurrent measurements of ADCP acoustic backscatter and suspended-sediment concentration at points throughout the water column at one or more stationary, vertical locations [Figure 1(A–B)]. The acoustic backscatter data from a stationary ADCP profile are time-averaged over the period during which the suspended-sediment point samples were collected. The calibration procedure requires that each physical sediment sample is temporally and spatially matched to a SCB value [Equation (1)]. A linear regression between the matched values is determined such that

$$\log_{10} \mathrm{SSC} = \mathrm{a} * \mathrm{SCB} + \mathrm{b} \tag{2}$$

where a is the slope and b is the y-intercept [Figure 1(C)]. Once the slope and intercept values have been determined for the calibration data (stationary verticals), any sequential ADCP data (e.g., transects or cross-sections) can be converted to SSC using the following equation:

$$\mathrm{SSC} = 10^{(\mathrm{a}*\mathrm{SCB}+\mathrm{b})} \tag{3}$$

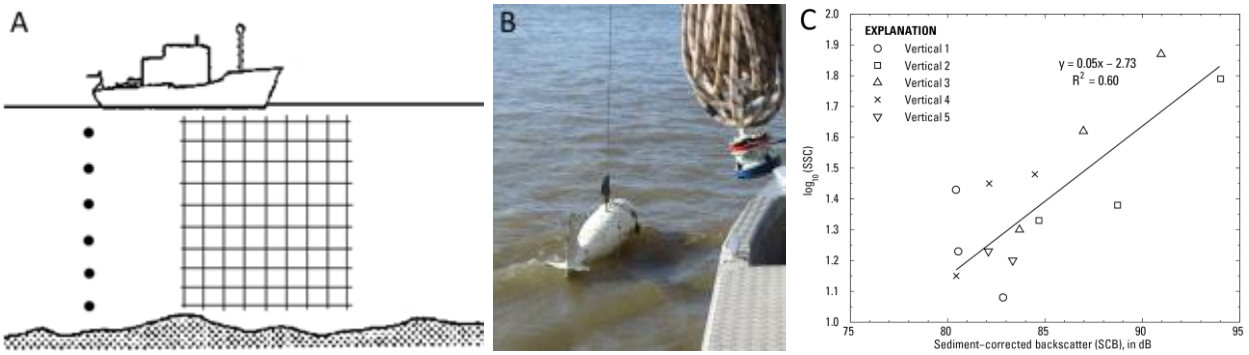

Figure 1 (A) Schematic showing physical sediment samples (points) and stationary ADCP profile time-series (grid). (B) Photo of suspended-sediment sampler and ADCP. (C) Example of linear regression between suspended-sediment concentration (SSC) and sediment-corrected backscatter (SCB).

RESULTS

Although a single vertical can be used to develop a calibration, research to date indicates that a more robust calibration results from using multiple verticals. A convenient method is to use the verticals associated with an equal-discharge-increment (EDI) suspended-sediment sample. This method consists of taking several point samples of suspended sediment throughout the water column in addition to the standard depth-integrated sample at each EDI vertical. The point samples are used to develop the calibration, and the EDI-computed SSC provides a standard measurement of suspended-sediment concentration with which to validate the composite value output by the software tool. An example of a calibrated cross-section is shown in Figure 2. The color contours represent the suspended-sediment concentration. A composite SSC value is reported for the cross-section which may be validated with an EDI composite or other reference measurement of suspended-sediment. When combined with ADCP velocity data, the sediment flux throughout the cross-section can be computed. The software tool provides all of these data visualization options, and additional information about the tool can be found at the USGS Sediment Acoustics webpage (http://water.usgs.gov/osw/SALT/).

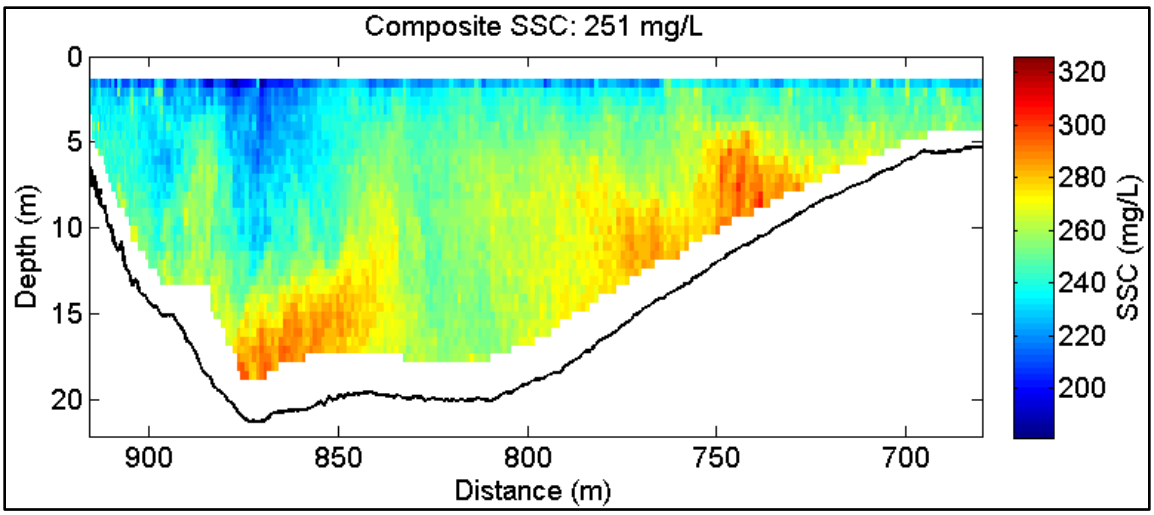

Figure 2 Calibrated cross-section showing color contours of suspended-sediment concentration.

The primary benefit of this method is the vast improvement in spatial scale. Side-looking ADCP deployments are best for continuous monitoring of suspended-sediment, but repeat cross-sections with a down-looking ADCP provide spatial and temporal scales unmatched by any other device. The main limitation of this calibration procedure is that each calibration is specific to the instrument (frequency and beam scale factors) and the particle-size distribution at each site. Changing sediment conditions cause a previous calibration to be invalid due to the complex relationship between sediment characteristics and acoustic backscatter. There is ongoing work to determine how transferable a calibration is over small changes in particle-size distribution for a single site. Another limitation is that this method only applies to measurements of suspended sediment, not bedload measurements. Because the data come from an ADCP, there exist the unmeasured areas on the top and bottom due to the blanking distance and side-lobe interference, respectively; although, estimation algorithms are under development.

SUMMARY

A calibration procedure is presented for converting ADCP acoustic backscatter data to suspended-sediment concentration, which is especially powerful when applied to a full channel cross-section. The calibration method relies on concurrent measurements of ADCP acoustic backscatter and suspended-sediment concentration at points throughout the water column at one or more stationary, vertical locations, and a software tool was developed to standardize and expedite the calibration process. As a result, it is possible to provide rapid measurements of sediment flux and distribution at spatial and temporal scales that are far beyond the capabilities of traditional physical samplers.

Abstract: Surrogate measurements of suspended-sediment concentration (SSC) are increasingly used to provide continuous, high-resolution, and demonstrably accurate data at a reasonable cost. Densimetric data, calculated from the difference between two in situ pressure measurements, exploit variations in real-time streamflow densities to infer SSCs. Unlike other suspended-sediment surrogate technologies based on bulk or digital optics, laser, or hydroacoustics, the accuracy of SSC data estimated using the pressure-difference (also referred to as densimetric) surrogate technology theoretically improves with increasing SCCs. Coupled with streamflow data, continuous suspended-sediment discharges can be calculated using SSC data estimated in real-time using the densimetric technology.

The densimetric technology was evaluated at the Rio Puerco in New Mexico, a stream where SSC values regularly range from 10,000-200,000 milligrams per liter (mg/L) and have exceeded 500,000 mg/L. The constant-flow dual-orifice bubbler measures pressure using two precision pressure-transducer sensors at vertically aligned fixed locations in a water column. Water density is calculated from the temperature-compensated differential pressure and SSCs are inferred from the density data.

A linear regression model comparing density values to field-measured SSC values yielded an R^2 of 0.74. Although the application of the densimetric surrogate is likely limited to fluvial systems with SSCs larger than about 10,000 mg/L, based on this and previous studies, the densimetric technology fills a void for monitoring streams with high SSCs.

INTRODUCTION

Surrogate measurements of suspended-sediment concentrations (SSCs) can produce continuous, real-time measurements at reasonable costs compared to the traditional collection and analysis of physical samples (Porterfield, 1972; Edwards and Glysson, 1999; Nolan et al., 2005; Koltun et al., 2006; Gray et al., 2008; Gray and Simões, 2008; and Gray and Landers, 2014). The state-of-the-art surrogate technologies as described by Gray and Gartner (2010) include optical backscatter (turbidity), laser diffraction, and hydroacoustics. Although these technologies are proving to be useful for continuously monitoring SSCs in operational programs, most tend to saturate – that is, reach an upper measurement limit – when SSC values exceed 4,000-8,000 milligrams per liter (mg/L) depending on the technology and the characteristics of the sensor selected. SSCs in flows in many rivers around the world, including many unregulated channels in the southwestern United States, episodically exceed 10,000 mg/L, sometimes by more than an order of magnitude (Beverage and Culbertson, 1964), thus rendering the aforementioned SSC

surrogate technologies ineffectual when most sediment transport occurs during higher flows. The densimetric SSC surrogate method effectively enables measurements of SSCs – theoretically with improving accuracy – as SSCs rise above about 10,000 mg/L. Although evaluations of the densimetric technology as a surrogate for moderate-to-high SSCs previously have been administered with mixed results (Larsen et al., 2001; Gray et al., 2010), new interest expressed by the Federal Interagency Sedimentation Project, in a surrogate technology capable of operating under high SSCs, has led to revisiting the densimetric technology.

Previous Research: Lewis and Rasmussen (1999) used precision-pressure transducers to calculate fluid density in a laboratory using glass-microspheres at an SSC of 542 mg/L to within ± 14 mg/L. Calhoun and Rasmussen (2001) also analyzed differential-pressure readings to estimate SSCs and reported good results in the laboratory. The results of field applications by Calhoun and Rasmussen in two creeks in northern Georgia were less convincing largely due to complications from variations in flow velocity, water temperature, and dissolved solids.

Sumi et al. (2002) successfully used two different pressure devices in Japan: (1) a floating, submersible device designed for use in reservoirs, and (2) a differential-pressure device mounted on the banks of a river requiring a submersible pump to deliver water to the sensors. However, the first device was limited to use in reservoirs and the second lacked in situ measurement capability. Hsu and Cai (2010) used two submersible pressure transducers and reported good results in the laboratory. Field results were limited to a single period runoff period, yet the preliminary findings were promising.

Larsen et al. (2001) used a prototype dual-orifice bubbler manufactured by Design Analysis Associates, Inc. (use of firm names in this report is for identification purposes only and does not constitute endorsement by the U.S. Geological Survey) for monitoring SSCs in a Puerto Rico stream. The in situ densimetrically derived SSC values generally were synchronous with the runoff hydrograph. However, the authors considered the maximum observed SSC values of about 17,000 mg/L to be marginal with respect to the low-end SSC measurement capability of the non-temperature-corrected device. The technology was considered worthy of additional research in rivers with high SSCs, in part because no other surrogate technology has been identified for monitoring highly concentrated streamflows.

The same densimetric dual-orifice bubbler used in Puerto Rico subsequently deployed at the Paria River at Lees Ferry, Arizona (Gray et al., 2010), also yielded mixed results in spite of SSC values that exceeded 100,000 mg/L, or about five times the maximum SSC value measured in the Puerto Rico study. It was surmised that bedforms might have intermittently buried the bottom orifice line, thus rendering as spurious any inferred SSC values.

Regarding the Puerto Rico and northern Arizona densimetric tests, Gray et al. (2010) concluded, “In spite of its sound theoretical underpinnings, the field performance of the Double Bubbler in Puerto Rico and northern Arizona, has yet to be fully resolved. Research is continuing into whether development and use of empirical relations from calibration data in lieu of the theoretical considerations are warranted. The required computational scheme presupposes that the SSC in the vertical profile between the sensors is more or less equal to that above the higher sensor. This assumption is difficult to verify and may not be valid. The technology is unreliable

for measuring SSC at less than about 10 g/L [10,000 mg/L], and the actual lower measurement threshold may be at a somewhat larger SSC. The technology is incapable of measuring SSC when the top orifice is out of water. Spurious data are numerous and are believed to be associated with flow turbulence or orifice blockage by bedforms. Continuous pressure-difference measurements may be useful in developing a continuous SSC trace under some circumstances but are not yet considered sufficiently reliable to replace traditional suspended-sediment-monitoring techniques."

In summary, previous studies support the theoretical truism that a positive correlation between SSC and values of fluid density exists in streamflow. However, no previous study has yet conclusively reported reliable, robust field results for inferring SSC values from continuous densimetric measurements. Results of the study described herein add to the knowledge gained from the aforementioned studies by determining the viability of a commercially available instrument for measuring in situ stream water density as a surrogate for SSC.

STUDY SITE AND METHODS

Rio Puerco Study Site: The study site (figure 1) is located at the Rio Puerco near Bernardo, New Mexico, U.S. Geological Survey (USGS) streamflow- and suspended-sediment gaging station (08353000) approximately 0.5-mile upstream from the confluence with the Rio Grande. The Rio Puerco is an ephemeral, incised arroyo in northwest New Mexico with a drainage area of 6,080 square miles. Streamflow is generally produced by summer monsoonal storms or dissipating fall tropical storms (Western Regional Climate Center, 2015). The daily discharge record since 1939 reports a maximum of 7,000 cubic feet per second (ft^3/s), a median of 39.0 ft^3/s and a mean of 126 ft^3/s, excluding flows less than 1 ft^3/s (USGS, 2015). Except for the headwaters, the stream flows through alluvium and valley fill dominated by fine sand-, silt-, and clay-size sediments in unlimited supply for fluvial transport (Nordin, 1963).

The Rio Puerco is renowned for conveying some of the world's largest SSCs. SSCs regularly range from 10,000 mg/L to 200,000 mg/L; Beverage and Culbertson (1964) reported a value of 564,000 mg/L measured on July 24, 1949.

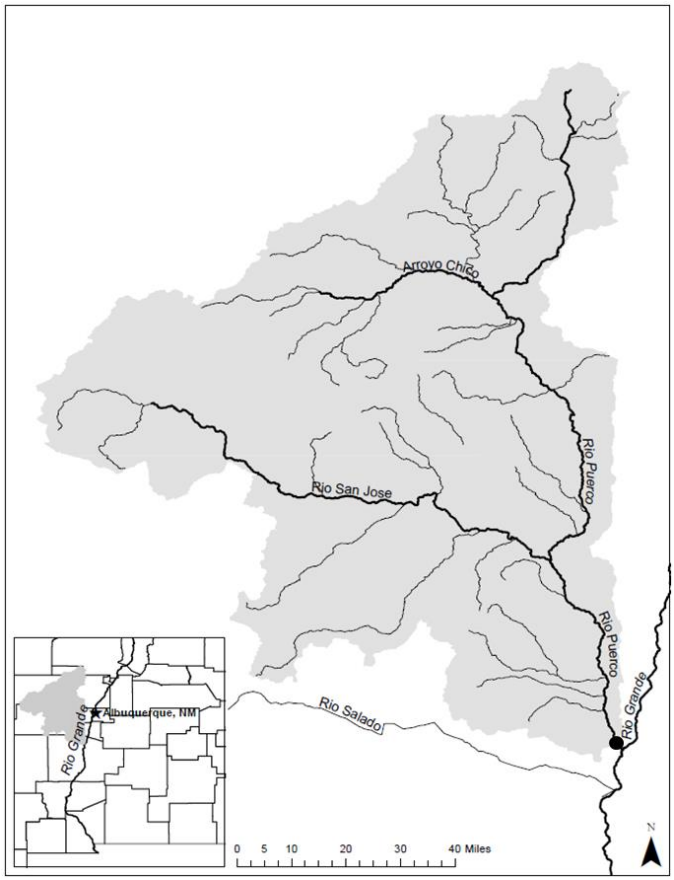

Figure 1 Map of the Rio Puerco watershed in New Mexico. The USGS Rio Puerco near Bernardo, NM, streamflow- and suspended-sediment gaging station (08353000) is located upstream from the confluence with the Rio Grande (black circle).

Methods: Simultaneous pressure readings are obtained using a constant-flow dual-orifice bubbler and recorder manufactured by Sutron Corporation. The two orifices are separated by a fixed distance and vertically aligned in the water column. Differential pressure, computed from the two simultaneous precision-sensor pressure readings, is used to determine the temperature-compensated density of the stream water. The simplified density equation, as given in the Sutron manual (Sutron, 2014), is:

$$\rho_{sw} = \frac{P_2 - P_1}{z} * 2.3066587 \quad (1)$$

where ρ_{sw} is the density of the stream water in grams per milliliter (g/mL), P_1 and P_2 are the pressures in lbs/in² of the upper and lower orifices, respectively, and z is the distance between the orifices, in feet. Figure 2 shows a schematic of the channel at the study site and the orientation of the orifices in the stream. As increases in SSCs correspond to concomitant increases in the density of stream water, the increased density is attributable to an increase in SSC, with some assumptions. Subtraction of the density of pure water, at the temperature of the stream water, results in a value that may be assumed to represent SSC, as shown in equation 2:

$$SSC_{est} = (\rho_{sw} - \rho_{pw}) * 1{,}000{,}000 \quad (2)$$

where SSC_{est} is estimated SSC in mg/L, ρ_{pw} is the density of pure water in g/mL at the temperature of stream water, and 1,000,000 is a conversion factor. Of necessity, equation 2 is based on the following assumptions:

1. both orifices reference the same water surface,
2. the SSC is large enough to exceed a minimum signal-to-noise ratio,
3. the density of suspended sediment and dissolved solids remain constant, and
4. no SSC gradient is present between the lower orifice and the water surface in the vertical water column.

A failure for the orifices to reference the same water surface, and (or) unacceptably low SSC values (assumptions 1 and 2) lead to a lower signal-to-noise ratio, which results in increased uncertainty in the estimation of SSCs, whereas a breakdown in the remaining assumptions (3 and 4) may result in biased data. Water density varies with temperature and as such the density data must be adjusted for ambient water temperature. Water temperatures were measured with a Forest Technology Systems (FTS) digital temperature probe located at the midpoint between the two bubbler orifices and was used to correct the density data. Although the density of water is temperature dependent, Skinner (1982) found that a 1 degree Celsius (ºC) change in temperature was equivalent to a SSC of 160 mg/L, which would be negligible in streams with exceptionally large SSCs.

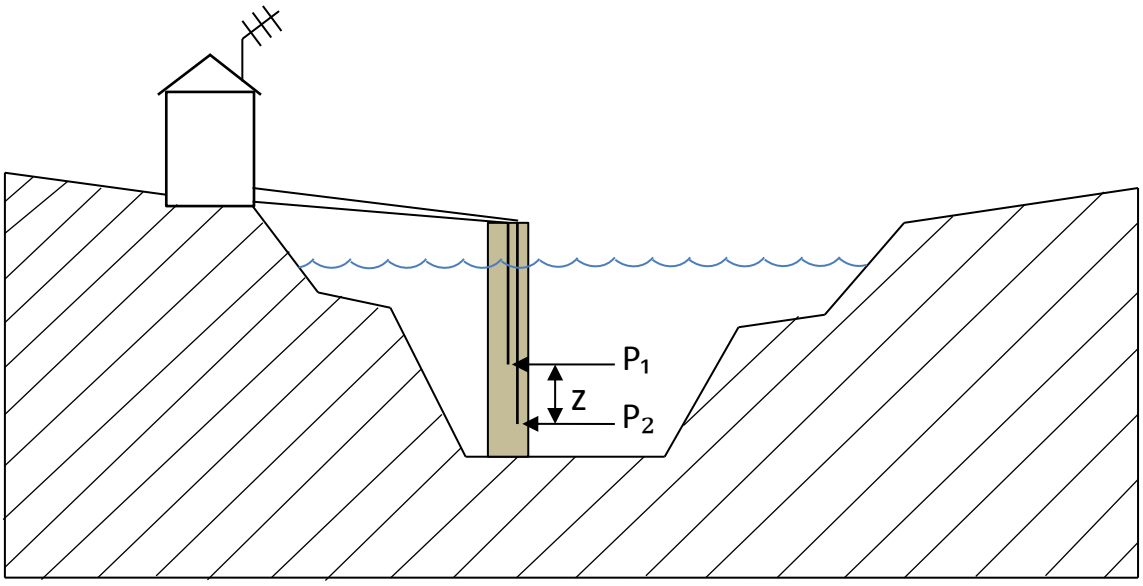

Figure 2 Schematic of the installation of the constant-flow dual-orifice bubbler at the USGS Rio Puerco near Bernado, NM, streamflow- and suspended-sediment gaging station (08353000). P_1 and P_2 represent the bubbler orifices at which depths their respective pressure readings are made. The distance, z, is the vertical separation between orifices. The data-collection platform and two automatic-pumping samplers are located in the gage house.

The two orifices at which pressure measurements were made were mounted in the channel with a vertical separation of 2 feet. Subsequent differential-pressure measurements require that the upper orifice be submerged by at least 0.2 foot. In general, the larger the separation between orifices and the greater the depth over the upper orifice, the stronger the derived signal-to-noise ratio, ergo, the greater accuracy of the computed SSCs.

Water samples for subsequent SSC analyses were collected using two automatic-pumping samplers (Teledyne ISCO 6712) with intake lines mounted in close proximity to the lower bubbler orifice. The samplers were triggered using a 1640 liquid-level actuator manufactured by Teledyne ISCO and samples were collected every 30 minutes during liquid-level actuator submergence. These point samples were compared with suspended-sediment samples collected manually with a depth-integrating isokinetic sampler using the equal-width-increment methods following USGS sampling protocols (Edwards and Glysson, 1999; Nolan et al., 2005; Gray et al., 2008; Gray and Landers, 2014). Samples were analyzed at the USGS New Mexico Water Science Center's sediment laboratory by methods described by Guy (1969). The comparison showed that suspended sediment in the stream is well mixed at this site.

RESULTS AND DISCUSSION

During the study period from July 2013 to September 2013, measured SSCs in the Rio Puerco ranged from 6,730-195,000 mg/L with a median value of 29,500 mg/L. During this period, runoff from monsoonal storms produced 14 discrete high flows (peak flows exceeding 30 ft^3/s). A total of 949 automatically pumped samples were collected and analyzed. Density values, calculated from differential-pressure measurements made every 15 minutes, ranged from 0.70-1.15 g/mL with a median of 1.04 g/mL. Water-temperature data were collected concomitant with the differential-pressure data every 15 minutes and ranged from 14.2ºC to 26.8ºC with a median temperature of 21.7ºC.

Figures 3-6 depict four of the larger flows during the study period (defined here as at least 24 consecutive hours of flow exceeding 30 ft^3/s) and show streamflow and observed and estimated SSCs (estimated SSCs were derived from equation 2). Estimated SSCs follow the general trend of observed SSCs, but estimated SSC values generally display a wide scatter due to noise in the differential-pressure readings, possibly induced from turbulence at or below the water surface. Although not included in this analysis, a moving average applied to the estimated SSC would smooth the curve, but differences between the observed and estimated SSCs would still be present.

In general, the estimated SSC values follow the same pattern as the observed SSC values. The densimetric surrogate estimated the peak SSC reasonably well for the flows shown in figures 3 and 4, but underestimated the peak for the flow shown in figure 5 and the beginning of the flow shown in figure 6. The densimetric surrogate tended to overestimate SSCs as the observed SSCs decreased. This is best shown in figure 5, but also is evident in figures 3 and 4. It is likely that SSC needs to be somewhat larger than 10,000 mg/L at this site for the densimetric surrogate to provide acceptably reliable data. Further investigation is required to better understand the operational constraints of this densimetric instrument at this site.

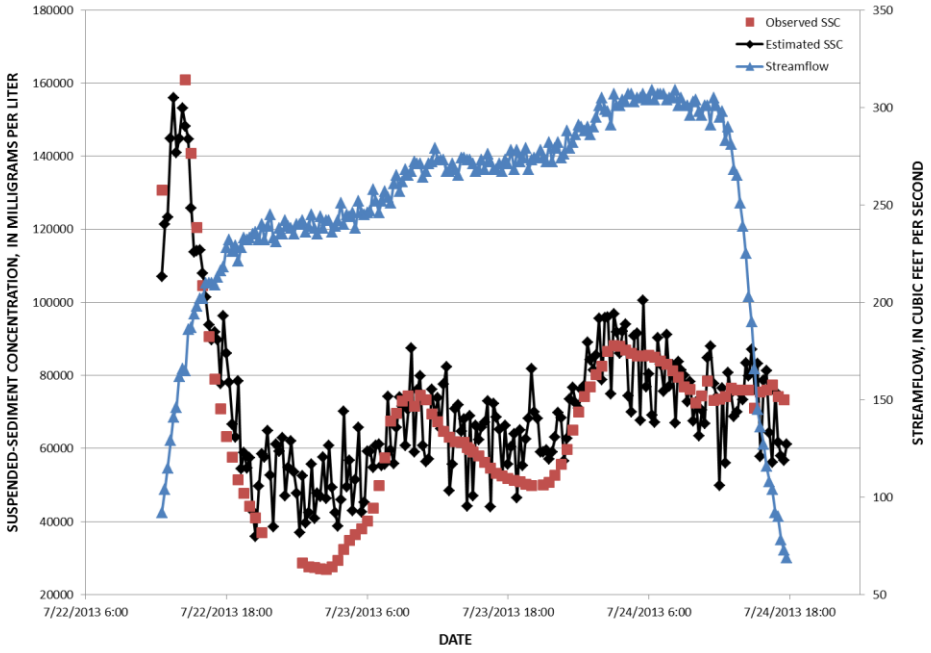

Figure 3 Estimated and observed suspended-sediment concentration and streamflow for July 22 – 24, 2013, at the Rio Puerco near Bernardo, NM, study site.

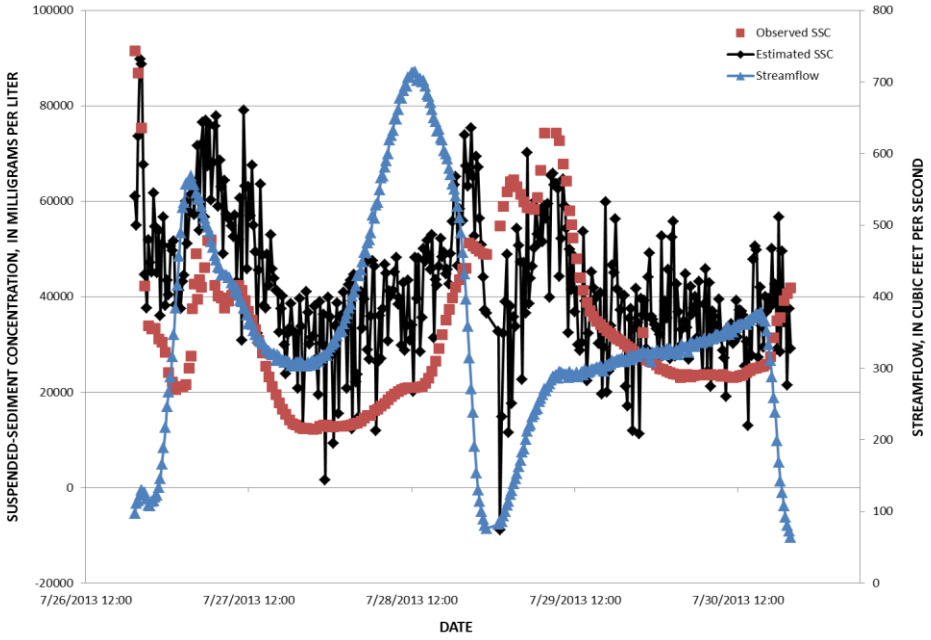

Figure 4 Estimated and observed suspended-sediment concentration and streamflow for July 26 – 30, 2013, at the Rio Puerco near Bernardo, NM, study site.

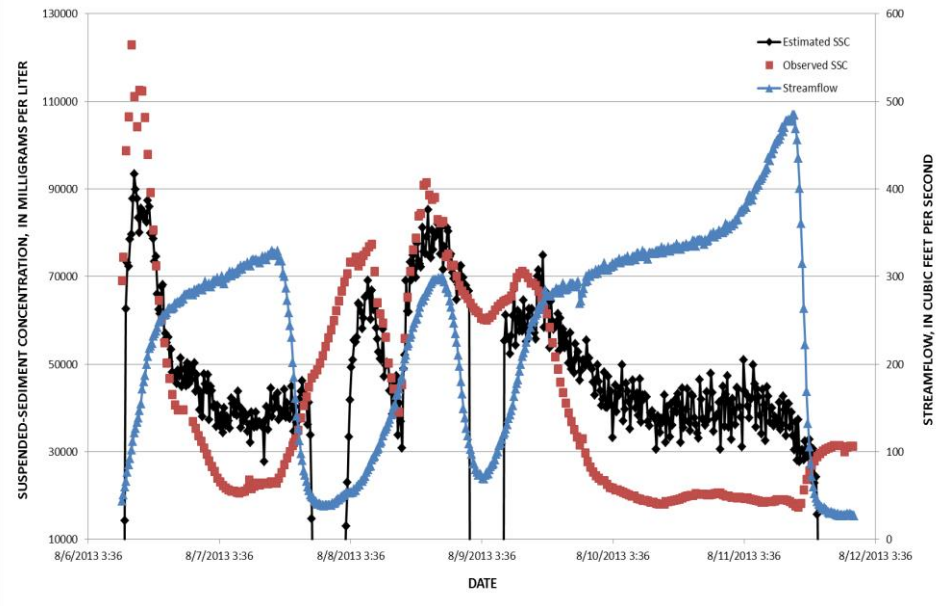

Figure 5 Estimated and observed suspended-sediment concentration and streamflow for August 6 – 12, 2013, at the Rio Puerco near Bernardo, NM, study site. The two periods near August 8 – 9 where estimated SSC drops below the x-axis were due to the water surface receding below the upper orifice during those periods.

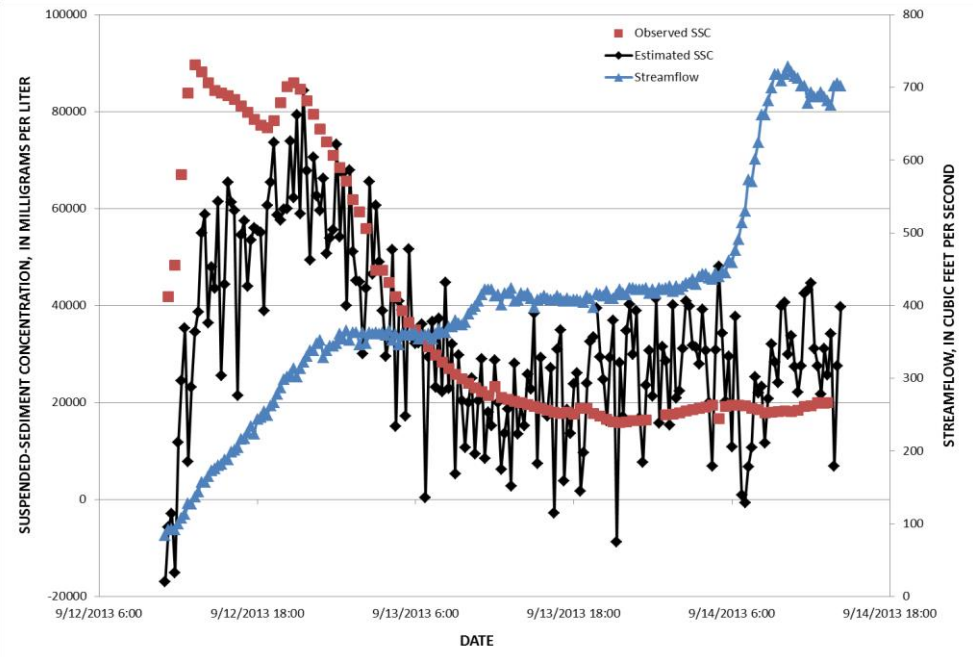

Figure 6 Estimated and observed suspended-sediment concentration and streamflow for September 12 – 14, 2013, at the Rio Puerco near Bernardo, NM, study site.

The data collected from the 14 periods of runoff were analyzed to identify and eliminate probable outliers. The resulting paired data—observed SSCs with estimated SSCs—were used to create a simple linear regression model (Helsel and Hirsch, 2002). Figure 7 shows the scatterplot; resulting ordinary least squares regression line; R^2; and the number of paired samples used in the regression. The coefficient of determination of 0.74 suggests that a reasonable correlation between estimated and observed SSC exists.

These data indicate that the densimetric suspended-sediment surrogate technology provides unequivocally superior estimates of SSC compared to estimates derived from a suspended-sediment-transport curve developed from streamflow and concentration data for the site (Porterfield, 1972; Gray and Simões, 2008). Because there is little correlation between streamflow and SSC at this site, it is difficult to accurately estimate SSC using the transport curve (figure 8).

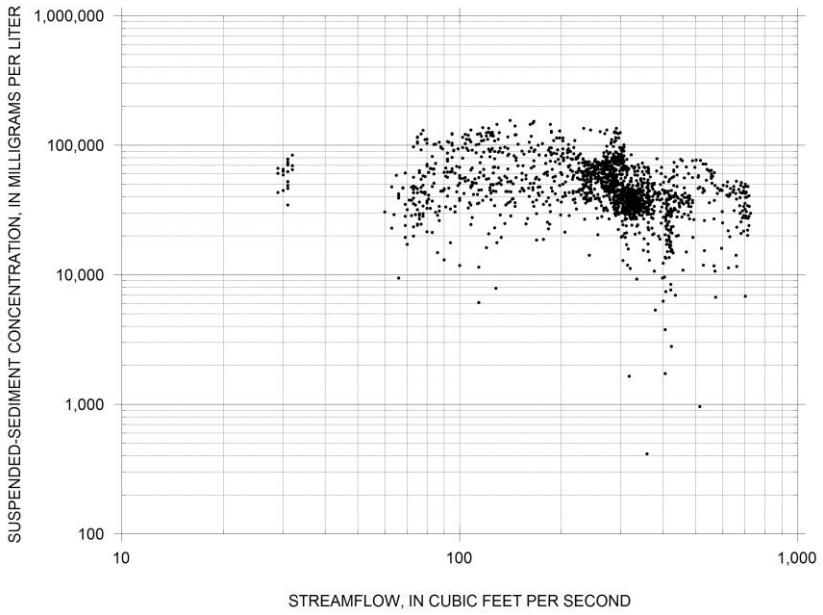

Figure 8 Scatterplot comparing observed suspended-sediment concentration to streamflow from paired data at the Rio Puerco near Bernardo, NM, study site during July to September, 2013.

CONCLUSION

The densimetric surrogate technology for continuously monitoring SSCs was developed to address a monitoring niche unfulfilled by any other surrogate technology: to provide reliable SSC data in fluvial systems that convey high-to-hyperconcentrated SSCs. Tests of the relation between densimetric and observed SSC values in New Mexico's Rio Puerco—renowned for conveying some of the largest SSCs in the world—in July-September 2013 during runoff from monsoonal storms yielded an R^2 of 0.74.

Much of the uncertainty in densimetric measurements is likely attributed to site-specific issues including turbulence at and below the water surface, the presence of low SSCs, and sufficient depth to achieve a computationally useful ratio of depth over the top orifice to depth over the lower orifice. In spite of the moderate accuracy of the technology as indicated by the R^2 of 0.74, two key characteristics – the temporal continuity of the technology and saturation-free performance – make this a valuable technology for monitoring sediment-laden streamflows.

The study results indicate that the densimetric technology is capable of providing an empirically derived SSC time series that is, or at least can be superior to those derived from a transport curve when SSC values exceed about 10,000 mg/L. The other sediment-surrogate technologies described by Gray and Gartner (2009) saturate at SSCs lower than or within the same approximate range at which the densimetric technique becomes effective. Hence, the densimetric technique is a demonstrably reliable method for monitoring highly concentrated and hyperconcentrated streamflows at the Rio Puerco site. Additional deployments of the densimetric technology are recommended at other rivers that episodically convey SSCs exceeding 10,000 mg/L to further test this technology and to produce continuous records of suspended-sediment transport where no reasonable alternative is available.

LARGE RIVER BED SEDIMENT CHARACTERIZATION WITH LOW-COST SIDESCAN SONAR: CASE STUDIES FROM TWO SETTINGS IN THE COLORADO (ARIZONA) AND PENOBSCOT (MAINE) RIVERS

Daniel Buscombe, Research Geologist, Grand Canyon Monitoring and Research Center, Southwest Biological Science Center, USGS Flagstaff, AZ, dbuscombe@usgs.gov;
Paul E. Grams, Research Hydrologist, Grand Canyon Monitoring and Research Center, Southwest Biological Science Center, USGS Flagstaff, AZ, pgrams@usgs.gov;
Theodore S. Melis, Physical Scientist, Grand Canyon Monitoring and Research Center, Southwest Biological Science Center, USGS Flagstaff, AZ, tmelis@usgs.gov;
Sean M.C. Smith, Assistant Professor, School of Earth and Climate Sciences, University of Maine, Orono, ME, sean.m.smith@maine.edu

Mapping subaqueous riverbed sediment grain size across channels and in nearshore areas typically used by fish and benthic invertebrates is difficult where and when the water flow is too swift or deep to wade yet impractical to access with large boats and instruments. Fluvial characteristics can further constrain sampling options, particularly where flow depth, water column turbidity or channel bottom structure prohibit use of aerial or bottom deployed imaging platforms.

Sidescan sonar returns that image swaths of the bed from a vessel have the potential to meet the technical shortfall confronting bed sediment change detection in large rivers. Inexpensive, easy to use sonar devices designed to be mounted to small durable vessels are commercially available. They are lightweight and have low power demands, providing opportunities for use in a large range of rivers by one or two personnel. The modern sidescan transducers are low profile and require minimal draft, making them suitable for imaging in very shallow water. Swath mapping using these devices has the potential to rapidly map bed sediments, structural features and large woody debris, with minimal logistics and cost. Coupled with a GPS or other type of vessel tracking, they can produce geo-referenced images of the acoustic returns and relate spatial variations in the signal ('bed texture') to the grain size of the bed surface sediments and structural changes (Figure 1).

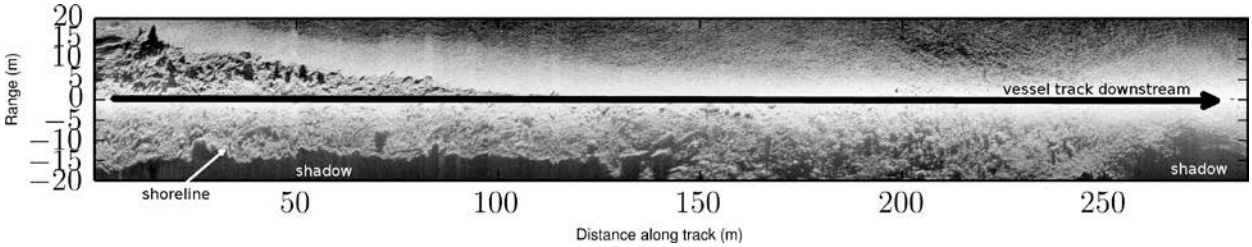

Figure 1 An example merged (port and starboard) sidescan sonar echogram. The transducer sends out a high-frequency (typically several hundreds of kHz) acoustic beam perpendicular to the vessel heading on either side (positive ranges are port and negative ranges are starboard) and records the amplitude of the returning echoes from a wide swath. One ping constitutes the simultaneous acquisition of data from the two sidescan beams at an instant, returning a swath composed of pixels whose intensity relates to the echo strength, determined by the acoustic impedance and reflection at those locations. A small strip of the bed is imaged with each ping,

building an echogram that provides near continuous coverage as the vessel moves slowly along-track (up or downstream).

The typical spatial resolution (pixel size) of a sonar signal return varies from decimeters to meters depending on range and acoustic parameters. The acoustic texture relates to morphological form roughness rather than the grain-scale roughness. The strength of the returned echo is a function of the bed sediment composition. A harder surface with greater acoustic impedance, such as bedrock and cobbles, will return more acoustic energy than a softer bed such as sand. The predictable relation between the sonar signal, acoustic texture and substrate properties provides a basis to distinguish dominant grain sizes and structures of a sedimentary environment (Figure 2).

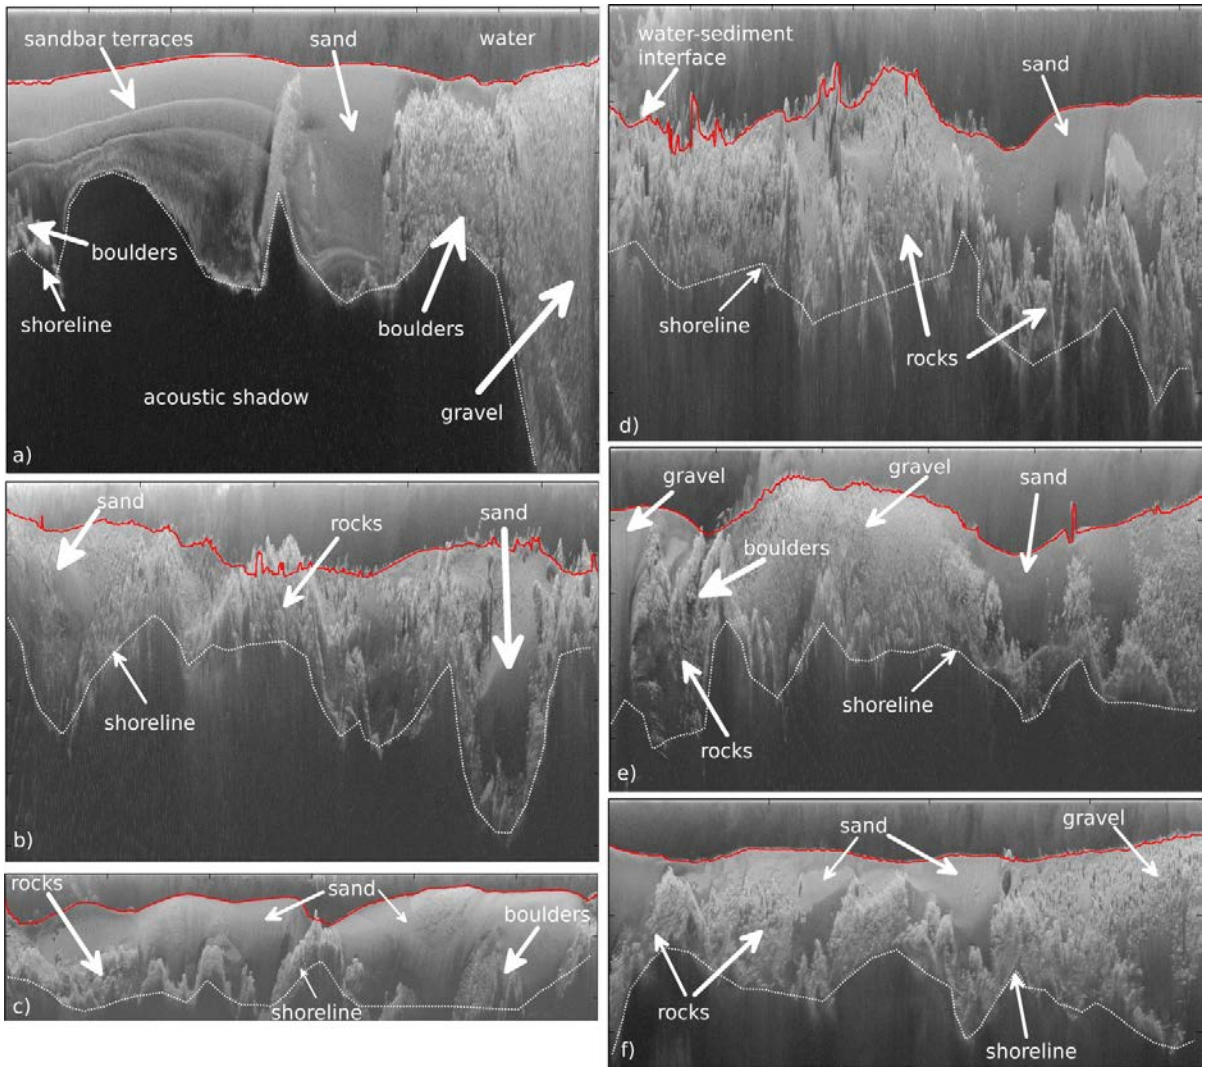

Figure 2 Examples of raw starboard sidescan sonar echograms (left to right, upstream to downstrean) collected with a Humminbird® instrument. The top of each image is the water column, and the bottom the acoustic shadow caused by the shoreline. Some sediment types have been identified. The label ‘rocks’ refers to bedrock outcrops. The line delimiting the water and the bed has been detected automatically. The challenge is to develop an automated means to

classify, in a robust manner, sediments that can be recognized by a trained eye. ®, Any use of trade, product, or names is for descriptive purposes only and does not imply endorsement by the U.S. government.

Here we discuss considerations in the use of sidescan sonar for riverbed sediment classification using examples from two large rivers, the Colorado River below Glen Canyon Dam in Arizona and the Upper Penobscot River in northern Maine (Figure 3). These case studies represent two fluvial systems that differ in recent history, physiography, sediment transport, and fluvial morphologies. The bed of the Colorado River in Glen Canyon National Recreation Area is predominantly graveled with extensive mats of submerged vegetation, and ephemeral surficial sand deposits exist below major tributaries. The bed is imaged periodically to assess the importance of substrate type and variability on rainbow trout spawning and juvenile rearing habitats and controls on aquatic invertebrate population dynamics. The Colorado River bed further below the dam in Grand Canyon National Park is highly dynamic. Tributary inputs of sand, gravel and boulders are spatially variable, and hydraulics of individual pools and eddies vary considerably in space and in response to varying dam operations, including experimental controlled flood releases to rebuild eroding sandbars. The bed encompasses the full range of non-cohesive sediments, deposited in complicated spatial patterns. The mobile portion of the Penobscot River is generally more uniform, and consists predominantly of embedded gravels interspersed between bedrock outcrops with small isolated sand patches in sections with modest or low gradients. Patches of large cobbles, boulders and bedrock outcrops are present in the lower reaches of the river near locations of two recent dam removal projects but are of limited extent below the "head of tide" on the river. Aggregations of coarse materials often correspond to locations with abrupt bed elevation drops in the Upper Penobscot River.

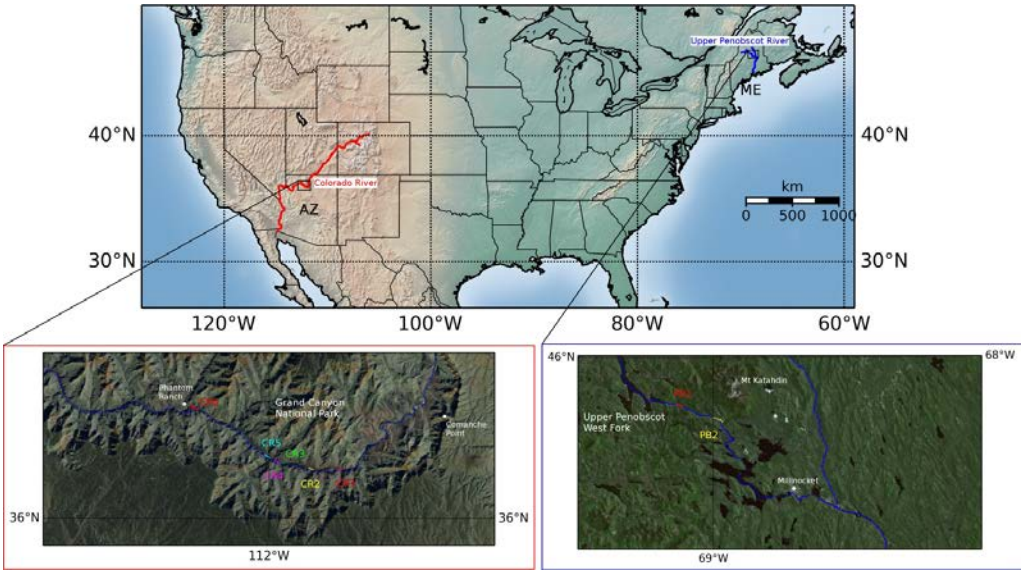

Figure 3 Location of the Colorado and Penobscot Rivers an d some sampling reaches (inset). The sites that will be discussed in this presentation are PB1 and PB2 on the Penobscot and CB1 through 6 on the Colorado.

First, we discuss data collection 'best practices' based on experience in varied environments. Second, we relate uncertainties in instrument positioning and boat attitude (heading and pitch) to sidescan bed-sediment texture measurements. Third, we present methods to relate raw echoes to backscatter amplitudes (in dB Watts) and acoustic impedances by correcting for transmission, spreading and absorption losses, the sonar footprint and instrumental factors such as time-varying transducer power. Fourth, we discuss the merits (and some pitfalls) of likely approaches to automated bed-sediment classification from sidescan imagery, such as textural classification based on machine learning and spectral signal decomposition. Finally, we present a promising spectral technique for automated sediment classification from sidescan echograms (Figure 4). The recursive application of the wavelet transform over small overlapping windows of the echogram provides a robust measure of variation in wavelengths of alternating patterns of strong and weak echoes. The greater this variation, the more textured the echogram and the coarser the substrate. The method provides an objective quantification of textures in physical units (length), for the purpose of riverbed sediment classification. We will evaluate this method using data from all contrasting case study sites.

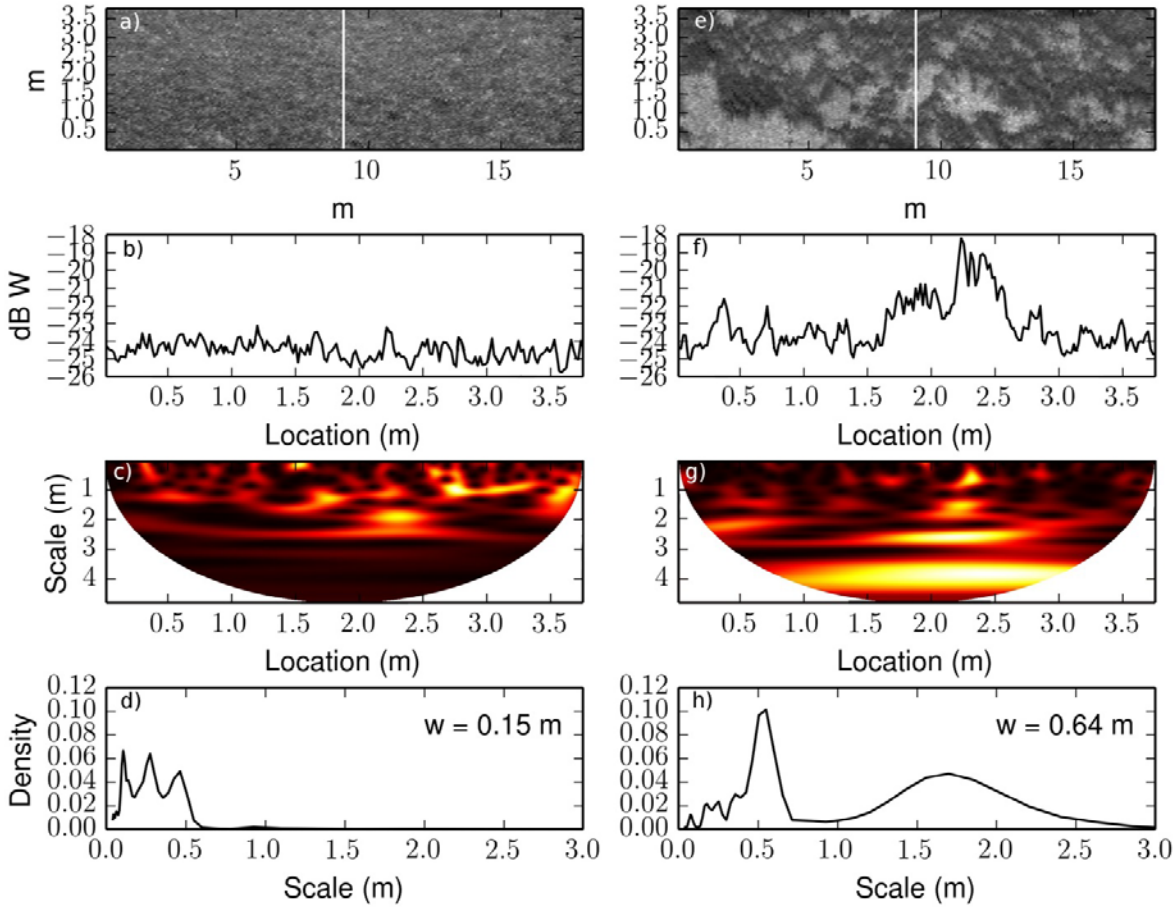

Figure 4 Example analysis of a small patch of homogeneous echogram texture: (a) a 200 x 200 pixel (~4 x 17m) window showing the textural signature from small well-sorted gravel at site in PB1 (Figure 3); (b) the trace through the white line in (a); (c) the continuous wavelet transform

of the data in (b) showing areas of high spectral power in lighter shades and low spectral power in darker shades; and (d) the normalized autospectral variance derived from (c) which shows spectral energy in a narrow band of scales. Panels e) through h) are the same for a 200 x 200 pixel (~4 x 17m) window showing the textural signature from small boulders at the same site. These different signatures for different substrate types are used to classify sediments in an objective and fully automated fashion.

RESERVOIR SUSTAINABILITY WORKSHOP AND NATIONAL RESERVOIR SEDIMENTATION TEAM

Timothy J. Randle, Supervisory Hydraulic Engineer, trandle@usbr.gov; Sean Kimbrel, Hydraulic Engineer, skimbrel@usbr.gov; and Kent L. Collins, Hydraulic Engineer, kcollins@usbr.gov; Bureau of Reclamation, Sedimentation and River Hydraulics Group, Denver, Colorado

ABSTRACT

A Reservoir Sustainability Workshop with national and international specialists was convened in Lakewood, Colorado, July 10-12, 2012 to develop and describe practical solutions for managing sediment for long-term reservoir sustainability. The workshop was sponsored by the Federal Advisory Committee on Water Information, Subcommittee on Sedimentation and the U.S. Society on Dams.

One of the recommendations made during the workshop was to form the National Reservoir Sedimentation Team. The Subcommittee on Sedimentation adopted this recommendation and formed this new team to provide short-course training on reservoir sedimentation and sustainability, provide web-based resources for agencies and the public, recommend interagency protocols for web-based storage and retrieval of reservoir survey datasets, encourage storage of reservoir capacity and sedimentation data in the national reservoir database RESSED, and formulate a white paper on reservoir sedimentation and sustainability.

INTRODUCTION

All rivers transport sediment of various sizes (e.g., clay, silt, sand, gravel, cobbles) and rates. Therefore, reservoirs located on a stream channel accumulate sediment over time unless sediments are trapped by an upstream reservoir. Coarser sediments (sand, gravel, and cobble) entering the reservoir deposit first and often form a delta at the upstream end of the reservoir (Figure 1). The formation of a reservoir delta depends on a significant supply of coarse sediment and the reservoir operating level (Morris and Fan, 1998). Finer sediments (clay and silt) deposit farther downstream along the reservoir bottom. Sediment often accumulates at all elevations of the reservoir. Outlets at most federal dams were typically designed to remain above the sediment accumulation during the first 50 or 100 years of operation (sediment design life). The rate of sediment accumulation depends on the upstream sediment supply and the trap efficiency of the reservoir.

RESERVOIR SEDIMENTATION IMPACTS

One of the most obvious impacts from reservoir sedimentation is the loss of water storage capacity (Figure 2), which will eventually lead to the reduced reliability of water supply and power. Reduced reliability will have the largest impact in regions exposed to multiple-year droughts, which may be exacerbated by the effects of climate change. Other serious impacts often occur long before the reservoir completely fills with sediment:

- Burial of dam outlets, water intakes, boat marinas, and boat ramps (Figure 3).
- Reduction in surface area for recreation (Figure 4).
- Increased dam safety risks from sediment loads against the dam, abrasion of outlets and spillways, and loss of functioning outlets (Figure 5).
- Degradation of the downstream channel bed and stream-bank erosion (Figure 6).
- Alteration of downstream channel and riparian habitat (Figure 7).
- Aggradation of upstream channels, which can lead to reduced conveyance capacity, increased flooding stage, and increased ground water table (which can cause waterlogging and soil salinization).

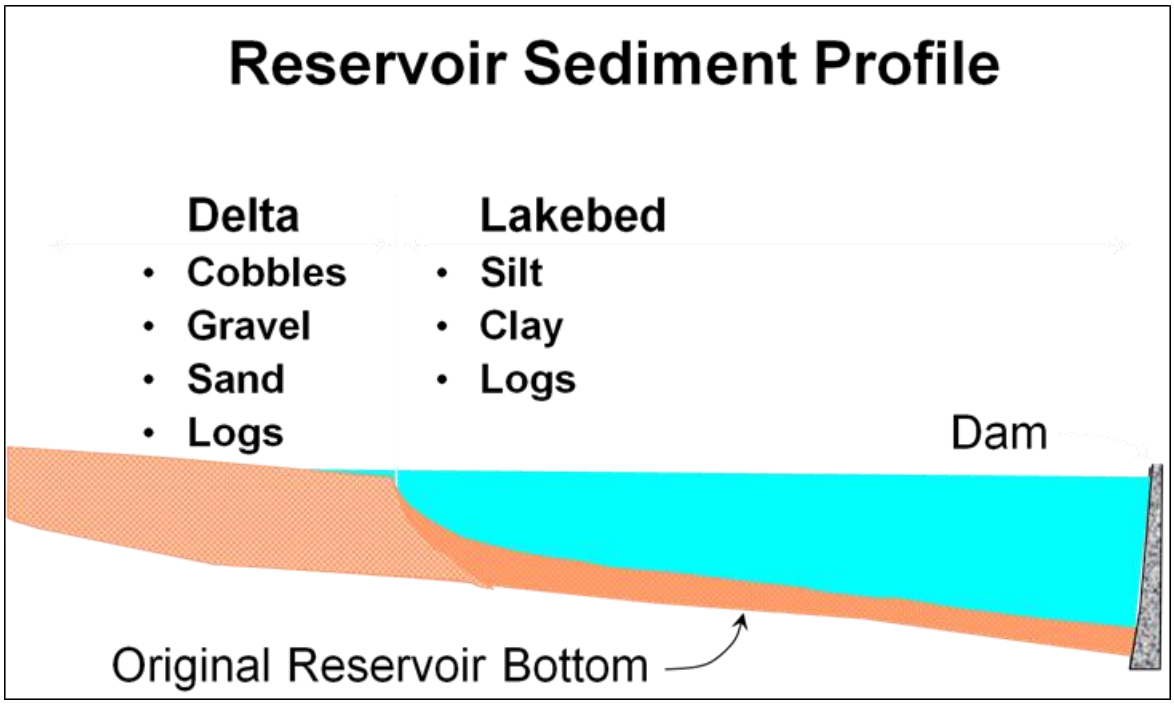

Figure 1 Typical longitudinal profile of a reservoir with a delta and lake bottom sediment deposits.

RESERVOIR SUSTAINABILITY WORKSHOP

The future project benefits of the nation's reservoirs are threatened by continued sedimentation. Therefore, a workshop of national and some international specialists was convened in Lakewood, Colorado, July 10-12, 2012 to discuss potential solutions to reservoir sedimentation (Randle and Collins, 2013). The workshop objective was to develop and describe practical options for managing sediment for long-term reservoir sustainability in the United States. The workshop was organized and sponsored by the Federal Advisory Committee on Water Information, Subcommittee on Sedimentation (SOS) and the U.S. Society on Dams, Hydraulics of Dams Committee. The Subcommittee on Sedimentation provided some financial support for the workshop.

The three-day workshop consisted of a series of sessions. Each session began with an invited lecturer (Figure 8) followed by four separate and concurrent small-group discussions that focused on specific questions. The small groups gave everyone an opportunity to provide input and allowed different groups to concurrently address different questions (Figure 9). Afterward, all participants reconvened for a summary of the four small group discussions. The questions that the small groups focused on are listed below:

- What are impacts associated with reservoir sedimentation?
- What are useful categories of reservoir sedimentation?
- What are the reservoir sediment monitoring recommendations?
- What are the effective reservoir sustainability methods?
- When are specific sustainability methods most applicable?
- What are the environmental effects of reservoir sediment management?
- What further research is needed and what are the priorities?

Figure 2 Sedimentation has almost completely filled the reservoir behind Matilija Dam near Ventura, California.

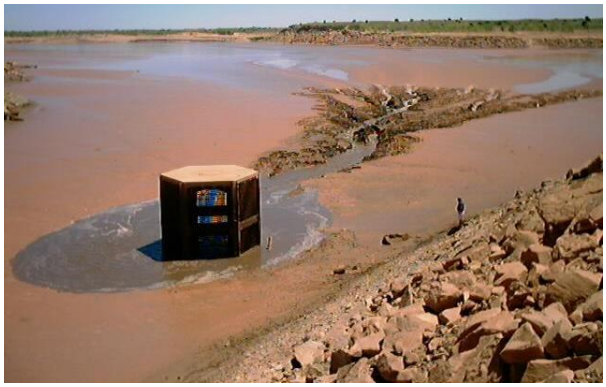

Figure 3 Reservoir sedimentation has impaired the outlet at Sumner Dam near Fort Sumner, New Mexico.

Figure 4 The reservoir delta has reduced the surface area available for recreation at Lake Powell near Hite, Utah.

Figure 8 Invited lecturers help to introduce each workshop topic.

Figure 9 Small group breakout sessions were used to concurrently discuss different aspects of each workshop topic.

The workshop was kept to a manageable size by inviting the following organizations with expertise in managing reservoirs and sedimentation:

- Subcommittee on Sedimentation Member Organizations
  - U.S. Army Corps of Engineers (Meg Jonas, Dan Pridal, John Remus, Jerry Webb)
  - U.S. Department of Agriculture
    - Agricultural Research Service (Matt Römkens)
    - Natural Resources Conservation Service (Kerry Robinson)
  - U.S. Department of the Interior
    - Bureau of Land Management (Robert Boyd, Andrew Moss, Dan Staton)
    - Bureau of Reclamation (Michael Beus, Kurt Brown, Kent Collins, Ron Ferrari, Blair Greimann, David Harpman, Victor Huang, Sean Kimbrel, Cassie Klumpp, Yon Lai, Jan Oliver, Tim Randle)
    - Geological Survey (John Gray, Kyle Juracek)
    - National Park Service (Patrick Mangan)
  - Environmental Protection Agency (Gina Christiano)
  - American Society of Civil Engineers (Tim Randle)
  - Colorado Water Resources Institute (Amanda Cox)
- U.S. Society on Dams, Hydraulics on Dams Committee (Marty Teal)
- North Fork Water Conservancy District (Tom Alvey, Trey Denison, Bruce Marvin)
- Los Angeles County Flood Control District (Chris Stone)
- Universities
  - Brigham Young University (Rollin Hotchkiss)
  - Colorado State University (Amanda Cox)
  - Kyoto University (Tetsuya Sumi)
  - Oregon State University (Desirée Tullos)
  - Stanford University (Tom Zigterman)
  - University of South Carolina (Enrica Viparelli)
- Consultants
  - Golder Associates Inc. (George Annandale)
  - Gregory L. Morris Engineering (Greg Morris)
  - WEST Consultants, Inc. (Marty Teal)

The following lectures were provided to introduce each workshop session and stimulate subsequent discussions among the small breakout groups:

- Reservoir Sedimentation Keynote Lecture (Gregory Morris, GLM Engineering)
- Sustainable Water Supply: Policy Implications (George Annandale, Golder Associates)
- Reservoir Sedimentation Categories (Kent Collins, Reclamation)
- Frequency and Extent of Reservoir Sediment Monitoring and the REServoir SEDimentation (RESSED) database (John Gray, USGS)
- Data Collection Technologies (Ron Ferrari, Reclamation)
- Reservoir Sustainability Options (Tetsuya Sumi, Kyoto University)
- Applicability and Cost of Reservoir Sediment Management Options (Rollin Hotchkiss, Brigham Young University)
- Elwha River Restoration Sediment Management (Tim Randle, Reclamation)
- Environmental Effects of Reservoir Sediment Management Options (Kyle Juracek, USGS)
- Modeling Turbidity Currents (Yong Lai, Reclamation)

RESERVOIR SUSTAINABILITY SOLUTIONS

Several categories of reservoir sustainability solutions exist. Combinations of reservoir sediment management methods may be needed to achieve sustainability:

- Watershed land-use practices can reduce the sediment yield entering a reservoir. A wide range of methods can be employed that reduce landslides (Figure 10), soil erosion, and stream-bank erosion.

- Sediment bypass around the reservoir would keep sediments from entering the reservoir. For example, an upstream diversion weir could be constructed to divert river flows with high sediment concentrations into a tunnel or pipe that conveys the sediment around the reservoir and past the dam (Figure 11).
- Passing inflowing sediments through the reservoir also would limit sediment deposition. The venting of turbidity currents through a low-level outlet in the dam (Figure 12) or drawing the reservoir down during periods of high sediment inflow would pass sediment through the reservoir.
- Sluicing of sediment during partial reservoir drawdown would help evacuate sediments near the sluice gates.
- Flushing of sediments previously deposited in the reservoir would help recover storage capacity. Emptying the reservoir is necessary to increase the flow velocity and sediment transport capacity through the reservoir (Figure 13). Downstream sediment concentrations can be very high during flushing.

Figure 10 Landslide stabilization in Japan reduces the watershed sediment yield.

Figure 11 A tunnel was constructed along the Miwa Reservoir in Japan to bypass river flows with high sediment concentration.

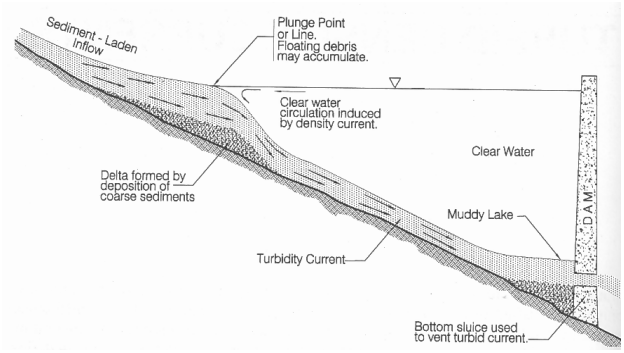

Figure 12 Sediment laden inflows can form a turbidity current along the reservoir bottom and it may be possible to vent this high sediment concentration through a low-level outlet in the dam (Morris and Fan, 1998)

Figure 13 Lowering the reservoir can result in the erosion and downstream flushing of sediments (Lake Aldwell behind Elwha Dam, Washington).

- Sediment removal also would help recover storage capacity. Sediment can be removed by hydraulic dredging (Figure 14), mechanical dredging (Figure 15), and dry excavation. Sediments can be conveyed from the reservoir by sediment slurry pipeline, truck transport, or conveyor belt. Removed sediments can be discharged into the downstream river channel or delivered to a disposal site.

Some sediment management methods would affect reservoir storage operations:

- Flushing that is implemented during the non-flood season by complete reservoir drawdown.
- Sluicing that is implemented during the flood season with partial or full reservoir drawdown.
- Dry excavation, which requires emptying reservoir and using conventional excavation equipment to remove sediment.

Figure 14 Hydraulic dredging of reservoir sediments for transport through a sediment slurry pipeline (Strontia Springs Reservoir, Colorado).

Figure 15. Mechanical dredging of reservoir sediments and transport by truck (Japan).

Other sediment management methods would have much less effect on reservoir storage operations:

- Upstream check dams.
- Bypassing sediment through or around the reservoir.
- Density current venting.
- Hydraulic dredging.
- Barge-based mechanical dredging.
- Hydrosuction sediment removal systems.
- Pressure sluicing under a full reservoir to remove sediment near the outlet.

WORKSHOP FINDINGS

Overview Findings:

- Continued reservoir sedimentation will eventually eliminate or substantially reduce the benefits for which the reservoirs were authorized, designed, and constructed. Sediment management alternatives exist to achieve sustainable reservoir management. The cost of these alternatives is not well known, but failure to manage reservoir sediment will eventually result in substantial dam decommissioning costs and either the loss of project benefits or increased costs of future water storage.
- Federal reservoirs are functioning as originally authorized and designed, which also means they trap sediment that is naturally transported by all rivers and streams. Policy makers likely are not aware that the numerous benefits provided by the nation's reservoirs are not sustainable over the long term without sediment management.
- Population increases over time will result in increased demand for water supply while reservoir storage capacity is being reduced due to sedimentation.
- In some regions, climate change may lead to increased hydrologic variability. Increased variability will reduce water supply reliability during droughts and increase rates of reservoir sedimentation during floods, which also reduces reservoir reliability.
- The present course of reservoir sedimentation will result in lost opportunities for future generations, force them to pay for dam decommissioning, and force them to choose more expensive water storage alternatives than those that were available to previous generations.

- Economic analysis of reservoir sediment management needs to account for inter-generational equity, the future value of reservoir storage, and the eventual dam decommissioning cost if no action is taken. A life-cycle design approach for reservoirs would promote sustainability over the traditional design-life approach.
- A great deal is known about reservoir sedimentation processes. More research is still needed, but enough is known to start addressing the problem.

Reservoir Sediment Monitoring:

- Reservoir sediment monitoring and reporting is needed to track and forecast sedimentation. A publicly available and updatable reservoir sedimentation database is also needed Reservoirs should be surveyed at minimum intervals based on the rates of sedimentation. Reservoirs should also be surveyed after significant inflow floods (e.g., after 10-year flood peak or greater).
- Reservoir sediment survey costs have substantially decreased over the past few decades while the quantity and precision of the data have greatly improved.
- Capabilities to continuously measure sediment transport through surrogate technologies (e.g., hydro-acoustics, turbidity) have also improved over time.

Reservoir Sustainability Solutions:

- Each reservoir sediment management method has a range of applicability. Guidelines are needed to help determine the most applicable sediment management method (or combination of methods) for a given reservoir.
- For each reservoir, eventually develop a plan for either long-term sustainability or decommissioning. Watershed and reservoir demonstration sites are needed to collect data, and test methods and models.
- Reservoir sediment monitoring data are needed to measure sedimentation rates and determine management priorities. Sediment monitoring data should include the volume and spatial distribution within the reservoir, grain size, bulk density, chemical composition, and cohesive properties.
- Environmental problems associated with reservoir sediment can be managed or mitigated with sufficient investigation and understanding of physical, chemical, and biological processes. Lack of understanding will result in unintended consequences.

Sediment Management Research Needs:

- Develop techniques or methods to reduce sediment measurement costs and improve the efficiency of measurements for sediment inflow and thickness within the reservoir, grain size, bulk density, and chemical characteristics.
- Develop methods or models to assess the effectiveness of watershed land-use practices.
- Develop reservoir sediment models to simulate turbulence and sediment entrainment, turbidity currents, and downstream effects.
- Develop improved design methods for dam outlets and bypass tunnels or pipes. Important topics would include the entrainment of sediment into outlets, controlling abrasion, and allowing for maximum reservoir drawdown.
- Develop improved methods for the treatment of contaminated sediment both in situ and at off-site locations.
- Develop improved understanding of how various species of fish or other aquatic organisms respond to periods of high sediment concentration.
- Develop economic analysis methods that account for intergenerational equity and the future value of water storage.
- Explore financial opportunities to pay for reservoir sediment monitoring and management.

NATIONAL RESERVOIR SEDIMENTATION TEAM

Based on the recommendations from the Reservoir Sustainability Workshop, the Subcommittee on Sedimentation has formed the National Reservoir Sedimentation Team (NRST), which is comprised of representatives from the Bureau of Reclamation, U.S. Army Corps of Engineers, other SOS-member organizations, universities, and consultants (Table 1 and Figure 16).

The Objectives and Mission of the NRST are listed below:

- Provide training on reservoir sedimentation and sustainability.
- Provide publically available web-based resources.
- Develop interagency protocols for web-based storage and retrieval of reservoir survey datasets.
- Encourage storage of sediment survey data in the national reservoir database RESSED.
- Formulate a white paper on reservoir sedimentation and sustainability.

Table 1 Founding members of the National Reservoir Sedimentation Team.

Name	Title	Organization
Mustafa Altinakar	Director and Research Professor, National Center for Computational Hydroscience and Engineering	University of Mississippi
Paul Boyd	Hydraulic Engineer, River and Reservoir Engineering Section	U.S. Army Corps of Engineers
Kent Collins	Civil Engineer (Hydraulics), Sedimentation and River Hydraulics Group	Bureau of Reclamation
Deborah Cooper	Research Hydraulic Engineer, River Engineering Branch	U.S. Army Corps of Engineers
Darrell Eidson	Hydraulic Engineer, Hydrology and Hydraulics Branch	U.S. Army Corps of Engineers
Ron Ferrari	Civil Engineer (Hydraulics), Sedimentation and River Hydraulics Group	Bureau of Reclamation
Rollin Hotchkiss	Professor and Chair, Department of Civil and Environmental Engineering	Brigham Young University
Meg Jonas	USACE	U.S. Army Corps of Engineers
Kyle Juracek	Research Hydrologist, Kansas Water Science Center	U.S. Geological Survey
Sean Kimbrel	Civil Engineer (Hydraulics), Sedimentation and River Hydraulics Group	Bureau of Reclamation
Matt Kondolf	Dept Landscape Architecture and Environmental Planning	University of California, Berkeley
Greg Morris	President	Gregory Morris Consultants
Peter Nelson	Colorado Water Resources Research Institute (CWRRI)	Colorado State University
Tim Randle	Reclamation Manager, Sedimentation and River Hydraulics Group	Bureau of Reclamation
Rene Vermeeren	Chief, Hydrology and Hydraulics Branch	U.S. Army Corps of Engineers
Frank Weirich	Iowa Institute of Hydraulic Research, Hydroscience and Engineering	University of Iowa

The NRST is currently focused on the first objective, which is training of reservoir sedimentation and sustainability provided through short courses or workshops, such as the Federal Interagency Sedimentation Conference and other times when possible. These short courses and workshops would be open to the public.

The next objective of the NRST is the development of web-based resources to be posted on the SOS website. These web-based resources would include the following types of information:

- Answers to frequently asked questions

- Protocols for answering new questions posed by the public
- Photo gallery
- Bibliography and publications

Figure 16 Photograph of National Reservoir Sedimentation Team members. Standing left to right are Rollin Hotchkiss, Deborah Cooper, Frank Weirich, Peter Nelson, Sean Kimbrel, Ron Ferrari, Meg Jonas, Tim Randle, Darrell Eidson, Paul Boyd, Kyle Juracek, Mustafa Altinakar, and Rene Vermeeren. Seated left to right are Greg Morris and Matt Kondolf.

The third objective of the NRST is to develop interagency requirements for web-based storage and retrieval of reservoir survey datasets. NRST members will brainstorm ideas to encourage the storage of sediment survey data in the national reservoir database RESSED.

As part of the fourth objective, the SOS website (http://ida.water.usgs.gov/ressed/) and RESSED database are excellent tools for acquiring, summarizing, and sharing information on reservoir sedimentation. Agencies and other organizations are also encouraged to make reservoir sedimentation data available to the public through RESSED. The NRST will be tasked with developing protocols for web-based storage and retrieval of reservoir survey datasets that would be hosted on individual agency web sites.

The last objective is to develop a white paper on reservoir sedimentation and sustainability to inform policy makers about the life-cycle approach to managing sediment in reservoirs.

SUMMARY AND CONCLUSION

The convening of the Reservoir Sustainability Workshop and the formation of the National Reservoir Sedimentation Team are key steps forward in the development of information and awareness about reservoir sedimentation and sustainability. The technical information and policy implications will be important for mangers of dams and reservoirs throughout the nation as they may seek to implement sustainable sediment management practices for the benefit of future generations.

PROGRESS TOWARD DEVELOPING A NATIONAL, DYNAMIC RESERVOIR-SEDIMENTATION DATABASE

John Gray, Scientist Emeritus, USGS, Office of Surface Water, Headquarters, Reston, VA
jrgray@usgs.gov

Progress toward efforts to develop publically accessible and updatable REServoir-SEDimentation survey information (RESSED) database – last described in the Proceedings of the 9th Federal Interagency Sedimentation Conference – is encouraging. Since 2009, RESSED has:

- Been successfully ported from Microsoft Access to the user- and web-friendly FilemakerPro database management system.
- A completely revised, logical, and modern schema.
- A beta-tested data-entry module.
- A quality-control function to ensure security for data-entry.
- A reports-production module.
- Data describing changes in capacities for hundreds of additional reservoirs as part of thousands of capacity surveys.
- Most reservoir capacity data available from the U.S. Army Corps of Engineers and the Bureau of Reclamation.
- Acquired permanent maintenance-level support of the U.S. Geological Survey.
- Interest and vocal support from Senior Staff, U.S. House of Representatives.

A number of challenges in the RESSED database-development effort remain. These include:

- A vexing number of ingrained, mostly historical errors in the stored data, although many errors have been identified and culled out.
- A desire expressed among some collaborators to enable porting of spreadsheet-based reservoir sedimentation data directly to RESSED, which raises a number data-transfer and data-quality issues.
- Insufficient resources to expand the development effort to include public-data entry, or to continue development of the version of RESSED envisioned to be most useful in the 21st century.

The eventual goal for the RESSED database is to provide an access for any valid user to enter and retrieve reservoir capacity-change and related data, and to interface it where advantageous with other applications, including the National Inventory of Dams, National Hydrography Dataset, and StreamStats. The time for enhancement of RESSED is now, given the need for early warning on reservoir-storage losses resulting from the inevitable and inexorable accumulation of sediment.

USACE RESERVOIR SEDIMENTATION SURVEY DATABASE (RESSED) ORACLE CONVERSION

Deborah Cooper, Research Hydraulic Engineer, US Army Engineer Research and Development Center, Vicksburg, MS, Deborah.R.Cooper@usace.army.mil

Abstract

Reservoirs are vital for providing flood risk reduction, water supply, energy generation, navigation, irrigation, recreation, and other services. Sediment deposition reduces the useful life of reservoirs, affecting their authorized function. Reservoir Sedimentation Survey Database (RESSED), a database in FileMaker Pro© (FMP) maintained by the U.S. Geological Survey (USGS), contains reservoir information from U.S. Army Corps of Engineers (USACE) districts and other federal agencies for updating and verifying data and creating reports concerning reservoir sedimentation. The data in RESSED can be used to calculate and track changes in reservoir storage characteristics, track and report current and future impacts of sedimentation, quantify sediment budgets, estimate erosion rates in a reservoir's watershed, and export data into other databases. Data captured from FMP to Oracle© provides a basic interface to view RESSED data in the CorpsMap©, an enterprise geospatial platform for USACE that is capable of communication with other data platforms. This paper will discuss the USACE-RESSED data conversion application.

INTRODUCTION

USACE manages more than 700 locks and dams that provide flood risk reduction, water supply, energy generation, navigation, irrigation, recreation, and other services. Sediment deposition (Figure 1) reduces the useful life of the reservoirs these dams produce, affecting their authorized function. More than 50% of USACE reservoirs report moderate to severe impacts of performance within their authorized function before 25% of storage capacity is lost due to reservoir sedimentation. Increasing deposition of sediment in reservoirs is recognized as a growing problem in the United States, with implications for impacts on water supply, water quality, and navigation. The 1996 National Water Quality Inventory (Section 305(b) Report to Congress) indicates that sediments are ranked as a leading cause of water quality impairment in assessed rivers and lakes (Kuhnle and Simon 2000). Quantifying the rate that sediment moves through or is deposited in a reservoir is vital to managing the nation's water resources. Reservoir sedimentation data is essential to assessing changes in reservoir capacity and future reservoir sustainability.

Locating and comparing datasets is challenging because reservoir sedimentation records are scarce, various methods of measuring can be incompatible, and the procedures may have high rates of measurement uncertainty. A *High Country News (HCN)* analysis of US Bureau of Reclamation (USBR) data provides a good example of why locating and comparing datasets is challenging. This analysis, which offers the most recent publicly accessible surveys for eight of

11 Western states, reveals that 35 USBR reservoirs have lost approximately 4.6 million acre-ft of storage capacity to sedimentation.

Figure 1 Sediment Deposition in Matilija Reservoir, CA (USBR 2010)

That's about 8% of total storage in USBR reservoirs, or enough water to serve at least nine million households. The surveys examined by *HCN* cover less than 10% of the dams managed by USBR. Other challenges are that many of USBR's surveys are two decades old and Utah was only able to locate data for 18 of its 133 reservoirs larger than 1,000 acre-ft (Weiser 2011). The lack of reservoir sedimentation data is not a state or regional issue rather it is a national issue. A standardized, web accessible database may provide more accurate data sets for analysis of the effects of sedimentation on reservoir sustainability.

The USGS manages the nation's largest reservoir sedimentation database, RESSED. RESSED, a database in FileMaker Pro© (FMP), is a comprehensive reservoir sedimentation database for U.S. reservoirs (http://water.usgs.gov/osw/ressed) containing data compiled by the Soil Conservation Service, now the Natural Resources Conservation Service (NRCS). Version 1.0 of this interactive and enhanced reservoir sedimentation survey database consists of a comprehensive compilation of reservoir information related to wet and dry surveys, storage, elevation, area capacity, reservoir operations, and other reservoir information for 1,824 large and small USACE, USBR, Tennessee Valley Authority (TVA), NRCS, and other federal, municipal, and utility agency reservoirs and lakes. The data in RESSED can be used to calculate and track changes in reservoir storage characteristics, track and report current and future impacts of sedimentation, quantify sediment budgets, estimate erosion rates in a reservoir's watershed, and can be exported into other databases.

To date, USACE districts have performed quality assurance and quality control on RESSED data. The Institute for Water Resources (IWR) is conducting ongoing research of reservoir sedimentation and the impacts of climate change on reservoir sedimentation through the Reservoir Sediment Information (RSI) research work unit and the USACE Response to Climate

Change Program. Data capture of reservoir survey and area capacity data from the USGS RESSED FMP platform became necessary to store and display reservoir information consistent with established USACE enterprise databases, such as the Corps Water Management System (CWMS) and the National Inventory of Dams (NID). Once the RESSED data was captured in CorpsMap©, USACE developed the Reservoir Sedimentation Information system production site for entering basic reservoir survey and capacity data for uploading data to RESSED. While the production site was developed with references to NID and CWMS databases, the data capture from RESSED established a platform for uploading data to RESSED. This paper will discuss the USACE-RESSED data conversion application.

RESERVOIR SEDIMENTATION INFORMATION SYSTEM PRODUCTION SITE

The Reservoir Sedimentation Information (RSI) system production site was developed by USACE to provide a comprehensive summary of USACE reservoir conditions. The overarching intent of this system is to store and display reservoir information to assist with evaluation of sedimentation trends and reservoir life expectancy with respect to a changing climate. The initial iteration of this dynamic system focuses on input and display of reservoir metadata. Reservoir information is available for viewing by all users. To edit or upload data requires the acquisition of permissions provided by an administrator.

To access the RSI production site users must:

1. Log on to https://maps.crrel.usace.army.mil/apex/f?p=303
2. Click the CAC Login button
3. Enter the 4-digit PIN

Upon logging into the system, the user will be able to view everything in the application as the read-only role of Data Reviewer. To obtain additional privileges of editing or uploading data, the user should email one of the points of contact (POC) listed on the Help tab. After emailing a RSI POC, if the user is eligible for additional privileges, the RSI Production Site team will grant the user District Data Manager (DDM) privileges based on the corresponding district. After the Production Site team grants privileges, the user will receive an email notifying him or her of a role change in RSI. The District Data Manager privilege will allow users to edit data for their specific district only, while still allowing them to view data from other districts as they did with the Data Reviewer role, i.e., the District Data Manager for the Vicksburg District can view any district's data but can only edit data for the Vicksburg District.

The RSI system production site consists of four main tabs: Home, Reservoirs, Map, and Help. Descriptions and graphic illustrations of each tab are provided below.

Home Tab

The Home tab provides introductory information on the RSI Production Site and describes each of the successive tabs (see Figure 2 below).

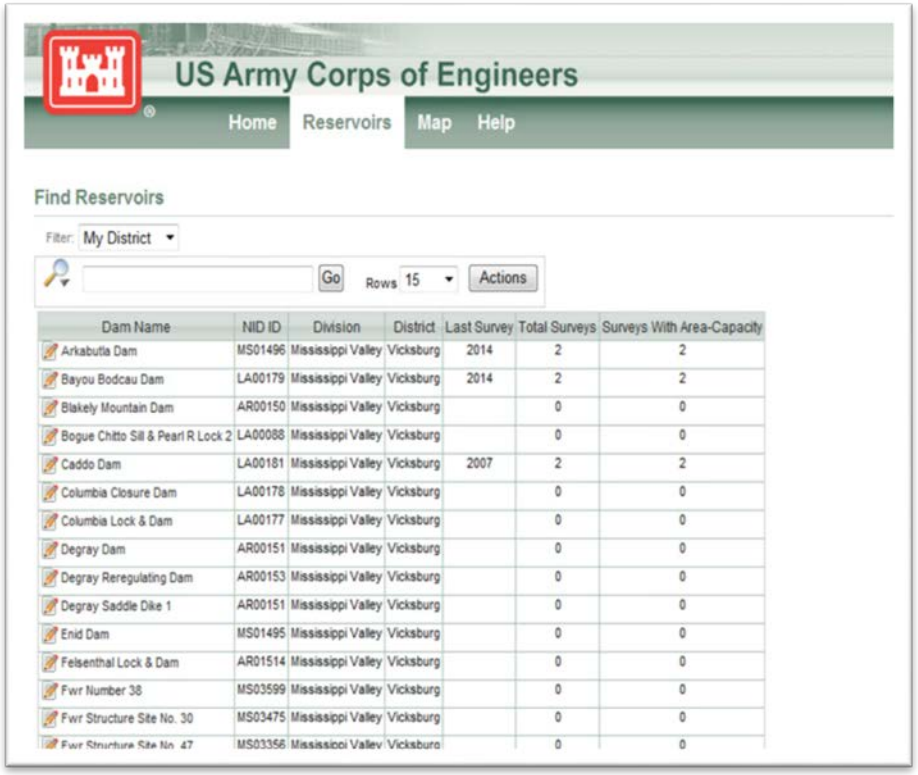

Figure 2 Reservoirs Tab

Reservoirs Tab

The Reservoirs tab allows a user to view detailed information about all USACE reservoirs listed in the NID database. The dam name, NID ID, division, and district are directly linked to the NID database and cannot be modified or edited within the RSI production site. Data associated with a particular reservoir, found in the last survey, total surveys, and surveys with area-capacity fields on the production site, can be viewed and, with special permissions, edited by the District Data Manager aligned to that particular reservoir. The dams can be filtered by an individual district or all districts. A reservoir can be located by typing the name of the reservoir in the search window and clicking "Go." The user can then click the pencil icon to view detailed information and/or enter data for the specific dam that was searched for. Five sub-tabs will appear under the Reservoirs tab: Detail, Surveys, Storage Allocation, Documents, and Graphs.

Detail Sub-Tab

The Detail sub-tab allows a user to view detailed information about a particular USACE reservoir. Information on this sub-tab is still directly linked to the NID database. A map showing the reservoir location and NID information is also displayed (shown in Figure 3 below).

Figure 3 Reservoirs Detail Sub-tab

Surveys Sub-Tab

Survey data is entered by clicking the "Add New Survey" button on the Surveys sub-tab and entering data under the Survey Detail tab (see Figure 4a below). Values with asterisks indicate mandatory fields. Clicking the "Add" button after entering all the required information displays the survey data in a table at the top of the page. Clicking the pencil icon next to an added survey and clicking a red "Upload Area-Capacity" arrow (Figure 4b) allows the user to upload Area-Capacity data for the corresponding survey. After uploading the Area-Capacity data, data can be edited in this window by clicking the pencil icon next to the row to be edited. Note that the Area-Capacity data can also be downloaded by clicking on a green "Download Area-Capacity" arrow.

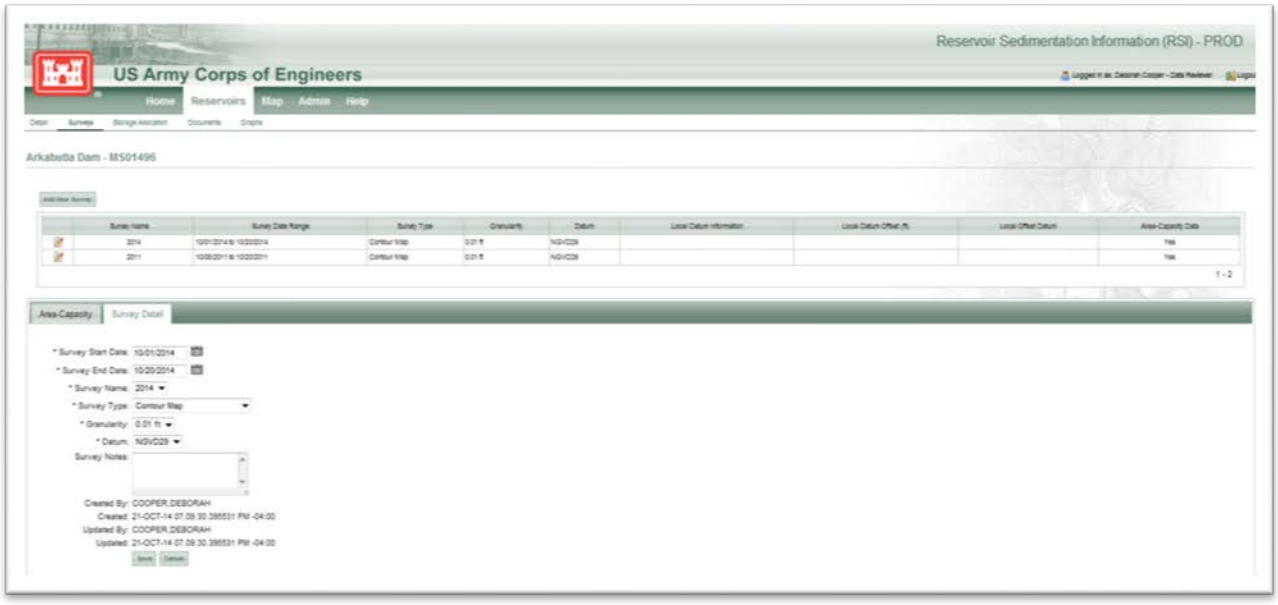

Figure 4a Reservoirs Surveys sub-tab and Survey Detail tab

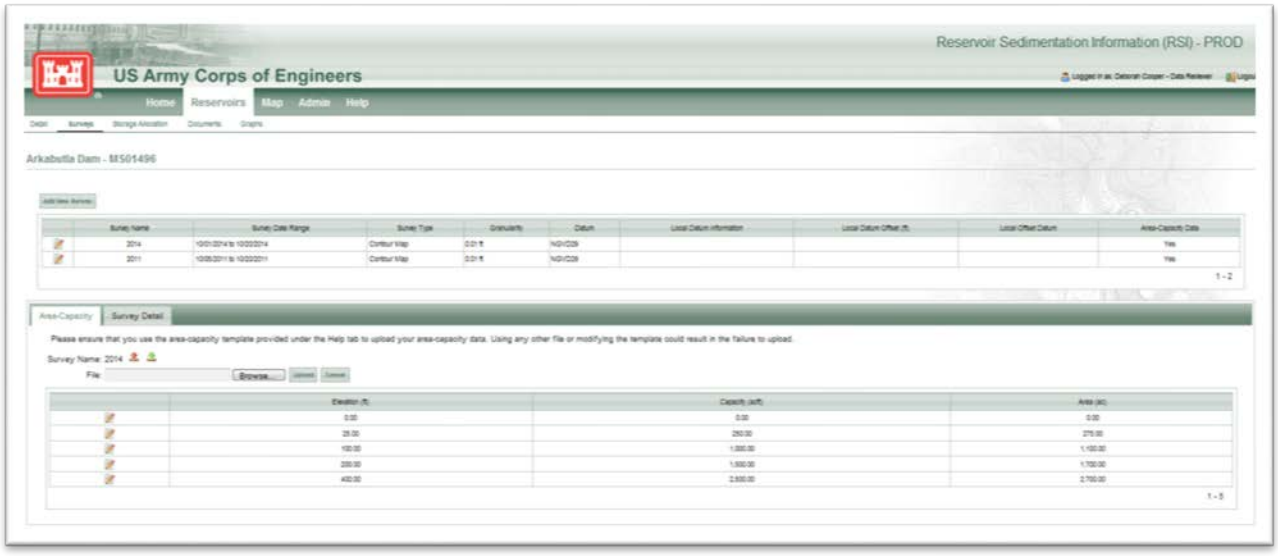

Figure 4b Reservoirs Surveys sub-tab and Area-Capacity tab

Storage Allocation Sub-Tab

Data from the Corps Water Management System (CWMS) is displayed under the Storage Allocation Tab. If reservoir data is not found in CWMS, no data will be displayed.

Documents Sub-Tab

The user can upload documents for storage under the Documents sub-tab. Area-Capacity spreadsheets, documents, images, maps, presentations, reports, videos, and other files can all be stored for retrieval on this site (shown in Figure 5 below).

Figure 5 Reservoirs Documents Sub-tab

Graphs Sub-Tab

Capacity data is plotted under the Graphs tab (shown in Figure 6 below). If the reservoir elevation data is entered in CWMS, data from the CWMS site can be plotted here as well.

Map Tab

The Map tab displays active reservoir survey data sites.

Help Tab

Technical assistance information, a RSI Quick Guide, and an Area-Capacity spreadsheet template (that must be used for uploading area-capacity data to the RSI System Production Site) are all found under the Help tab. Users must use the provided Area-Capacity template to ensure that data is properly uploaded and displayed in the Reservoirs Surveys window. To enter data for additional reservoirs, the user must begin the process again by navigating to the Reservoirs tab. On the Reservoirs tab, the user can then search for and locate another reservoir to initiate survey data input.

Figure 6 Reservoirs Graphs Sub-tab

CONCLUSION

Testing of the RSI system production site will be initiated by district input of survey and area-capacity data in FY15. The plan is to expand the site to include additional reservoir data as it becomes available, enhance the input tools, and standardize the reservoir data analysis across USACE. The RSI production site will ensure that districts can maintain the most currently available and consistent data from databases such as RESSED, CWMS, and NID. It does this by using the provided Oracle© interface to view RESSED data in CorpsMap© and as a mechanism for the USACE data platform to communicate with RESSED as well as other data platforms.

RESERVOIR SEDIMENTATION AND SUSTAINABILITY IN USACE: STATUS REPORT

Meg Jonas, Senior Hydraulic Engineer, USACE Headquarters, Engineering & Construction, Washington, DC, meg.m.jonas@usace.army.mil;

Abstract Sediment deposition in Corps reservoirs reduces the useful life and can severely impact authorized project purposes including flood risk management, hydropower, recreation, water supply, and environmental quality. Within the United States, the US Army Corps of Engineers (USACE) maintains and operates almost 400 dams and reservoirs for flood damage reduction. Sedimentation affects (or will affect) all these projects to some degree, and may be one of the most significant impediments to long-term sustainable operation. Reservoir sedimentation and sustainability are closely linked. Anticipated future conditions (decreased firm yield due to climate change, along with increased demand for water) will work in conjunction with the diminished reservoir storage due to sedimentation to reduce our reliable water supply. This paper will discuss the current status of data on Corps projects and types of impacts that have been observed. It will also cover ongoing Corps activities related to reservoir sedimentation and sustainability, including efforts that are proposed or underway at various Corps projects to mitigate the impacts of reservoir sedimentation. Activities related to reservoir sedimentation fall under multiple components of USACE. This paper will review and summarize those activities across the organization. USACE is involved in the Reservoir Sustainability Task Committee and the National Reservoir Sedimentation Team (under the ACWI Subcommittee on Sedimentation). This paper will provide an update on USACE activities related to reservoir sustainability.

INTRODUCTION

Reservoir sedimentation problems affect multiple business lines within the Corps, and related activities are funded by multiple programs. This paper will identify current ongoing efforts and stakeholders within the Corps.

RESERVOIR SEDIMENTATION SURVEYS

Reservoir sedimentation surveys are performed by each individual Corps district. Funding normally comes out of reservoir project funding. Surveys are often deferred in order to fund higher priority items. However, other funding sources may become available: funds that cannot be expended on other projects, or unusual funding sources such as ARRA. These other funding sources often have a very short window of opportunity, and the key to obtaining them is the district's ability to move quickly, that is, their readiness to take advantage of funding that comes up suddenly. Sponsors also fund surveys.

All the aspects of a reservoir sedimentation survey are determined by the district, including:

- Type of survey (range line or bathymetric)
- Extent of survey (entire flood control pool or a portion thereof)

- Use of aerial survey data to augment hydrographic survey data
- Who performs the survey (contractor or in-house staff)
- Method of data reduction, and who performs it (contractor or in-house staff)

There is significant variability among Corps districts in all aspects of reservoir sedimentation surveys.

RESERVOIR SEDIMENTATION DATABASE

USACE has been working with USGS on a reservoir sedimentation database, RESSED, to facilitate national reporting of reservoir sedimentation survey results, survey status, and other items (sediment management measures, sedimentation problems, etc.) One key element is obtaining data from each individual Corps district to populate the database.

Under the Responses to Climate Change program, the Corps is evaluating the potential impact of climate change on reservoir sedimentation. Multiple activities are being performed under this program. One activity includes reviewing available sediment information to identify data gaps and estimate the costs required to bring reservoir sedimentation information up-to-date.

CORPS PROGRAMS AND ENTITIES WITH INTEREST IN RESERVOIR SEDIMENTATION

Multiple Corps programs and entities have aspects related to reservoir sedimentation. The most significant are listed below.

Operations. The operation of each reservoir project is affected by reservoir sedimentation and related problems, which may include lack of access to boat ramps, inability to operate outlet works, blockage of water supply intakes, and other impacts.

Water Supply. Sedimentation normally has the most significant impacts on water supply storage.

Responses to Climate Change (RCC). Climate change may impact sediment yields. The RCC program has funded work on reservoir sediment information (discussed above), as well as other studies such as paired reservoir studies. A study of Coralville Reservoir by Rock Island District evaluated the impacts of storage loss due to sedimentation (under current conditions) on spillway flows for simulations of historic flood events.

Committee on Channel Stabilization. This Headquarters-level committee is composed of experts in alluvial channel processes and river engineering from throughout the Corps. Reservoir sedimentation falls under this committee's area of expertise, and the committee (or individual committee members) have been involved in many ongoing efforts.

RESEARCH AND DEMONSTRATION PROGRAMS RELATED TO RESERVOIR SEDIMENTATION

There is no program dedicated solely to reservoir sedimentation and sustainability research. The research and demonstration programs listed below cover multiple items, some of which are related to reservoir sedimentation:

- Flood Risk Management Research Area
- Regional Sediment Management
- Engineering with Nature
- Great Lakes Tributary Modeling Program

GUIDANCE RELATED TO RESERVOIR SEDIMENTATION

The following Corps guidance addresses reservoir sedimentation:

Engineer Manual (EM) 1110-2-4000, Sedimentation Investigations of Rivers and Reservoirs. Provides guidance on procedures for river and reservoir sedimentation investigations (1995, currently being updated).

Engineer Regulation (ER) 1110-2-4001, Notes on Sedimentation Activities. This regulation prescribes general requirements for submittal of annual reports on Corps of Engineers activities in the field of sedimentation (1981).

Engineer Regulation (ER) 1110-2-8153, Sedimentation Investigations. This regulation prescribes the procedure and rationale for conducting sedimentation investigations in support of the hydrologic analysis and hydraulic design of civil works projects, and environmental impact analyses (1995).

TRAINING RELATED TO RESERVOIR SEDIMENTATION

There is currently no Corps training offered related to reservoir sedimentation. Corps personnel are assisting in the short course on reservoir sedimentation and sustainability at the 2015 SedHyd conference.

EXAMPLES OF DISTRICT PROJECTS RELATED TO RESERVOIR SEDIMENTATION

The list below gives some examples of district activities.

Baltimore District, Susquehanna River Basin. Watershed assessments and sediment transport modeling have been performed to evaluate alternatives at Conowingo Dam, with the goal of protecting water quality, habitat and aquatic life in the lower Susquehanna River and the Chesapeake Bay.

Tulsa District, Neosha River. The Kansas Water Office has requested approval to dredge sediment from the conservation pool of John Redmond Reservoir in order to restore water supply storage capacity that has been lost to sedimentation.

Kansas City District, Kansas River Basin. Reservoir sustainability efforts have been initiated to evaluate alternatives for sediment management alternatives at Perry Lake and Tuttle Creek Lake.

Omaha District, Missouri River. The district is evaluating sediment flushing at Gavins Point Dam in Phase II of its Lewis and Clark Lake Sediment Management Study as part of the Missouri River Recovery Program.

Los Angeles District, Santa Ana River. Orange County Water District (OCWD) is proposing a demonstration project in which sediment would be removed from behind Prado Dam, and conveyed to the Lower Santa Ana River below the dam for re-entrainment.

INTERAGENCY ACTIVITIES RELATED TO RESERVOIR SEDIMENTATION

The Corps is represented on the ACWI Subcommittee on Sedimentation (SOS). The Corps also has representatives on the SOS working group on reservoir sedimentation and sustainability (the National Reservoir Sediment Team). The SOS passed a resolution on reservoir sustainability, which was recently approved by ACWI.

OTHER ACTIVITIES

Personnel from Omaha District are working on projects in the Mekong River Delta, along with personnel from the US Bureau of Reclamation.

SUMMARY AND CONCLUSIONS

There are many Corps activities related to reservoir sedimentation and sustainability. This is a “first cut” at listing all pertinent Corps activities, and is no doubt incomplete. Next steps include making the list of activities more complete, and improving coordination between these activities.

ANALYSIS OF EXTREME FLOOD SIGNATURE: CAN 2-D HYDRAULIC MODELING MATCH OBSERVATIONS?

Rebecca Kallio, Hydraulic Engineer, Bureau of Reclamation Technical Service Center, rkallio@usbr.gov;
Jeanne Godaire, Geomorphologist, Bureau of Reclamation Technical Service Center, jgodaire@usbr.gov

INTRODUCTION

Paleoflood hydrology is critical to the understanding of flood magnitude-frequency responses because it extends the timescale of the gaged record to include extreme floods that occurred prior to human observation. Paleoflood studies usually produce flood chronologies that can be used to improve flood-frequency analysis and flood hazard evaluations. Paleoflood studies rely on assumptions of shear stress values necessary to erode stream terraces with stable soils and the predictive capability of the hydraulic model to generate accurate peak discharge estimates to produce a paleoflood signature, deposition on or erosion of a stream terrace surface. While a range of values is reported that includes uncertainty in the peak discharge estimates, only limited comparisons between physical observations of large historical floods and the model simulations of the same events have been performed. These comparisons typically have involved historical floods that are decades old and therefore many of the flood indicators have been removed or obscured from field observation. A post-flood investigation of a recent extreme flood can provide a more robust estimate of the uncertainty in model predictions of surface erosion and deposition and can also provide greater overall understanding of flow dynamics during extreme floods and the shear stress values necessary to leave a signature, erosion or deposition of surface sediment.

This study poses the following questions: (1) how well does the hydraulic model simulate a recent, extreme flood; (2) do field observations and model predictions indicate surface erosion in the same areas during an extreme event; (3) do field observations and model predictions infer sediment deposition in the same areas during an extreme event; and (3) what are the limitations of the model and paleoflood studies in general to predict the modification of stream terraces or areas of sediment deposition during extreme floods?

To answer these questions this study will: (1) survey high water marks and make field observations and interpretations of erosion and deposition during a recent large flood; (2) construct 2D hydraulic models to simulate the extreme flood; and (3) compare model predictions with the surveyed flood stage and real world observations of erosion, deposition and other modifications to the stream channel.

PALEOFLOOD HYDROLOGY

Paleoflood hydrology has been used for the past century in a wide variety of settings throughout the world (Costa, 1986; Patton, 1987; Baker et al., 1988). Early studies by Mansfield (1938) on the Ohio River and Jahns (1947) on the Connecticut River recognized that historical floods on those rivers overtopped stream terraces that had not been inundated for thousands of years. The stratigraphic record present along streams in the form of terrace and flood plain deposits can be direct indicators of the magnitude of large floods on a river and may be 10 to 100 times longer than conventional stream gaging records of large floods (e.g., Patton, 1987; Baker, 1989; Jarrett, 1991).

One widely-used technique in paleoflood studies uses the fine-grained sedimentological record that accumulates in backwater areas (slackwater) to construct a detailed history of past floods (e.g., Patton et al., 1979; Kochel and Baker, 1988). This technique can be extremely useful in characterizing the frequency of large floods, but can fall victim to the inherent assumption that a sequence of slackwater sediments represents a complete and continuous record of floods at a particular site. In addition, the physical setting of a backwater site may not be ideally suited for reconstructing or accurately estimating the peak discharge for the flood associated with a particular sequence of slackwater deposits in one-dimensional hydraulic models. Two-dimensional hydraulic modeling (e.g., Denlinger et al., 2002) can aid in estimating peak discharges in these complex geometries.

Another methodology uses the age of a terrace surface that lacks clear evidence of recent inundation, erosion and deposition, or alternatively displays evidence for long-term stability, to establish an upper limit to flooding. This non-inundation approach can be very useful in flood hazard assessment because geomorphic and stratigraphic information derived from the terrace surface can provide an upper limit or bound on the age and magnitude of extreme floods (Levish, 2002). Rather than constructing a detailed record of past floods, the non-inundation approach focuses on identifying a non-exceedance bound. Establishing a non-exceedance bound is accomplished by identifying terrace surfaces that serve as limits for the paleostage of large floods and estimating ages for those terraces (Figure 4). These bounds do not represent actual floods, but instead limits the peak flood stage over some measured time interval. Simply stated, a non-exceedance bound is a maximum stage that has not been exceeded in the time period since the terrace surface stabilized. The maximum stage can be used to estimate peak discharge given some knowledge of the channel characteristics.

SETTING

The study reach is located along Cottonwood Creek in El Paso County near Colorado Springs, Colorado approximately 60 miles south of Denver (Figure 1). The Cottonwood creek watershed is about 18.9 mi^2, heading in the southern portion of the Black Forest region and draining to the southwest into Fountain Creek. A flood of record during June 2012 on Cottonwood Creek provided an ideal dataset to study recent flood signatures and physical/hydraulic properties associated with a large-magnitude flood in a small watershed. The study reach is located within the city of Colorado Springs open space and begins 150 feet downstream of the East Woodman Bridge, extending downstream 5,800 feet to just upstream of Rangewood Drive Bridge. Cottonwood Creek is incised into Cretaceous bedrock and about 10-20 ft. below housing developments. Limited grade control features and other human structures within the reach provide a mostly natural setting in which to study the geomorphic characteristics of the flood. Drainage area associated with the study reach is approximately 10.2 mi^2 as documented at the USGS stream gage no. 07103980.

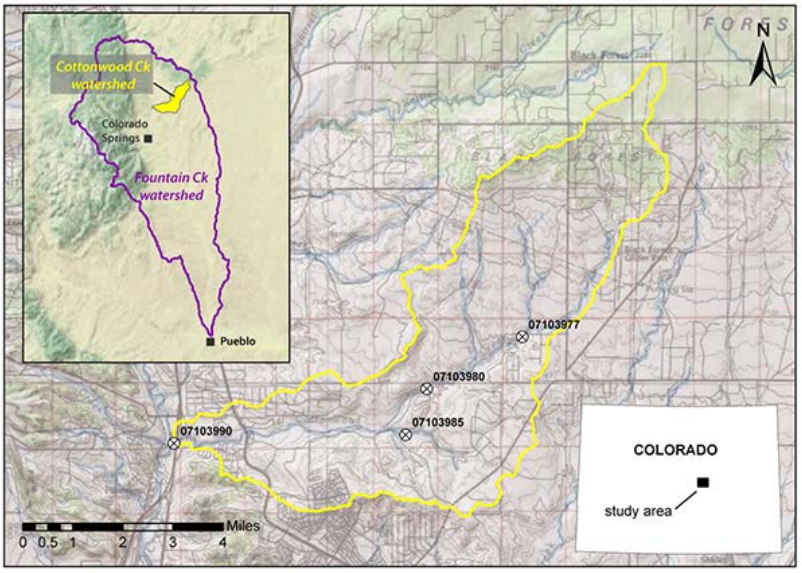

Figure 1 Cottonwood Creek study reach located downstream of East Woodman Road near Colorado Springs, CO. USGS stream flow gage stations are denoted on the map with cross hatched circles.

THE JUNE 6, 2012 FLOOD, COTTONWOOD CREEK, COLORADO SPRINGS, CO

Peak flows on Cottonwood Creek typically occur during the summer months of June through September and are commonly caused by convective storm systems which deliver moisture in the form of intense thunderstorms in the late afternoon and early evening hours. The flood of June 6, 2012 peaked between 8:15 and 8:30 pm and had a peak discharge of 1,610 ft^3/s at USGS stream gage no. 07103980 (Cottonwood Creek at Woodmen Road near Colorado Springs, CO), which was the peak of record for the 20-year history of the stream gage (Figure 2). The flood lasted approximately 2 hours with a slightly more gradual rising limb and a steep falling limb. Within about 81/2 hours, flows had returned to less than 10 ft^3/s at the stream gage. During August 2013 a larger-magnitude peak discharge of 3,500 ft^3/s was recorded after the field survey of high water marks.

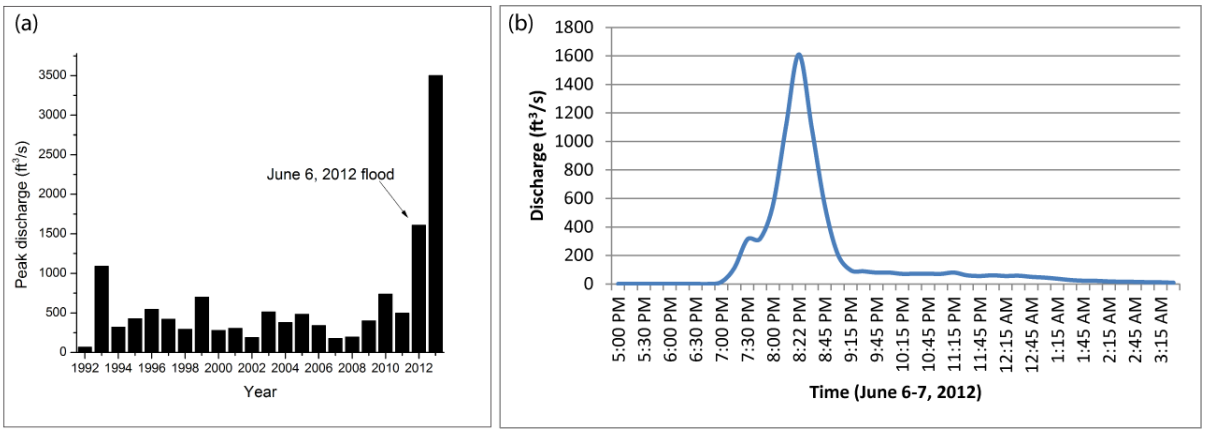

Figure 2 Hydrologic data, Cottonwood Creek at Woodmen Road near Colorado Springs, CO (USGS gage no. 07103980). (a) Peak discharge data; (b) runoff hydrograph, 15-minute discharge data, June 6-7, 2012.

MODEL SELECTION

Reclamation Technical Service Center (TSC) utilizes hydraulic modeling as part of paleoflood studies to estimate peak discharge magnitude associated with the stage of slackwater deposits and stream terraces. The majority of detailed paleoflood studies have used Sedimentation and River Hydraulics 2D (SRH-2D) (Lai, 2008) for 2D hydraulic modeling. This study used SRH-2D to test the current methodology that is incorporated into the paleoflood studies. SRH-2D can analyze flow complexities of the interaction between the main channel, banks, and floodplain that are best represented with an unstructured arbitrarily-shaped mesh.

SRH-2D was used to model flow under steady and unsteady-state conditions. Steady state analysis was used to determine whether modeled depth averaged maximum water surface elevations matched field observations and to compare the modeled depth average maximum shear stress values with erosional and depositional areas. Unsteady-state flow modeling was performed to examine the variation in shear stress values at different points in the flood hydrograph for selected observation areas. To define the SRH2D downstream boundary condition, an Army Corps of Engineers Hydrologic Engineering Center River Analysis System (HEC-RAS) (U.S. Army Corps of Engineers Hydrologic Engineering Center, 2010) model was constructed for the study reach. The HEC-RAS model was extended 650 feet downstream of the study reach to ensure the boundary condition would not impact SRH2D model results.

DATA COLLECTION

This section describes the field survey, topographic, and geomorphic data that were collected for this study. The collection methods, locations, and data uncertainty are described.

Survey Data and Terrain Development

The terrain developed for the study reach used a combination of in-channel surveyed points and contour data. Site specific survey points were collected by the authors on June 5, 2013 to identify the stage and lateral extent of the June 6, 2006 flood and to further define the channel topography. The June 6, 2012 flood was the event of record and it was assumed that the highest high water marks were a result of this event. To define the flood stage and lateral extent, we surveyed trim lines, flotsam and tops of sandy flood deposits. An effort was made to find the highest flood indicators to identify the peak stage of the flood. In order to define channel topography, survey points were collected to capture the channel thalweg, sand bars and banks. All survey points were collected using Real Time Kinematic (RTK) Global Positioning System (GPS) equipment. An NGS Online Positioning User Service (OPUS) solution was obtained for control at the base station. Positional accuracies for RTK and this survey are +/- 0.05 feet horizontally and +/- 0.10 feet vertically. The survey used NAD 1983 (2011) Epoch 2010.00, State plane coordinates,

Colorado Central zone in U.S. Survey Feet (USFT), based on station Marshall Field Cors Arp with coordinates 1298154.39 N and 3448788.1 W.

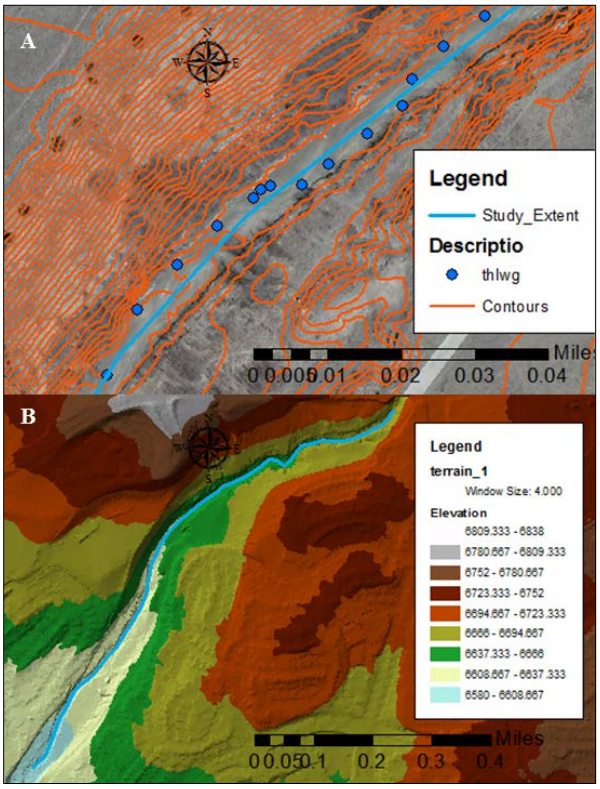

Figure 3 A) Example of survey data and contour lines along Cottonwood Creek, B) Terrain developed for the study reach.

The City of Colorado Springs contracted with Sanborn to provide a digital orthoimagery dataset. The imagery was acquired over approximately 240 square miles of the City of Colorado Springs, Colorado. Sanborn acquired new 0.5-foot pixel imagery of the Colorado Springs area in the spring of 2010 during leaf-off conditions. The acquisition was performed using Sanborn's UltraCam-D digital camera system and aircraft equipped with AGPS/IMU. Digital orthoimagery was produced using existing DEM, updated as needed to support production of the orthoimagery. The City of Colorado Springs used the imagery to develop 2-foot contour lines for the Cottonwood Creek basin.

The digital imagery of the study reach was collected while water was in the stream; therefore, the channel survey points collected in 2013 were used to define the channel bed and then combined with the 2-foot contours to develop a t errain for the study reach (Figure 3). GPS surveyed points were taken along the stream bank and compared to Sanborn contour data. The points were within the ±1 foot tolerance and provide confidence in the topographic data.

Geomorphology

Surficial geologic mapping involves the delineation of surficial geologic features on the landscape. When mapping along river corridors, these features typically include stream terraces, bedrock outcrops, axial and tributary stream channels, eolian landforms, and other deposits along valley margins, such as landslide deposits and glacial deposits. Surficial map units are landforms that can be grouped together based on similar physical or geomorphic characteristics such as position in the landscape, surface morphology, sedimentology, soil development and process of formation. Deposits in this study are mapped along the Cottonwood Creek stream corridor and therefore are typically composed of fluvially-derived sediments and are landforms that were created and modified by fluvial processes. The extent and character of these features provide information concerning controls on lateral and vertical channel movement over longer time frames than the historical period and many times are important factors in explaining variation in channel morphology along the length of the study reach. Surficial geologic units defined in this study are described on the basis of surface morphology, character of deposits, vertical and lateral relation to other mapped units, relative or absolute age, and geographic location. Stratigraphic descriptions were performed on a limited number of exposures along the channel banks using sedimentological terminology from Boggs (1995) and soil nomenclature from Birkeland (1999) in order to understand the depositional processes associated with the stream deposits. Five Sediment samples were collected from the surface of alluvial deposits near model observation points along Cottonwood Creek and submitted for particle size analysis and bulk density determinations at Colorado State University Soil, Water and Plant Testing Laboratory. Bulk density samples were collected using a soil core sampler.

Flood observations were made during field work in July and August 2013. Types of features that were noted included depositional features such as sand bars, flotsam and debris lines. Scour features included trim lines, scoured bedrock and vertical bank exposures. When combined the observations reveal the stage of flood waters and areas where the channel was scoured both vertically and laterally during the flood.

GEOMORPHIC OBSERVATIONS AND MAPPING

In order to compare the geomorphic effects of the June 6, 2012 flood with model predictions, high water marks and other features created during the flood were documented during field observations. T he main goal of the geomorphic mapping of flood features was to determine areas of deposition and erosion along the channel during the 2012 flood. Areas that were above the level of low bars were mapped based on whether they appeared to be primarily depositional or erosional areas. Depositional areas consisted of abundant flotsam and sand deposits which were deposited on younger terraces or in areas of recirculation, such as upstream of sharp meander bends, or in small tributary or sideslope gullies along the margins of the channel (Figure 4). Erosional areas consisted of scoured bedrock benches, and areas with distinct trim lines or vertical bank exposures of fluvial sediment or bedrock. Low bars were not mapped as areas of deposition because these areas are also modified by lower stage flows than the 2012 flood.

A surficial geologic map was also produced to show the extent of the channel, channel bars, terraces (labeled younger and older on a relative scale), bedrock benches and bedrock outcrops in the channel. Mapped flood features generally correspond to specific landforms that were mapped in the reach; for example, many depositional areas were located on younger stream terraces and erosional areas were located on bedrock benches. Mixed depositional and erosional areas occur within the channel itself but cannot be related to the 2012 flood because they have been modified by more recent, lower flows.

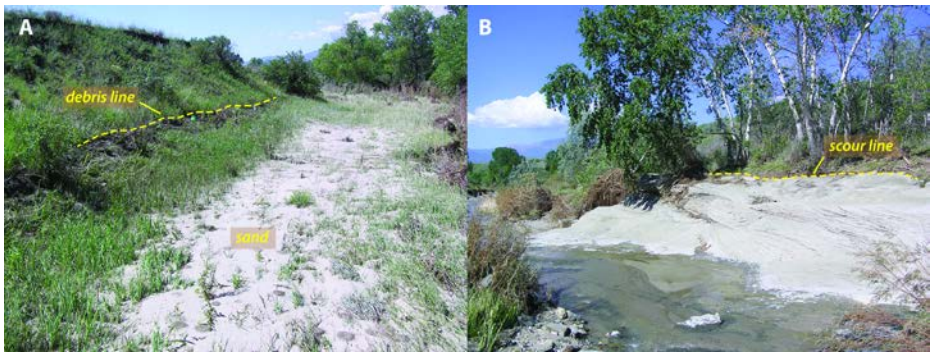

Figure 4 Example of erosional and depositional areas; A. depositional area showing sand and debris line from recent flood; B. erosional area showing scour line on bedrock outcrop.

HYDRAULIC MODELING

Boundary Condition

Hydraulic models require an exit boundary condition to converge on solutions for various hydraulic parameters. SRH-2D requires either a r ating curve or a known downstream water surface elevation to satisfy a b oundary condition. There was no flow or stage data at the downstream end of the model. As such, a HEC-RAS model was developed for the Cottonwood Creek Study using HEC-geoRAS (U.S. Army Corps of Engineers, 2010) to develop the geometry. The HEC-RAS model was extended far enough beyond the downstream boundary of the 2D model that the computed water surface elevation in the HEC-RAS model at the station of the outlet of the 2D model was not influenced by the boundary.

The flow data was obtained from USGS gaging station located at cottonwood creek for the June 6, 2012 flooding event. A manning's n of 0.03 and 0.06 was selected for the main channel and the left and right bank, respectively for the channel roughness (Chow, 1959). The HEC-RAS boundary condition used for both steady-state and unsteady-state was the normal depth. The normal depth can be determined by the slope of the channel and Cottonwood Creek has a slope of 0.025 ft/ft that was derived from the contour data. This HEC-RAS boundary condition will be referred to the regular boundary condition. We performed a boundary conditions sensitivity analysis and altered the slope to 0.03 ft/ft and 0.02 ft/ft.

Mesh Generation

Table 1 Manning's n values selected for study reach areas.

Material Type	High n	Mid n	Low n
Channel	0.035	0.03	0.025
Overbank grass	0.055	0.05	0.045
Overbank shrub	0.08	0.07	0.075
Overbank tree	0.1	0.095	0.09

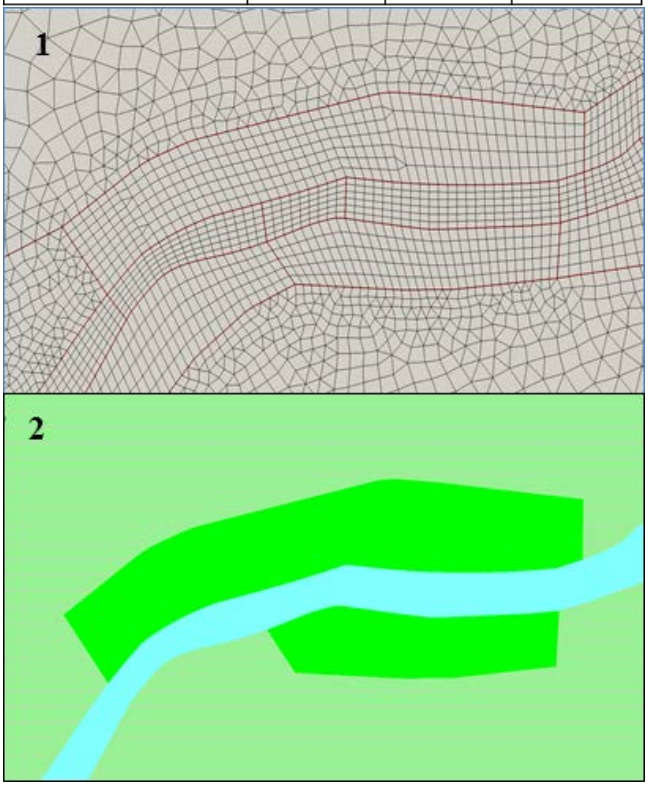

Figure 5 (1) Quadrilateral elements in the main channel and triangular elements on the over bank areas. (2) Material properties for the main channel, the dense vegetated area, and grassed and small shrub vegetated area.

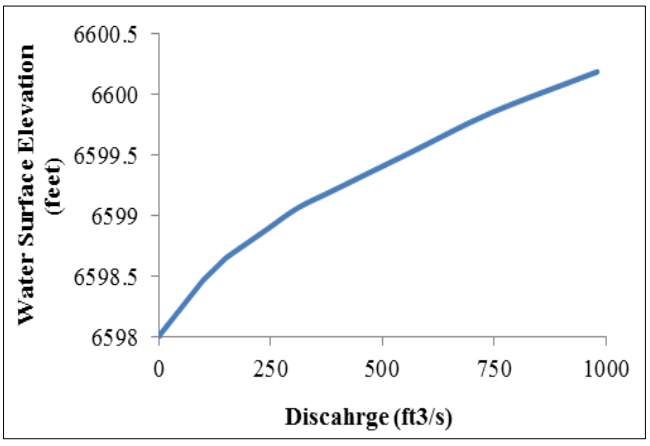

Figure 6 The rating curve developed at River station 812.67 feet for SRH-2D unsteady-state model downstream boundary condition.

Two main components of the 2D model are the mesh and the topography. The mesh was constructed in Surface water Modeling System (SMS) version 10.1 and contains all spatial data such as ground/bed elevations, channel roughness, and overbank roughness. Elevation values are stored at each node while roughness values are stored in each element (Figure 5). The average cell size within the main channel was 10 feet longitudinally and 8 feet laterally. Mesh cell sizes increased with increasing distance from the main channel. The entire mesh contained 17,320 cells. The mesh elevation is imported from ArcGIS and is interpolated to each mesh node. Roughness is assigned to polygons created to construct the mesh. Based on site visit observations and aerial photography the study reach was broken up into four roughness areas: the main channel, overbank grass, overbank shrub and overbank tree (Table 1) and were estimated from (Chow, 1959).

Model parameters

The 2D model was run under both steady state and unsteady state conditions with slightly different input parameters. For steady-state flow the inlet discharge was 1610 ft^3/s. The model had a simulation time of 74 hours with a time step of 2 seconds. Three boundary conditions of 6599.71 feet, 6600.21 feet, and 6600.71 feet developed from the HEC-RAS model were modeled to observe where water surface elevations converged to a common elevation. Convergence indicates the boundary condition no longer impacts the water surface elevation. Model results downstream of this location would be considered void since they are driven by the boundary conditions and not flow dynamics of the river system.

For the unsteady flow model the total time simulated was 80 hours and a time step (model time integration) of 1 second. A rating curve was used for the downstream boundary condition. The rating curve was taken from the HEC-RAS model at river station 812.67 feet (Figure 6).

Soil Samples and Shear Stress

Julien (1998) defined the critical shear stress as the beginning of motion when the ratio of hydrodynamic focus exceeds the submerged weight of a particle.
Julien developed a graphical relationship between critical shear stress and median grain size d_{50} on a flat horizontal surface (Table 2). This method also assumes that fractions of sediment enter motion at the same values of applied shear stress.

Table 2 Threshold shear stress conditions for granular material at 20˚ C (Julien, 1988).

Size Class	Shear Stress Range (Pa)
Medium Silt	0.010-0.083
Coarse Silt	0.084-0.110
Very Fine Sand	0.111-0.145
Fine Sand	0.146-0.194
Medium Sand	0.195-0.270
Coarse Sand	0.271-0.470
Very Coarse Sand	0.471-1.260

In previous paleoflood studies, these values have been used to infer surface erosion of stream terraces when the critical shear stress is exceeded during a modeled flood. Discharges necessary to produce the critical shear stress and inundate a particular stream terrace are given a range based on uncertainty in the model, topography, and flood stage associated with the range of critical shear stress values.

Field evidence of surface erosion or stability is used as an indicator of whether floods have recently overtopped terrace surfaces, providing lasting visible evidence of surface modification. These modifications take the form of secondary or overflow channels, bar and swale topography, channel splay deposits, or reentrant channels near the downstream ends of terrace surfaces. Soil/stratigraphic evidence in the form of truncated or buried soils would also indicate overtopping of the terrace surface. On the contrary, soils that show long term stability indicate the lack of flooding on the terrace over the timeframe of the developing soil. Discharge estimates for overtopping terraces with stable soils rely on these critical shear stress values in order to define a range of discharges that would erode the soil if the discharge had occurred over the timeframe of the developing soil (Levish, 2002).

The hypothesis for this study was that critical shear stress values should exceed the threshold critical shear stress on erosional surfaces and be below the threshold critical shear stress on depositional surfaces, thus reflecting higher stream power in the areas that were eroded. To test whether critical shear stress can be used to differentiate erosional versus depositional areas, we collected sediment samples from the upper 10cm of surface sediments on stream terraces at three different sites, COTT2, COTT3, and COTT4.The locations of the sediment samples correspond to the locations of stratigraphic descriptions of terrace deposits. Particle size analysis was completed for all three sites, whereas bulk density was completed only for COTT2 and COTT3 (Table 3). Bulk density was not completed for COTT4 because the sample lacked cohesion and crumbled apart during sampling. Soils were analyzed and characterized at the Soil, Water and Plant testing Laboratory at Colorado State University in Fort Collins, CO. Based on the soil samples data we concluded that the critical shear stress for our study reach was a very coarse sand corresponding to a threshold shear stress of 0.55 Pa.

Table 3 Soil sample results for Cottonwood creek.

Sample ID	Bulk Density (g/cm^3)	% Retained By Sieve Size (mm)						% Composition			Texture
		2	1	0.5	0.25	0.106	0.053	Sand	Silt	Clay	
COTT2	1.50	2.92	4.37	8.89	15.38	18.54	8.82	56	18	26	Sandy Clay Loam
COTT3	1.59	1.61	1.89	8.23	51.95	9.08	3.85	75	8	17	Sandy Loam
COTT4	N/A	1.91	3.75	6.49	28.45	32.28	2.83	74	6	20	Sandy Clay Loam

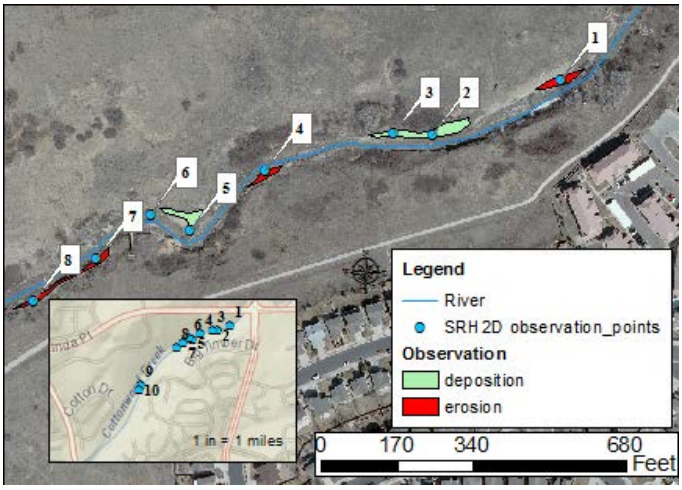

Figure 7 Location of observed erosion and deposition and the monitoring shear stress points in the SRH-2D model.

We wanted to determine if the threshold critical shear stress identified in the soil samples was exceed in the study reach, how much it was exceeded by, and for what duration. SRH-2D allows users to identify monitoring points, locations where simulated results are recorded at each time step. Ten monitoring points were placed within field observation polygons identified as areas of deposition and scour that were associated with the 2012 flood (Figure 7) Monitoring points 1, 4, 7, and 8 were located in polygons with observed erosion and monitoring points 2, 3, 5, 6, 9, and 10 were located within polygons where deposition was observed.

RESULTS

Model Extent

The results of the HEC-RAS model for the three boundary conditions provided three water surface elevations for SRH-2D steady-state downstream boundary conditions of 6600.71 feet, 6600.21 feet, and 6599.71 feet. The SRH-2D steady-state model water surface elevations for the high, regular, and low modeling scenarios were plotted (Figure 8) and show that the boundary condition had no impact for model results upstream of 4933.69 (HEC-RAS station 812.67 feet). The model extent in this study refers to all results upstream of station 812.67 feet.

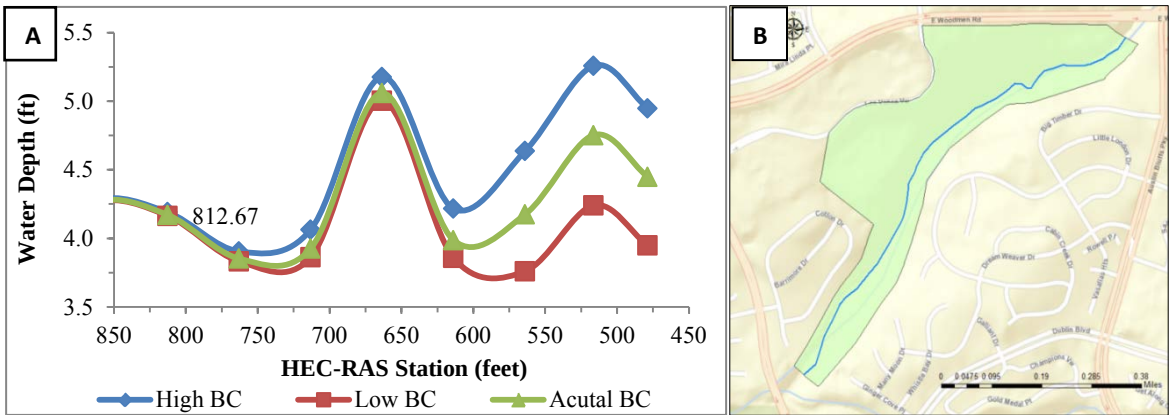

Figure 8 A) The 2D water surface profiles results for high downstream boundary condition, "Reg" or Regular downstream boundary condition and Low boundary conditions. B) The SRH-2D modeling extends to project station 4933.69 feet.

Model Uncertainty – Water Surface Elevation

Model uncertainty for water surface elevation was estimated to be ±1.02 ft. for the modeled reach. The modeled water surface elevation uncertainty was computed using the sum in quadrature equation (Taylor, 1997):

$$\sigma_\tau = \sqrt{\sigma_s^2 + \sigma_r^2 + \sigma_d^2}$$

Where σ_τ = absolute error, σ_s = topography error, σ_r = the roughness error, and σ_d = the error in the discharge measurement.

The terrain data for the study reach was developed from contours and surveyed points. Because there are two sources of data to develop the terrain the sum in quadrature equation was used to define the topographic uncertainty. The contour data is at 2 feet intervals which has an uncertainty of ± 1 foot. The vertical error associated with the surveyed point is ±0.1 feet. The total error for topography (σ_s) is 1.01 feet.

Roughness uncertainty (σ_r) was set at 0.03 ft. by comparing the difference in water surface elevation between selected roughness values and a 25% increase in roughness at a flow of 1610 ft^3/s. Differences in modeled water surface elevations ranged from 0.43 to 0 feet. An average value of 0.03 feet was used as a general indicator.

For a flow measurement to qualify as "good" under USGS standards it should be within ± 5 percent of the true value and a "poor" measurement is considered to have greater than 8 percent error (Sauer & Meyer, 1992). The daily discharge measurements at Cottonwood Creek generally receive a fair or poor rating. The 2012 water year report indicates that records are fair to poor because flow is affected by erosion-control and livestock-watering reservoirs and groundwater withdraws. For purposes of uncertainty estimation, the error in a given flow value was assumed to be ± 8 percent (e.g. 128.8 ft^3/s for 1610 ft^3/s). This translates to an estimated water surface elevation uncertainty (σ_d) of ± 0.17 feet at 1610 ft^3/s.

Water surface elevation fit

A comparison between the measured water surface elevations and the modeled steady state water surface elevations determine how well the model replicated flow depth. The survey points identified as flotsam were used as the

measured water surface elevation and were compared to the water surface elevations for the SRH-2D unsteady model (Figure 9). A comparison of 49 locations along the study reach found that the modeled water surface elevation was on average 0.81 feet above the measured water surface elevations. This indicates an over prediction of water surface elevation, on average, by 1.2 feet in the upper reach (River Stations 5746.36-4160.24), slightly over predicted water surface elevation by 0.3 feet in the middle reach (River Stations 4532.63-2736.01), and over predicted water surface elevations on average 1.1 feet in the lower reach (<2736.01 River Station) of the model.

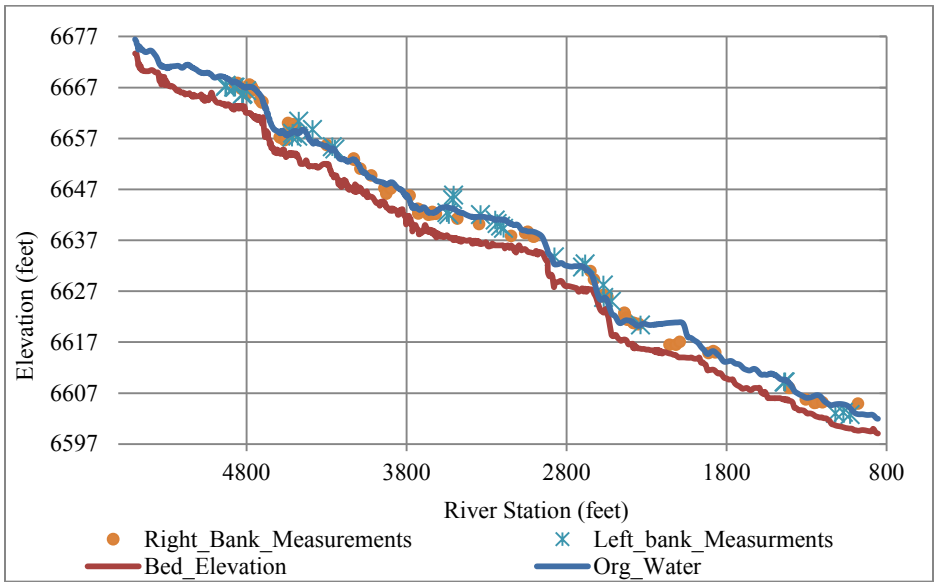

Figure 9 A comparison between the field measured and computer modeled water surface elevations for Cottonwood Creek study reach.

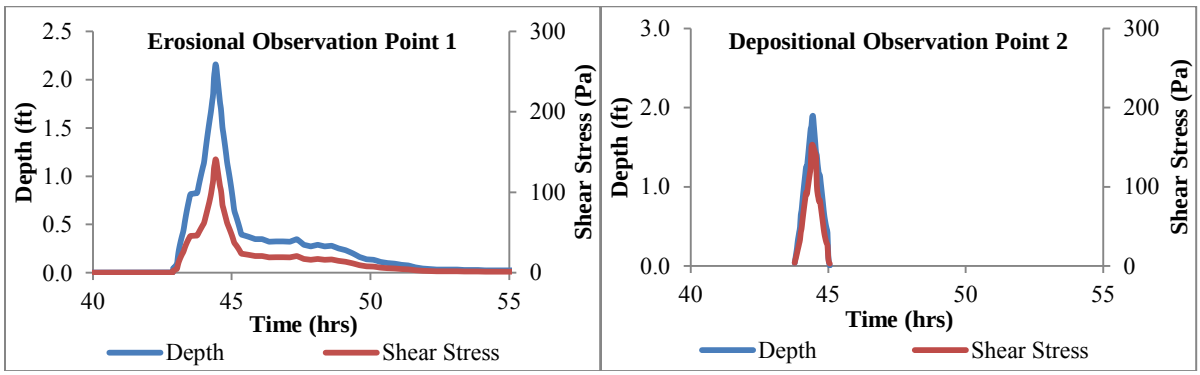
Critical Shear Stress Analysis

The ten SRH-2D monitoring points provided time series data for flow depth and critical shear stress. These values were plotted together against time (Figure 10). There was no flow at monitoring points 5, 6, 7, 8 and 10. For the monitoring points that did receive flow, they all exceed the critical shear stress values of 0.55 Pa. Although all surfaces showed modification in the form of either deposition or erosion, the methodology used in the paleoflood studies would have only assumed surface erosion above the critical shear stress value. Observation points 1 and 4 showed signs of erosion; however, observations sites 2, 3, and 9 were all mapped as locations where deposition had occurred. Observation points 1 and 4 had modeled peak critical shear stress values that were between 300 and 700 times larger than the threshold critical shear stress. They also experienced shear stresses that exceeded the threshold critical shear stress for over ten hours. Observations points 2, 3, and 9 had modeled peak critical shear stresses that were between 80-300 times larger than the threshold critical shear stress for durations around one hour.



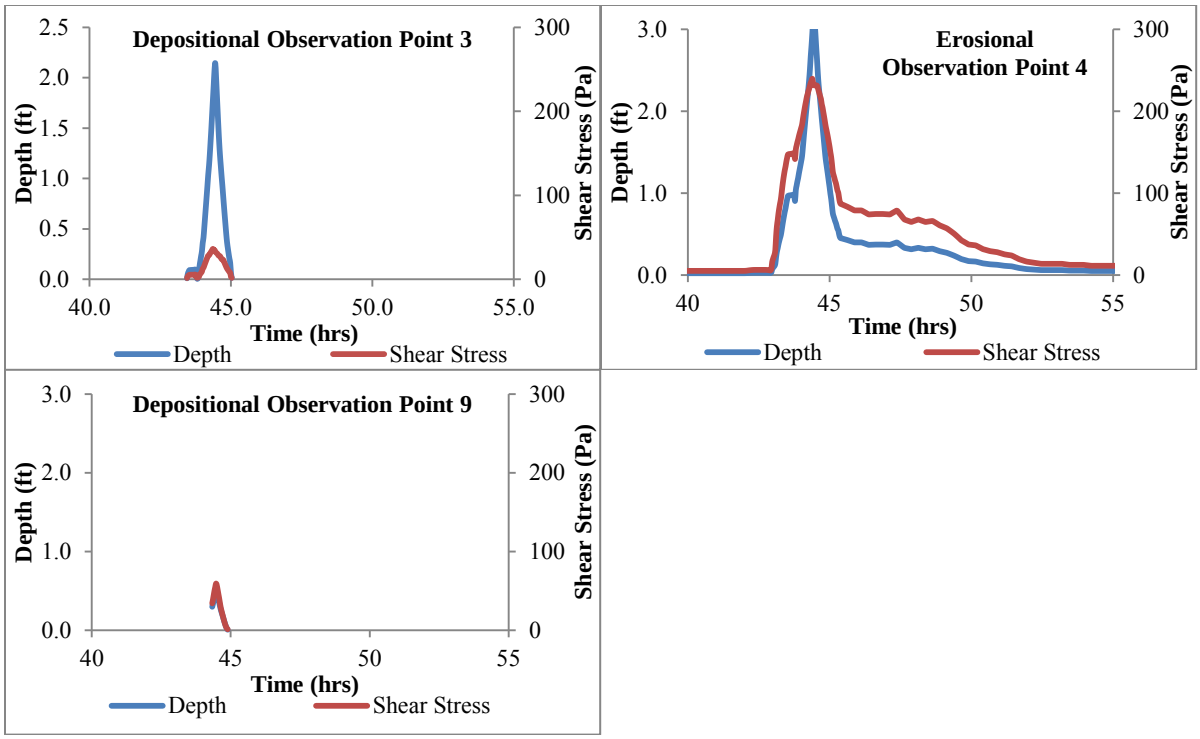


Figure 10 The charts plot the change in shear stress and depth over time for the describe monitoring points. Note the proposed threshold critical shear stress of (0.55 Pa).

DISCUSSION

Comparison of modeled water surface elevations and stage of high water marks

Modeled water surface elevations were within approximately 1ft of the field surveyed high water marks. Because the hydraulic model had a water surface elevation uncertainty of 1.02 feet this fit is within the range of uncertainty and is considered satisfactory. Higher resolution topographic data inside the channel would have the greatest impact on reducing the hydraulic model uncertainty. Finally, the uncertainty in collecting water marks is very difficult to quantify. Flow around objects in the channel is dynamic and complex where debris can be deposited throughout the hydrograph, making it difficult to discern the correct flood stage from the high water marks. Debris can be super elevated from in channel vegetation or obstructions, can be entrained during the hydrograph rising limb, or be suspended during the peak and then deposited during the falling limb at a lower channel elevation. To ensure high quality measurements of high water marks, a large number of measurements should be taken to rule out the mentioned outliers. This study measured over 233 high water marks over a one mile study reach and was considered satisfactory.

Comparison of steady state model output and field observations

For depth-averaged values in the steady state model, the SRH-2D model shows good correspondence with field observations. In other words, higher shear stress is computed in areas that were mapped as erosional and lower shear stress values are computed for areas that were mapped as depositional. Deviations from this pattern occur along the margins of the surfaces at their boundary and in transitional areas between erosional and depositional areas, where high shear stress values are computed at the upstream portions of the depositional areas.

Comparison of unsteady state model output and field observations

Results from the unsteady flow modeling at observations points along the study reach show that threshold critical shear stress is exceeded at every observation point regardless of whether the observation point was within an erosional or depositional area. We concluded that the Julien defined critical shear stress for our study site was not a

good predictor of erosion or deposition. The three assumptions of the Julien method (flow occurs over a plane bed, the particles shape are uniform, and the particles are non –cohesive) may have contributed to the low correlation. Our study site had steep bed slopes, segments of bedrock, and bank vegetation all of which affect the flow of sediment. Our soil samples had as high as 26% clay content indicating particle cohesion. Finally, natural stream systems have imbrication or armoring of the bed. It is likely that our site could have had imbrication or interlocking sediment particles of varying shape impacting sediment transport. These three conditions may have contributed to the poor correlation between the Julien comparison of grain size and critical shear stress and our site.

Maximum shear stress values also varied and appeared to have no distinct difference in values between erosional and depositional surfaces. The results also show that the duration and depth of inundation on erosional surfaces was much greater than on depositional surfaces, which may be the reason why these areas experienced greater removal of sediment.

CONCLUSIONS

Geomorphic observations of an extreme event can provide insight into flood dynamics. One dimensional and two dimensional modeling provided quantitative data on flow velocities, depths and shear stress for the June 6, 2012 flood. There was a strong agreement between field observations and modeled results of flood stage. Anomalies occurred in locations where three dimensional flow effects were likely during the flood. Critical shear stress as an indicator of surficial erosion is currently used to develop non-exceedance bound discharges for paleoflood studies; this research shows that the critical shear stress value can only be used to develop a minimum stage and discharge required to modify a fluvial surface; other parameters should be explored to better define the range of peak discharges for paleoflood studies.

SETTING THE STAGE FOR CHANGE: GEOMORPHIC RESPONSE OF A SECONDARY CHANNEL ON THE RIO GRANDE

Jonathan AuBuchon, Hydraulic Engineer, Bureau of Reclamation, Albuquerque, NM, jaubuchon@usbr.gov; Mark S. Nemeth, Supervisory Civil Engineer, Bureau of Reclamation, Albuquerque, NM, mnemeth@usbr.gov.

INTRODUCTION

Anthropogenic and natural changes have influenced the morphology of the Rio Grande over the last century, especially in the reach below Cochiti Dam. The channel degradation that followed the closure of Cochiti Dam (1973) resulted in a floodplain that is rarely inundated and a river that is narrower and deeper, creating bank erosion and habitat diversity concerns as documented by Happ (1948), Dewey et al. (1979), Lagasse (1980), Salazar (1998), Scurlock (1998), Richard (2001), Makar et al. (2006), Massong et al. (2008), and Makar and AuBuchon (2012).

Makar and AuBuchon (2012), Richard (2001), and Shah et al. (2006) document the decrease in the frequency of the large magnitude floods, the sediment supply, and the mobility of the medial and point bars. The increased bar stability has simultaneously allowed an increase in vegetation establishment, which has increased the stability of the banks and the channel planform. Over the last few decades the channel has continued to narrow through incision and vegetation encroachment, both of which have served to further isolate the main channel from its floodplain. At the same time the exposure of a dominant gravel fraction in the bed material as shown by Salazar (1998) and Bauer (2009), and vegetation encroachment on the banks and bars has reduced the degrees of freedom for the river to adjust, increasing the channel stability and uniformity.

In the river reach below Cochiti Dam (~ first 5 miles downstream) recent analyses by AuBuchon and Bui (2014) have shown that the active channel width has fluctuated around 200 feet and the slope has flattened to about 0.0012 over the last 2–3 decades. The channel planform has also abandoned some of its variability with a decrease in the average number of channels from 2–3 prior to 1962 to about 1–2 since 1972. The sinuosity still fluctuates slightly, although not to the extent that it did prior to 1962, suggesting that there are local areas of instability amidst the observed stability.

PROJECT DESCRIPTION

In 2008, the U.S. Bureau of Reclamation constructed a project about four miles south of Cochiti Dam that combined erosion control and habitat restoration goals. The design at this location blocked off an existing side channel where there was a bank erosion concern and constructed a new secondary channel slightly downstream. This new side channel was constructed through a relatively stable island feature deposited in the 1950s; this date was based on tree-ring aging performed by Bio-West (2005). The composition of the island deposits are primarily gravels among a matrix of sand, as shown in the red circle on Figure 1.

The side channel was designed by Bio-West (2006; 2007) to mimic other naturally occurring side channels in the area. The design bottom width was about 10 to 25 feet, with a 5.5-foot to 7-foot design depth range from the island surface. While initial draft concepts explored the possibility of planting vegetation on the channel sides to provide stability, this was quickly abandoned in favor of allowing the river freedom to adjust. The high banks of the island surface were estimated by Bio-West (2005) to be about 8 to 10 feet above the river bed. This information, coupled with observations of bank erosion at similar locations, suggested that the river would be able to move the sediment at this site, creating an opportunity for the river to adjust the channel dimensions.

During construction the side channel outlet was moved downstream to avoid removing a mature stand of cottonwoods. This resulted in a channel length increase of about 100 feet. The relocation effort also took advantage of existing sparsely vegetated areas through which the new channel could be constructed, one of which is shown staked out with pink flagging in Figure 1. The actual constructed bottom width of the channel was about the width of two wheel tractor-scrapers (CAT 621G), or about 20 feet as shown in Figure 2. The actual excavated depth was estimated to be about 5 feet.

OBSERVATIONS

In the years since the construction of the new side channel, the river's morphological response has created a rich variety and complexity of stream features. High spring snow melt flows during the initial years of the project (see Figure 3 where flows are above 3500 cfs for an extended period of time in 2008 [55 days], 2009 [28 days], and 2010 [7 days]) provided the energy for change, creating width, depth, and sinuosity changes. The erosion of bed and bank material during the initial years (2008 to 2010) created a sediment source (sands and coarser materials) for the river. This is a significant change since the closure of Cochiti Dam in 1973, as Shah et al. (2006) and Richard (2001) found that Cochiti Dam, just 4.5 miles upstream, has had a high trapping efficiency, close to 98%. The initial years of high flow not only created a sediment source, but they also winnowed the finer material out of the channel bed (see Figure 4) and deposited bars that have a nominal size in the very coarse gravel range (see Figure 5, 2009 survey).

The high spring runoff years were followed by lower spring snow melt flows that allowed the establishment of plant species. Summer monsoon flows between 2011 and 2014 have also brought additional sediment into the reach. Of particular note are the higher turbidity measurements in 2013 shown in Figure 3. In 2013, an unusually high discharge from a tributary of the Rio Grande upstream of the project site blocked the river and created conditions that significantly increased the local turbidity throughout the reach. This event, as well as other smaller sediment spikes, shown in Figure 3, during the monsoon seasons of 2011, 2012, and 2014, likely contributed additional finer material, as was noted in a 2014 re-survey of the bed material present on the 2009 surveyed bar (see Figure 5). It should be noted that the gravel predominant in the 2009 measurement was still present in the 2014 measurement, just overlain by finer material. These observations indicate that both water and sediment have helped shape the river's morphological response on the constructed side channel.

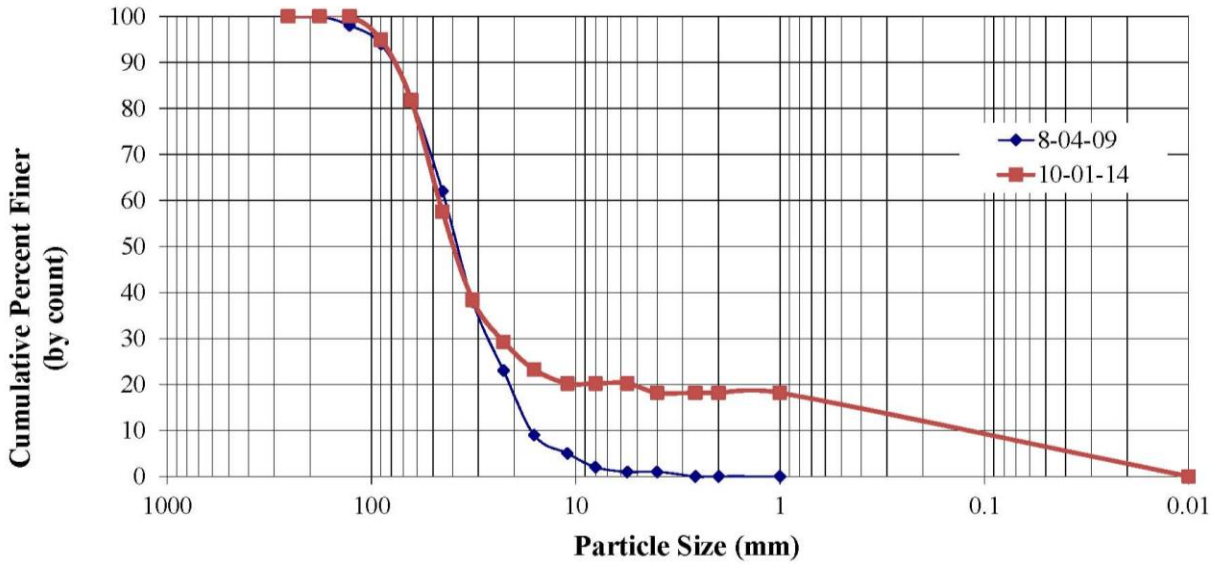

Figure 5 Grain size distribution plots (by count) of a bar forming on river left between CI-52.3B and CI-53.5B. Results are from measurements conducted using Wolman's (1954) methodology.

The specific morphological response of the constructed side channel is shown in planimetric view in Figure 6. A study of Figure 6 reveals not only a change in width and sinuosity, but also that the development of the meander bends is reflective of the locations where a major curvature was introduced during construction. Over the sequence of the provided aerial photography, this curvature has become more pronounced with downstream migration of the meander bends. Also of note in Figure 6 is the appearance of small channels on the backside of some of the meander bars which may indicate potential channel cutoffs and additional channel changes in the future.

Changes in the profile view over roughly the same time period are shown in Figure 7. The water surface elevation plot in Figure 7 reveals that the slope is adjusting with time (from ~0.0024 in 2009 to ~0.008 in 2012). The bed elevation plot in the same figure reveals a similar slope reduction (from ~0.0031 at the time of construction to ~0.0023 in 2009). The bed elevation plots also show the increase in depths along the thalweg with time. The August 2009 bed survey used an Acoustic Doppler Current Profiler (ADCP), so a higher resolution of the bed topography was possible. The January 2009 survey measured the depths at four cross section line across the constructed side channel; the profile plot only shows the deepest depth recorded at these four locations. Cross-sectional areal changes on the constructed side channel are shown in Figure 8. This figure provides a graphic illustration of the increase in cross section area (changes in width and depth) from construction to after the first two major spring runoff events in 2008 and 2009.

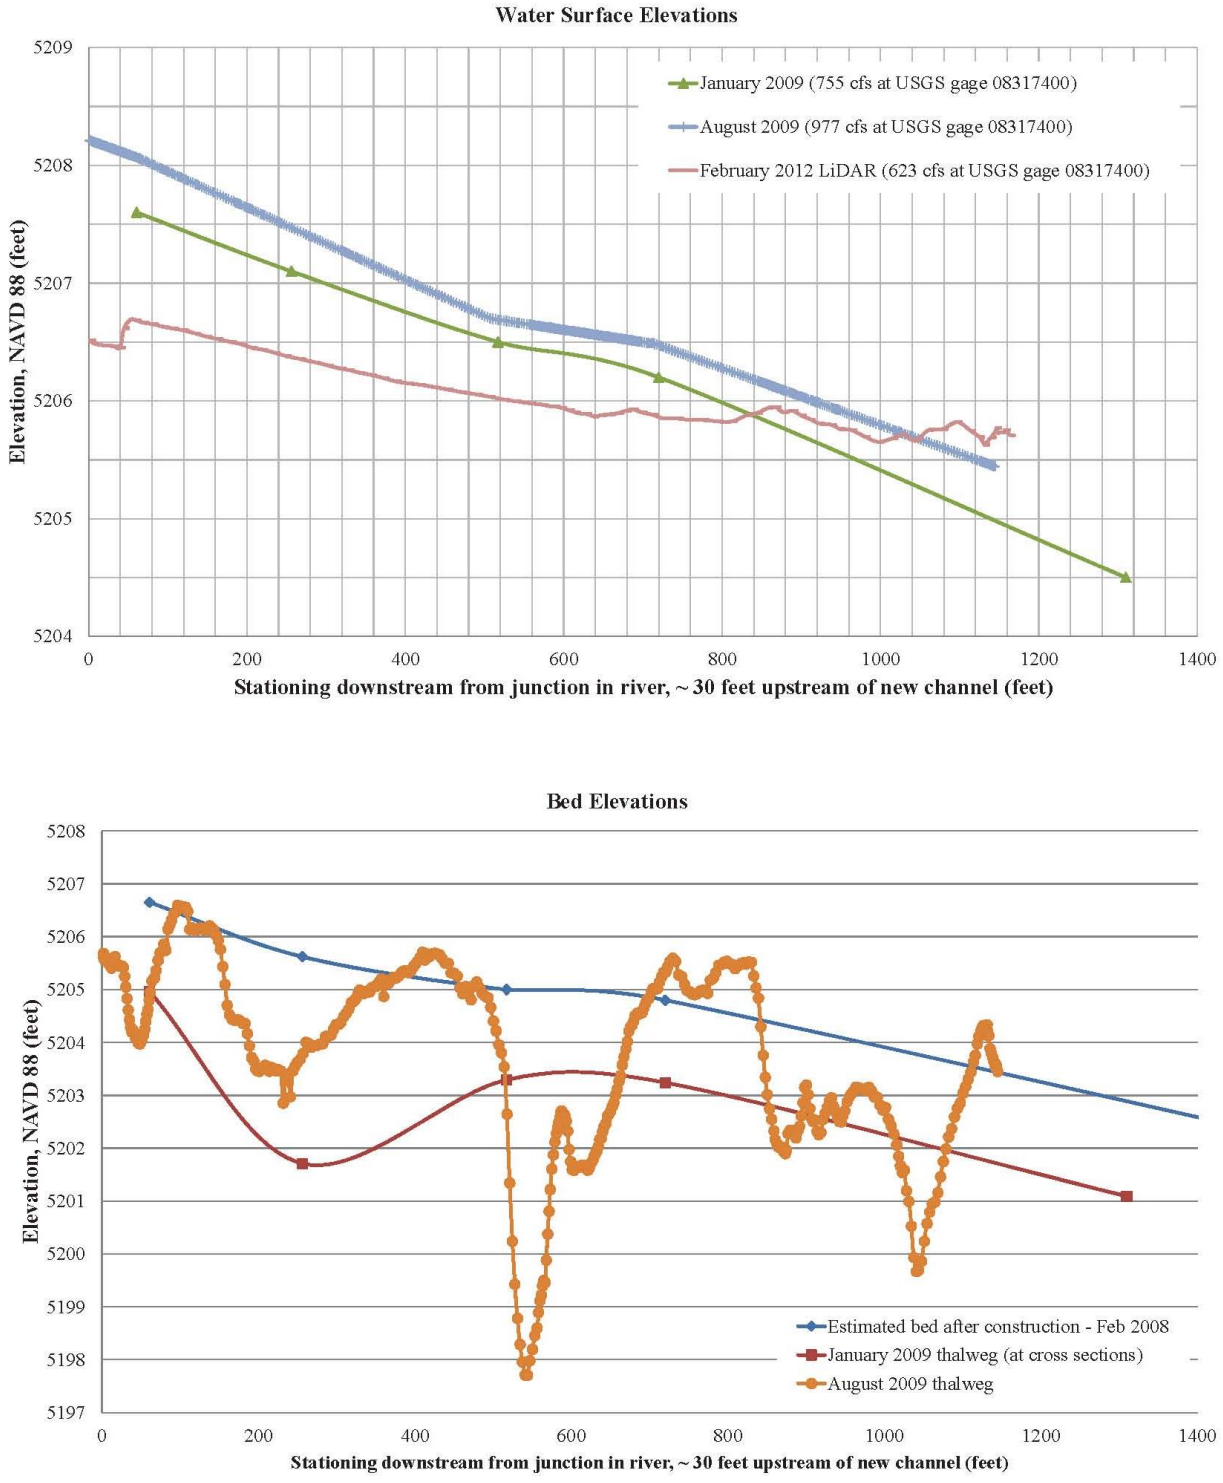

Figure 7 Slope changes on constructed side channel through time.

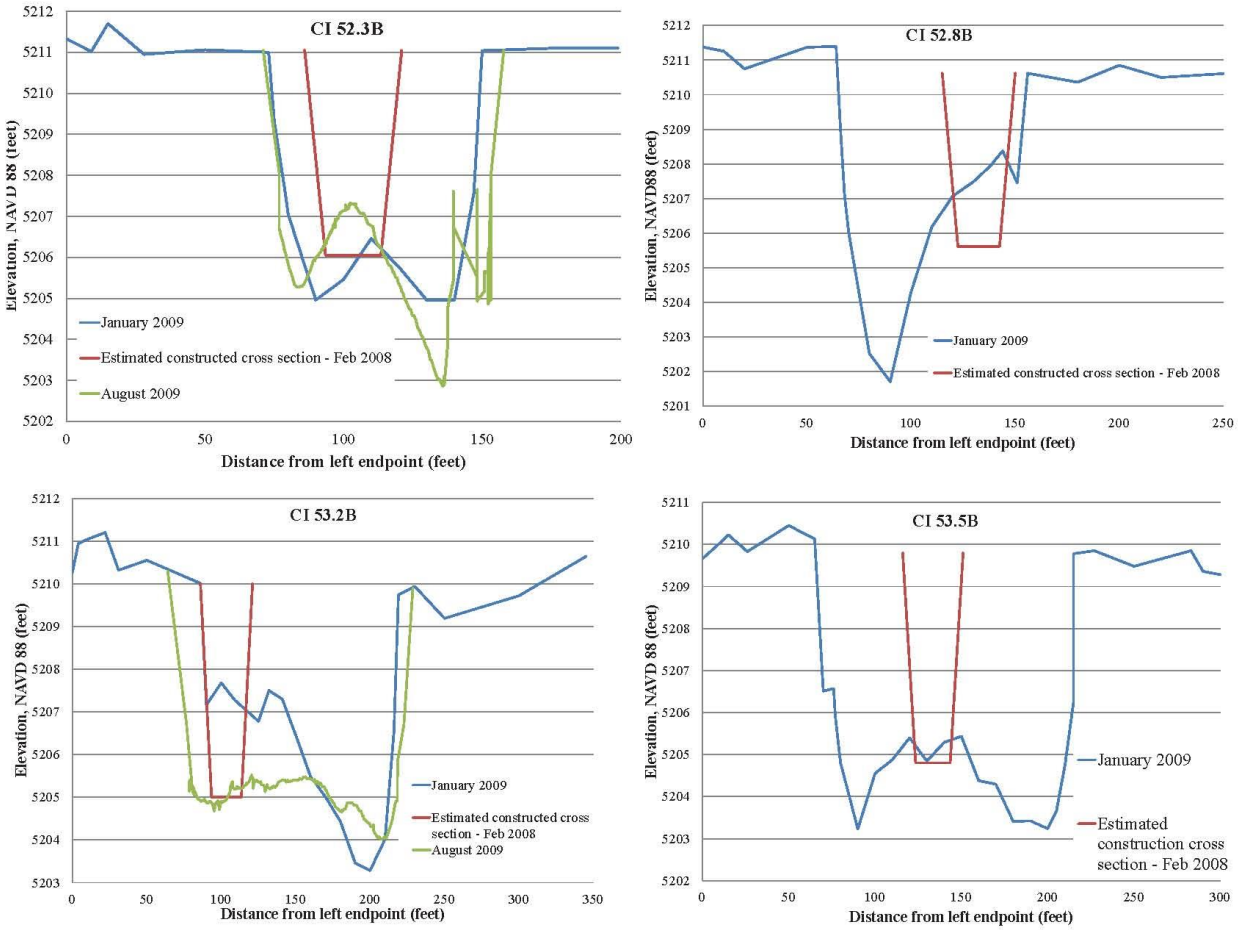

Figure 8 Cross-sectional changes on constructed side channel through time. Top two cross-section graphs are in the upper half of the constructed side channel. The bottom two cross-section graphs are in the lower half of the constructed side channel.

A summary of the planimetric changes that occurred on the constructed side channel is provided in Table 1. These changes were measured from the aerial photography shown in Figure 6. A similar planimetric analysis (Table 2) was performed using the same aerial photography sets on an upstream existing side channel. The constructed side channel showed a significantly more diverse morphological response than the existing side channel, with a larger range in the variability of number of bars, size of bars, and number of dead vegetation clusters in the channel. The side channel that was abandoned during construction was also assessed using this planimetric analysis (see Table 3), but for the time period prior to construction, this included three sets of aerial photography prior to the closure of Cochiti Dam. The width and sinuosity increases in the constructed side channel were seen to be similar to the abandoned side channel responses prior to construction of Cochiti Dam. Similarly, the quantity of bars observed in the constructed side channel was on par with the abandoned side channel up to about 1992; the volume of sediment available before Cochiti Dam though was far in excess (see maximum bar size) of what the constructed side channel could generate. The constructed side channel, though, had a significantly higher number of dead vegetation clusters than the abandoned channel, even before the closure of Cochiti Dam.

Table 3 Planimetric measurements of abandoned side channel from aerial photography.

	1949	**1962**	**1972**	**1992**	**2001**	**2006**
Average width (feet)	407	264	137	126	123	119
Sinuosity	1.04	1.11	1.13	1.38	1.41	1.30
Number of bars	9	4	5	4	2	2
Minimum bar size (square feet)	1,052	8,745	537	460	27,249	1,329
Maximum bar size (square feet)	177,638	222,716	50,210	74,713	52,283	4,385
Number of dead vegetation clusters in channel: trees, wood piles, clumps of vegetation matted together, etc.	1	1	1	3	3	5

While there was likely some dead vegetation that made its way to the side channel from upstream, the larger wood piles were a result of trees that were left near the constructed side channel and which fell into the river as the side channel widened and deepened (Figure 9). In effect, the toppled trees created irregularities in the flow that increased the local channel sinuosity and width, in addition to providing traps for sediment, seeds, and other debris carried by the river (Figure 9). It is likely the presence of these trees that have helped create the rich

variety and complexity of morphological features that have developed over time, as can be seen in the time sequence of photographs in Figure 10 and Figure 11.

RECOMMENDATIONS

Experience with the fluvial geomorphic response of this secondary channel on the Rio Grande can provide a basis for recommendations for future stream restoration projects. These are shown below.

- Know your river's history. Understanding the historical morphological response and the changes in the system drivers, like water and sediment, is key in developing design concepts that work with the river processes to meet a variety of design goals.

- Know your river now. Spend time in the field, with repeat visits during different seasons to assess changes in the vegetation, bed and bank materials, and general river responses over time. Understand whether your system can benefit from an increase in the sediment supply and what size sediment would be beneficial. In addition, assess if there are potential sources and sinks for this sediment within your design area.

- Provide freedom for the river, where possible, to be a river. Let the river adjust the channel dimensions, especially in areas where the additional sediment supply is needed. Keep large trees near the constructed edges of the channel that may fall into the channel and cause complex flows that create rich and diverse morphological forms that cannot be replicated with construction equipment.

- Plan for an adaptive management process to best take advantage and document morphological changes that occur after construction.

BANK EORISON MODELING WITH SRH-2D ON THE RIO GRANDE, NEW MEXICO

Yong G. Lai, Ph.D., Hydraulic Engineer, Technical Service Center,
U.S. Bureau of Reclamation, Denver, CO, ylai@urbr.gov

Abstract A number of sites along the Rio Grande in New Mexico have been experiencing significant bank erosion. A good understanding of bank erosion along the river is necessary for habitat restoration projects and river maintenance planning. This includes the ability to estimate future bank erosion location and its rate. The new geofluvial model SRH-2D, which couples lateral bank erosion modules with the original vertical mobile-bed erosion model, has been developed recently. The model has been verified elsewhere as a useful numerical model that simulates simultaneously the vertical stream bed erosion and lateral bank erosion. In this study, the new SRH-2D is used to evaluate whether the new model is applicable to Rio Grande bank erosion modeling, and the study also establishes the modeling procedure. A specific site at RM 111 on the Rio Grande, New Mexico, is selected for the purpose.

INTRODUCTION

Stream bank erosion is a natural geomorphic process occurring in all alluvial channels; it can be an important form of channel adjustment in unstable alluvial environments. Hence bank erosion should be accounted for in geomorphic analyses, river restoration, dam removal, and channel maintenance projects. Along the Rio Grande in New Mexico, for example, many sites have been experiencing bank erosion. These sites need frequent river maintenance work and the cost can be prohibitive if unmanaged. A good understanding of the bank erosion locations and retreat rates is necessary for river maintenance prioritization, planning and project design. Numerical modeling assessment is a viable alternative for these purposes.

In recent years, one-dimensional (1D) and two-dimensional (2D) numerical models have become important tools for predicting channel responses. For example, a number of stream-specific mobile-bed sediment transport models are becoming available for project applications such as HEC-RAS, SRH-1D, CONCEPTS, CCHE2D and SRH-2D. They are versatile and offer extensive capabilities and choices in modeling the vertical stream bed changes (a few also have the lateral erosion modeling capability). Recently, SRH-2D has been extended to include the bank erosion modules; this new geofluvial capability has been tested, validated and applied to a number of rivers (Lai and Wu 2013; 2014; Lai 2014; Lai et al. 2015a; 2015b). This new development motivated the present study; and it intends to answer the question of whether the current state-of-the-art multi-dimensional geofluvial model SRH-2D can be useful in predicting bank erosion on the Rio Grande. In the past, a few bank erosion sites on the Rio Grande were assessed through field study and using a point-based bank erosion model (Bankhead et al. 2012). However, the point-based models have limited use for predicting future changes. More advanced geofluvial modeling was sought by the Bureau of Reclamation Albuquerque Area Office. In this study, I report the application of SRH-2D to a particular bank erosion site on the Rio Grande, New Mexico (River Mile 111). The study has the following objectives: (a) establish the application and calibration procedure of SRH-2D to the field case, and (b) assess the model performance by comparing the model results with the field data. The study paves the way for future potential applications of SRH-2D to the Rio Grande for bank erosion assessment; it also

adds to the list of successful applications of SRH-2D for combined vertical and lateral erosion modeling.

ABOUT THE STUDY SITE

The bank erosion site selected for the present study is located at River Mile (RM) 111, downstream of the San Acacia Diversion Dam, on the Rio Grande, New Mexico. A series of historical aerial photographs are available between 2002 and 2012 and they are used to help delineate the bank erosion processes at the study site. In particular, the bank retreat distance is obtained and is used to calibrate the numerical model in this study.

The modeling starts from October 2005 and ends in September 2010, about a 5-year modeling period. The aerial photographs from January 2006 and in the summer of 2010 are shown in Figure 1. In the plot, the 5-year bankline retreat is also displayed. The October 2005 terrain used by the model is reconstructed from the July-August 2005 cross sectional data surveyed by Tetra Tech., Inc., and the 2003 DTM data and 2012 LiDAR in dry areas such as bank tops and floodplains. Photos taken at the RM 111 site during a field trip by the author on February 6, 2013 are shown in Figure 2.

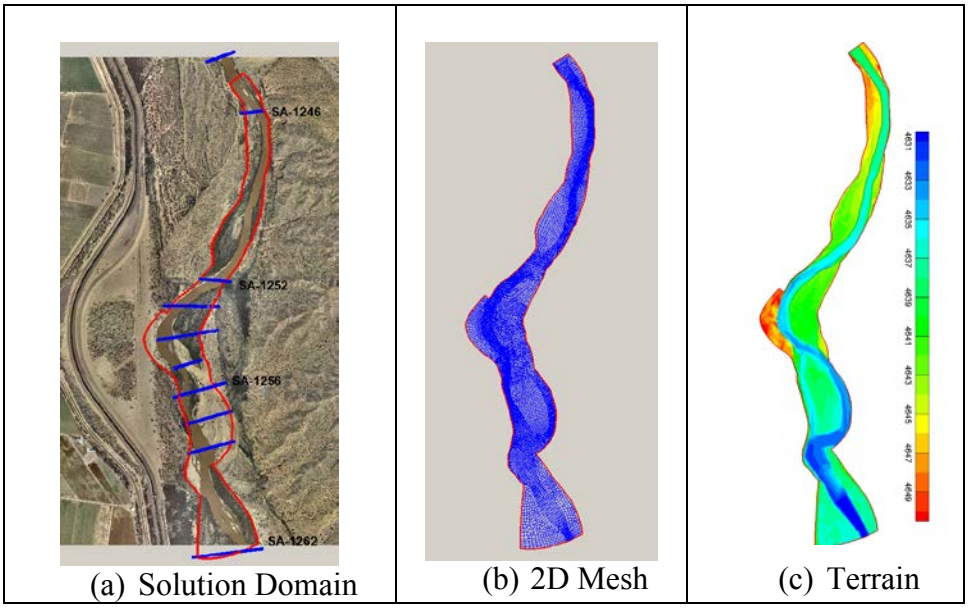
NUMERICAL MODEL AND MODELING DETAILS

SRH-2D Model Description SRH-2D is a teo-dimensional, depth-averaged, hydraulic and sediment transport model for river systems under development at the Bureau of Reclamation. The hydraulic flow model, documented by Lai (2008; 2010), has been widely used by internal and external users. The sediment transport mobile-bed module is used to predict stream-bed vertical changes and has been described by Lai and Greimann (2008; 2010) and Lai et al. (2011). The sediment module tracks multi-size, non-equilibrium sediment transport for suspended, mixed, or bed load for both cohesive and non-cohesive materials. In recent years, SRH-2D has been developed to include bank erosion modules. Two bank modules are developed: the uniform retreat module and the mechanistic failure module. The two adopt the same basal erosion (lateral erosion) algorithm given a shear stress distribution on a wetted bank. The main difference lies in the mass failure algorithm. The uniform retreat module assumes that the bank is retreating uniformly as a whole. The mass failure process is computed by assuming that a constant bank angle (e.g., the angle of repose) is maintained, and the loss of the bank material equals to the basal erosion. The uniform retreat module is developed primarily for uniform non-cohesive banks undergoing the dry granular and shallow slide processes. It may also be applied to cohesive banks or banks with other mass failure processes if only gross bank retreat amount is of the interest, when actual physical processes are too complex to model, or if there is a lack of measured bank data. The mechanistic failure module is developed primarily for multi-layer cohesive banks; the development is based on t he Bank Stability and Toe Erosion Model (BSTEM) as reported by Simon et al. (2000; 2011) and Langendoen and Simon (2008). The integration of key BSTEM algorithms into SRH-2D was documented by Lai et al. (2013; 2015a).

The technical details of the geofluvial modeling capability of SRH-2D are not reported herein; interested readers are referred to the review by Lai (2014), along with other works by Lai and Wu (2013; 2014) and Lai et al. 2015a. With the latest SRH-2D, main channel fluvial processes may be solved with the regular 2D depth-averaged mobile-bed module, while the lateral bank erosion processes are solved with bank modules. In this study, the latest geofluival SRH-2D model is used and the uniform retreat bank module is used.

Modeling Procedure Modeling is carried out in two stages: hydraulic analysis and bank erosion mobile-bed analysis. Hydraulic analysis is a necessary step to check and verify the model development and setup; the results are needed as the initial condition for bank erosion modeling. Often it also helps guide a proper selection of the solution domain (model boundaries) and the development of the mesh. Bank erosion modeling is carried out after the hydraulic analysis is completed. SRH-2D modeling, in general, is carried out in the following steps: (1) Selection of the solution domain; (2) Mesh generation for the solution domain; (3) Topography and flow roughness and bed gradation representations on the mesh; (4) Model calibration; and (5) Model application. Steps 1-3 are discussed first; followed by hydraulic analysis and bank erosion modeling for model calibration. In this study, model application is not carried out due to limited scope of the study.

Solution Domain, Mesh and Initial Terrain The solution domain may be limited by the availability of terrain data and the area of interest. For this study the solution domain is shown in Figure 3a. It runs from cross sections SA-1243 to SA-1262 and has a longitudinal extent of about 1.8 miles. The upstream boundary is located upstream of SA-1246 and the downstream boundary is located near SA-1262. A 2D mesh is generated with the Surface Water Modeling System software (SMS). It consists of a total of 11,722 mixed quadrilateral and triangular cells and 11,584 nodes (Figure 3b). Once the 2D mesh is generated, the October 2005 terrain and bathymetric survey data are interpolated onto the 2D mesh. The terrain represented by the 2D mesh is shown in Figure 3c.



(a) Solution Domain (b) 2D Mesh (c) Terrain

Figure 3. Solution domain (Left), 2D mesh (Middle) and terrain (Right) at RM 111 study site

Flow Resistance and Bed Gradation The flow resistance and initial bed/subsurface sediment gradations are two major model inputs. The flow resistance is computed with the Manning's roughness equation. In this study, the Manning's coefficient of 0.026 is used in the main channel and bare bars based on the study carried out in the reach upstream of San Acacia Diversion Dam (Lai, 2007). No separate calibration for the roughness coefficient is carried out due to lack of data.

Initial bed and subsurface sediment gradations are represented by four bed zones as shown in Figure 4a. Each zone is assigned with thickness of the surface and sub-surface layers along with the sediment gradation (cumulative sediment size distribution). Sediment gradation surveys were carried out by Bauer (2006) between June 15-20, 2006 and again between July 17-19, 2006. These survey data are used for the present modeling. The survey points within the study area are displayed in Figure 4b while the gradations of these survey points are plotted in Figure 4c and d.

(c) Points 51 through 56

(d) Points 50 trhough 56

Figure 4. Zonal partition of the solution domain for bed gradation, survey points and the measured cumulative distribution at survey points

Boundary Conditions and Other Model Inputs A time-series flow hydrograph from July 2005 to the end of 2010 is used for the simulation; the data are based on the runoff data recorded at the USGS San Acacia Floodway station (#08354900) (Figure 5a). The time series discharges are used as the upstream boundary condition. The upstream sediment supply is based on the capacity equation of Parker (1990) since the measured sediment flux data are unavailable. Discharges less than 1,000 cfs are excluded from sediment modeling as done by Lai (2009) and Lai (2011) for the Rio Grande since low flows do not change the channel morphology appreciably and the exclusion reduces the computing time. At the downstream boundary, the normal depth boundary condition is applied. The normal depth assumption is adequate for the present study since the selected downstream boundary is located quite far away from the RM 111 bend which is the zone of interest of the study; the outlet is also located in a relatively straight channel.

A total of seven sediment size classes are used, from 0.002 to 125 mm, to represent the bed material load. The partition of the seven classes is shown in Table 1. The sediment erosional rate

potential uses the Parker (1990) sediment transport equation. The bedload adaptation length is chosen to be 170 ft (about the average channel width of the study reach), and the active layer thickness is 30 mm which is about twice the mean particle diameter in the main channel.

Table 1. Size ranges of each sediment size class

Sediment Size Class	Size Range (mm)
1	.002 to .0625
2	.0625 to .25
3	.25 to .5
4	.5 to 2.0
5	2.0 to 8.0
6	8.0 to 32
7	32 to 125

Bank Module Inputs Additional input parameters are related to the bank properties for a coupled geofluvial modeling; the right bank within the bend is simulated as shown in Figure 5b. In the figure, both bank toe and top lines are displayed. The mesh within the bank zone consists of quadrilateral cells and has a total of five lateral nodes. Longitudinally, fifteen (15) bank profiles are simulated; the toe and top nodes of each bank profile are displayed in Figure 5b as black dots.

A separate input file is used for the bank erosion module and it contains bank erosion input parameters for each of the 15 banks. The input parameters are summarized below:

- A constant time step of 1 hour is used for the bank erosion module (as compared with 5 seconds time step for the flow and sediment transport modeling);
- Each bank is simulated using the uniform retreat module with the following input parameters;
    - All banks have the same bank porosity of 0.4 and critical shear stress of 0.0 Pa, with the initial angle of the bank profile unchanged;
    - The volumetric composition of the bank sediment in terms of the seven size classes in Table 1 is specified as: 13%, 29%, 29%, 29%, 0%, 0%, and 0%; and
    - The erodibility coefficient is calibrated and the final values were: 2.0e-5 for banks 2 to 10; 5.0e-6 for banks 11 to 12; 2.0e-6 from banks 13 to 15.

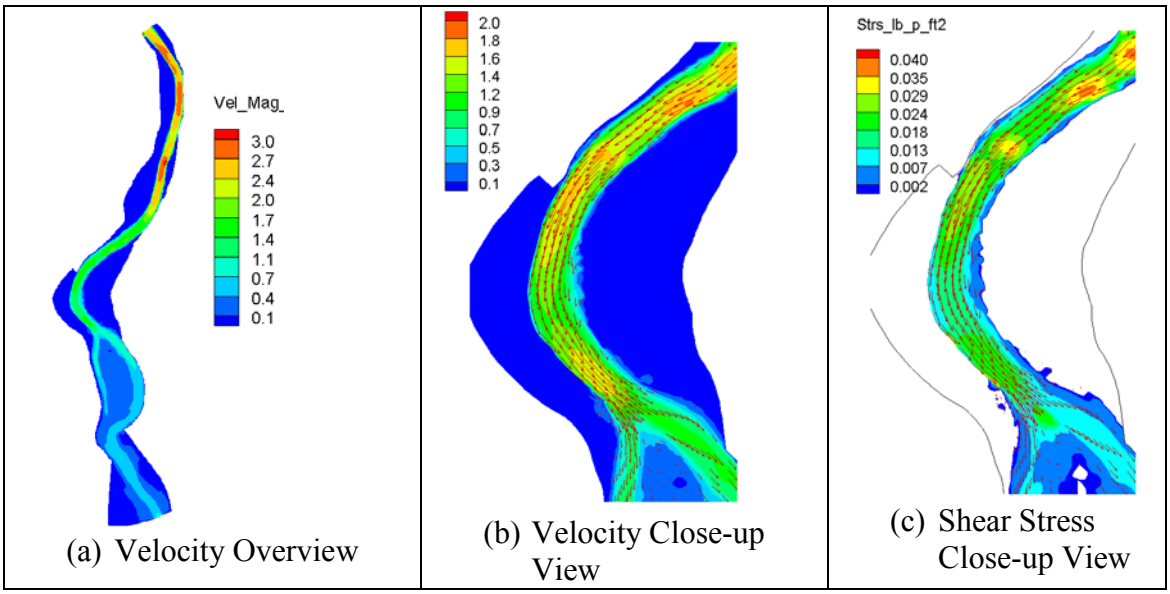
RESULTS AND DISCUSSION

Simulation is carried out from October, 2005 to September, 2010. First a constant discharge of 1,000 cfs is simulated without the bank erosion module. The flow results are discussed first since it is used as the initial condition. It is also used as the cutoff discharge for the bank erosion mobile-bed modeling. The bank erosion modeling results are presented and discussed afterwards.

Flow Results The predicted flow velocity and shear stress for the 1,000 cfs discharge are shown in Figure 6 (shear stress unit conversion: lb/ft^2 = 47.838 Pa). The results show that flow in the upstream section above the bend has higher velocity and shear stress than the downstream section, due possibly to narrower upstream cross sections. The RM 111 bend is only subject to moderate fluvial loading with shear stress around 1.0 Pa at the 1,000 cfs flow. This is a bit surprising considering that this bend has been subject to bank erosion over the study period. Without bank erosion modeling, the hydraulic flow results alone may be used infer the bank erosion mechanisms. First, the bank at the bend might consist of weaker materials than those upstream, owing to geological reasons or vegetation roots, as the shear stress is not very high. The field observation by the author in February, 2013 seemed to confirm the above conjecture. It was found that the banks at RM 111 composed of very fine, unconsolidated, easily erodible materials. Also, the banks were mostly bare without much vegetation presence except near the downstream section. Second, non-fluvial processes such as seepage and/or piping may contribute to bank erosion. If this is the case, rainfall events would also influence the erosion process and a fluvial based method alone might be insufficient to capture all processes. At the best, the erodibility coefficient used by SRH-2D model needs to take the non-fluvial processes into consideration. Without detailed field study and monitoring data, I could not identify the processes for sure.



(a) Velocity Overview

(b) Velocity Close-up View

(c) Shear Stress Close-up View

Figure 6. Simulated velocity and shear stress at 1,000 cfs discharge with the 2005 terrain

Bank Erosion Modeling Results Bank erosion mobile-bed modeling is carried out in an attempt to calibrate the model using the bank retreat data computed from the historical aerial photographs. The modeling study assumes that fluvial processes are responsible for the bank erosion at the RM 111 site. For the modeling, the erodibility coefficient is chosen as the main calibration parameter.

All model input parameters and initial and boundary conditions have been discussed above. The calibration model run starts the simulation in October 2005 and ends in September 2010. The final 2010 bankline predicted by the model is plotted in Figure 7 and it is represented by the red dots of both bank toe and top points. In the figure, the January 2006 and summer 2010 historical aerial photographs are also shown for comparison. It is seen that the calibrated model did a reasonably good job in capturing the bank retreat over the 5-year period; up to about 78 feet of bank retreat distance is predicted at a few cross sections which is in agreement with the historical data.

With the calibration model, erodibility coefficient is chosen as the primary calibration parameter. However, its value has to be changed along the outer bank with a large reduction of erodibility at the downstream section of the bank. The calibrated model uses the following erodibility values: 2.0e-5 for banks 2 to 10; 5.0e-6 for banks 11 to 12; and 2.0e-6 from banks 13 to 15. A reduction of erodibility for banks 11-15 is justified as the banks in this area were reinforced by the presence of the vegetation as shown in Figure 7a as well as the photos shown in Figure 2.

During calibration it is found that a very small critical shear was required in order to simulate the bank erosion reasonably. This may or may not be physically correct. I attribute the cause to the poor representation of the terrain in the bend area.

CONCLUDING REMARKS

The new geofluvial SRH-2D model, which coupled bank erosion modules with the mobile-bed model, is applied to predict the bank erosion at RM 111 on the Rio Grande, New Mexico. The simulation starts with the reconstructed river terrain representing the October 2005 river condition, and ends in September 2010. The 5-year simulation is carried out by using the actual, recorded daily discharge at the USGS gaging station 08354900, the Rio Grande Floodway at San Acacia, NM. The study finds that SRH-2D model is robust and ready to use with its uniform retreat bank erosion module for engineering applications. The main bank erosion calibration parameter is the erodibility coefficient that quantifies the rate of retreat at each simulated bank. The erodibility coefficient is used to represent primarily the fluvial processes. The effect of vegetation protection may also be included. However, the erodibility coefficient may also be used to represent non-fluvial processes if they are identified and quantified in the field. Once calibrated, the numerical model can perform a reasonable job in predicting the right amount of bank retreatment.

Despite the success, there are areas that need further attention and improvements in the future. They include the following:

- Field study is recommended at bank erosion sites focusing on identifying the dominant bank erosion mechanisms. SRH-2D is developed primarily for fluvial processes. If non-fluvial processes are also important, the model would be less accurate, although the erodibility coefficient can be adjusted to take non-fluvial processes into account to a certain extent.
- The terrain data, mainly in the main channel of the retreating banks, are too scarce in the present study. We believe the October 2005 terrain reconstructed from the available data is not accurate enough for this study. High uncertainty in the terrain may cause doubts on

the reasonableness of the calibrated erodibility coefficient. Erodibility should be a physical parameter; however, it is possible that the calibrated value of this study may also contain a non-physical portion that is necessary to compensate the high uncertainty of the terrain data. In the future, a bathymetric survey near the banks is recommended for SRH-2D bank erosion modeling in order to predict potential future bank changes more reliably if such data are not already available or too sparse.

COMPLEX GEOMORPHIC RESPONSES TO BASE LEVEL FLUCTUATIONS: A CASE STUDY ON THE RIO GRANDE UPSTREAM OF ELEPHANT BUTTE RESERVOIR

Nathan Holste, Hydraulic Engineer, Bureau of Reclamation, Denver, CO, nholste@usbr.gov

INTRODUCTION

The Rio Grande has episodically become disconnected from the Elephant Butte Reservoir pool in southern New Mexico after drought-induced periods of drastic reservoir recession, most recently from 1998 to 2004. Relatively high sediment loads coupled with low water discharge and a flat valley slope caused the river channel to lose form within the reservoir delta. Water and sediment could not be effectively delivered to the reservoir pool due to the lack of an established channel, which led to high evapotranspiration water loss within the delta area. Therefore, a channel was constructed between 2000 and 2004 to reconnect the river to the reservoir pool. Annually recurring adaptive maintenance of the excavated channel has been required to remove accumulated sediment, clear vegetation, and repair spoil berms. Upstream of the delta area, concerns have included sediment plugs that blocked the main channel and headcuts that caused bank instability and habitat loss. These issues motivated an assessment of channel conditions and dynamics within a geomorphic framework that considers the primary physical processes that govern alluvial river morphology. A reach length of 60 miles was evaluated from Elephant Butte Dam to the Highway 380 Bridge, with emphasis on the subreaches closest to the reservoir pool.

This reach of the Rio Grande is highly dynamic and behaves with a great deal of complexity. The geomorphic drivers of water discharge and sediment load, coupled with the primary control of downstream base level (reservoir pool) elevation, have varied significantly from the early 1900s to the present. After a period of initial reservoir filling that followed dam construction in 1915, the reservoir water surface has fluctuated over a vertical range of 150 feet (a shift in the horizontal water surface of around 32 river miles) corresponding to wet and dry climatic periods. Given that the Rio Grande's water and sediment inputs are varying while the downstream control is changing, it is clear that a complex series of responses should be expected. The river's planform, cross-sectional shape, slope, bed elevation, and other morphological characteristics are continuously changing in response to alterations in water discharge, sediment load, base level, and anthropogenic actions (Schumm, 1977; Watson et al., 2007).

The relationship between upstream geomorphic drivers and the downstream control often results in a sediment imbalance upstream of the reservoir pool. An imbalance between sediment supply and sediment transport capacity is the prevailing condition within this reach of the Rio Grande, which causes frequent channel adjustments over both space and time. Analysis demonstrates that the slope and bed elevation of the Rio Grande through this reach respond to a rising or falling reservoir pool. Locations near the reservoir pool tend to adjust quickly, while channel response further upstream occurs later in time and at a lesser rate. Backwater effects from the reservoir may amplify or dampen channel adjustment to upstream water and sediment discharge. Although periods of degradation have been initiated when a high flow event occurs while the reservoir pool is low, aggradation is the most dominant characteristic of this reach.

Sediment balance implies a relative equality between the material made available to a stream from a watershed (sediment supply) and the capacity of a stream to convey the available material (sediment transport capacity). Sediment supply to a river is primarily a function of water discharge and the quantity and characteristics of available sediment. Sediment transport capacity is determined by the channel morphology and its interaction with flowing water. The fundamental cause of most channel and floodplain adjustments is an imbalance between sediment supply and transport capacity (Lane, 1955; Schumm, 1977). Figure 1 shows that the rate of sediment transport in a river, or section of river, is governed by a limited sediment supply (supply limited) or a limited transport capacity (capacity limited) (Julien, 1998). The relative magnitude of these two variables determines the response of the river. Where an alluvial river system has excess transport capacity, typical adjustments include channel incision, bank erosion, and potential planform change from a braided sand bed channel to a single thread, mildly sinuous channel with a coarser bed. Additionally, a reduction in sediment supply generally results in a narrower, deeper channel with a flatter local slope and increased sinuosity. Where a river has excess sediment supply and limited transport capacity, channel aggradation will occur. Aggradation usually causes a wider, shallower channel with a steeper slope, decreased sinuosity, and reduced flow capacity (Reclamation, 2012).

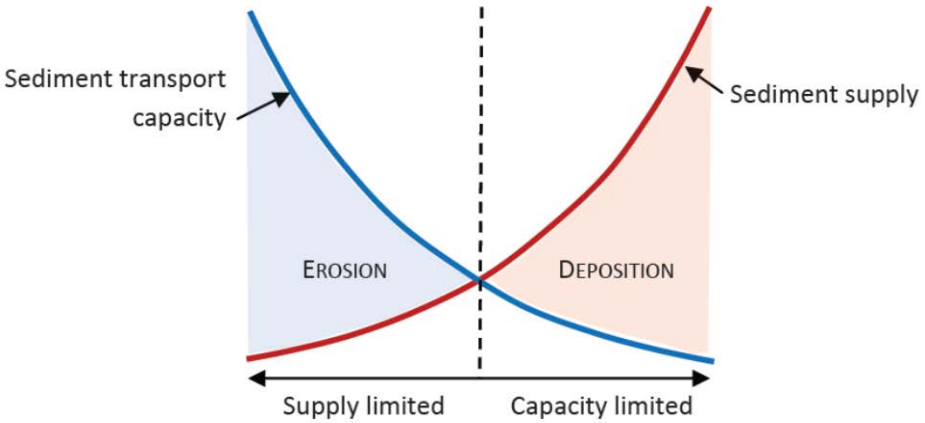

Figure 1 Sediment transport and supply curves (after Julien, 1998).

Lane (1955) proposed a qualitative relationship for adjustment in alluvial streams as a function of sediment supply and transport capacity. This relationship, known as Lane's balance ($Q_s d_{50} \sim QS$), states that the river's sediment load (Q_s) and median sediment size (d_{50}) are proportional to the river's water discharge (Q) and slope (S). Although the relationship is indeterminate, it provides a conceptual framework for evaluating the direction of change that would restore balance to a river system where one or more of the parameters have been altered. The concept of Lane's balance and sediment balance was first discussed by Davis (1895), who explained how the gradient of a stream adjusts so that the capacity to do work (related to sediment transport capacity) is equal to the work that must be done (related to sediment supply). Davis's description of work is essentially the river's ability to effectively transport the available water and sediment. The river morphology adjusts in an attempt to balance the energy of the flow with the sediment regime.

GEOMORPHIC DRIVERS

Sediment balance, or imbalance, is affected by two types of factors: drivers of channel adjustment and controls on channel adjustment (Makar and AuBuchon, 2012). During a period of years, decades, or centuries, the primary drivers that determine alluvial channel morphology are the flow regime and sediment load (Schumm, 1977; Watson et al., 2007).

Flow Magnitude, Frequency, and Duration: On the Middle Rio Grande, flood and sediment control dams have altered the hydrologic regime by reducing flood peaks. Natural climate cycles have also affected streamflow characteristics. During dry periods from 1943–1978 and 1996–present, most of the recorded peak flows are substantially less than 5,000 cfs and the annual flow volume is typically less than one million acre-feet. Wetter cycles from 1903–1942 and 1979–1995 resulted in peaks significantly greater than 5,000 cfs and annual flow volumes greater than one million acre-feet. The sequencing, or relationship, between monsoon and spring runoff events contributes to the sediment balance complexity because much of the sediment is supplied to the river during monsoons and transported during spring runoff flows.

Figure 2 illustrates the total annual valley flow volume, as calculated by combining values from the Rio Grande at San Marcial (USGS Gage 08358500), Rio Grande Floodway at San Marcial (USGS Gage 08358400), and the Rio Grande Conveyance Channel at San Marcial (USGS Gage 08358300). The gage locations are combined in order to maintain consistency across the period of record while accounting for operation of the Low Flow Conveyance Channel (LFCC) from 1952 to 1975 and 1983 to 1985. The annual flow volume incorporates both the magnitude and duration of flow events so it is a good indication of the energy provided to the river. The channel planform has narrowed and become more uniform as decreased peak flows have not reworked the channel to the degree it had been in the past (Makar and AuBuchon, 2012). It is evident that flows upstream of Elephant Butte are quite dynamic; the variability exists within wet-dry cycles and across the entire period of record.

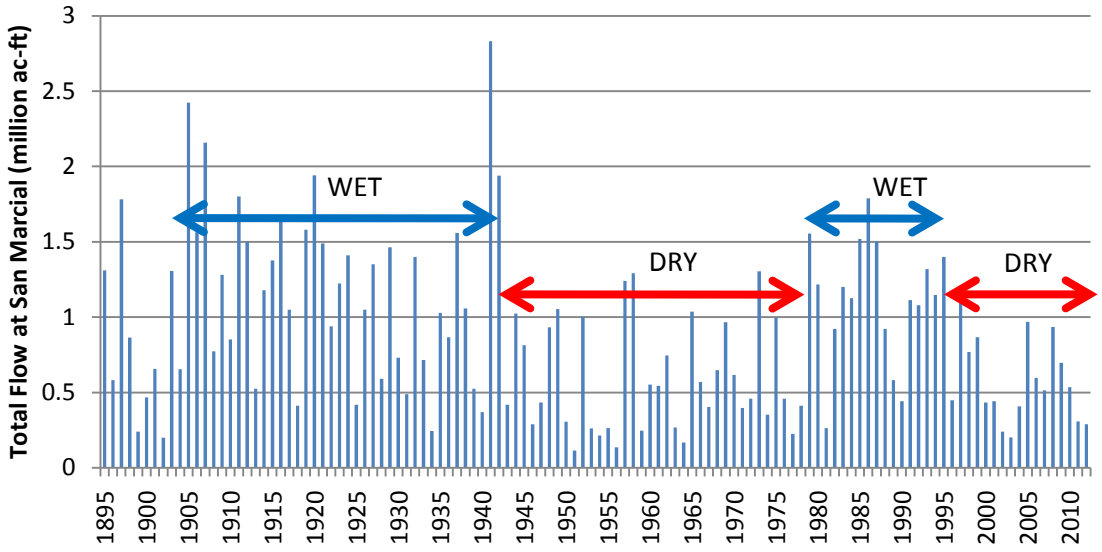

Figure 2 Annual valley flow volume at San Marcial (1895–2012).

Sediment Supply: Sediment supply is coupled with water discharge as the primary drivers of channel morphology and is also half of the sediment balance relationship. For an alluvial channel, sediment particles at a given location must have been eroded from within the watershed above the cross section and transported by flow from the place of erosion to the cross section (Julien, 1998). The Rio Grande is a sediment-laden river with many sources contributing to the total load including upland erosion (overland flow), tributaries (arroyo flow), and bed/bank erosion (main channel flow). Sediment supply is difficult to quantify due to the highly spatially and temporally variable physical processes that are not easily measured.

Sediment loads have been reduced on the Middle Rio Grande as a result of reduction of peak flows, deposition in reservoirs, and other sediment control measures (Makar and AuBuchon, 2012). Figure 3 is a double mass curve of cumulative suspended sediment load versus water discharge at San Marcial. It should be noted that suspended load is only a portion of the total load and does not include coarser particles that are transported near the bed. A steeper slope on the graph indicates that a greater volume of sediment is being carried for an equal discharge, as compared to a flatter slope that represents a smaller volume of suspended sediment for the same discharge. The figure shows a high concentration of sediment from 1955 to 1977, a slightly lower concentration from 1978 to 1982, and an even lower concentration from 1983 to 1992. Beginning in 1993, the concentration increased for a period through 2006, after which it decreased again between 2007 and 2012. Data from future years may show if a true shift occurred in 2007, or if the current period is statistically similar to 1993–2006.

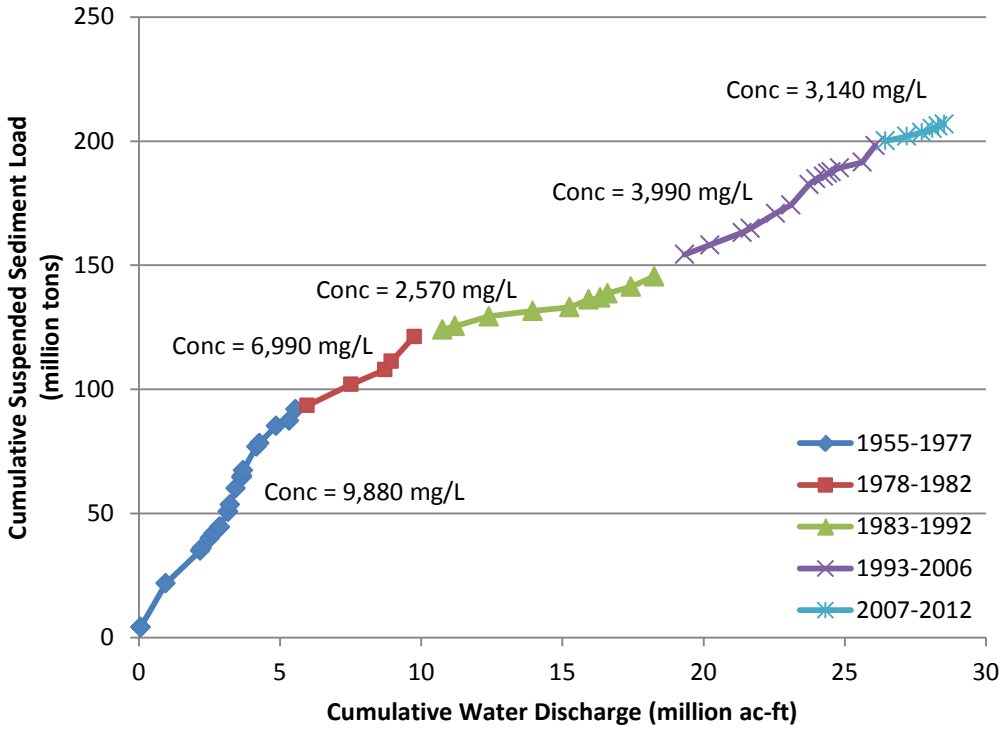

Figure 3 Cumulative suspended sediment load versus discharge at San Marcial Floodway Gage.

GEOMORPHIC CONTROLS

Controls can be defined as factors that limit or influence the effect that drivers have on channel adjustment (Makar and AuBuchon, 2012). These factors are further characterized as channel and floodplain controls or base level control.

Channel and Floodplain: The channel boundary consists of the stream bed and stream banks; the material composition of these features significantly affects channel planform and cross-sectional geometry. Bed and banks that are erodible allow the river to freely shift shape, position or pattern. The relative stability and roughness of the bed and banks often determines whether the channel will adjust laterally or vertically. When sediment transport capacity exceeds supply, a channel with an erodible bed and resistant banks will tend to incise. Over time, the bed material may coarsen and incision may continue below the vegetative root mass elevation, thus stabilizing the bed and destabilizing the banks. At this time, lateral erosion of the banks will occur as described in the Channel Evolution Model (Schumm et al, 1984; Watson et al., 2007). Coarser bed and bank material typically provide enhanced stability, but fine-grained cohesive sediments may also be relatively erosion resistant. The presence of clay layers has been well documented within the study area (Hilldale, 2003; Bauer, 2007). Cohesive silt and clay are usually most prominent on bars and floodplain surfaces, although there have been observations of clay spanning the entire width of the riverbed. Existing clay layers may have been deposited long ago in former overbank or reservoir pool areas, but there is also a significant amount of cohesive material deposited annually by arroyo flows. Bed material grain size is classified as fine sand (0.125–0.25 mm) for the majority of the study reach and medium sand (0.25–0.5 mm) for the most upstream 10–20 miles. Coarsening has occurred during the previous 40 years, a trend that is consistent with other reaches throughout the Middle Rio Grande (Makar and AuBuchon, 2012).

Floodplain characteristics also act as a control on channel adjustment. A well-connected floodplain where overbanking flows frequently occur provides a negative feedback mechanism that dissipates energy during large floods. A positive feedback loop occurs in channels with a disconnected floodplain as the energy is confined to the channel and increasing velocity and shear stress are amplified. Floodplain confinement is a control that limits lateral migration and the width of overbanking flow due to natural geologic outcrops or artificial levees. Lateral constraints confine sediment-carrying flood waters and may increase the depth of deposition because the available area is reduced. Deposition across a river and floodplain cross section is not uniform, owing to the vertical sediment concentration profile and local site conditions. Many cross sections within this reach show a channel perched above the floodplain, and a floodplain perched above the valley. Overbanking flows within these areas are often separated from main channel flows, thereby reducing channel sediment transport capacity and contributing to sediment imbalance. A perched system is indicative of disequilibrium and increases the probability of channel avulsions or levee breaches.

Base Level: Base level, the downstream limit of the stream network and origin of the thalweg profile, controls the longitudinal water surface profile for typical alluvial rivers. Changes in base level have the potential to initiate instability within the river system (Watson et al., 2007). Table 1 distinguishes the primary causes of bed elevation change that progresses downstream from that

of an upstream progression. Base level lowering, such as a drop in reservoir pool elevation, locally increases slope at the channel outlet (e.g., reservoir delta) thus increasing sediment transport capacity. If the increased capacity exceeds sediment supply, the abrupt break of slope (headcut or knickpoint) migrates upstream through the system. The peak rate of degradation is dependent on discharge and usually occurs fairly quickly and then slows over time, while also declining at further distances upstream. Incision may trigger bank instability that generates lateral erosion and channel widening. Bank erosion provides additional sediment input to the stream and the system oscillates through a series of adjustments to the new base level until relative stability is restored. (Stability may never be restored if the base level continues to fluctuate and there is not a balance between sediment supply and transport capacity.) In the absence of a geologic control, the final gradient resembles the same form as the original slope, but at a lower bed elevation throughout the affected reach (Knighton, 1998; Watson et al., 2007).

Table 1 Main Causes of Streambed Elevation Change (adapted from Knighton, 1998).

Type of Bed Elevation Change	**Upstream Driver: Cause of Downstream Progression**	**Downstream Control: Cause of Upstream Progression**
Degradation	water discharge increase; sediment supply decrease	base level fall
Aggradation	water discharge decrease; sediment supply increase	base level rise

Conversely, a rise in base level reduces local transport capacity at the river/pool interface and initiates or increases deposition. Lai and Capart (2008) conducted physical and numerical modeling to examine longitudinal delta profile evolutions over time for a constant base level and a steadily rising base level. For both cases, the greatest amount of aggradation occurred at the intersection of the pool water surface and the riverbed, while the rate of aggradation decreased further upstream. The rising base level models showed that the zone of greatest aggradation moved upstream in response to the advancing reservoir pool shoreline. At a constant location significantly upstream of the reservoir pool, there was more aggradation during the rising base level experiment than the steady base level experiment.

Reservoir and Riverbed Elevation Analysis: Construction of Elephant Butte Dam began in 1908 and was completed in 1916, with water storage operations beginning in 1915. The dam's spillway is an uncontrolled ogee crest weir and has a crest elevation of 4452.5 feet in the NAVD88 datum (Ferrari, 2008). The reservoir pool filled fairly rapidly between 1915 and 1920, and then declined slightly until large floods in 1941 and 1942 completely filled the reservoir. Between 1942 and 1951, the average annual pool elevation dropped 114 feet. The reservoir pool stayed fairly low through the end of the dry period in 1978 and then increased 101 feet to full pool elevation in 1986 due to large flows in the 1980s. The reservoir was essentially full between 1985 and 1995 before declining slightly through 1998. Between 1998 and 2004, the average pool elevation dropped 90 feet. A moderate increase of 35–40 feet occurred between 2004 and 2009 prior to a similar decrease of 30–40 feet through 2012.

Figure 4 shows a time series plot of the pool water surface elevation compared to the riverbed elevation at San Marcial. San Marcial is about 42 miles upstream of Elephant Butte Dam, 31 miles upstream of the average 2012 pool elevation, and 5 miles upstream of the full pool

elevation. The largest rates of aggradation (1920–1948 and 1978–1995) have occurred during periods of increasing or full reservoir pool elevations. Periods of riverbed degradation (1949–1972 and 2005–2011) correspond to low or decreasing reservoir pool elevations. The periods of degradation began during large spring runoff events of 1949 and 2005, both about 7 years after the reservoir pool started to lower. Bed elevation stabilized briefly from 1950 to 1956, before large flows in 1957 and 1958 initiated a more constant degradational trend through about 1972. The 1949–1972 degradation rate was only about one half to one third that of the recent rate, most likely due to the substantially higher historical sediment load (Figure 3). Short-term degradation during 1937 (Happ, 1948), 1991, and 1995 was caused by avulsions or sediment plugs that reduced upstream sediment supply. A sediment plug also occurred in 2005, but the degradational effect persisted over a longer period of time because of the lowered reservoir pool. All three of the primary degradation causes (Table 1) were present during the 2005 spring runoff: water supply increase, sediment supply decrease, and a lowered base level. Although degradation has occurred during the identified periods, the overall dominant historic trend is aggradational. The average riverbed elevation at San Marcial has increased by about 21 feet since 1895 and by about 18 feet since Elephant Butte water storage began in 1915.

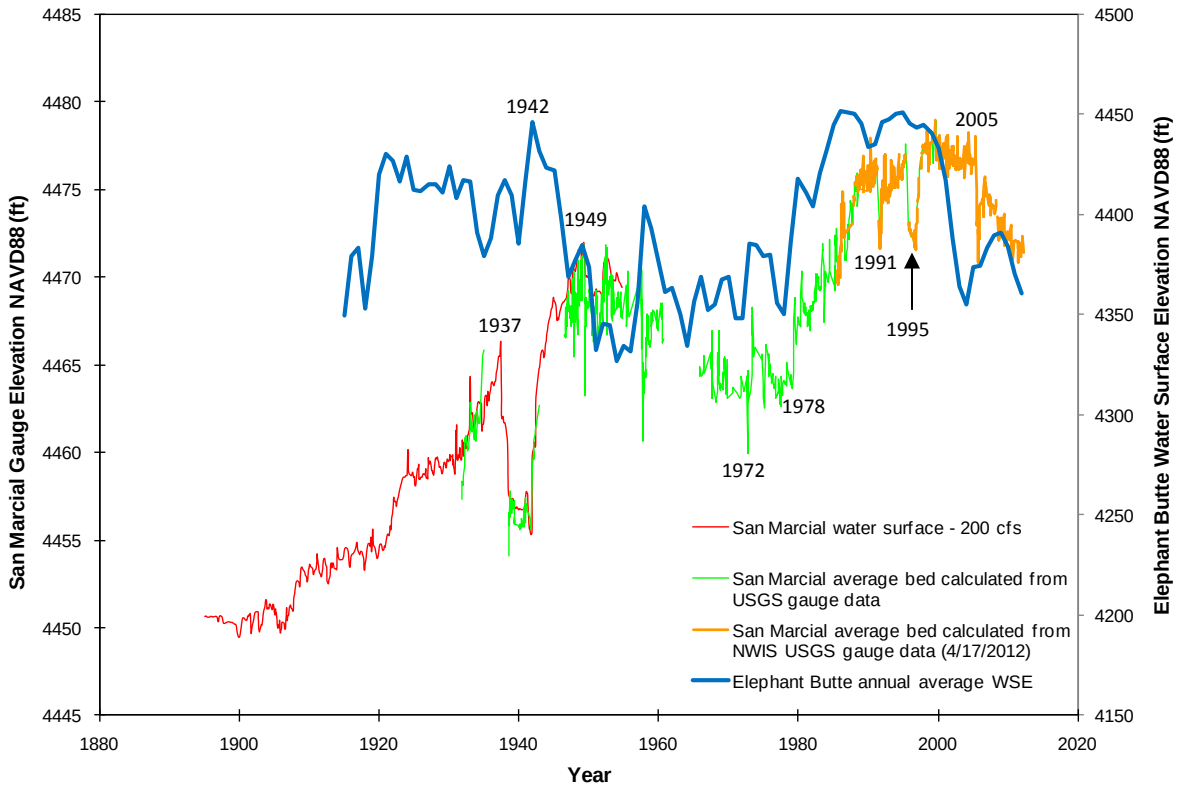

Figure 4 Elevation changes of the USGS San Marcial gage and Elephant Butte Reservoir pool over time (modified from Makar 2013, pers. comm.).

It is instructive to consider the various geographic locations of the reservoir pool shoreline in the context of the river and reservoir longitudinal profiles. Figure 5 overlays six different pool

elevations on surveyed profiles from 1915, 1988, 1999, and 2007. The two most apparent observations from the graph are the sediment deposition along the length of the profile and the tremendous range in horizontal and vertical reservoir pool locations. It is evident that the original 1915 slope was fairly uniform from the dam upstream to EB-10 (near San Marcial). The more recent profiles show a break in slope (pivot point or knickpoint) at the Narrows where the greatest amount of historical aggradation has occurred. This is also the historical average pool elevation, corroborating the model results of Lai and Capart (2008). Degradation at the Narrows and locations further upstream can be observed in the profiles between 1999 and 2007, corresponding to a decline in reservoir pool elevation. Strand and Pemberton (1982) describe the development of a topset slope and foreset slope during the delta formation process. They found that, on average, the topset slope is half of the original channel slope and the foreset slope is 6.5 times steeper than the topset slope. The grade break between the two slopes is known as the pivot point, which becomes a knickpoint or headcut within the river channel after the pool water surface lowers. This process sets up conditions that promote upstream migration of riverbed degradation after a period of reservoir lowering.

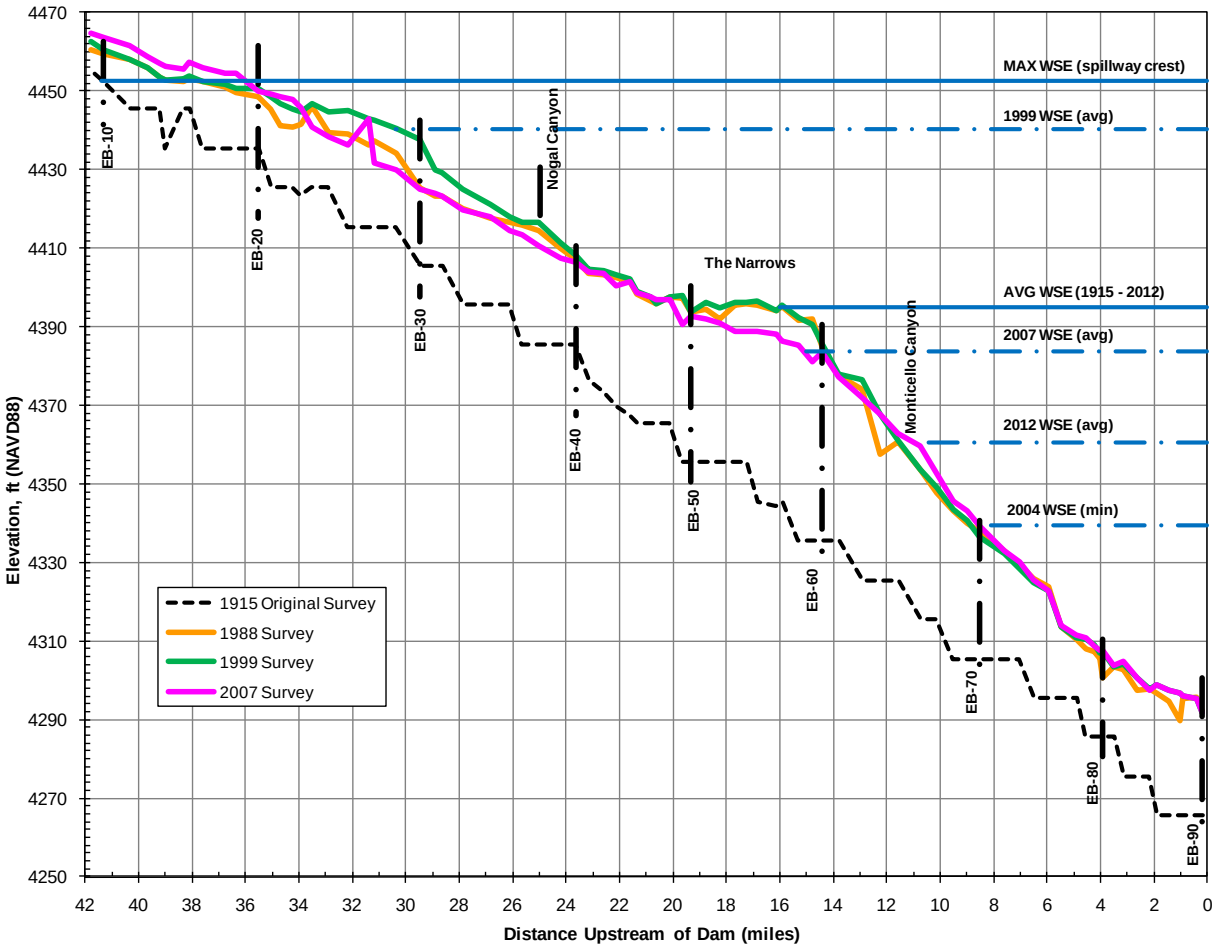

Figure 5 Elephant Butte Reservoir longitudinal profiles and pool elevations (modified from Ferrari, 2008).

Comparing the 1999 and 2004 reservoir water surfaces within the context of the longitudinal profiles also shows why channel excavation was needed to maintain a connection from the river to the reservoir pool. The flat slope in many areas combined with low flows and relatively high sediment loads did not provide enough energy for the river to carve its own channel through several miles of delta. After initial construction was completed in 2004, the channel has required annual maintenance to adapt to the dynamic nature of the delta area. Concerns were expressed that the recurring maintenance may cause reach-wide riverbed degradation, which led to a more detailed analysis of the constructed channel during the maintenance period. Figure 6 demonstrates that during recurring maintenance, the average thalweg elevation responded directly to the reservoir pool: aggradation occurred between 2004 and 2010 as the pool elevation increased and degradation occurred between 2010 and 2012 while the pool receded. In this dynamic and complex system, geomorphic effects that may have been caused by maintenance actions are not discernable compared to the significant effects from the geomorphic drivers and the primary control of base level elevation.

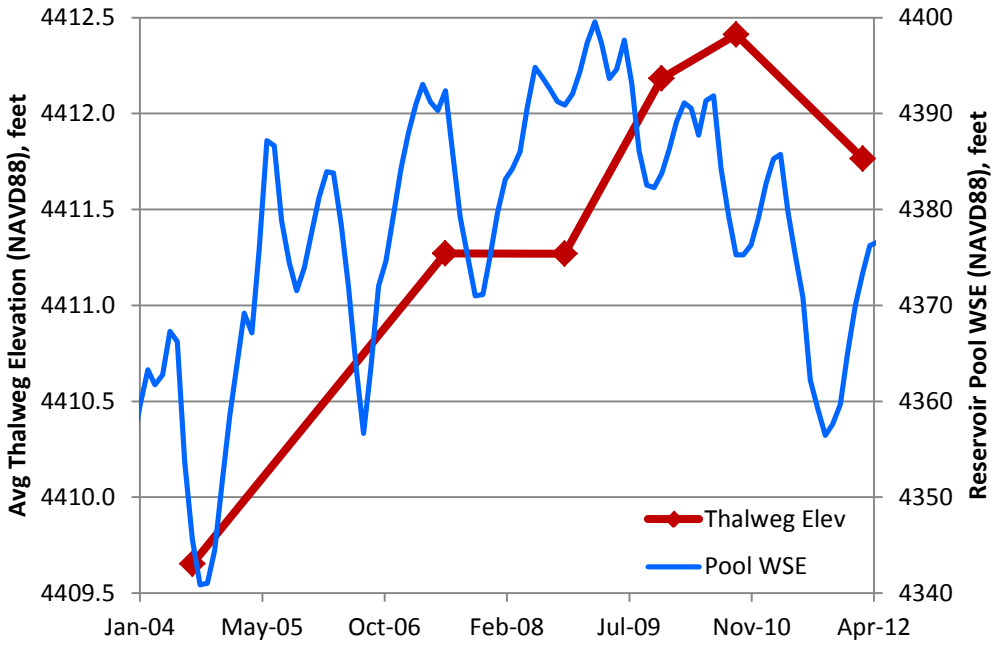

Figure 6 Distance-weighted average thalweg elevation over time for the constructed channel (between EB-28 and EB-50) during recurring channel maintenance.

Reservoir and Riverbed Slope Analysis: River slope is one of the best indicators of the river's ability to do morphological work (Watson et al., 2007) and, as discussed earlier, slope directly affects the transport capacity and sediment balance of a river system. An increase or decrease in the river slope over time provides insight regarding the river's response to changes in upstream drivers (water and sediment discharge) and downstream control (base level). Changes in slope are a measure of the relative bed adjustment between the upper and lower sections of a reach; if all cross sections aggraded or degraded equally the slope would not change. A steeper slope that provides increased transport capacity would result from aggradation at the upper portion of a reach and/or degradation at the lower end. A flatter slope that provides reduced transport

capacity could be created by degradation at the upstream section of a reach and/or aggradation downstream. Figure 7 presents thalweg profiles of the Rio Grande from the Highway 380 Bridge to the Narrows between 1999 and 2012. The pivot point corresponding to the reservoir pool elevation and the upstream depositional wedge are clearly evident in the 1999 profile. Little change occurred during the 1999–2004 low flow years before upstream headcut migration occurred during the 2005 spring runoff. The 2005 profile also shows the sediment plug near RM 72 and the deposition between RM 46–50 of material eroded from upstream. Finally, there is a zone of convergence between RM 74–78 where the profiles are relatively constant for all years.

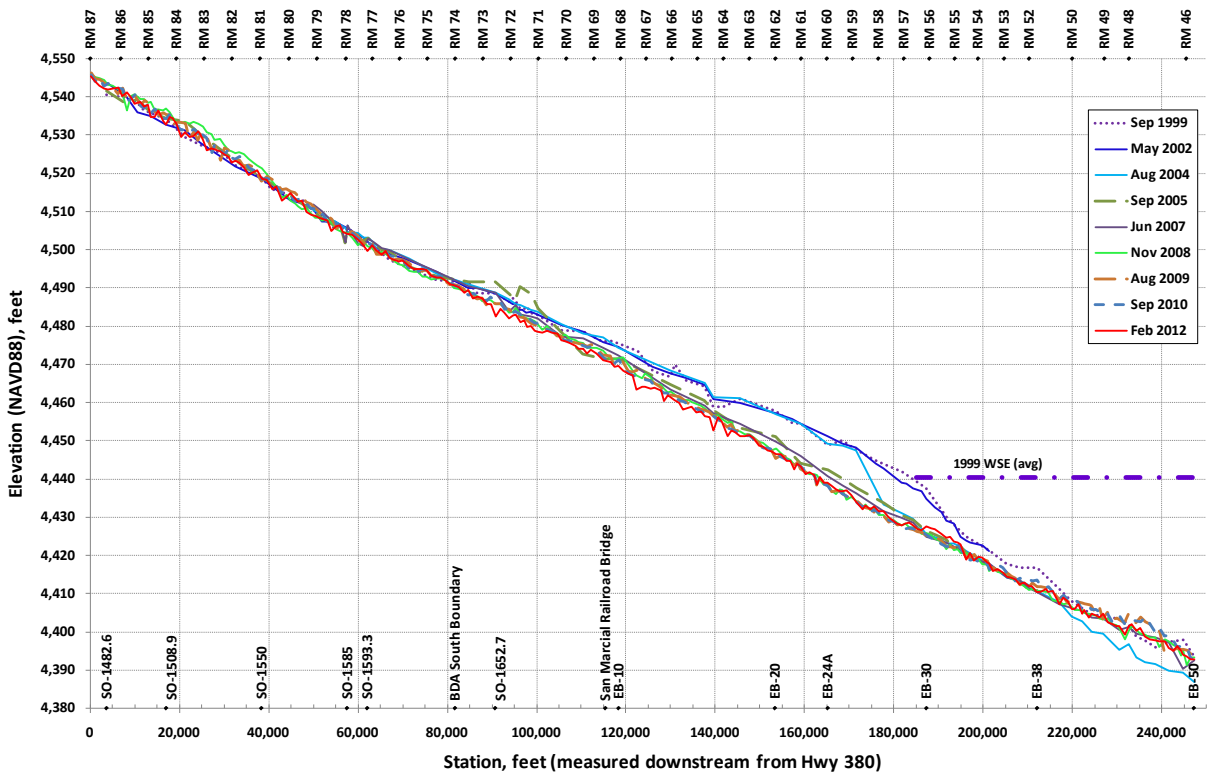

Figure 7 Thalweg profiles from Highway 380 Bridge to the Narrows.

Figure 8 shows the relationship between channel slope and reservoir pool elevation, and also channel slope over time for different Rio Grande subreaches upstream of the reservoir pool. The upper subreach contains 9 miles, measured along the thalweg, from near RM 68 to near RM 60 (EB-10 to EB-24A) and the lower subreach contains 9 miles, from near RM 60 to near RM 52 (EB-24A to EB-38). Results for the entire 18-mile reach are also shown for comparison. Subreach and reach lengths, in addition to longitudinal profile stationing, were measured along the 2010 thalweg. The lower subreach was partially inundated by the reservoir pool in 1999 and includes the transition into the channel construction work area that began in 2000. The lower subreach also includes the 1999 pivot point at EB-30 and is assumed to be the critical subreach in which transport capacity must exceed sediment supply for a headcut to migrate upstream of RM 60. Downstream of the lower subreach, the section between EB-38 and EB-50 was not included because data were not always available, and it should also be noted that this area is flatter as the Rio Grande enters the Narrows. The figure illustrates the highly variable slope over

time as the river attempts to adjust to changes in downstream base level or upstream drivers. The lower subreach is particularly sensitive to the reservoir pool and the river slope trend closely follows the pool elevation. Although the response is not as dramatic, the slope adjustment of the overall reach is also in sequence with the reservoir pool elevation, steepening when the pool elevation drops and flattening when the pool elevation rises. For the upper subreach, the change in slope is out of phase with changes to the pool elevation. This indicates a delayed response in which the upper subreach adjusts to changes in the lower subreach. Note that lines connecting discrete slope values in the graphic illustrate trends over time (direction of slope change), and actual channel slope values are labeled on the reversed y-axes (steeper slopes are near bottom of graph).

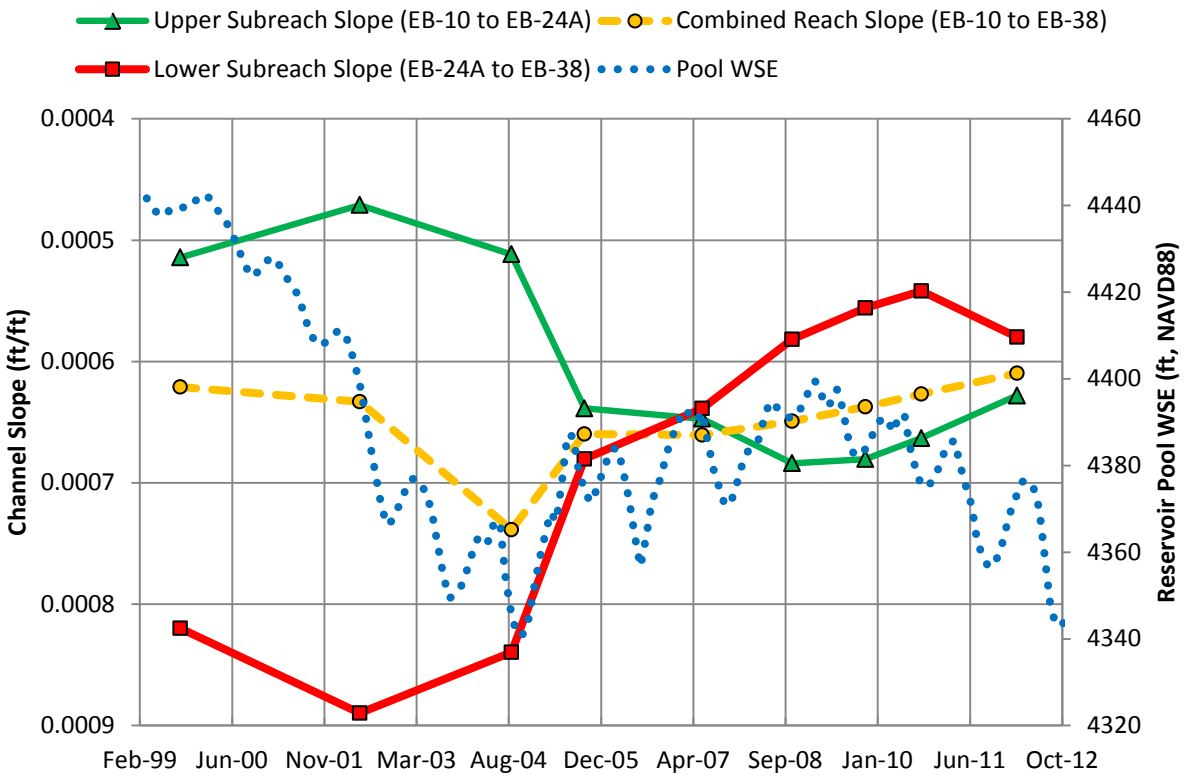

Figure 8 Changes to channel slope and reservoir pool elevation over time (1999–2012).

Using a constant water surface elevation in the reservoir at the average 2008 level, mobile bed modeling results predict that the stable slope between RM 78 and RM 46 is flatter than the existing slope. This means that a combination of aggradation in the lower portion of the modeled reach (~RM 62–46) and degradation in the upper portion of the modeled reach (~RM 62–78) is expected for the given hydrology, sediment, and base level conditions (Reclamation, 2012). As part of a sensitivity analysis, Reclamation (2012) also found that for some discharge scenarios this reach did not achieve equilibrium even after 120 years of simulation. The model results support the empirical conclusion that the Rio Grande upstream of Elephant Butte Reservoir is inherently unstable and terms such as equilibrium or stable slope do not apply for timescales less than about 100 years.

RESTORING ALLUVIAL FAN CONNECTIVITY FOR POST-FIRE FLOOD ALLEVIATION AND SEDIMENT REDUCTION

Dave Rosgen, Ph.D., Professional Hydrologist, Wildland Hydrology, Fort Collins, CO, Dave@wildlandhydrology.com; Brandon Rosgen, Hydrologist, Wildland Hydrology, Fort Collins, CO, Brandon@wildlandhydrology.com

INTRODUCTION

The Waldo Canyon Fire burned 18,247 acres within the foothills and mountains of the Rampart Range immediately northwest of Colorado Springs, Colorado, in El Paso County. The fire started Saturday, June 23rd, 2012, and was fully contained Tuesday, July 10th, 2012, after destroying 346 homes. The four major watersheds affected by the Waldo Canyon Fire were Camp Creek, Douglas Creek, Fountain Creek, and West Monument Creek. Using GIS, these four watersheds were delineated into 89 sub-watersheds.

A post-fire *Watershed Assessment for River Stability and Sediment Supply (WARSSS)* study was conducted within the four watersheds impacted by the Waldo Canyon Fire in the fall of 2012 and completed in April, 2013 (Rosgen, 2006; Rosgen *et al*., 2013a). The *WARSSS* study is a cumulative watershed effects analysis that quantifies changes in water yield, hillslope erosional processes, and stream channel impacts, including streambank erosion due to disturbance. The assessment found that the prevailing consequences of the Waldo Canyon Fire included: 1) an increased magnitude and frequency of peak flows; 2) accelerated sediment yield from hillslope erosional processes, including rill, gully, and debris flow/debris torrents; 3) streambank erosion and channel enlargement due to destruction of riparian vegetation and increased flows; and 4) channel incision and subsequent abandonment of fluvial features, including alluvial fans.

The results of the *WARSSS* study form the foundation for a multi-watershed master plan to direct restoration efforts to reduce delivered sediment, restore the stability and function of the stream and riparian systems, and accelerate the watershed recovery processes (Rosgen *et al*., 2013b). The results were used to develop design scenarios for post-fire restoration priorities directly related to individual erosional processes by specific sub-watershed location.

This paper focuses on one of the restoration design scenarios related to restoring alluvial fan functions to meet the primary restoration objectives. Ephemeral, fan-head trenches (gullies) within alluvial fans were raised to reconnect to the original fan surface to reduce the flood and debris flows that were directly routed into the trunk stream. Once connectivity of the fan was restored, flood flows were dispersed and sediment was stored. Fill material for the gully was obtained from excavating sediment detention basins at the start, middle, and lower sections of the fan, and braided channels were constructed on the fan surface to match the natural channel form. Log crib walls were constructed for grade control on the upslope end of the sediment detention basins with log sills buried flush on the fan surface to prevent channel incision. An example is presented on the flow and sediment response of restoring alluvial fan function.

IMPACTS OF THE WALDO CANYON FIRE

Rill and gully erosion is common within the fire-scarred landscape associated with soils comprised of highly-weathered grussic granite from Pikes Peak Batholith (Figure 1). Such rills and gullies increase the time of concentration of flows that lead to increased peak flows and associated debris flows.

The post-fire floods and debris flows resulted in major destruction to property and loss of lives. Damage to water transmission lines caused millions of dollars of damage to infrastructure to the Colorado Springs Utilities (Figure 2). A fatality occurred due to debris flows similar to the one shown in Figure 3 that occurred on Highway 24 following a post-fire storm in August, 2013. Furthermore, a 1.0-inch in 30 minute precipitation event created a 1,100 cfs debris flow in Williams Canyon (2.69 mi^2 drainage area with a bankfull discharge of 9.0 cfs) (Figure 4). The sediment supply from debris flows overwhelmed multiple receiving streams and induced stream aggradation (Figure 5). The erosional debris accumulated in downstream channels (Figure 6) and reservoirs (Figure 7).

High rates of sediment are also delivered downstream with subsequent flows when streams become incised in the erosional debris. The incised gullies increase sediment transport capacity due to the increased slope and decreased

width/depth ratio (Figure 8). Further channel aggradation was evident in the receiving streams due to the very high sediment supply delivered from upstream.

Hydrology Impacts: The effects of wildfire on increased peak flows and associated channel source sediment are well-documented (Moody, 2001; Kunze and Stednick, 2006; Moody and Martin, 2009). Relatively frequent precipitation events associated with high intensity, short duration storms are related to unusually large flood peaks (Neary *et al*., 2005; Moody and Martin, 2001a). Jarrett (2013) demonstrated that relatively frequent precipitation events following wildfires result in extremely rare, infrequent flood magnitudes; the predicted peak flows for a given precipitation by drainage area are shown in Figure 9 (Jarrett, 2013). A post-flood, 1.0-inch in 30 minute storm (frequent return period) generated 1,100 cfs (a rare flood) in Waldo Canyon associated with a 1.7 mi^2 drainage area and a bankfull peak flow discharge of 10 cfs. In Northfield Gulch (associated with a drainage area of 0.5 mi^2 and a bankfull discharge of 3.0 cfs), a 1.0-inch per hour storm predicted a flood peak of 210 cfs, where the observed value was 180 cfs (Figure 10).

Stednick and Webb (2014) indicated that post-fire floods can be up to three orders of magnitude greater than pre-flood conditions. Post-fire peak flows have been reported on the Hayman fire in Colorado on small drainage basins that can vary from 600 csm ($ft^3/sec/mi^2$) to over 1,064 csm from a 4.3-inch storm (Robichaud and Wagenbrenner, 2009). Post-fire peak flows have increased from 3.7 csm to over 600 csm on North Douglas Creek on the northern end of the Waldo Canyon Fire.

Moody and Martin (2001b) state that high sediment yields may persist for four to seven years following wildfires. However, hydrologic recovery in certain landscapes is much longer than anticipated; for example, the Hayman fire that burned 12 years ago is still producing high peak flows and disproportionately high sediment yields compared to pre-fire conditions (Rosgen *et al*., 2013a; Stednick and Webb, 2014). Sediment supply recovery from debris flows and associated channel source sediment related to peak flows is not rapid.

The influence of the loss of vegetative cover on streamflow response following wildfires is critical in addressing restoration strategies for recovery (Beanvides-Solorio *et al*., 2005). Hydrologic recovery and decreasing flow-related, channel source sediment is a long-term proposition related to re-establishing the riparian community following wildfires in Colorado. However, decades will be required to reach a full hydrologic utilization due to the cold climate, relatively low precipitation, steep slopes, shallow soils, high elevations, and short growing seasons.

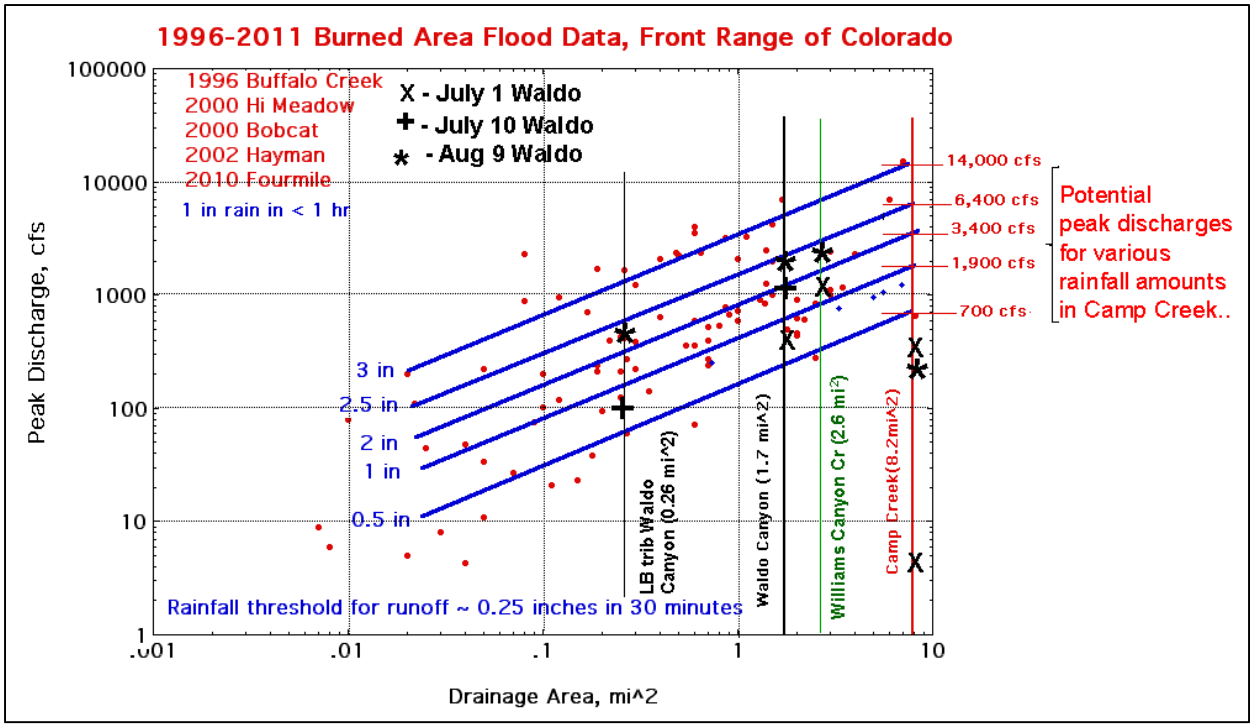

Figure 9 Peak flow data for various precipitation rates by drainage area for various burned watersheds on the Front Range of Colorado (Jarrett, 2013).

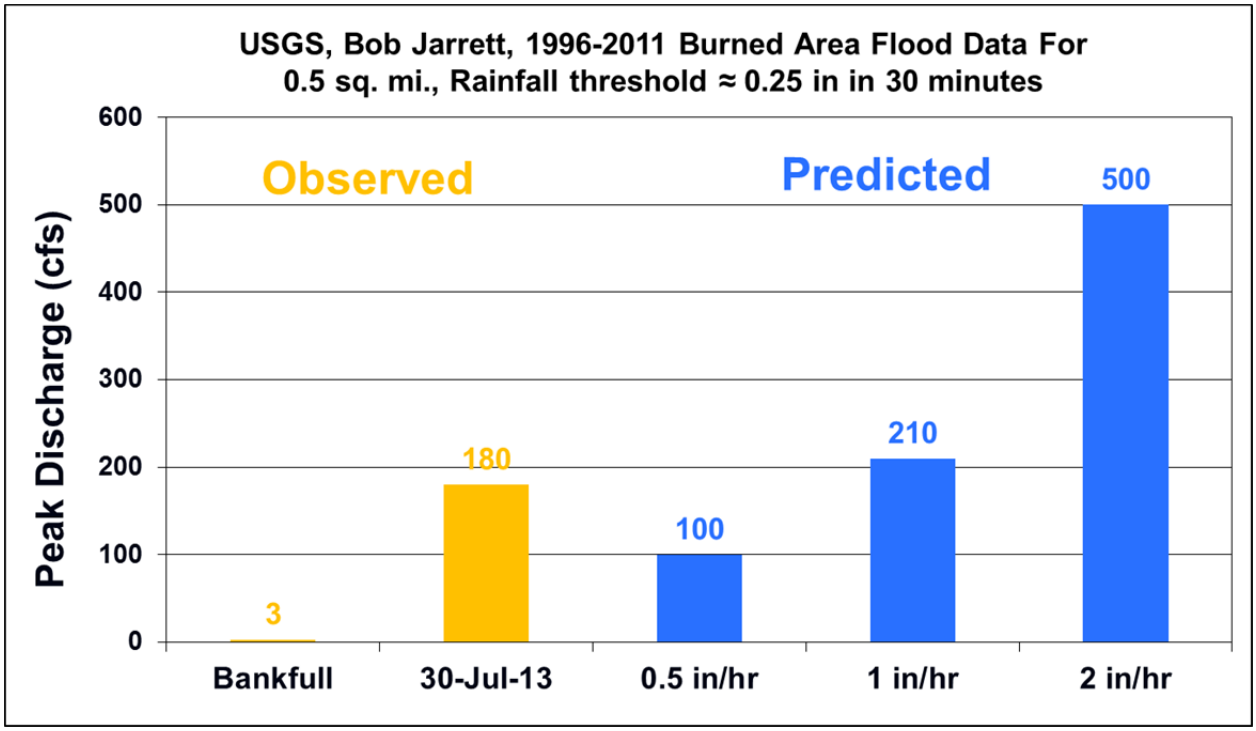

Figure 10 Predicted versus observed post-fire peak discharge for Northfield Gulch by storm intensity rates (Jarrett, 2013).

POST-FIRE ASSESSMENT AND MASTER RESTORATION PLAN

In total, 89 sub-watersheds and 237 miles of stream channel were evaluated within the four major watersheds impacted by the Waldo Canyon Fire to quantify the sediment supply from hillslope, hydrology, and channel processes (Rosgen *et al*., 2013a). The sediment supply was evaluated for each sub-watershed and was totaled for the entire fire area. The total introduced sediment from the Waldo Canyon Fire is estimated to be *51,479 tons/yr*.

The surface erosion from hillslope processes accounted for approximately *18,085 tons/yr*, or 35% of the total introduced sediment. Contributions from roads and trails accounted for approximately *2,035 tons/yr*, or 4% of the total introduced sediment.

Channel processes were evaluated for each stream reach by sub-watershed using the stability methods in *WARSSS* (Rosgen, 2006). The FLOWSED/POWERSED model was used to evaluate sediment transport capacity, and streambank erosion rates were estimated using the BANCS model. Overall, the sediment yield from streambank erosion accounted for *31,480 tons/yr*, or 61% of the total sediment yield (Rosgen *et al*., 2013a). Moody and Martin (2001b) predicted that 80% of introduced sediment from wildfires was from channel sources and 20% was from hillslopes based on the assessment of other fires on the Colorado Front Range.

Changes in hydrology were evaluated using the WRENNS model (USEPA, 1980); post-fire changes in water yield and peak flows were estimated based on the severity of the burn, the percentage of the watershed burned, pre-existing stand composition, and precipitation by elevation/aspect zone. The results from WRENNS were used to determine the flow-related increases in sediment yield using the FLOWSED model.

The results of the *WARSSS* study were used to direct a multi-watershed mater restoration plan (Rosgen *et al*., 2013b). Priority areas for restoration were established for each sub-watershed based on the highest risk and highest sediment producers from the *WARSSS* analysis. Design scenarios were developed to represent the range of stream types and stability conditions that require restoration within the watersheds using representative and reference reaches. The appropriate scenario can then be extrapolated to other reaches of the same stream type, landscape type, and stability condition.

Post-fire rehabilitation often focuses on hillslope processes because of the fast recovery rates; remediation to reduce surface erosion often includes aerial seeding, mulching, planting trees, placing contour logs on burned slopes, and contour trenching. The majority of the work completed by the USDA Forest Service BAER (Burned Area Emergency Rehabilitation) teams focused on surface erosion processes. Although it is important to maintain surface soils and revegetate as soon as possible, the restoration designs must also account for channel source sediment, which contributed 61% of the total sediment yield. The recovery of channel processes is often slow due to the long-term, peak flow increases and associated debris flows, especially in incised and entrenched stream systems. The remainder of this paper focuses on one of the restoration scenarios that accounts for excess channel source sediment related to incised and entrenched stream systems within alluvial fan landscapes.

RESTORING ALLUVIAL FAN CONNECTIVITY

Active alluvial fans and associated braided channels are the natural solution to sediment detention of the erosional material delivered from upper slopes to prevent direct sediment introduction into main trunk streams. The braided, D stream types are the natural, functioning channels on active alluvial fan surfaces that deposit sediment, decrease velocity, increase infiltration, and attenuate flood peaks (see Rosgen, 1994, 1996, for stream type descriptions).

A functioning alluvial fan as displayed in Figure 11 was enlarged following the major 1982 Lawn Lake Flood in Rocky Mountain National Park, Colorado. The Lawn Lake Flood was estimated to be the largest flood since the end of the last glacial retreat at the start of the Holocene period, 10,000 years ago (Jarrett and Costa, 1986). Extensive debris flows were deposited on the fan surface from the upstream lake breach and the associated high energy/high sediment supply from A3a+ stream types that cut into unconsolidated, glacial till with lateral moraine deposits of boulders, cobble, gravel, and sand. The natural grading of the fan deposited the coarser, boulder material at the apex and decreased the surface grain size to sand at the lower lobe. The fan prevented the bulk of the coarse, erosional debris from reaching Fall River, located immediately below the fan, as shown three days following the flood in

Figure 12. Regardless of the magnitude of the flood, the Fall River retained its naturally stable morphology due to its stable riparian corridor and floodplain connectivity.

Figure 11 Alluvial fan and braided, D stream type on the Roaring River in Rocky Mountain Park following the 1982 Lawn Lake flood.

Figure 12 Fall River in Rocky Mountain National Park, one-quarter mile below the alluvial fan of the Lawn Lake Flood. This photo was taken three days following the flood that was estimated at approximately 14,000 cfs.

Fan head trenches, or incised channels associated with A, F, and G stream types, often form due to the increased post-fire stormflow peaks (Figure 13). When stream channels abandon the fan surface and become incised in alluvial fans, they become high supply and high transport systems; thus the sediment yield is not only routed from farther upstream but is cut through portions of the fan deposit as well. The incised streams have increased velocity, stream power, and sediment transport capacity, thereby delivering excess sediment to the receiving streams. Under this scenario, the alluvial fan ceases to properly function.

Figure 13 A fan-head trench, an F4 stream type, incised in grussic granite soils within an alluvial fan on a tributary to Trail Creek following the Hayman Fire of 2002 in the South Platte River basin, Colorado.

An example of the fan head trench scenario occurred on North Douglas Creek within the Waldo Canyon Fire area. Deposition from debris flows on a fan surface is shown in Figure 14 following a storm; within one month following the deposit, an 8.0 ft headcut gully developed at the same location (Figure 15).

Figure 14 Erosional debris deposited on North Douglas (note the curved tree).

Figure 15 Channel incision (G4 to F4 stream type) at the same location as shown in Figure 14 (note the arrow directed to the same curved tree).

Restoration Design: To reduce the sediment delivered to mainstem stream systems from anticipated debris flows, the fan head trenches associated with incised A, G, and F stream types were reconnected to the alluvial fan surface with fill material to naturally create a braided, D4 stream type. Sediment debris basins were excavated to obtain the material to reconnect the incised channels with the original fan surface and to provide for sediment storage and help attenuate flood peaks. Once the basins are filled, the flood debris is designed to spread onto the fan surface with a braided channel system that will persist as long as there is a high sediment supply.

The restoration design is shown in Figure 16, featuring an interlocked crib wall to prevent headcutting during runoff events. Additional log or rock sills are located within the gully fill on the fan surface to prevent future channel incision and maintain fan function (Figure 16).

If the basins are cleaned out on a frequent basis and clear water discharge results, then a single-thread, B stream type can be constructed at the lowest basin on the fan lobe to direct streamflows to a receiving stream that overtop the basin. The B stream types are stable stream types found on inactive alluvial fans or when the incised channels become stabilized through stream succession processes in confined fluvial landscapes (Rosgen, 1996).

Where possible, restoring active fan function is the top priority for all ephemeral, 2nd and 3rd order streams affected by the Waldo Canyon Fire. The following is a summary of the specific objectives of this design scenario:

- Store sediment before it is delivered to downstream channels
- Reduce the accelerated streambank erosion rates
- Eliminate any advancing or future headcuts
- Develop sediment detention storage basins
- Attenuate flood peaks

Case Example: North Douglas Creek: Based on the *WARSSS* assessment, North Douglas was identified as a high priority sub-watershed due to the high probability of debris flows and flow-related sediment increases located immediately above thousands of homes in Colorado Springs. An incised, F4 gully over 6.0 ft deep was cut into a large alluvial fan in the sub-watershed. Although the drainage area is only 1.7 mi^2 with approximately 12.0 cfs bankfull discharge, the *WARSSS* assessment predicted approximately *10,000 tons/yr* of sediment from post-fire storms (Rosgen *et al*., 2013a).

Five sediment basins were constructed along the large alluvial fan to obtain sufficient material to fill the incised channel and to accommodate the predicted sediment yield (Figure 16 and Figure 17). The Water Resources Department at Colorado State University monitored the flows and sediment in North Douglas Creek to obtain detailed data on reactivating alluvial fans and creating sediment basins (Stednick and Webb, 2014). Streamflow measurements were obtained above the first basin, and each basin was monitored following storm events.

Following a July 1, 2013 storm, *2,751 tons* were stored in the first basin with a flow of 120 cfs (an order of magnitude higher than bankfull discharge). The constructed basin (Figure 18) is compared to the post-fire storm results depicting a completely filled basin (Figure 19). By the end of the storm season following eight, individual storms, all five basins were filled with an estimated *10,000 tons* of sediment (Stednick and Webb, 2014); additionally, one foot of sediment deposited on the fan surface, and a braided, D4 stream type was created naturally (Figure 19). In all but the last storm, no flows or sediment were delivered downstream of the last basin on the fan; the last storm on September 23, 2013, associated with over 773 cfs from a 7.0-inch rainstorm, filled the sediment basins and resulted in minor flows and sediment delivered downstream without incident or reported damage.

The relationship between the sediment captured in cubic yards versus peak flow discharge is shown in Figure 20 as developed by Stednick and Webb (2014). This relationship does not include the last storm that produced 773 cfs and the sediment that overfilled the basins and deposited on the fan surface.

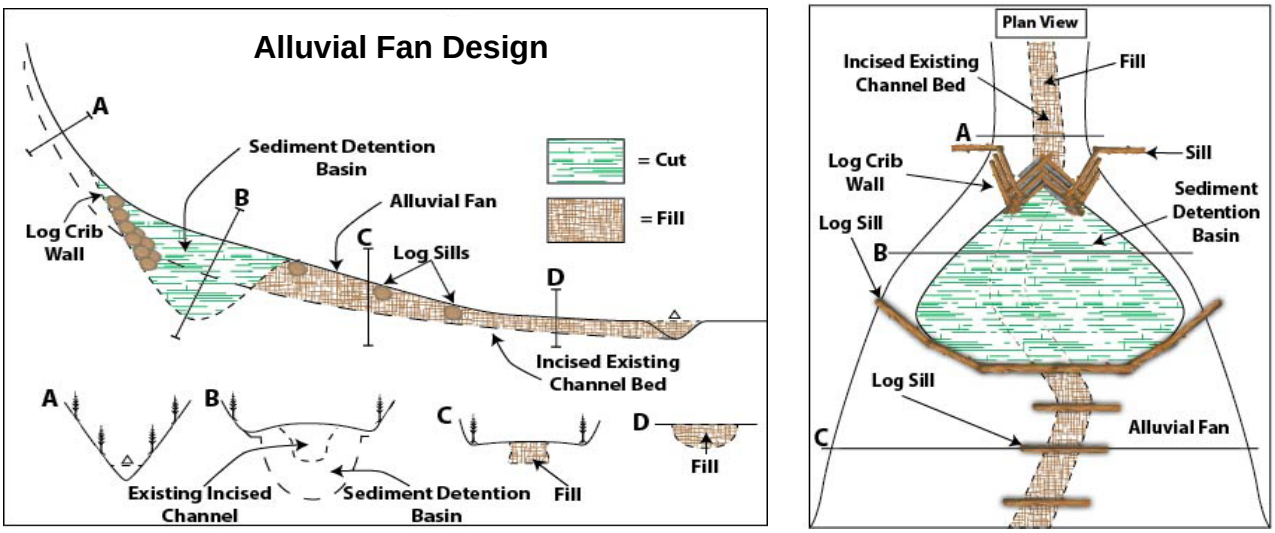

Figure 16 The design to reactivate alluvial fans and create braided, D stream types featuring a proposed debris basin with a crib wall and log sills (Rosgen, 2013b).

Figure 18 Newly constructed debris basin and crib wall on North Douglas Creek where the excavated material was used to fill the deep and wide gullies (note the arrow indicating the location of the rock and exposed root wad).

Figure 19 The debris basin completely filled with sediment and ash deposits, looking downstream on fan surface, North Douglas Creek (note the same exposed root wad and rock as shown in Figure 18).

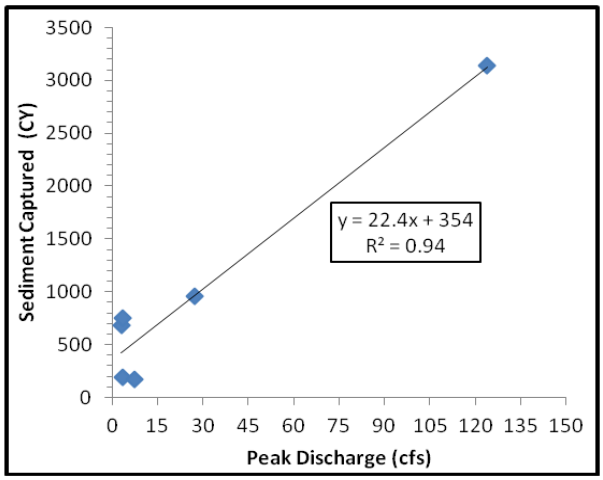

Figure 20 Relation of sediment storage by flow discharge; this does not include the 773 cfs streamflow that filled the basins and deposited one foot of sediment on the fan surface (from Stednick and Webb, 2014).

Discussion: The estimated design, oversight, and implementation costs of the debris basins vary between $4.00−$10.00 per ton of sediment saved. The costs per ton to dredge sediment from downstream reservoirs for water storage varies between $90.00−$120.00 per ton; thus it is much more cost effective to retain the sediment within the watershed. The reduced risk to downstream homeowners and the mitigation of potential adverse ecological impacts associated with sediment deposition in stream channels also provide strong motivation for implementing this approach.

Overall, restoring the alluvial fan connectivity with detention basins has saved thousands of tons of sediment from being directly delivered to the urban development immediately below the Waldo Canyon Fire perimeter. Over 40 sediment basins were constructed in 2013 on many of the high risk tributaries and all were successful at reducing delivered sediment. Due to the efficiency of the sediment detention basins, the City of Colorado Springs has since established a permanent basin at the end of the chain of basins on North Douglas Creek to reduce future flooding and sediment problems above adjacent subdivisions; the basin will be cleaned out when filled with sediment from future storms. Furthermore, the Forest Service BAER team recently approved the debris basin approach to be considered in their arsenal of recommended treatments nationwide.

Restoring alluvial fan connectivity with sediment detention basins was also successfully implemented in 2012 on numerous tributaries within the Trail Creek Watershed affected by the Hayman Fire of 2002 (Rosgen, 2011). The performance of these basins following post-fire storms promoted the application on the Waldo Canyon Fire and elsewhere. The approach was subsequently implemented within the Shultz Fire Burn Area in Flagstaff, Arizona (Natural Channel Design, Inc., 2012), saving thousands of tons of sediment from damaging downstream subdivisions.

SUMMARY

The erosional and depositional processes must be understood following wildfires to appropriately prescribe treatments that address the impairment. Restoration priorities by process and locations are always challenging when faced with limited budgets and time constraints. The challenge presented to managers is to have the most effective measures available that properly address the erosional processes when faced with post-fire rehabilitation prescriptions, which must be cost-effective, low risk, and meet specific objectives. The recent application and positive performance of reactivating alluvial fans for extensive sediment reduction and flood attenuation due to post-fire impacts shows excellent promise to assist in future flood restoration/rehabilitation efforts.

Goodrich, Research Hydraulic Engineer, USDA-ARS-SWRC, Tucson AZ, USA, dave.goodrich@ars.usda.gov

Abstract: Precipitation and runoff records from several burned watersheds have been used to evaluate the performance of the AGWA/KINEROS2 modeling scheme that Department of Interior Burned Area Emergency Response (DOI BAER) teams use to assess risk immediately following a wildfire. Although DOI BAER teams use this parameterization/modeling framework to assess the relative change in watershed behavior following a wildfire by driving the model with National Oceanic and Atmospheric Administration (NOAA) design storms, calibrations performed on actual events using rainfall estimations provided by rain gages and radar provide insight into the model's performance, and potentially inform changes and developments to the AGWA parameter estimation scheme. Results indicate that current parameter modifications made by AGWA to represent fire provide reasonable results for DOI BAER risk assessments, though additional modifications to saturated hydraulic conductivity may be necessary to represent a broader range of storm sizes and intensities.

INTRODUCTION

Runoff response to rainfall changes following a wildfire (DeBano et al., 1998). This is a result of the removal of canopy cover and organic litter (duff), which decreases interception and surface roughness respectively. Hydrophobic soils can also form as a result of wildfire, which can reduce infiltration rates. The loss of interception, decrease in surface roughness and decrease in infiltration rates all contribute to an increase in surface runoff. This increase in surface runoff presents a risk of flooding and erosion. Hydrologic modeling is often used in order to anticipate this risk, and target areas for mitigating efforts.

AGWA Background: AGWA (see: www.tucson.ars.ag.gov/agwa or http://www.epa.gov/esd/land-sci/agwa/) is a GIS interface jointly developed by the USDA-Agricultural Research Service, the U.S. Environmental Protection Agency, the University of Arizona, and the University of Wyoming to automate the parameterization and execution of a suite of hydrologic and erosion models (SWAT and KINEROS2 – the latter with the Rangeland Hydrology and Erosion Model (RHEM) and the Water Erosion Prediction Project (WEPP) for hillslope erosion options). Through an intuitive interface the user selects an outlet from which AGWA delineates and discretizes the watershed using a digital elevation model (DEM). The watershed model elements are then intersected with nationally available data sets for soils and land cover to derive the requisite model input parameters. The soils layer provides a texture-based estimation of saturated hydraulic conductivity (Ks), and the land cover layer provides information associated with land cover types, such as percent cover, interception, and hydraulic

roughness (Manning's *n*). With the addition of a burn severity map, AGWA can be used to change the existing land cover to reflect burned conditions.

The key challenge to using AGWA in a post-fire context is developing rules to change important model parameters (canopy cover, interception, saturated hydraulic conductivity and hydraulic roughness) as a function of the original cover type and the degree of disturbance based on the burn severity map. To account for burn effects, AGWA reduces the percent canopy cover (CC) parameter using a land cover look up table. Currently for severe, moderate, and low burn severity the CC for a given land cover vegetation class is reduced by 50%, 32%, and 15%, respectively (Burns et al., 2013). AGWA increases the soil texture based Ks using equation (1) based on percent canopy cover (CC) for all land cover types; therefore reductions in CC due to fire will decrease Ks from pre-fire conditions which result in an increase in post-fire runoff.

$$Ks = Ks_{soil} * e^{0.0105*CC} \quad (1)$$

However, preliminary calibration efforts have shown that changes to land cover look-up tables for burn severity alone were insufficient to calibrate Ks for several of the events examined in this study. This could imply that the model input for soils is not sufficiently representative of reality, that the CC reduction percentages are not large enough, that hydrophobic conditions have developed, or that Ks is also a function of rainfall intensity or amount.

METHODS

Changes in soil infiltration and hydraulic roughness are often a result of fire (Canfield et al., 2005). They are also sensitive parameters in the KINEROS2 model (Yatheendradas et al., 2008) and were therefore altered during calibration to match observed runoff in an attempt to determine how they might be altered in AGWA post-fire lookup tables. Gridded searches of the saturated hydraulic conductivity (Ks) and hydraulic roughness (n) parameter space were conducted using the Nash-Sutcliffe (NSE) and the Kling-Gupta Efficiencies (KGE) in order to determine their optimal calibrating multipliers. Multipliers were used to alter parameter values in order to maintain the spatial variability of the parameters given by the spatial data layers, while keeping the number of calibrating parameters small. For this initial investigation the CC parameter was set to zero, and calibrating multipliers were applied to all hillslope model elements in the watershed.

Storms of various sizes at three different small watersheds, Marshall Gulch (8 km^2) in the Santa Catalina Mountains outside of Tucson Arizona, Starmer Gulch (3 km^2) on the Las Alamos National Lab, New Mexico, and Eagle Creek (21 km^2) near Ruidoso, New Mexico, were used in this effort. These storms ranged in total accumulated rainfall depth of 6 to 41 millimeters, observed total outflow volumes ranged from 0.25-4.6 millimeters yielding runoff to rainfall ratios of 0.02-0.25. Peak flows ranged from 0.2-5.9 millimeters/hour. All storms used for analysis were reasonably well modeled with the lowest NSE value being 0.64.

RESULTS

Initial calibrations indicated that there is a correlation between the calibrated Ks values (figure 1), calibrating Ks multipliers (figure 2) and the total depth of the rainfall in an event. This will be explored further with the intention of determining rainfall intensity based thresholds for calibrating Ks multipliers.

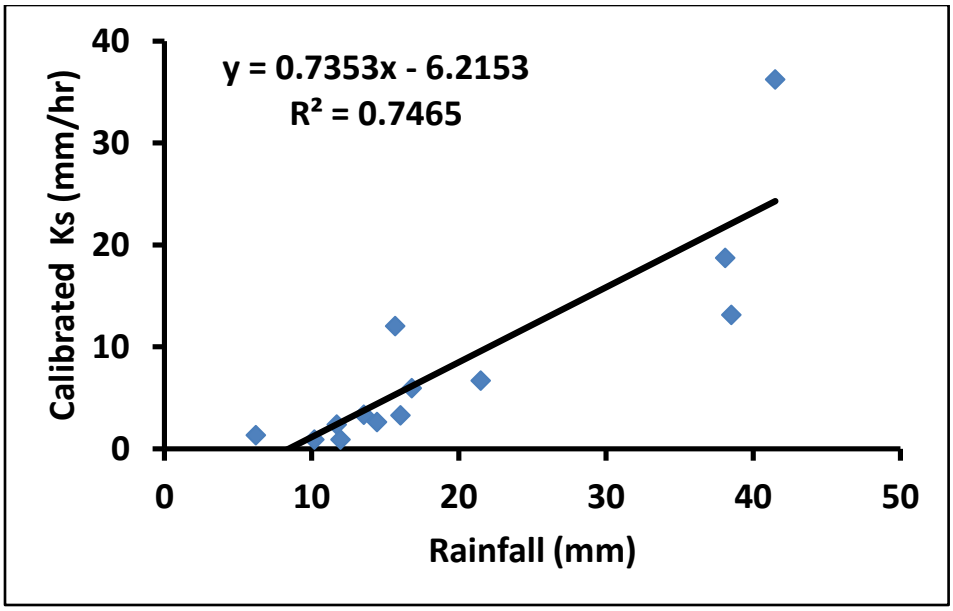

Figure 1 Correlation of rainfall amounts and calibrated Ks values (mm/hr).

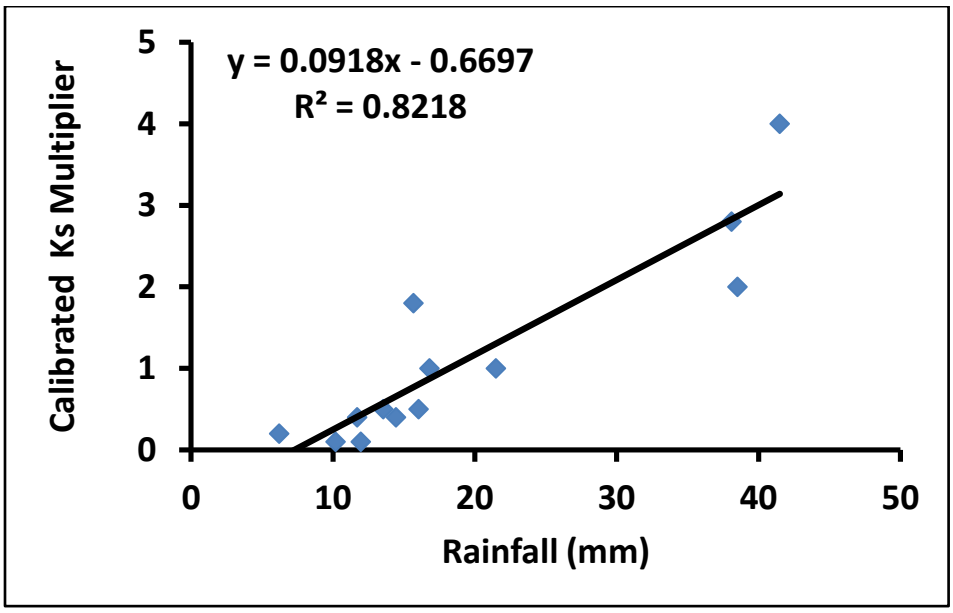

Figure 2 Correlation of rainfall amounts and calibrated Ks multiplier values.

Although many burned watersheds had stream flow and rain gages installed following a wildfire, pre-fire data is rarely available, and storm events appropriate for model calibration are infrequent. The record of data at Marshall Gulch following the 2003 Aspen Fire is the longest record of stream flow and rainfall data used in this study. Dating from 2003-2013, this record gives the opportunity to use data from ten years following a wildfire as a proxy for pre-fire conditions. The storms of 7/29/2003 and 7/15/2013 show that it takes much less rainfall on a burned landscape (figure 3, table 1) to generate similar peak flow on a forested landscape (figure 4, table 1). This is the difference between a storm that is likely to occur every year and a NOAA twenty-five year return period, one-hour design storm.

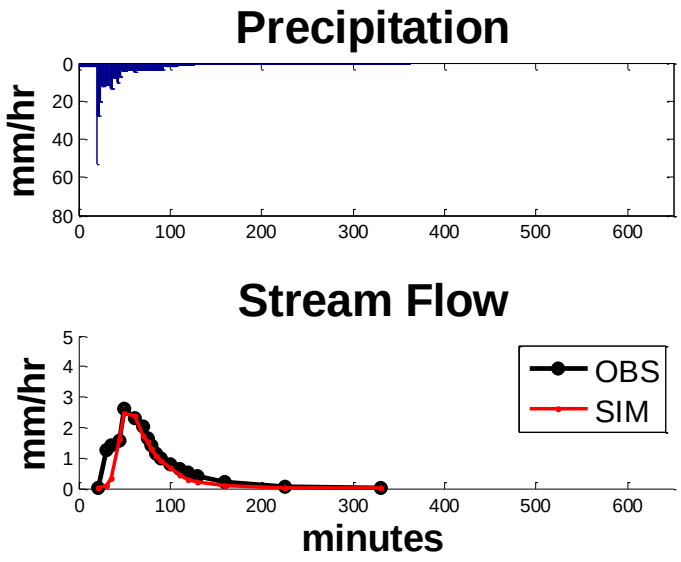

Figure 3 Hyetograph from storm of 7/29/2003 (upper) and simulated and observed streamflow (lower) at the Marshall Gulch Pima County Flood Control gage using Ks and roughness parameters listed in table 1.

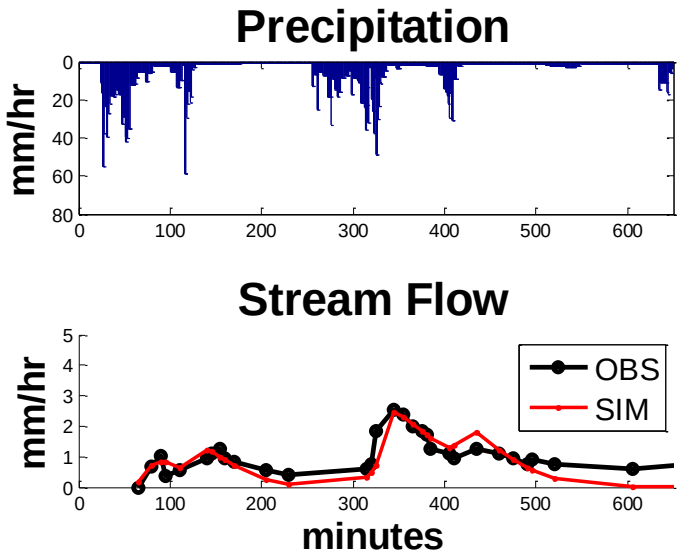

Figure 4 Hyetograph from storm of 7/15/2013 (upper) and simulated and observed streamflow (lower) at the Marshall Gulch Pima County Flood Control gage using Ks and roughness parameters listed in table 1.

Table 1 Rainfall, runoff to rainfall ratio (RO Ratio), observed (OBS) and simulated (SIM) stream flow, Nash-Sutcliffe Efficiency (NSE), and calibrated values of Ks and Manning's *n* (n) for storm events 7/29/2003 and 7/15/2013.

			Peak (mm/hr)		Volume (mm)				
Storm	Rain(mm)	RO Ratio	OBS	SIM	OBS	SIM	NSE	Ks	n
7/29/2003	10.19	0.25	2.62	2.46	2.57	1.96	0.75	1.35	0.03
7/15/2013	58.73	0.21	2.52	2.47	12.43	6.92	0.64	4.50	1.28

The Marshall Gulch responses to storms similar to a NOAA five year return period, one-hour design storm also show quite different behavior for burned (figure 5, table 2) and unburned conditions (figure 6, table 2). Peak flows for burned conditions were nearly five times greater than forested conditions.

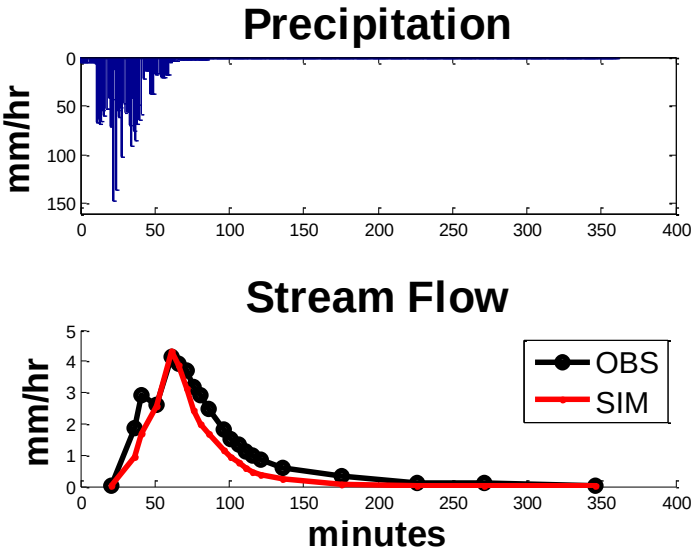

Figure 5 Hyetograph from storm of 7/24/2003 (upper) and simulated and observed streamflow (lower) at the Marshall Gulch Pima County Flood Control gage using Ks and roughness parameters listed in Table 2.

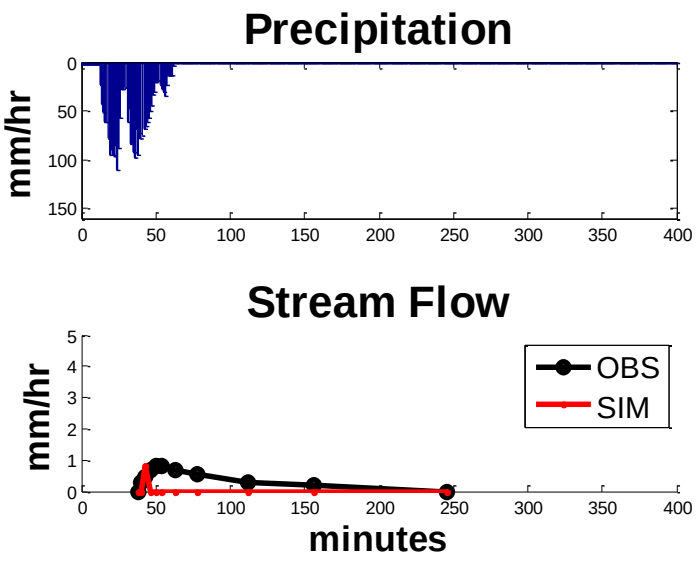

Figure 6 Hyetograph from storm of 7/27/2013 (upper) and simulated and observed streamflow (lower) at the Marshall Gulch Pima County Flood Control gage using Ks and roughness parameter listed in Table 2.

Table 2 Rainfall, runoff to rainfall ratio (RO Ratio), observed (OBS) and simulated (SIM) stream flow, Nash-Sutcliffe Efficiency (NSE), and calibrated values of Ks and Manning's *n* (n) for storm events 7/24/2003 and 7/27/2013. Rainfall amount is equivalent to NOAA five year return period, one-hour design storm.

			Peak (mm/hr)		Volume (mm)				
Storm	Rain(mm)	RO Ratio	OBS	SIM	OBS	SIM	NSE	Ks	n
7/24/2003	41.49	0.11	4.14	4.34	4.58	3.23	0.85	36.00	0.06
7/27/2013	44.60	0.02	0.83	1.17	0.72	0.06	-0.54	15.00	1.44

DISCUSSION

Figures 3 through 6 and tables 1 and 2 demonstrate that the calibrated model better reproduces the 2003 event (burned conditions) hydrographs than the 2013 event (proxy for unburned conditions) hydrographs. This is likely because the KINEROS2 model only represents overland flow generation as infiltration excess, the expected dominant runoff process in burned conditions/areas, and in unburned, forested conditions shallow subsurface flow is an important runoff process which KINEROS2 does not represent. In addition events with low runoff ratios are difficult to model as the uncertainties associated with observed rainfall can be a very large part of the overall runoff signal (high noise to signal ratio – Goodrich et al., 2012).

The difference in the observed responses to the storms of 7/24/2003 and 7/27/2013 provided an opportunity to see how well the AGWA relative difference approach used by DOI BAER teams anticipates change in response to a NOAA five year, one-hour design storm. Hydrographs of the uncalibrated simulated flows at the outlet of Marshall Gulch are shown below (figure 7). The percent change in peak flow for the modeled flows was 456% (table 3), i.e. peak flows in burned conditions are expected to be roughly 5.6 times greater than unburned conditions. For observed

flows a 399% (table 3) increase was calculated, i.e. peak flows in burned conditions are expected to be roughly 5 times greater than unburned conditions. This comparison of storms shows that the method used by DOI BAER would have been a very reasonable estimate of peak flow for use in risk assessment.

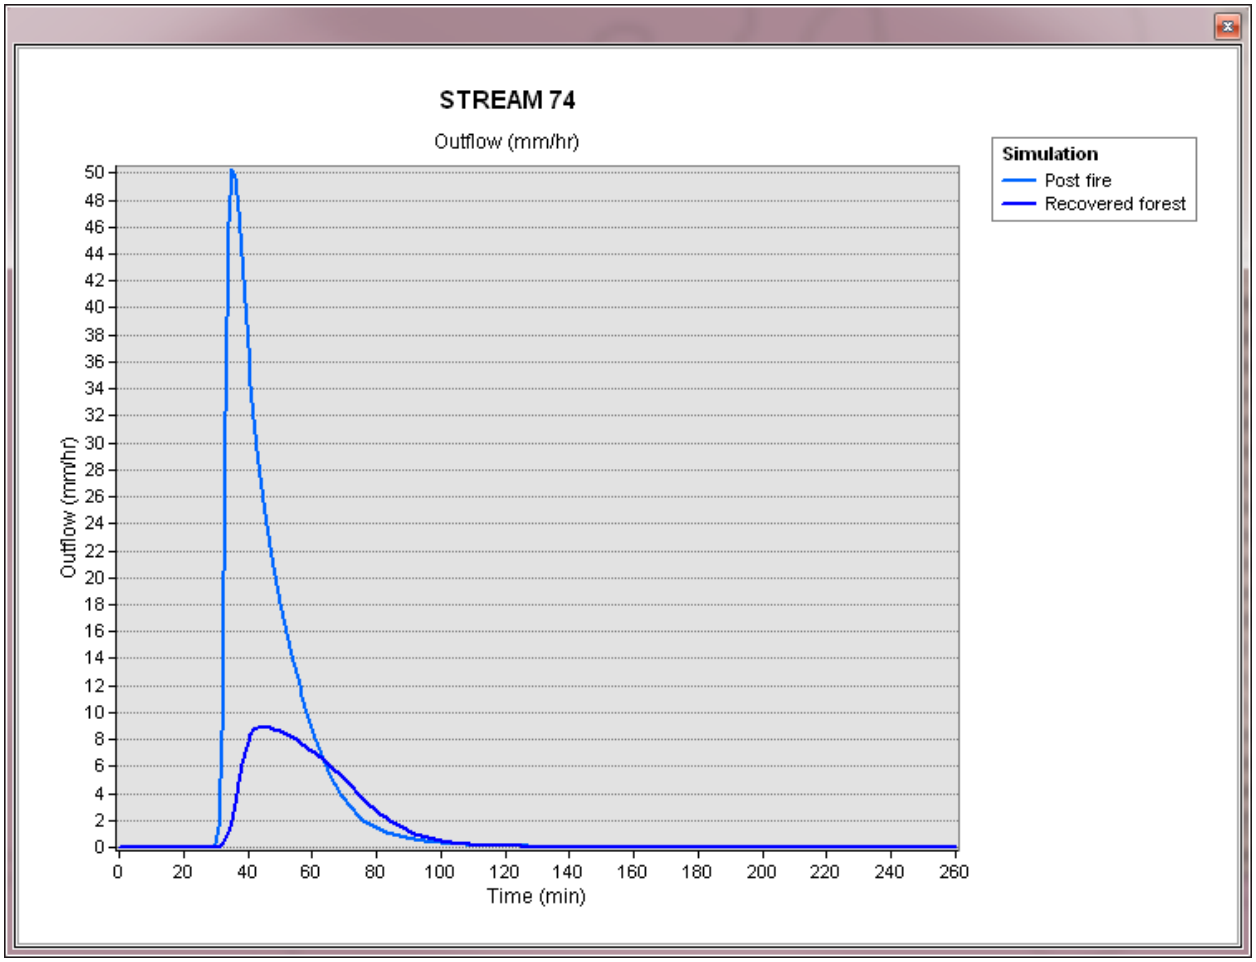

Figure 7 AGWA hydrograph output for uncalibrated KINEROS2 simulations of unburned and burned conditions responding to a NOAA five year, one-hour design storm.

Table 3 Percent change determined by modeling results and by observed data for NOAA five year, one-hour return storm.

	AGWA/K2	OBS
Unburned Conditions Peak Flow (mm/hr)	9	0.83
Burned Conditions Peak Flow (mm/hr)	50	4.14
Percent Difference	456	399

FUTURE WORK

Further investigations will be made using both rain gage records and bias corrected radar precipitation estimates to determine if thresholds can be established for calibrating Ks multipliers

for differing intensities of rainfall. Additional storms from Marshall Gulch, Starmer Gulch, Eagle Creek, and other watersheds will be calibrated to determine how similar or different the calibrating multipliers for Ks and surface roughness are at different locations. Once the correlation between rainfall intensity and Ks is better understood, refinement of this parameter for post-fire modeling use will be performed by including canopy cover values and applying calibrating multipliers only to burned hillslope elements in order to improve post-fire modeling use. Watershed recovery as a function of time since fire will also be investigated using post-fire events over long periods of time where they are available. In addition, remotely sensed estimates of cover condition over time will be assessed to see if they provide a reasonable surrogate measure for recovery.

Abstract Forests deliver a number of important ecosystem services including clean water. When forests are disturbed by wildfire, the timing, quantity and quality of runoff are altered. A modeling study was carried out in a forested watershed in California to determine the risk of wildfire, and the potential post-fire sediment delivery from approximately 6-ha hillslope polygons within a 1500-km^2 basin following a wildfire event. Wildfire intensity was estimated with the FlamMap prediction tool and fire risk with the FSim tool, based mainly on topography, current vegetation conditions, and wind speed and direction. The estimation of soil burn severity was based on predicted flame length for each modeled 30-m pixel and the prefire vegetation for each hillslope polygon. Sediment delivery was estimated from each hillslope polygon using the Water Erosion Prediction Project (WEPP) Model in a GIS framework. Polygons that generated the greatest amount of sediment, impacted other values at risk in the basin, or were critical for reducing fire spread were "treated" by reducing the amount and type of fuel available for a wildfire. The fire and erosion models were run a second time for treated conditions to see if the treatment resulted in a reduced fire intensity and probability, and hence a reduced erosion rate. The estimated erosion rates the first year after the fire dropped from 46 Mg ha^{-1} before treatment to 26 Mg ha^{-1} for polygons that had received fuel treatments. If the reduction in the probability of wildfire occurrence and the effects of a quarter century of fuel treatments are considered together, then the treatments are predicted to significantly impact long-term (century scale) erosion rates by lowering "average annual" erosion rates by 19%.

INTRODUCTION

Managers in fire-prone watersheds are looking for ways to protect communities, forest resources, municipal water supplies, and other societal values from the detrimental and expensive effects of wildfire. Increased fuel loads from past decades of fire suppression (Agee 1993; Keane et al. 2002) and climate change (Flannigan et al. 2000; Westerling et al. 2006) are increasing the risks of large, high severity wildfires in Western forests and shrublands. These high-severity fires in turn increase the risk of flash floods and surface erosion (Forrest and Harding 1994; Robichaud et al. 2013). Increased post-fire erosion rates can severely degrade water quality and reduce reservoir storage capacity (Tiedemann et al. 1979; Moody and Martin 2001; Neary et al. 2005). In response to these risks, land managers responsible for protecting forestlands and watersheds, especially those that provide municipal water supplies, are considering ways to mitigate the effects of wildfire on water resources through the use of fuel reduction treatments (Sidman et al. 2015). Fuel reduction treatments, such as thinning and prescribed burning, have been shown to be effective in modifying fire behavior and fire severity (Cochrane et al. 2012; Reinhardt et al. 2008). A reduction in fire severity can then reduce threats to important ecosystem services including the availability of clean water, recreation opportunities, and timber, as well as fish and wildlife habitat. However, the costs associated with fuel reduction treatments can limit their application (GAO 1999 and 2007; Sampson et al. 2000).

A study was carried out on 1500-km^2 of the Upper Mokelumne Basin to see if the costs for fuel reduction treatments can be justified. The basin is located on the western slope of northern California's Sierra Nevada Mountains. The North Fork of the Mokelumne River cuts through granite to form deep canyons

and flows through a rugged landscape with granite domes, much like its neighbor to the south – Yosemite National Park. The vegetation ranges from mixed oak woodlands below 900 m, to mixed conifer forests between 900 and 2000 m. Between 2000 and 2750 m the forests are dominated by California Red Fir (*Abies magnifica*), and above 2750 m barren rock outcrops predominate. The Mokelumne Wilderness area encompasses much of the Northern portion of the watershed. Recreational activities include fishing and camping, but the river is particularly famous for white water rafting and kayaking. The basin is an important water source for agriculture and provides drinking water to 1.3 million residents of in the San Francisco Bay area. The Mokelumne River also provides hydropower with a generating capacity of 215 MW. The extensive forest stands within the basin are under both public and private ownership. Much of the forested land is at risk to wildfire as evidenced by the 2004 Power Fire (70 km^2) within the basin (Figure 1), and the nearby Rim (2013; 1,040 km^2) and King (2014; 390 km^2) fires. Major landowners include the U.S. Forest Service, Bureau of Land Management, and Sierra Pacific Industries (Buckley et al. 2014).

In order to spatially prioritize fuel treatments and to determine the economic value of increasing treatments compared with a "do-nothing" scenario during this time of increasing fire threat, the U.S. Forest Service, The Sierra Nevada Conservancy, and The Nature Conservancy brought together a diverse set of stakeholders to form the Mokelumne Avoided Cost Analysis (MACA) committee (Buckley et al. 2014). Stakeholders included land, water and utilities managers, federal, state and local agencies, local stakeholders, and environmental organizations. The MACA committee developed a methodology to forecast the impacts of fuel treatments on wildfire risks and erosion rates in watersheds both before and after wildfire in order to link the benefits associated with fuel treatments with their costs.

MODELING APPROACH

To forecast the benefits of fuel treatments on the Mokelumne Basin we modeled erosion under four distinct conditions:

1) current vegetation conditions in the absence of fire;
2) after a fire assuming current fuel conditions;
3) after proposed fuel treatments; and
4) after a fire following the application of proposed fuel treatments.

The mapped erosion predictions following wildfire (condition 2, Figure 1) in conjunction with the burn severity predictions, asset locations within the basin and other considerations were used by the MACA Advisory committee to plan and prioritize fuel reduction treatments within the basin. The application of these treatments which included prescribed fire and mechanical and hand thinning could impact erosion rates within the watershed, so the effects of these treatments were modeled for the third condition. Fuel treatments were planned for elevations between 300 and 2,000 meters in the watershed covering most of the mixed conifer forests. Fuel loading and canopy cover were assumed to be changed as a result of these treatments. The effect of treatments on burn severity was then modeled and new predictions of burn severity were used to model post-fire erosion after treatments for the fourth condition. Our modeling results were used in two ways. The first application was to prioritize treatments based on post-fire erosion risk (Figure 1). The second application was to synthesize our modeling results from the four runs to quantify the watershed benefits and compare them to the cost of treatments to determine whether the costs of proactively treating forests prefire are justified by the savings from either not having a wildfire occur or from a reduction in wildfire severity.

We used three different models sequentially to quantify the reduction in sediment due to fuel treatments within the Mokelumne basin. The first model, FlamMap (Finney 2006), was used to predict burn severity both before and after proposed fuel reduction treatments. Probability of fire occurrence was modeled using the Fire SIMulation system (Fsim, Finney et al. 2011). The Water Erosion Prediction Project (WEPP)

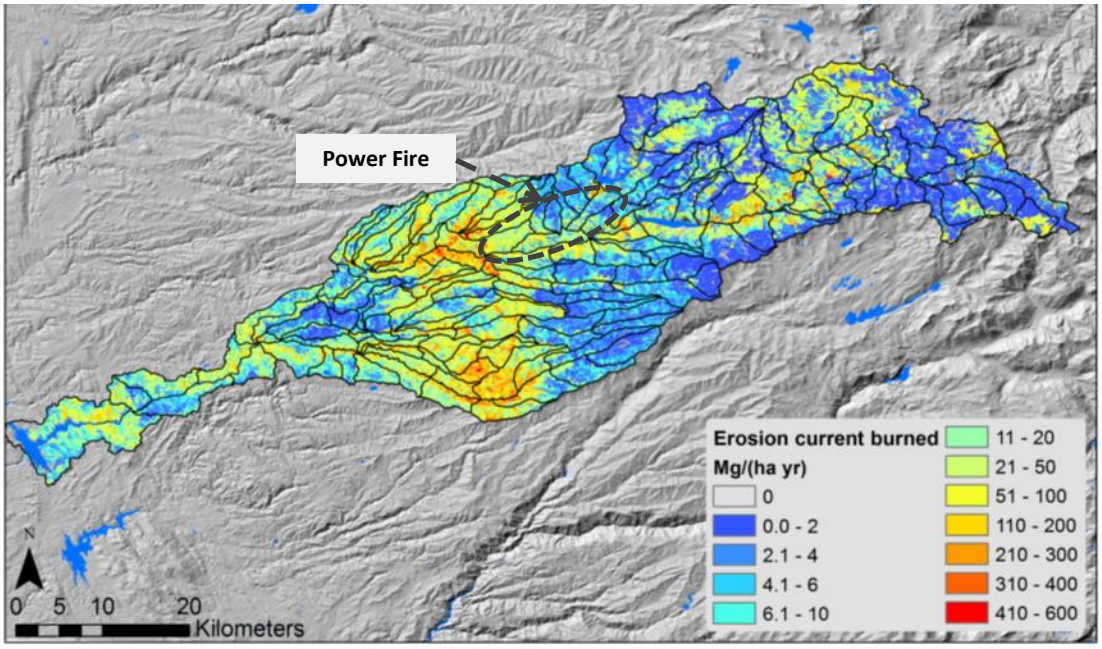

Figure 1 Map of predicted post-fire erosion for the first year after the fire for the Mokelumne Basin for current (untreated) vegetation conditions. The area burned by the 2004 Power Fire is outlined

model (Laflen et al. 1997) used burn severity predictions from FlamMap to predict hillslope erosion following wildfire both before and after treatments.

FlamMap FlamMap is a spatial fire behavior model that uses land cover, topography, and fuel characteristics data from the Landfire database (Rollins 2009), along with fuel moisture and weather data (Finney 2006). Resulting fire behavior predictions are pixel-based (30-m resolution) and include fire line intensity (kW m^{-1}), heat per unit area (kJ m^{-2}), and flame length (m). The soil and vegetation burn severity category and ground cover for erosion modeling were determined from the predicted flame length for each pixel (Table 1). Determining where to make the cutoffs in flame length for severity categories was based on the distribution of severity observed on post wildfire field studies and the distribution of fire severity following a recent fire in the basin (Power Fire, 2004; Figure 1).

FSim The Fire SIMulation system (FSim) uses historical weather data, topography, past wildfire ignitions, fuel and vegetation data to simulate wildfire ignition, fire growth, and suppression (Finney et al. 2011). The model estimates burn probability by simulating 10,000 to 50,000 years of fire seasons under the same vegetation and fuel conditions. Burn probability is the number of simulations in which a pixel burns divided by the total number of simulations (Finney et al. 2011). For the Mokelumne basin, FSim was run using vegetation data from the same Landfire database as the other modeling activities, but at a 90-m resolution. Modeling was carried out for three elevation zones in order to account for differences in ignition patterns. Calibration runs were undertaken to adjust parameters in order to match predictions with historical fire occurrences for each zone. Once calibrated, the model was run for 40,000 fire seasons. Additional details can be found in Buckley et al. (2014).

WEPP WEPP is a process-based model that predicts runoff and sediment yields from planar hillslopes and small, unchannelized watersheds (Flanagan and Nearing 1995). The surface hydrology component of the WEPP model uses climate, soils, topography, and vegetation input files to predict infiltration, runoff volume, and peak discharge for each simulated storm or snowmelt runoff event. WEPP then uses the

Table 1 WEPP soil and vegetation severity categories as determined by flame lengths predicted by FlamMap

	FlamMap Flame Length (m)			
	0	0 – 1.2	1.2-2.5	2.5≤
WEPP Burn Severity Category	Unburned	Low	Moderate	High
WEPP Soil Category and ground cover (%) if pre fire vegetation was grass	Unburned 60-80	Low 60	Low 45	Low 15
WEPP Soil Category and ground cover (%) if pre fire vegetation was forest	Unburned 99	Low 60	Low 45	High 15

same inputs and runoff predictions to calculate rill and interrill erosion, as well as sediment yield from the hillslope (Flanagan and Nearing 1995). The need to predict post-fire erosion rates across the entire 1500-km^2 Upper Mokelumne Basin necessitated the use of the Geo-spatial interface for the Water Erosion Prediction Project (GeoWEPP) (Renschler 2003). GeoWEPP facilitates the use of WEPP across large areas by converting GIS data into WEPP input files, running WEPP, and then compiling the results into a spatial maps and text summaries.

DEVELOPMENT AND COMPILATION OF INPUT DATA

Prior to preparing model inputs, land cover, soil and topography data were collected in the watershed at various elevations and forest conditions from multiple sources to ensure accuracy. The Landfire vegetation files used as input to the fire spread models were modified to incorporate detailed local knowledge of site conditions. These same files were used to support prefire WEPP runs, and to aid in developing post fire soil and vegetation files. For the spatial WEPP modeling, the Upper Mokelumne Basin was divided into 244 sub-watersheds averaging about 6 km^2 in area, using a Digital Elevation Model (DEM) and ESRI watershed tools, in order to address climate variability and for computational efficiency. Sub-watersheds were used to create smaller raster inputs (DEM, soil, land cover) for batch files. These batch files were then modeled in a batched version of GeoWEPP (Miller et al. 2011). In the cases where the sub-watersheds contained more than one drainage outlet or the model failed to run, the sub-watersheds were rerun using GeoWEPP for ArcGis 9.3. The resulting erosion prediction maps from the batch runs were then merged into a final erosion map for each of the four conditions (Figure 1).

Climate Data WEPP uses a stochastic weather generator called Cligen (Nicks et al. 1995) to generate a daily weather sequence, including the precipitation amount and duration, minimum and maximum temperatures, dew point, mean solar radiation, and wind speed and direction. The input to Cligen is from a database of more than 2,600 long term climate stations within the United States. The U.S. Forest Service has complemented this database with Rock:Clime, an interface to Cligen that estimates mean monthly rainfall amounts between stations (Elliot et al. 1999; Scheele et al. 2001). The interface also allows users to change the number of wet days within a month, and to alter the average maximum and minimum temperatures either manually, or based on an adiabatic lapse rate for maximum temperature of -6°C km^{-1} and a lapse rate for minimum temperatures of -5°C km^{-1} between the nearest weather station and the site of interest (Scheele et al., 2001). The interpolation is particularly important in mountainous areas such as the Mokelumne Basin because of the large changes in climate conditions that occur with changes in elevation over relatively short distances (Table 2), as well as the paucity of climate stations in remote mountainous areas. The interpolation procedure in Rock:Clime modifies the monthly precipitation for a selected climate station based on elevation and PRISM data (Parameter-elevation Regressions on

Table 2 Stochastically generated climate zones for the Mokelumne Basin

Physical Elevation Range (m)	Climate Zones	Modeled Elevation (m)	Avg Annual Precip (mm)
100 – 300	Tiger Low Rock:Clime/PRISM	259	799
300 – 600	Tiger Low2 Rock:Clime/PRISM	535	951

≥2400	Twin Lakes High Rock:Clime/PRISM	2646	1438

Independent Slopes Model, Daly et al. 2004). The PRISM database with a spatial resolution of 4 km^2 is used by Rock:Clime.

Three NOAA weather stations in the Cligen database are located within or near the Mokelumne Basin. These stations (Twin Lakes, Calaveras Big Tree, and Tiger Creek; Figure 2) were used to develop an additional five climate files with the Rock:Clime interface. The additional climates were needed to account for the impacts of elevation changes in the watershed (Table 2). Each climate input file contained 50 years of daily stochastically-generated weather data. The average elevations of the initial WEPP sub-watersheds were then used to select the appropriate climate zone (Figure 2) for each sub-watershed.

Land cover and plant/management input files for WEPP Land cover data were obtained from the Landfire Project (Rollins, 2009). For this analysis, we used the Landfire land cover data that were modified with field observations for the fire modeling runs (Buckley et al. 2014). In addition to making the process more efficient by using the same data set, this ensured consistency across the modeling efforts. We then reclassified the land cover data layer into WEPP database cover types (e.g. Forest, Young Forest, Shrubs, Bunch or "Good" Grass, Sod or "Poor" Grass) in order to model background erosion rates from the Mokelumne Basin without fire. In the WEPP database, the land cover type is linked to both vegetation and soil properties (Elliot 2004).

For modeling post-fire conditions, the FlamMap burn severity maps from before and after fuel reduction treatments were used to reclassify land cover into unburned, low, moderate, and high burn severity classes (based on Table 1). In order to model the potential erodibility effects of the fuel reduction treatments, we used the map of proposed treatments developed for this analysis (Buckley et al., 2014). We assumed that the prescribed fire treatments would have a low severity soil condition for the year following the treatment with 85 percent ground cover, and the thinning-only treatments would have unburned soil properties and 90 percent cover (Elliot and Miller 2004).

Soils Data For the WEPP modeling, we used Landfire soil layers that were derived from STATSGO (STATe Soil GeOgraphic) data (USDA 1991). This dataset included: maximum soil depth; percent rock fragments (> 2.0 mm), sand, silt, and clay. The percent-sand, -silt and -clay layers were used to classify each soil pixel into one of the four soil texture classes represented in the WEPP forest soil database (sandy loam, loam, silt loam, and clay loam). WEPP input parameters (e.g., effective hydraulic conductivity, soil albedo, and interrill and rill erodibility) specific to each soil texture class were then used in the modeling (Elliot et al. 2000). Soil properties were based on the predicted burn severity and the type of vegetation that burned (forests, shrubs or grasses).

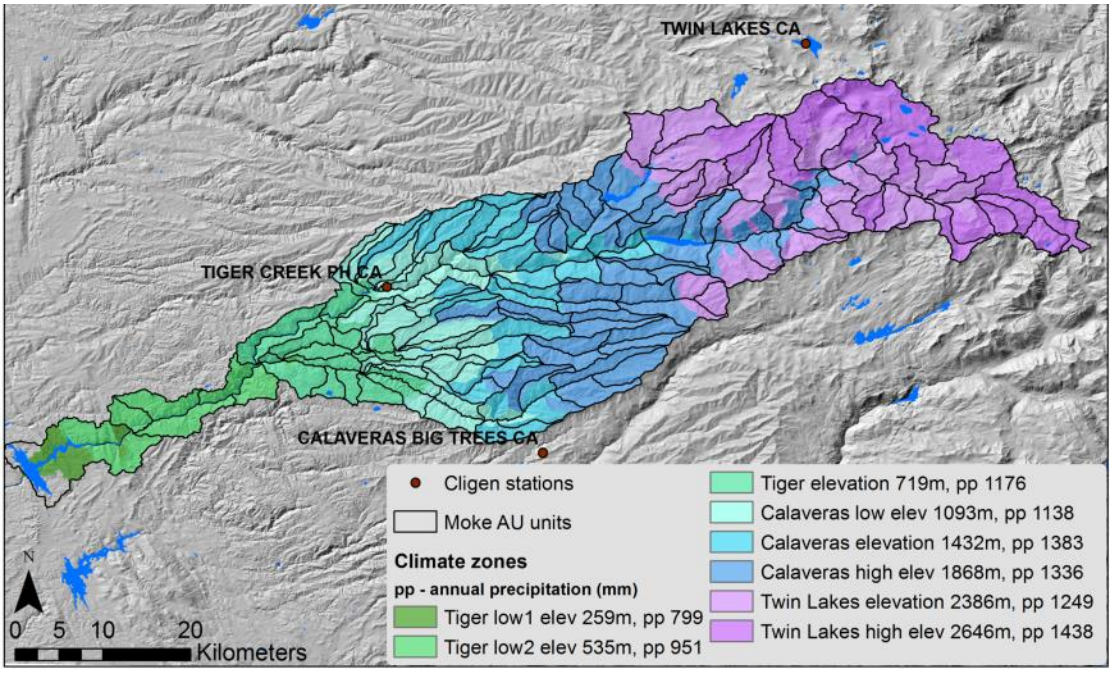

Figure 2 Map displaying the distribution of climate zones within the Mokelumne Basin and showing the boundaries of the Analysis Units (AUs)

RESULTS

Sediment delivery from hillslopes in the Mokelumne Basin was estimated and mapped for four conditions. The first condition determined background erosion rates without fire under the current vegetation conditions. Average erosion in the unburned basin was 0.67 Mg yr^{-1} ha^{-1} for the entire basin and 0.4 Mg yr^{-1} ha^{-1} in the lower elevation portion of the watershed where treatments were planned. Forested hillslopes typically did not generate significant erosion, but the steep, barren rocky slopes in the upper portions of the basin were highly erosive as is typical of high elevation areas in the Sierra Nevada Mountains (Brooks et al. 2010). The next run used the FlamMap predictions of burn severity under the current vegetation conditions to predict post-fire erosion (Figure 1). Average first year post-fire hillslope erosion in the Mokelumne Basin was 32 Mg yr^{-1} ha^{-1}, 50 times higher than the unburned conditions.

The mapped post-fire erosion predictions for current conditions along with the fire modeling results and other considerations were used by the MACA committees and stakeholders to help plan and prioritize a fuel reduction treatment strategy within the basin. The treatment selection process focused on reducing risks from fire and post-fire sediment to water utility and other infrastructure (Buckley et al. 2014). Wilderness and roadless areas were for the most part excluded from the analysis as treatments could not be carried out in these areas and they do not possess infrastructure that would be threatened by wildfire. An online GIS platform was created to allow stakeholders to review the data and then easily select treatment analysis units and provide a rational for their decisions. The watershed was divided into 148 potential treatment Analysis Units (AUs) with an average area of 10 km^2 (Figure 2). The post-fire erosion and burn probability maps were averaged by AUs and then classified into five risk quantiles. To further help stakeholders choose AUs for treatments, additional map layers containing towns, roads, building densities, land ownership, topography, transmission lines, hydropower facilities, wilderness areas, and water conveyances were provided. Stakeholder and MACA committee selections were then combined and through an iterative process, 46 AUs were selected for treatment. Recent studies indicate the minimum

Table 3 Summary of the results from the four hillslope erosion model runs for the entire Mokelumne Basin

	Current Condition	Fire Following Current Condition	Treatment Effects	Fire Following Treatment
Average Erosion in Basin	0.67 Mg ha^{-1}	32 Mg ha^{-1} in year 1	0.69 Mg ha^{-1}	26 Mg ha^{-1} in year 1
Range	0 – 84 Mg ha^{-1}	0 – 566 Mg ha^{-1}	0 – 84 Mg ha^{-1}	0 – 535 Mg ha^{-1}
Standard Deviation	3.0 Mg ha^{-1}	55 Mg ha^{-1}	2.5 Mg ha^{-1}	44 Mg ha^{-1}

Table 4 Summary of results from the four hillslope erosion model runs for only the treated portions of the Mokelumne Basin

	Current Condition	Fire Following Current Condition	Treatment Effects	Fire Following Treatment
Average Erosion in Basin	0.40 Mg ha^{-1}	46 Mg ha^{-1} in year 1	0.69 Mg ha^{-1}	26 Mg ha^{-1} in year 1
Range	0 – Mg ha^{-1}	0 – 566 Mg ha^{-1}	0 – Mg ha^{-1}	0 – 535 Mg ha^{-1}
Standard Deviation	2.5 Mg ha^{-1}	69 Mg ha^{-1}	2.5 Mg ha^{-1}	36 Mg ha^{-1}

area needed to be treated in a watershed to lower burn probability is 10-20% (Finney et al. 2007) and that strategically treating 35% would be ideal for reducing risks (Ager et al. 2013). The proposed treatment AUs covered about 29% of the Upper Mokelumne watershed (Buckley et al. 2014), which is more than enough to reduce fire probability within the entire watershed.

The application of these treatment prescriptions, which included prescribed fire, biomass removal, and thinning, would not only impact fire behavior, but also could result in soil erosion, so the effects of these treatments on soil erosion were modeled for the third condition. Fuel treatments were planned only in the lower portions of the watershed and the average predicted erosion rate from these treatments was 0.69 Mg yr^{-1} ha^{-1}, an average increase of 0.02 Mg yr^{-1} ha^{-1}over the current condition run without treatments. Canopy cover and fuel loads decreased as a result of these treatments and the treated landscape was modeled in FlamMap. The treated FlamMap burn severity predictions were used to model the first year post-fire erosion for the treated watersheds. The average first year post-fire erosion rate (after fuel treatments) for the whole watershed was 26 Mg yr^{-1} ha^{-1}, or 6 Mg yr^{-1} ha^{-1} less than the average post-fire erosion rates without treatments (Table 3). In the second year post-fire, erosion rates for both the current conditions and treated conditions would likely drop to only 10% of their first year post-fire values, and return to pre-fire levels in year three post-fire (Robichaud et al., 2008). If only the treated portions of the basin are considered; the reduction in post-fire erosion between the current conditions and treated runs is even greater: 20 Mg yr^{-1} ha^{-1} (Table 4).

Predictions of both burn severity and post-fire erosion rates are comparable to field and satellite derived measurements collected in or near the basin. Model validation of post-fire erosion is very difficult given the high variability in post-fire erosion rates and uncertainties involved when predicting future fire effects and climate scenarios. However, the ratio of high, moderate, and low burn severity from the FlamMap derived predictions for post-fire burn severity were consistent with a satellite-derived map of burn severity for the burned areas of the Power Fire that burned within the Mokelumne Basin in 2004. Field measurements of post-fire erosion rates from the nearby Cannon Fire ranged from 2.5-15 Mg yr^{-1} ha^{-1}

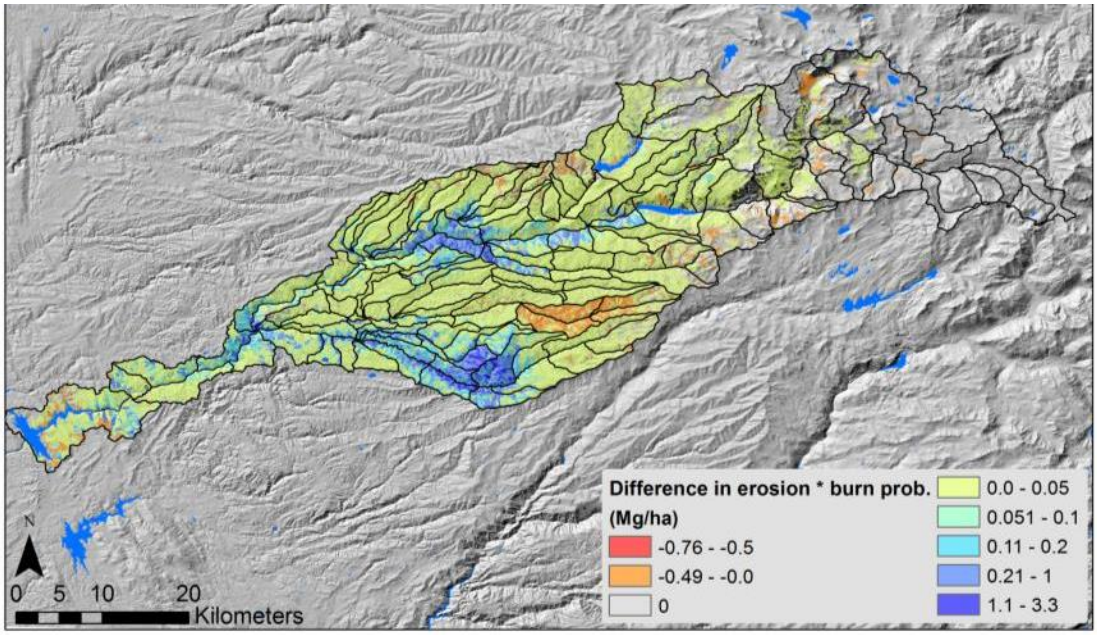

Figure 3 Map of the differences between post-fire erosion predictions for current conditions x burn probability for current conditions and post treatment x burn probability post treatment.

(Robichaud et al. 2008) and the Cannon Fire site is drier than the Mokelumne Basin, with a mean annual precipitation of only 658 mm compared to the range of 799-1438 mm expected in the Mokelumne Basin. Erosion rates measured following other wildfires further south in the Sierra Nevada Mountains were 25 Mg ha^{-1} (mulched) to 46 Mg ha^{-1} (untreated) for a high severity site in the Cedar Fire (Robichaud et al. 2013), where the annual precipitation was 398 mm yr^{-1}. While these comparisons do not validate our modeling, they do demonstrate our results are reasonable.

Frequency of Burning The fire behavior modelers (Buckley et al. 2014) also provided spatial predictions of fire probability derived from the FSim model (Finney et al. 2007) for both current conditions and after the application of fuel reduction treatments. One of the benefits of fuel reduction treatments is a decrease in fire probability due to changes in fuel load properties and canopy, a benefit that can extend into untreated areas. The probability of fire in a given year is fairly low for most of this relatively moist basin, with a fire return interval about 300 years for the forested areas. In order to incorporate fire probability into erosion modeling, it is necessary to multiply the sediment predicted following a wildfire event by the probability of that fire occurring (Elliot, 2013). We can do this for both the untreated and treated post fire erosion estimates. Figure 3 is a map of the difference between the first year post-fire erosion under current conditions multiplied by current burn probability and first year post-fire erosion following treatments multiplied by burn probability after treatments. Overall the modeled treatments are predicted to decrease burn severity, fire probability and post-fire erosion rates. The average reduction in post-fire erosion for the entire basin due to fire between the current conditions and post treatment was 0.05 Mg yr^{-1} ha^{-1}. This metric, however, does not allow us to examine the effects of the treatments on erosion rates in the absence of fire. In order to estimate long term (century scale) "average annual" erosion rates we needed to consider all four conditions (Elliot, 2013).

To estimate "average annual" erosion rates we needed to account for erosion in both fire and non-fire years, as well as the effects of treatments on erosion rates and burn probabilities (Elliot 2013; Miller et al. 2011). Under current conditions, long term hilllslope erosion rate *Average Erosion*$_{cc}$ can be represented

by Equation 1. If we assume the effects of fuel reduction treatments last 25 years, then Equation 2 represents long term erosion rates *Average Erosion*$_{tr}$ with regular fuel reduction treatments.

$$Average\ Erosion_{cc} = E_{cc\_fire} * bp_{cc\_fire} + (1 - bp_{cc\_fire}) * E_{nf} \quad \text{(Eq 1)}$$

$$Average\ Erosion_{tr} = E_{tr\_fire} * bp_{tr\_fire} + (1 - bp_{tr\_fire}) * (24 * E_{nf} + E_{tr})/25 \quad \text{(Eq 2)}$$

where:

E_{cc_fire} is the mapped post-fire erosion rates for current conditions.
E_{tr_fire} is the mapped post-fire erosion rates following fuel treatments.
E_{tr} is the mapped erosion rates due to the effects of the fuel treatments.
E_{nf} is mapped erosion rates for current conditions in the absence of fire.
bp_{cc_fire} is the mapped probability of fire under current conditions.
bp_{tr_fire} is the mapped probability of fire following fuel treatments.

These equations were used in conjunction with our four model runs to develop long term "average annual" erosion rates for the treated portions of the basin with and without fuel reduction treatments every twenty five years. Model results for long term average erosion rates for current conditions were 0.64 Mg yr^{-1} ha^{-1} (Equation 1 averaged for hillslopes selected for treatment, if they were not treated), compared to 0.52 Mg yr^{-1} ha^{-1} if the designated treatment area is in fact treated as modeled (Equation 2 averaged for all treated hillslopes if they were treated). Our predictions indicate that regular treatments will significantly reduce long term overall erosion rates by lowering the "average annual" erosion rate by 19%.

DISCUSSION

The goal of the MACA committee was to determine whether an economic case could be made for increased investment in fuel reduction treatments in the Upper Mokelumne Basin in the face of increasing wildfire threats. This is a challenging task as it is difficult to assign economic value to resources such as fish and wildlife habitat, tourism and recreational opportunities, and cultural sites, which ultimately were left unquantified in the final analysis. To simplify the analysis the committee focused on resources that could be readily assigned a dollar value. These included the avoided sediment costs as well as the cost of homes, infrastructure, treatment implementation costs, timber, carbon sequestration, and fire suppression and cleanup costs. Based on the fire model results and expert review, five fires from the modeling became the focus of the economic analysis, such that those five fires (or similar ones) are likely to occur within the watershed over a 30-year period. The fire behavior models predicted a significant decline in both fire size and intensity due to fuel treatments. Low and high estimates of the dollar value of the resources that would be lost if one of the five fires occurred were tabulated with and without the fuels treatments. The analysis predicted that the economic benefits of the fuels treatments were two to three times more than the costs of treatments. Total treatment cost for the 46 Analysis Units (AUs) was estimated to be $68 million (including maintenance costs over 30 years) compared to the lower estimated avoided cost of $126 million and the higher estimate of $224 million if those fires burned on an untreated landscape. The assumptions of the potential fire size and potential costs of future fires were intentionally conservative. Over the 30-year time frame, the five fires are predicted to burn a total of 21,000 ha with high severity, accounting for 27 percent of the burned area (Buckley et al. 2014). Contrasting this with two major recent wildfires that occurred on either side of the Mokelumne Basin, the Rim Fire (2013) burned 104,000 ha and the King Fire (2014) burned 39,000 ha, with 38 and 47 percent respectively, of their area burning at high severity (http://www.fs.fed.us/postfirevegcondition/index.shtml). These individual fires were much larger and burned at a higher severity than the modeled fires that were used to create cost estimates, therefore the potential costs associated with our modeled future fires are likely underestimated.

Avoided cost due to sediment may have been undervalued by this process due to an inability to sufficiently quantify the potential impacts to aquatic and recreational resources, hydropower and treatment

costs from potential post-fire sediment depositions in key reservoirs. The estimated value of avoided sediment costs was approximately $1 million, attributed to lost water storage potential. This is a relatively small amount compared to the costs associated with saving structures ($32-$45.6 million) or avoiding cleanup costs ($22.5 million) (Buckley et al. 2014). The hydroelectric utility operating in the Mokelumne Basin was not concerned about sediment as the watershed is equipped with multiple water conveyances that allow the utility select different water sources (Buckley et al. 2014). The water utility relies on upstream hydroelectric dams to trap sediments before they reach the Pardee Reservoir at the lower end of the basin where most of the drinking water intakes are located. Loss of reservoir storage capacity was not a concern to either utility company, but this attitude could change due to persistent drought conditions in Western states, with reduced snowpack due to climate change (Mote, 2006) or if one of the water storage reservoirs were lost due to a reduction in useful storage capacity. The Tiger Creek Afterbay reservoir with a storage capacity of 4.8 million m^3 was constructed in 1931 for a hydroelectric plant. A rudimentary bathymetric survey carried out in 2013 estimated storage has dropped to just 1.2 million m^3, a loss of about 75% of its original capacity (Buckley et al. 2014). Elsewhere in the U.S., loss of water reservoir storage capacity in watersheds recently impacted by wildfire has cost water utilities millions of dollars in additional water treatments and dredging expenses. Denver Water has spent $26 million treating drinking water and dredging Strontia Springs Reservoir following the Buffalo Creek (1996) and Hayman (2002) wildfires and the Los Angeles County Public Works plans to spend $190 million dredging four reservoirs impacted by sediment from the 2009 Station Fire (US Department of Interior, 2013). In California, state legislators are considering increasing reservoir storage capacity, the cost of storage for new usable water averages $20/$m^3$ for the proposed reservoirs (http://www.fresnobee.com/2014/06/01/3956458/should-calif-add-new-dams.html). The loss of reservoir storage due to sediment from a single 28,000 ha fire delivering only a tenth of its sediment to the reservoir (about 100,000 m^3) would be $2 million.

CONCLUSIONS

By linking fire behavior and post-fire hydrology models we were able to create a risk assessment map that allowed land and water managers in the Mokelumne Basin to prioritize fuel reduction treatments to protect both land and water resources. These managers are seeking ways to mitigate post-fire erosion and flooding before a wildfire occurs. The potential for dramatic increases in post-fire runoff, erosion and sedimentation is well documented. The importance of targeting limited fuel treatment resources to areas where the greatest benefits are achieved is gaining recognition as society increasingly understands the importance of improved watershed management. Work is ongoing to improve the application of these models and their linkages in order to provide land managers with increasingly refined and spatially-explicit data that will help them to better protect valuable water resources in fire prone regions.

CLIMATE CHANGE IMPACTS AND MITIGATION/ADAPTATION: COPING WITH WEATHER EXTREMES FROM AN ENGINEERING STUDENT'S PERPECTIVE

Brittany R. Bennett, M.S.E. Candidate, The Catholic University of America, Washington, D.C., 19bennettb@cardinalmail.cua.edu

Abstract: Nowadays civil engineering students of engineering should be knowledgeable about global climate change, due to the fact that it is one of today's greatest challenges our society faces to existing and future infrastructure. For example, in the case of all water-related infrastructure and planning, design, construction, maintenance and operation, there are increasing impacts from extreme weather events. Future engineers need to be prepared for meeting those challenges for mitigation and/or adaption with a result of climate resilience. Federally developed resources and regional case studies will be drawn upon in order to provide useful guidance to water engineering students, or current engineers embracing a climate change approach. The unique perspective of a current student will also provide useful feedback in the development of higher education.

INTRODUCTION

Due to a changing climate, the USACE has identified that "all infrastructure is potentially affected and needs adaptation". Following the 2009 request of President Obama, an interagency Climate Change Adaptation Task Force has crafted numerous recommendations for policy. These include useful guiding principles and strategies for many agencies. At an operational level, regional water resources and related structures (e.g. hydropower dams, water treatment plants) have been studied and some adjustments made.

OBJECTIVES

1. Clarifying relevant climate impacts to water infrastructure, based on the current state of climate science.
2. Determining the actionable goals for intersecting climate and water sectors.
3. Identifying the key strategies for determining risk and associated, imperative, action, and measure which are applicable to various projects.
4. Compiling a useful directory of decision-making and planning tools, which are existing or in-development .
5. Analyzing examples of responsive adjustments made or identified as needed by U.S. water entities.
6. Providing suggestions for relevant preparation in higher education.

CLIMATE IMPACTS TO U.S. WATER INFRASTRUCTURE

Climate is average weather over a time, and a prime environmental factor that determines the life of an area. The climate is warming, not for the first time, but this time it is largely due to the activities of humans and there is now a scientific consensus. Changes to natural cycles in response to man-made activities, especially the hydrologic cycle, must be understood for managers within reliant sectors and for climate users, in order to make sustainable decisions.

Significant changes in temperatures and precipitation patterns affect local water budgets, streamflows, runoff patterns, and extreme weather events. The US has seen the greatest temperature increase and increase in weather extremes, while in the UK there have been more studies on watershed change. The challenges are most significant in urban areas where infrastructure was built to handle a particular environment that is no longer what it was today, and in rural areas where human practices cannot be improved to mitigate global change, and resources for adapting are limited.

Water budgets quantify the hydrologic cycle in the open system including parts in land, air, and in between. A water budge can be considered at the global and regional scales. It accounts for rates of water movement and changes in water storage in a specific unit. Calculations can be done to predict changes and availability. While the concept is simple, accurate determinations are difficult to obtain due to the number of uncertainties present at every scale. There are two sources of uncertainty in water-budget calculations: natural variability and error in measurements. Natural variability occurs in all aspects of the hydrologic cycle, and is becoming more difficult to predict.

The change of temperature is a controlling factor. Higher temperatures allow for larger amounts of water vapor to be to be stored in the atmosphere and cause rates of evapotranspiration to increase. These shifts affect the dynamics of water storage and movement. This is source of complication because the budget is no longer held in steady amounts in the various categories and locations. Quantities and properties for specific watersheds are shifting significantly.

In the past century, changing streamflow and runoff rates have been observed for most rivers and steams. In the US, increasing streamflows have been observed in the East. In the Central US major river basins streamflow and runoff are decreasing. Annual precipitation has been increasing in most of the US, except for in the Midwest, where it has been decreasing. Annual flows of the Colorado, Rio Grande and San Joaquin river basins have decreased 8-20%. Frequency of heavy precipitation events has been increasing throughout most of the US as well. In the Western US and Alaska, storage re-charge is impacted by decrease in the contribution of ice melt.

While the measured extremes now occurring may be greater in the US, it is in the UK that more studies are being done to model climate impacts on strategic river flows. Model projections for the River Medway, in England found a persistent lowering of mean daily river flows for all months and for all projection time slices. This signal was evident, even after considering for uncertainties in the exercises. (Cloke, 2010)

The effect of temperature on soil moisture may account for the lower runoff amounts for some watersheds. Dry soil will absorb more of the rainfall, contributing to more interflow and groundwater flow. However, the driest soils, which can become caked, may not readily absorb rainfall, leading to higher rates of runoff at the beginning of a rainfall event. Droughts are a significant concern. In the US, they have not been found to be increasing in frequency, because they already occur with annual frequency in the Midwest. However, the length of the droughts, and decrease in rainfall may be steadily increasing. The distance in these regions from large water sources, make the situation more fragile.

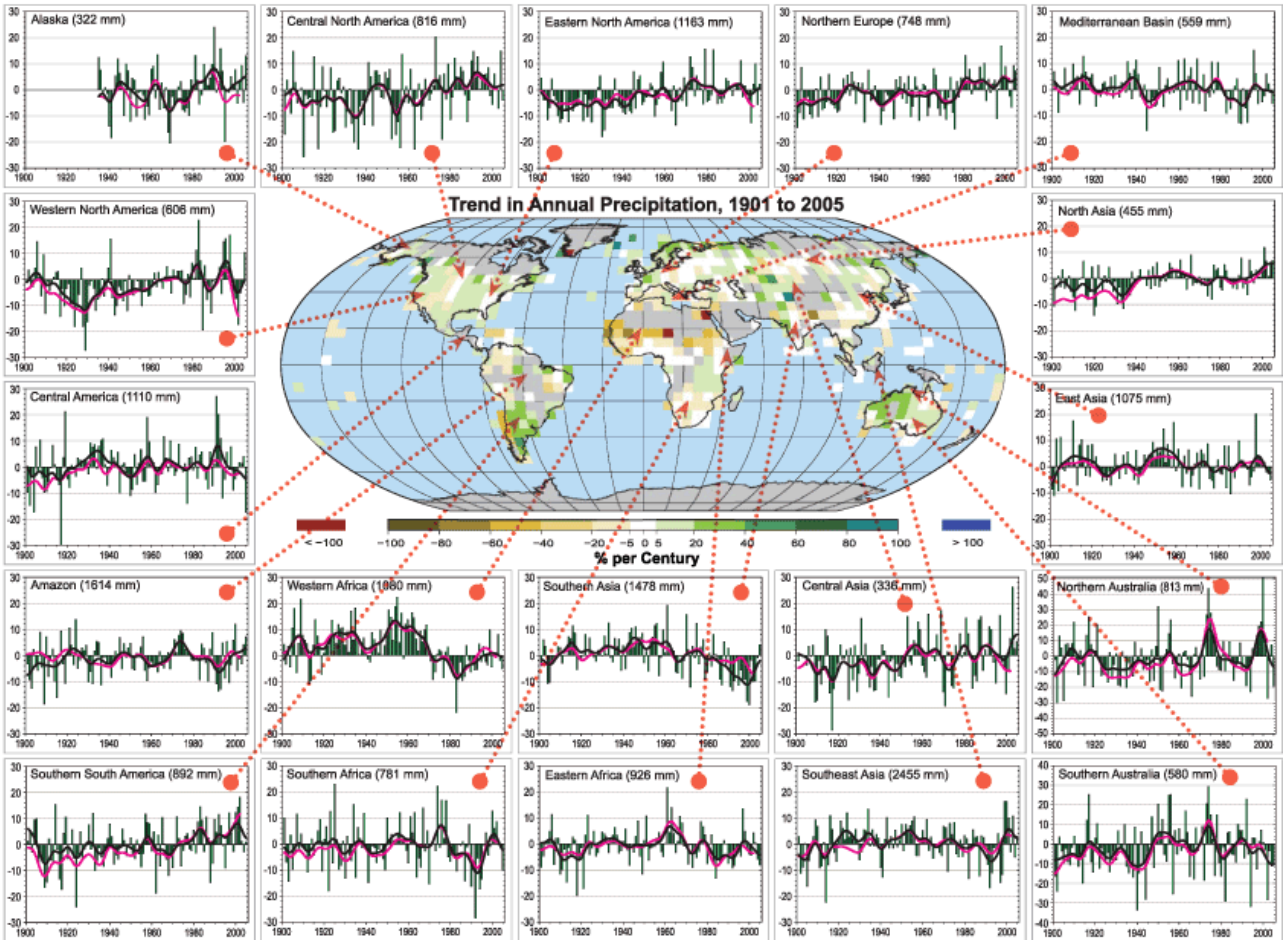

Figure 1. The diagram shows annual precipitation trends (1901-2005) at various regions (Source: IPCC Fourth Assessment Report, 2007, Chapter 3, Figure 3.14).

Temperature increase can cause higher rates of evapotranspiration. Surface waters exposed to higher temperatures see a greater loss in evaporation, and decrease in stored quantity. The additional water vapor passing into the atmosphere may be steadily retained, reducing storage in lakes and rivers. Some of the additional water vapor may also be transported across watersheds in shifting patterns, and contribute to the more extreme rainfall events.

The properties of the local watershed are the significant determinations of hydraulic characteristics in an area. These include total area, slope, elevation, soil and rock types and permeability, storage, density, roughness, and antecedent moisture content. Some of these features are influence by the hydro-meteorological changes discussed above, and others are undergoing change with land use patterns. Land use shifts together with climate shifts, contribute to total watershed change. It's important that future development planning take both of these into account.

Storage, run-off, and antecedent moisture content in particular, are hydraulic characteristics within watersheds which are affected by climate. Both of these measures change continuously but notable shifts may occur with climate change as well as notable extremes.

Antecedent moisture content (AMC) is the relative wetness or dryness of soil prior to a rainfall event. Run-off, infiltration, and interflow are highly affected by AMC. Factors which influence AMC include air temperature, humidity and wind levels, as well as evaporation and transpiration rates. Climatic changes in air temperature, humidity (water vapor), and evapotranspiration rates can alter AMC content.

In regions which experience higher temperatures for longer periods of time, soils may be drier prior to more rainfall events, leading to higher initial infiltration, greater interflow, and lower run-off. Yet, in the cases where temperatures remain high and rainfall events are less frequent, it is possible for caking and cracking to occur in the soil. This can cause initial flooding, because the rainfall is not as ready absorbed. The cracking phenomenon has been observed temporally in clay soils, in particular (Kishné, 2010). While climate changes can influence this dynamic, it will vary with the local soil type.

Periods of freezing and frost also influence soil moisture content. The storage capacity and moisture content of limestone soils increase with freezing and frost events. In the case of increased temperatures, regions with these types of soils may see a reduction in total storage capacity. This could cause more runoff and less moisture availability. (White, 2001)

Climate change slightly increases transpiration rates, yet a large factor in climate change CO2 slightly decreases transpiration rates. The increase in temperature causes plants to transpire more, while greater concentrations in CO2 close the stomata and lead to less transpiration. This dynamic underscores the complications in distinguishing local impacts from global. In general, the increase in temperature has the greatest effect. (State of California)

Land uses also highly influence evapotranspiration and runoff. Shifts in regional land use from undeveloped land, cropland, or woodland to urban and industrial uses decrease the % of evapo-transpiring land which has plant, soil, or water surface. Landscape changes such as these, lead to increased rates of run-off and decreased rate of evapotranspiration. Surface cover is an important input along with precipitation, soil type and moisture conditions. Some models are being developed which can run various surface cover (or development) scenarios. These models are useful, in that they can help determine the impact of greening in urban areas for the purpose of adapting to climate change. (Gill, 2012)

The hydrologic changes mentioned above, all impact the availability of water as resource. It is becoming increasingly important to understand the implications of climate change at the regional and local levels where demands occur. Changes in the global climate have impacts which cross many kinds of borders, whether they are natural or political boundaries. Climatic shifts are influences the extremity of weather events and in some cases the area storm events may cover can include multiple watersheds, states, or countries. The land uses in one region can influence the climate of another region, which in turn influence the hydrology.

Land use is a factor which can be controlled, although the effects of past use can be difficult to eliminate or restore. Models which can run various development scenarios with changing inputs may become increasingly necessary. Management changes occurring are due to the frequencies

in extreme weather events. Management areas include maintaining water availability, controlling floods, operating exposed infrastructure, and managing particular ecosystems and species populations.

Structural difficulties arising from climate change on land are dealing with increasing salinity and soil saturation, and to a lesser extent (depending on the region) sea level rise. Increasing salinity affects drinking water and necessary treatment. Salinity also impacts various ecosystems which may provide other services such as food, medicine, wood products, or storm protection. Preparation for increasing salinity should include planning and mapping for protection, changes in practice, or exclusion from expensive engineering. Increasing soil saturation may contribute to landslides, structural instability or collapse, and changes in agricultural production. Preparation for increasing soil saturation could follow a similar strategy.

ACTIONABLE GOALS FOR CLIMATE AND WATER SECTOR

The actionable goals for the water sector and associated fields of engineering in dealing with climate change, are simply to continue to meet long-established goals, in face of modern changes to the environment. According to the USACE's webpage on adapting to climate change:

> *"The US Army Corps of Engineers (USACE) must be able to perform our missions and operations despite dynamic conditions, whether these result from climate change alone or in combination with other global changes such as demographic shifts, land use/land cover changes, world population growth, aging infrastructure, persistent conflict, declining biodiversity, globalization, climate variability and change, and changing social values and economic conditions."*

From the perspective of an engineering student, this implies a need for gaining knowledge and familiarity with certain challenges, such that whatever the engineer designs or operates has a longevity and can withstand predicted shifts from a current condition (e.g. rainfall, moisture, wind speeds, etc.), wherever it is located. It is implied that these challenges are to be met with diligence, and not ignorance to the current state of knowledge. The engineer, should in fact draw from the available science and from the predictions which are being made by climate scientists. This may seem challenging. How does the engineer know where to find this information, and how do they communicate with other specialists?

KEY STRATEGIES

Strategies related to climate change, may deal with either mitigation or adaption. Mitigation strategies can occur at individual or micro-level. Numerous actions taken at that level can which all have the same impact of reducing emissions. However, adaptation requires more coordination and occurs at the socio- or macro-level. Adaptation involves different groups or sectors finding the best way to respond to the same phenomena.

The current state of the science is sufficient enough, at this point, that application can begin. An important feedback loop is beginning in climate science, as scientific investigation informs the experience and experience will inform future investigation.

A lot of key organizational changes have occurred recently within key scientific and administrative bodies. Publications from a number of reports from various industries and agencies have also been made public. Action at some level has begun in nearly all states and agencies. At this point, it seems that most of the changes have occurred at the scientific and political level. This information and policy are great directives to further more useful advances in mitigation and adaptation.

It is important to move from scattered action to strategic action which occurs to some degree at every level, because the impacts are broad. Emissions cannot be simply reduced in a single region or industry, with the expectation that the temperature and precipitation increases or decreases will return back to normal. There needs to be a high level of coordination across sectors and political boundaries.

Key Bodies, Legislation, and Reports:

- IPCC
- USGCRP - United States Global Change Research Program
- White House CEQ Federal Instructions for Adapting
- Regional GHG initiative (NEUS)
- CA AB32 Act (California "Global Warming Solutions Act")
- NRC report (adaptation)
- Insurance companies report
- Security Exchange Commission disclosure
- EIA's – incorporating climate change impacts
- USACE – "all infrastructures potentially affected and need adaptation"

In particular, the White House CEQ's Federal Instructions, given to all federal agencies a couple years ago, contains principles useful to various fields. They are summarized below.

- *Adopt Integrated Approaches:* Adaptation should be incorporated into core policies, planning, practices, and programs whenever possible.
- *Prioritize the Most Vulnerable*: Adaptation strategies should help people, places, and infrastructure that are most vulnerable to climate impacts and be designed and implemented with meaningful involvement from all parts of society.
- *Use Best-Available Science*: Adaptation should be grounded in the best-available scientific understanding of climate change risks, impacts, and vulnerabilities.
- *Apply Risk-Management Methods and Tools:* Adaptation planning should incorporate risk-management methods and tools to help identify, assess, and prioritize options to reduce vulnerability to potential environmental, social, and economic implications of climate change.
- *Apply Ecosystem-based Approaches:* Adaptation should, where appropriate, take into account strategies to increase ecosystem resilience and protect critical ecosystem services on which humans depend, to reduce vulnerability of human and natural systems to climate change.

(http://www.whitehouse.gov/administration/eop/ceq/initiatives/adaptation)

The best available science is being done in many places, but much of it related to climate change

has been reviewed and summarized by IPCC. The next assessment will be done next year. Four reports are currently available. (http://www.ipcc.ch/publications_and_data/publications_and_data_reports.shtml#.UKf1MYdZWv0)

The best technologies and applications for climate change adaptation leverage the internet, and compile data from multiple sources. These data inputs can be used to inform management of GHG emissions, by flagging the greatest uses and indicating where the easiest or greatest reductions can be made. Utilizing various performance technologies can generate savings which may be found in many areas including labor, time, travel, physical infrastructure, energy, and consumption. Due to the large volume of data can and is being generated from connecting so many 'things', some new references are being made to 'big data' and the 'internet of things'.

The key will be learning to efficiently interpret this data and digest it. This is still a largely intuitive process, which requires more training of managers in what to look for, how to look, and how to use the information available. While 'things' are becoming more and more connected and better understood it's important that 'people' (e.g. managers of various sectors or resources or organizations) remain just as connected, so that advances are shared in a timely way. An example where that dynamic plays out is in the case of environmental requirements for data server storage (Jonassen, 2012). While it is now known that they still function properly under moderate ambient temperatures, many centers are still cooled. These situations could be adapted for easy savings in energy use and emissions.

DIRECTORY OF TOOLS, EXISTING AND IN-DEVELOPMENT

An up-to-date list will be included as part of the presentation / poster

CASE STUDIES OF ADAPTATION TO CLIMATE CHANGE IN THE U.S. WATER SECTOR

The majority of case studies on this topic are in the assessment and planning stage. A few examples:

1. The NDWAC report identifies current water sector needs and challenges utilities face when attempting to mitigate and adapt to the impacts of climate change ("Overview of Climate Ready Water Utilities Working Group Report.").
2. Metropolitan Washington Council of Governments inter-agency initiative ("Climate Change - Building Resilience") focuses on mitigation, in compliance with federal direction, and resiliency.
3. The District Department of Transportation (DDOT)'s Adaptation Plan includes water infrastructure ("Climate Change Adaptation Plan")

RECOMMENDATIONS FOR HIGHER EDUCATION

A number of important inputs in hydrology are changing temporally leading to changes in water availability. While the many changes are being studied by experts in different areas, barriers

remain for effective management of water resources and adaptation of urban areas. Some recommendations can be made to reduce these barriers and better sync management change with climate change so that adverse impacts are decreased, and so that students are properly trained and prepared to enter these fields.

The first two suggestions are related to engineering as a whole, wherein clarification would improve education, and wherein students themselves may make contributions. The rest are primarily focused on the realm of improving higher education through specific course integrations.

Terms: Within this paper many terms were used, some interchangeably and some not well-explained. Not all managers will be familiar with the list of terms related to climate. Various fields have preferred terms, or unique terms. More uniform terminology and metrics could make current scientific understanding more accessible and communication across disciplines/sectors more efficient. Uniform metrics would allow for the more efficient education and training of managers, as well as give them tools to more quickly assess key local changes and adaptation options. Improvements could also be more clearly made and shared. Students in multiple disciplines would be able to collaborate more effectively, enabling conversations which lead to deeper understanding and more creative solutions to problems in their communities.

Economics and community-based approaches: No models were found in the research of this paper which related climate change to specific economic valuations of various ecosystem services. This is an important factor in decision making. Many engineering students are educated in economics for the purpose of managing projects. However, because the impacts of climate change are so broad, and because the economic implications are not well understood, these students are at a disadvantage in today's workplace. In real-world projects, the involvement of local community may be a key concern in adapting regional areas. Therefore it is suggested that students become familiar with community interaction. Motivated citizens (a.k.a. the end-users of services and products such as roads or drinking water) may find the time and interest in monitoring local watershed changes, and reporting these inputs to experts in modeling. They may also communicate with managers to inform them of practicality of land use changes in response to these changes. Students should be introduced to a community-based approach to managing and developing water-related projects. Practically speaking, this could be addressed by including modules in existing and sometimes required management courses, by new courses on climate management, or by recommending courses on economic development or introductory courses on environmental/climate science.

Integration of sustainability criteria to engineering degree program accreditations: Example:

- The National Architectural Accrediting Board (NAAB) is updating the criteria it uses to accredit degree-granting architecture schools in the U.S. to include full integration of sustainability criteria (instead of requiring unique courses on sustainability). This could likewise, be instituted by the Accreditation Board for Engineering and Technology (ABET).

Science and sustainability courses: Examples:

- Sustainability course (http://architecture.cua.edu/res/docs/Curriculum/SustainMinorCourses-2014-082014.pdf)

- LEED lab (http://www.leedlab.com)
- Technologies for Sustainable Societies (http://osoc.berkeley.edu/catalog/gcc_search_sends_request?p_dept_cd=CIV+ENG&p_title=&p_number=292A)
- Introduction to environmental science (a standardized course)

Other courses: Examples:

- Climate Change Mitigation (http://osoc.berkeley.edu/catalog/gcc_search_sends_request?p_dept_cd=CIV+ENG&p_title=&p_number=107)
- Adapting roads (http://www.idrrim.com/ressources/documents/5/2710,ROADAPT-course-October-20-21.pdf)
- Alternative energy (http://eecs.cua.edu/renewable-energy/index.cfm)
- Introduction to environmental engineering (a standardized course)

DOWNSTREAM SEDIMENT IMPACTS ON FISH RESTORATION, RIVER DYNAMICS, FLOODPLAIN DEVELOPMENT, AND WATER QUALITY FROM BREACHING THE ELWHA AND GLINES CANYON DAMS, NEAR PORT ANGELES, WASHINGTON

Dr. Frank Reckendorf, Fluvial Geomorphologist, Reckendorf and Associates, Salem, Oregon, frecken@mac.com
Dr. Barry Southerland, Fluvial Geomorphologist, NRCS, WNTSC, Water Quality and Quantity Technology Development Team, Portland, Oregon, barry.southerland@por.usda.gov

INTRODUCTION

The Natural Resources Conservation Service (NRCS) in Washington generated a request for post-project appraisals of Engineered Log Jams (ELJs) in December of 2005. In February of 2006 the Washington NRCS in Spokane, and the West National Technical Support Center of NRCS in Portland, Oregon, assembled an interdisciplinary team including two fluvial geomorphologists, a fisheries biologist, and a stream-mechanics engineer. They were to study the results of the ELJs Implementation since the mid1990s in the State of Washington. One major study site was the ELJs on the Lower Elwha River. During the 2010 evaluation of the Lower Elwha it was decided to extend the study to look at the effects of sedimentation on the Elwha River and the ELJs once a large dam removal project started in 2011. We monitored 49 ELJs on the Lower Elwha River between 2006 and 2013.

Two hydroelectric dams were constructed on the Elwha River by a private company in the early part of the last century. Elwha Dam was constructed in 1910, and the Glines Canyon Dam in 1925. They were constructed without regard to fish passage facilities, although regulations were in effect in Washington at the time. The dam's lack of fish passage decimated native populations of salmon including spring Chinook known to exceed 100 pounds. The dams altered the natural hydrologic regime, caused downstream scour to occur below both dams, and an increased transported particle size passing through the spillway, because the coarser material is trapped. The downstream scour after the dams are built causes there to be an increase insize because the flow contains less load. This condition is called hungry water. In addition, the altered hydrology caused an increase in downstream temperatures, and decreased transport of large woody debris (McHenry et al., 2007).

STUDY AREA

The Elwha River watershed is in the Olympic Peninsula, with its headwaters on the slopes of Mt. Olympus in Olympic National Park. About 80 percent of the Elwha River watershed lies within the Park boundaries. Limited development occurs within Olympic National Park, so the Elwha has largely remained in its natural condition above the dams.

Construction began on the Elwha Dam, located at RM 6, in 1913. The dam was 108 feet high. Construction began on the Glines Canyon Dam, located at RM 13, in 1926. This dam was 220 feet high. The portion of the Elwha River impacted by sediment that is discussed in this study

extends from RM 2.5 to the mouth at the Puget Sound near Port Angeles. The ELJ study site is located between RM 2.25 and RM 1.33, downstream of both dam sites.

SETTING

The watershed has a drainage area of 325 square miles. The period of record, including pre-dam construction and pre-breaching, had a bankfull discharge in the range between 6,500 to 8,250 cfs with a drainage area of 270 square miles to the ELJs. Table 1 shows the recent high flows of significance since ELJ implementation.

Year	Discharge (cfs)	Log Pearson III
2002	25,700	9Q
2003	29,700	17Q
2006	20,900	5Q
2007	35,900	37Q
2010	22,300	6Q
2013	11,100	1.6Q

Table 1 USGS Gage 12045500

The tortuosity, defined as R_c/W_{bkf}, (Rc is Radius of Curvature and W_{bkf} is Width at bankfull Q), in the ELJ evaluation reach varied from 2.5 ft/ft to 2.6 ft/ft. Prior to dam removal the Elwha was migrating laterally towards the left streambank at the study site. Local scallop patterns were present on the left streambank, and excessive streambank loss is still a major concern.

The Elwha River is typical of many Northwestern rivers that have undergone channel modification by straightening, gravel removal, and destruction of the riparian vegetation. Historically, under natural conditions the Elwha River was a pool/riffle, gravel-bed system. The riparian area functioned hydraulically with the river adding a large woody debris component that was functionally important for salmonid habitat. After the dams were constructed, the Elwha River lost legendary fish runs of ten species, destroying the habitat complexity. Before the dams were removed, it provided limited spawning and rearing habitat for remnant populations of native Pacific Salmon (McHenry et al., 2007). Two species, Chinook salmon and bull trout, are listed as threatened under the Endangered Species Act and steelhead is proposed for listing (McHenry et. al, 2007).

The construction of the two dams changed the hydraulics, sedimentation, and meander geometry downstream. The absence of sediment loads below the dams caused scour to occur downstream all the way to the mouth of the Elwha River. The bed load component played a much greater role in determining the medium load size in the river with the dams in place, causing an increase in the bed material load.

The post-dam hydraulics caused roughly three feet of downcutting to a coarse cobble material with a d_{50} of roughly 190 mm.

Figure 1 Downcutting shown in the left portion exposed an old channel, which is, now, a floodplain. The right portion of the image shows this old channels remnant floodplain as it was 50 years ago.

Figure 2 Close up of the streambank of the remnant floodplain shown in the right part of Figure 1. This figure shows a cantilever overhang that is sloughing as described by Reckendorf (2009 and 2010).

There was still sediment contributed to the Elwha River from the uncontrolled drainage area below the dams, including streambank erosion such as shown in Figures 1 and 2, and from sediment that was passed through the spillways of both dams. Prior to dam removal, the Lower Elwha study area had a bimodal sediment distribution, with some of the gravel bed with a d_{50} of roughly 50 mm associated with the current flow regime. In addition, part of the bed and bar had a d_{50} of roughly 130 mm, associated with coarse (cobble) bed material exposed through the downcutting process. The maximum d_{50} was roughly 200 to 225 mm (coarse cobbles). The velocity that could transport a 225 mm particle with a flow depth of 10 feet is estimated to be 15 ft/second (Simon and Senturk, 1977).

The post-dam downcutting resulted in the exposure of coarse streambanks (Figure 3) and in cobble beds and bars throughout the Lower Elwha, as shown in Figure 4.

Figure 3 The coarse cobble bed materials on a bar and in the lower bank prior to breaching the dams.

Figure 4 Coarse bed material next to an ELJ prior to dam breach.

There was an estimated 18 million cubic yards of gravel, sand, and silt accumulated in the two reservoirs (NPS, 2015). There was a projected potential release of 13 million cubic yards after the dams were breached (Glines, 2014). Sediment from the dams was expected to move downstream in pulses associated high flows. The largest sediment pulse, or flux, would be expected to occur after the major draw-down of the Elwha Dam and partial draw-down of Glines Canyon Dam in 2011. For the 2011-2012 winter runoff, the maximum post-breach Q was 10,300 cfs.

Observations at the upper end of Glines Canyon Dam in October of 2013 indicated new deposition of coarse gravel with an average size of 25 mm. There were also some small gravel bars with an estimated d_{50} of 10 mm. However, most of the post reservoir deposition was sand.

Extensive sedimentation after the two dam breaches likely caused sediment intrusion into spawning gravels of the type pointed out by Reckendorf and Van Liew (1988), and Everett, Lotspeich, and Meeham (1982). These studies showed that even a small sediment supply in winter runoff of sand and silt particles caused sufficient packing of sediment intruded into the gravel above spawned eggs to reduce dissolved oxygen to lethal levels for salmonid egg survival. Streamflow under normal circumstances would have kept new redds saturated with dissolved oxygen as water is pushed through the open gravel.

DAM REMOVAL EFFECTS

The Elwha Ecosystem and Fisheries Restoration Act of 1992 authorized the Department of Interior to remove the dams beginning in 2009. Dam removal started in September of 2011. The Elwha Dam was fully removed by March of 2012. The Glines Canyon Dam was partially cut down from 220 to 60 feet by then, and was fully removed by the spring of 2014.

According to the Peninsula Daily News (Rice, 2011) the storm events on December 9 through 11, 2011, caused the flushing of 1.5 to 2.0 million cubic yards of sediment from Lake Mills above Glines Canyon Dam and Lake Aldwell above Elwha Dam. The newspaper reported that a three-storm event raised the peak flow on the Elwha River to 17,000 cfs. This caused extensive streambank erosion resulting in the loss of riparian trees along the river.

Sedimentation started large, new lateral and center bars, which appeared when the flow receded after the 2011-2012 runoff. During the 2012 event, a new first flat depositional surface developed at RM 2.5, at the upstream end of the evaluation reach. The top of the first flat depositional surface formed about 2.5 feet above the adjacent new lateral bars, which is shown in Figure 5, as observed in 2013. This new first flat depositional surface has been observed upstream as far as RM 12.8, at the Elwha River Bridge near Glines Canyon Dam. Figure 6 is an example of the consistent first flat depositional feature in the study area, and it occurs all the way downstream to the mouth of the river.

Figure 5 The top of the first flat depositional surface formed about 2.5 feet above the adjacent new lateral bars, as observed in 2013.

Figure 6 An example of the consistent first flat depositional feature in the study area. It occurs all the way to the mouth of the river at the Puget Sound.

A new flat depositional surface is apparent around ELJs such as shown in Figures 7. This new first flat depositional surface varies in height from 2.5 feet to 3.0 feet above the adjacent lateral bars. The first flat depositional surface is still growing from deposition that occurred during recent winter runoff.

The first flat sedimentation after the first dam flush (pulse) and the new bar deposition have essentially covered most of the coarse cobble channel and bars. The new first flat depositional surface extends right into ELJs such as shown in Figures 7 and 8, and has filled pools created by the ELJs.

Figure 7 A new flat depositional surface is apparent around an ELJ.

Figure 8 Another new flat depositional surface apparent around an ELJ.

The gravel that had previously been deposited above Glines Canyon Dam now has the opportunity to pass through the sites where the Glines Canyon and Elwha Dams once stood, and can now again provide gravel substrate to the lower reach of the ELJ study site. The size of the gravel that now reaches the channel area developed through the old Lake Mills has a d_{50} with a typical range between 10 to 25 mm.

Side channels along the Elwha River received extensive sedimentation essentially filling side channels. The falling stage of the post-breach hydrograph, with subsequent flood events, partially opened up new side channels. The side channels evaluated in 2013 had extensive new first flat depositional surfaces.

Deposition on the ELJs was observed to be as high as three feet above the first flat depositional surface on ELJ logs. This depositional surface is not continuous and reflects scour during subsequent breach flood flows. This likely occurred during the falling stage of post-breach events but could also have occurred in subsequent events. However, the post-scour effects have not transported the sediment out of the pools under the ELJs.

On the Lower Elwha, most of the pools, including pools under ELJs constructed between 1999 - 2011, filled with sediment during the 2011–2012 winter runoff. This occurred again during the 2012 – 2013 winter runoff, which filled the pools constructed in 2012. There are 49ELJs in the 2013 evaluation; whereas, there were 37 in the original study. From the thirty seven observed in 2007, three ELJs had washed out. Six ELJs were added in 2013 after the winter runoff of 2012 - 2013. Therefore, 37 ELJs could have been impacted by the sediment releases in 2011, 2012, and 2013.

Observations in October 2013 found that 35 of the 37 observed in 2007 were very shallow or non-existent such as those shown in Figure 7. There was essentially no summer refuge or adult holding pools for salmon under the 35 ELJs as the pools filled with sediment. Where the Elwha has been narrowed by opposing ELJs, identified as 10-1 and 10-2, scour has kept the pools under the two ELJs open for summer refugia.

As reported by the Peninsula Daily News (Rice, 2011) the large December 2011 runoff greatly impacted the water supply for the water intake for the Elwha Tribe Hatchery. The water intake for the City of Port Angeles was also significantly impacted by the sediment flux from the two dams.

CONCLUSIONS

After the two dams on the Elwha River had been constructed, there was extensive downcutting in the downstream reaches of the Lower Elwha River. Roughly three feet of river bed downcut to a coarse cobble surface with a rough d_{50} of 190 mm. There is post-dam sedimentation of small gravel with a rough d_{50} of 10 to 25 mm. Before the dam breaches, most locations on the Lower Elwha had a bi-modal distribution of average particle sizes. There was gravel with an average d_{50} of 50 mm associated with coarse cobbles with a d_{50} of 190 mm, and a maximum d_{50} of 225 mm.

The average flow velocity that could transport an average size of 225 mm is 15 feet per second (fps).

Such a flow velocity of 15 fps has probably not occurred in post-dam time, so the coarse cobbles likely represent a paleo-channel formed in Holocene or Late Pleistocene time. By comparison the average flow that would transport a d_{50} with an average size of 50 mm (pre-breach flow regime) would have a velocity of 8 fps. The post-dam flow sized particles could easily be transported by flood runoff in historic time.

The Elwha Rivers hydrologic regime has substantially changed because of the removal of the two dams. Extensive sedimentation created a new first flat depositional surface along many of the lateral bars that covered the coarse-cobble substrate. The sediment flux also created new lateral bars and greatly expanded center bars. The sediment pulses in the 2011-2012 and 2012-2013 events extensively filled the side channels, and they are gradually opening again.

ELJs that were installed along the Elwha starting in 1999 had their foundations in coarse cobbles, for the most part. This coarse-grained foundation adds to their stability. The post-dam sedimentation filled most of the pools under the ELJs constructed between 1999 – 2011, such that there is little summer refugia for salmon, especially adults. Two of the ELJs still have good pools that can be used for summer refugia. These two are opposite one another and have constricted the channel width such that there is increased shear stress on the channel bed and bank (which is the ELJ) so scour keeps the pools open. This would appear to be one solution to maintain pools under the ELJs in the future. The difficulty will be to keep the Elwha channel, which is presently wide, confined between ELJs.

Sedimentation is still occurring in the Lower Elwha, and sediment is being added to the first flat depositional surface, and to existing ELJS> Sedimentation is likely intruding into spawning gravel. It will likely constrain new spawning as long as large sediment loads get reworked down the channel with winter pulses of sediment.

The reworking of sand and fines sediment from the reservoir as well as that now deposioted on bars, will likely constrain being able to have clean flushing flows that sour out the polls under ELJs in the foreseeable future. This along with the sediment intrusion into spawning gravels ,from the excess sediment supply, will also constrain recovery of salmon populations for some time.

SANDBAR GROWTH AND DECAY ON THE MISSOURI RIVER DURING THE HIGH FLOWS OF 2010 AND THE HISTORIC 2011 FLOOD

Jake Gusman, P.E., Project Manager, WEST Consultants, San Diego, CA, jgusman@westconsultants.com; Vicki Tripolitis, EIT, Hydraulic Engineer, WEST Consultants, San Diego, CA, vtripolitis@westconsultants.com; Cameron Jenkins, P.E., Hydraulic Engineer, WEST Consultants, San Diego, CA, cameronj@westconsultants.com; Christopher Svendsen, P.E., Hydraulic Engineer, U.S. Army Corps of Engineers, Omaha District, Omaha, NE, christopher.j.svendsen@usace.army.mil; Daniel Pridal, P.E., Chief, Sedimentation and Channel Stabilization Section, U.S. Army Corps of Engineers, Omaha District, Omaha, NE, daniel.b.pridal@usace.army.mil

Abstract: The U.S. Army Corps of Engineers, Omaha District implements an Emergent Sandbar Habitat (ESH) construction program on the Missouri River to create nesting habitat for the interior least tern and piping plover bird populations. Beginning in August 2010, high flows prompted the Corps to initiate physical monitoring of six sites to document whether the flow level and duration were sufficient to create sandbars suitable for nesting. In 2011, a historic flood resulted in dam releases reaching 160,000 cfs, approximately a 0.2% annual chance exceedance (500-year) event. The monitoring period was extended to capture sandbar formation during this event and to document the subsequent degradation once the high water had receded.

Analysis of the data for the high flows of 2010 and 2011 yielded important insights regarding the sediment volume change at each site, total sandbar area, individual sandbar characteristics (wetted perimeter to area ratio, average side slope, average sandbar height, etc.), and the mechanisms for sandbar growth and decay. A two-dimensional, fixed-bed hydrodynamic model was constructed for one of the survey sites using the ADH (ADaptive Hydraulics Modeling System) program. Computed flow depth, velocity, and shear stress were analyzed during periods of sandbar growth and decay. For the highest flows, there was a zone with highly transient sandbars—a zone in which bed material was continuously moving, depositing, and eroding. These highly transient sandbars did not persist after the floodwaters receded. As expected, sandbars were more likely to persist in areas of reduced shear stress, velocity, and depth.

The location of the thalweg versus the location of major sandbars has a strong correlation to the sandbar decay rate. In periods when the thalweg was close to the major sandbars, the decay rate was significantly higher. As the thalweg moved away from the sandbars (e.g., toward one of the banklines), the decay rate was lower. Based on the survey data, wind erosion was not a significant factor in sandbar decay following the 2011 flood. The rate of sandbar erosion was directly related to sandbar area. Sites with the largest sandbars generally eroded at the highest rate. Finally, the sandbar area at each site was projected 10 years into the future based on observed sandbar growth/decay, thalweg location, and site characteristics.

INTRODUCTION

Emergent Sandbar Program: The U.S. Army Corps of Engineers, Omaha District implements an Emergent Sandbar Habitat (ESH) construction program to create nesting habitat (see Figure 1) for the interior least tern (*Sternula antillarum)* and piping plover (*Charadius melodus*) bird populations. In contrast to islands, sandbars are temporary formations and comparatively dynamic in nature that change dramatically in form and extent both within and among seasons. The ESH program was implemented based on the Amended Missouri River Biological Opinion (BiOp) issued in 2003 by the U.S. Fish and Wildlife Service. The BiOp provides the Corps with reasonable and prudent alternatives with respect to providing sufficient ESH acreage in order to support least tern and piping plover populations on the Missouri River. The BiOp also suggests that the flows from Gavins Point be used to create ESH. The Corps has not attempted to utilize flows for the creation of ESH. Instead, the Corps has relied on mechanical construction to augment ESH acres, but high water events occurring in 2010 and 2011 resulted in the natural formation of ESH.

Figure 1 Missouri River Sandbar Habitat

Recent High Flows and Sandbar Monitoring: Discharge from Gavins Point Dam exceeded 45,000 cubic feet per second (cfs) from late August through mid-December 2010 (see Figure 2)—the first instance of extended flows of this size since the ESH program began. Flow contributed by the James River (1960 RM 800) and Vermillion River (RM 772) increased this flow to greater than 50,000 cfs during this period, peaking at over 63,000 cfs on 4 August 2010. The Corps initiated physical monitoring of six sites to capture sandbar response to the large flows. The goal was to document whether the flow level and duration were sufficient to create sandbars suitable for nesting. In 2011, the historic flood resulted in dam releases reaching 160,000 cfs, approximately a 0.2% annual chance exceedance (500-year) event. The ESH

monitoring period was extended to capture the formation of sandbars during this event and to document the subsequent degradation once the high water had receded.

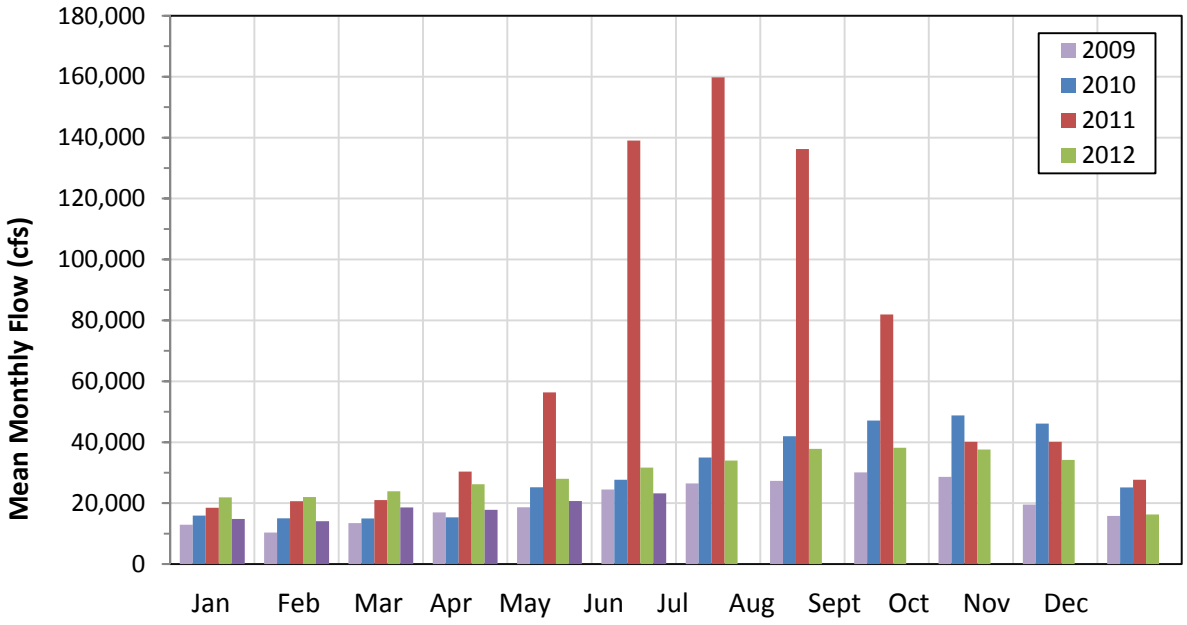

Figure 2 Gavins Point Dam Mean Monthly Flows

SEDIMENT VOLUME CHANGE

High-density hydrographic surveys, with an average of 10 cross sections per mile, were completed in 1995 and 2013. The high-density data sets were merged with LiDAR survey data of islands and overbanks to create elevation surfaces (see Figure 3 for an example). The difference between the two surfaces was then used to identify major changes in sediment volume. An elevation change over 15 feet was considered a major change. There are 45 locations with elevation differences over 15 feet with 33 of them based on erosion and 12 based on deposition (see Figure 4 for example). Most of the major erosive areas are locations where the river has encroached on its banks. However, some of these erosion areas are located further away from the banks.

Between 1995 and 2013, net erosion exceeded 55 million cubic yards within the study reach (approximate 1960 River Mile 753 to 810). The study reach was divided into six segments and only one (RM 790.3 to 800) showed net deposition (3.4 million cubic yards). The highest net erosion occurred in the most downstream segment (RM 753 to 763), totaling over 22.3 million cubic yards. Table 1 shows the volume change for all six segments.

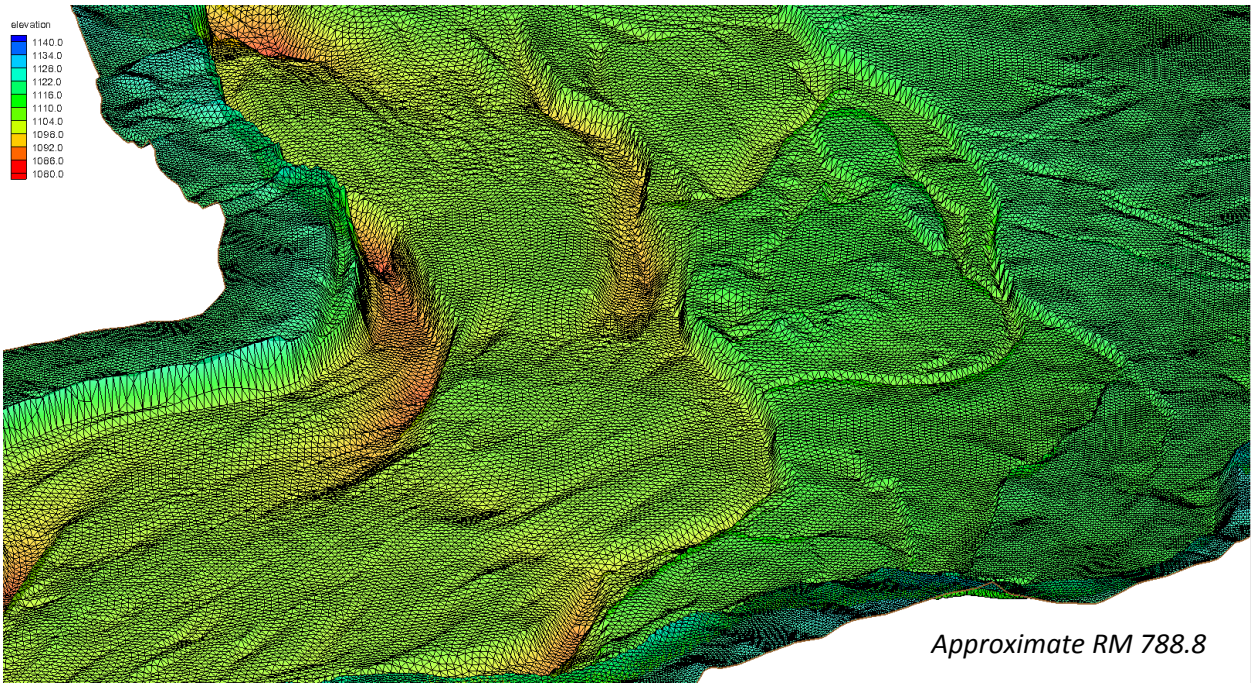

Figure 3 Example of a Finished Surface

Table 1 Volume Change (1995 to 2013) based on High-density Survey and LiDAR Data

Segment	Segment Boundary		Change in Volume (cubic yards)		
	Sediment Range	1960 RM[1]	Erosion[2]	Deposition	Total
1	783.6 – 793.9	753 – 763	(28,766,000)	6,397,000	(22,369,000)
2	793.9 – 804.2	763 – 771	(17,394,000)	10,206,000	(7,188,000)
3	804.2 – 814.7	771 – 780.5	(25,823,000)	11,867,000	(13,956,000)
4	814.7 – 824.1	780.5 – 790.3	(17,449,000)	7,661,000	(9,788,000)
5	824.1 – 834.5	790.3 – 800	(10,167,000)	13,539,000	3,372,000
6	834.5 – 845.1	800 – 810	(11,175,000)	5,950,000	(5,225,000)
Total	783.6 – 845.1	753 – 810	(110,774,000)	55,621,000	(55,153,000)

1. Approximate 1960 river mile location.
2. Values in parentheses represent negative numbers, i.e., areas of erosion; positive values are shown without parentheses and represent deposition.

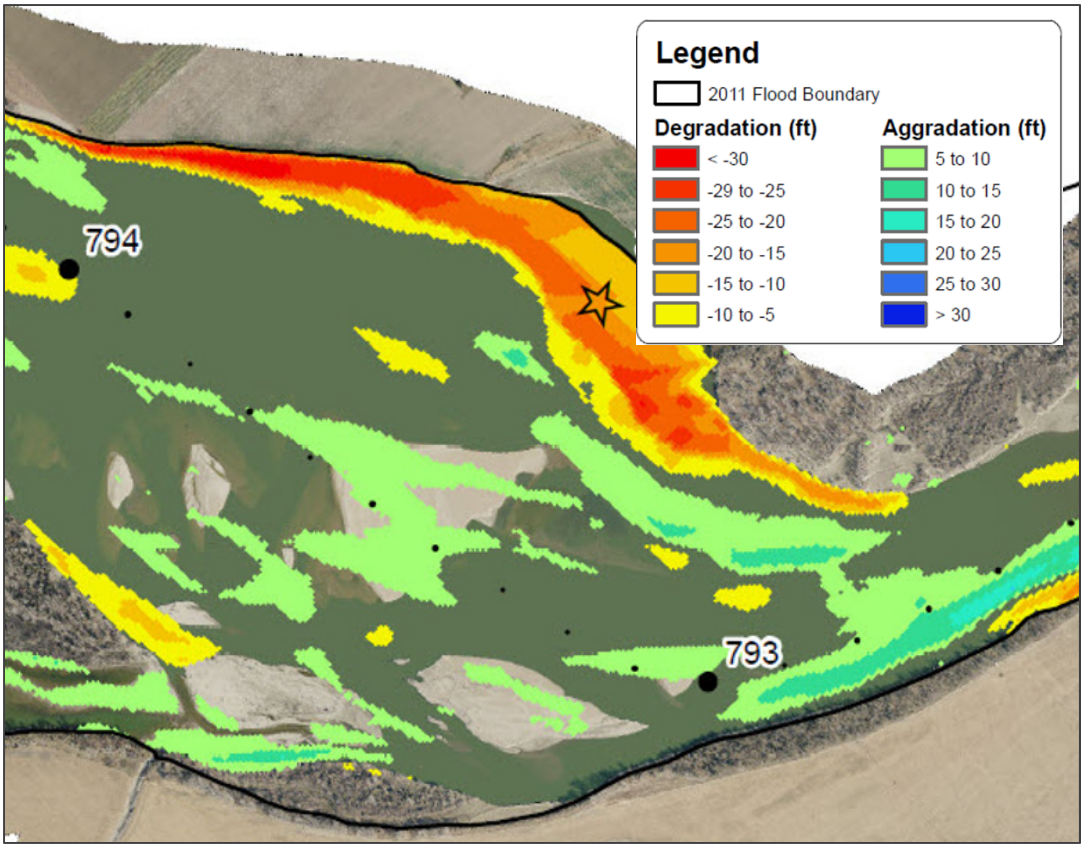

Figure 4 Example of Major Elevation Change (River Mile 793 to 794)

ESH SURVEY SANDBAR AREA ANALYSIS

Sandbar Survey Sites: The ESH surveys were conducted at approximate 1960 river miles 761, 770, 776, 782, 793, and 795, for sites ranging from a half mile to a mile in length (see Figure 5). The average width of the sandbar sites ranged from 2,759 feet (Site 761) to 4,100 feet (Site 770). The average site width was approximately 30 percent larger than the average width of the corresponding river segment. Most sites lie within fairly straight stretches or with slight bends in the channel. However, Site 776 is located near the apex of a sharp bend. Although Site 782 is located within a fairly straight section of the river, it differs from the other straight section sites because it is located just downstream of a large vegetated island that splits the channel flow. Sites 795 and 793 are within the same segment, and located only two miles apart.

In general, two surveys were performed per year in 2010, 2011, and 2012, with one survey in 2013. To evaluate the survey results, sandbar elevations and areas were analyzed at the 10-, 50-, and 90-percent exceedance flow levels (i.e., the flow level exceeded 90 percent of the time). To be considered a sandbar, a minimum area of one acre was required at the 90-percent flow level.

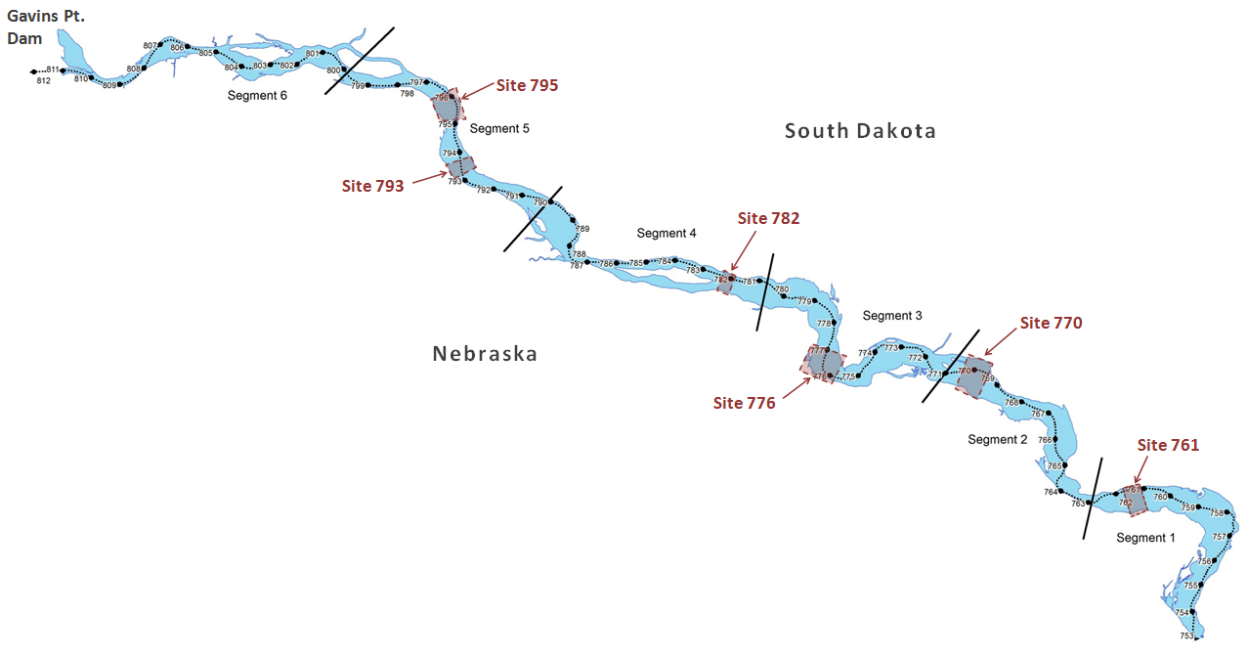

Figure 5 Missouri River ESH Sites and Study Extents

Total Sandbar Area: The total sandbar area was estimated at each study site for each season surveyed. These areas were then used to estimate the rates of growth and decay of the sandbars during the study period, and for use in projecting the rates of decay 10 years into the future.

Emergent sandbar habitat acreage is defined by USACE (2011) as all bare or sparsely vegetated sandbars available to terns and plovers. By definition, this encompasses new ESH (non-vegetated sandbars) as well as old ESH (sandbars that have aged and been subject to limited vegetation encroachment and erosion). Aged sandbars, however, should not be confused with islands that have woody riparian vegetation. Sandbars have only sparse plant cover and little or no woody vegetation. In the current study, islands were not considered ESH, and were not included in total sandbar area computations. In addition, point bars (formed on the inside of river bends) and shoreline deposition were not included in the total area. Figure 6 shows an example of what was included when determining total sandbar area.

All but two of the sites had the largest ESH area occur during summer 2011—Sites 761 and 776 had the largest ESH during fall 2011. Overall, the results show significant increases in ESH area (90-percent flow level) during the historic 2011 flood—from an average of 60.6 acres per mile in winter 2010 to 136.5 acres per mile in summer 2011 (see Table 2). ESH area ranged from 55.8 acres per mile (Site 776) to 223.5 acres per mile (Site 770) in summer 2011. At the 10- and 50-percent flow levels, average ESH went from 0.5 and 25.5 acres per mile in winter 2010 to 52.2 and 94.0 acres per mile, respectively, in summer 2011. After the historic flood, the average total sandbar area (90-percent flow level) decreased to 51.4 acres per mile by fall 2013 (20.0 and 44.4 acres per mile for the 10- and 50-percent flow levels).

Table 2 Average Total Sandbar Area per Mile

Season/ESH Level	Site Average (acres/mile)		
	10%	50%	90%
Fall 2010	0.5	15.6	63.5
Winter 2010	0.5	25.5	60.6
Summer 2011	52.2	94.0	136.5
Fall 2011	48.3	86.8	117.2
Spring 2012	35.5	66.6	85.7
Fall 2012	23.1	48.7	58.1
Fall 2013	20.0	44.4	51.4

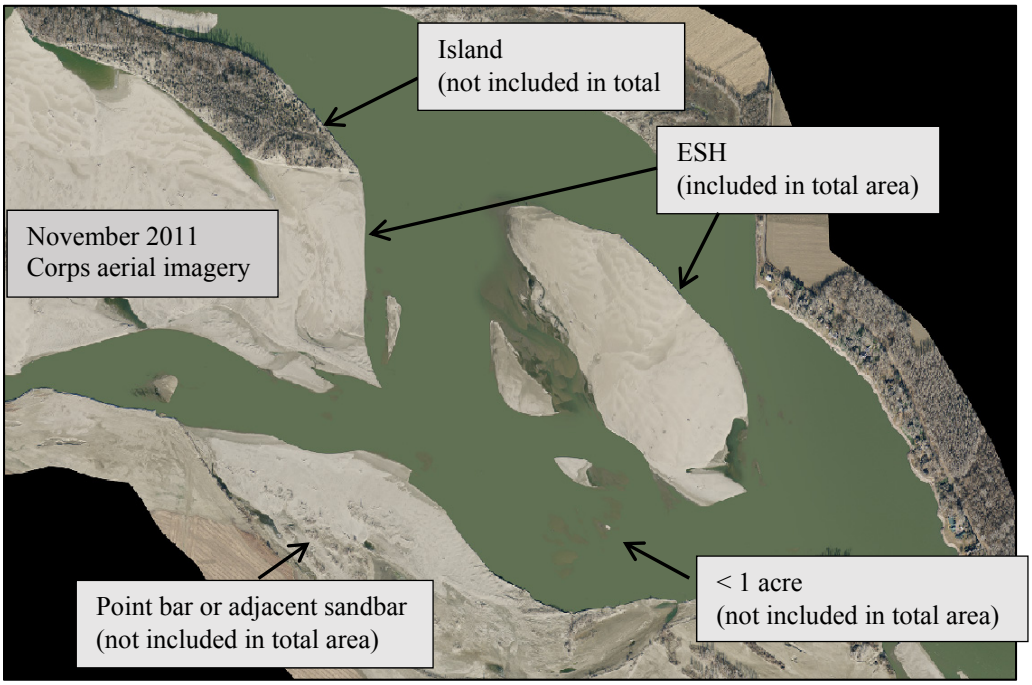

Figure 6 Example of Areas Included and Not Included in Total ESH Area

Sandbar Characteristics: In winter 2010, the average size of an individual sandbar (90% flow level) ranged from 2.2 acres at Site 782 to 31.9 acres at Site 795. The average sandbar size was 14.1 acres across all sites. In fall 2011, the average size of an individual sandbar (90% flow level) ranged from 14.6 acres at Site 782 to 78.6 acres at Site 776. The average sandbar size was 37.2 acres across all sites. Overall, the habitat formed during the 2011 flood was much larger in total area compared to the ESH formed in winter 2010. Although the total area at each site was greater in fall 2011, there were more sandbars in winter 2010 (25 versus 17 across all sites).

Wetted perimeter to area ratios (90% flow level) ranged from 369 feet per acre (Site 793) to 1,119 feet per acre (Site 782) in winter 2010. In fall 2011, sandbars were much larger. As a result, the wetted perimeter-to-area ratios were much lower overall, ranging from 146 feet per acre (Site 776) to 298 feet per acre (Site 793). The average sandbar height above the 90% flow

level was 1.1 feet in winter 2010 (ranging from 0.7 to 1.4 feet). The average height increased to 3.3 feet by fall 2011 (ranging from 2.1 to 4.3 feet). In winter 2010, the average sandbar slope was 1.4 percent. By fall 2011, it had increased to 2.0 percent.

Geomorphic and Bed Material Impacts: Thalweg depths and movement were analyzed at the 50-percent flow level (see Figure 7 for an example). The average thalweg generally deepened due to the high flows of 2010, as well as between summer and fall 2011. Thalweg movement varied between sites. For some sites, there was only minor change between seasons, while other sites experienced significant movement from season to season. The average bed material size (D_{50}) did not change significantly during the 2011 flood, indicating that the riverbed is largely homogeneous and the sandbar sites are not bed material limited.

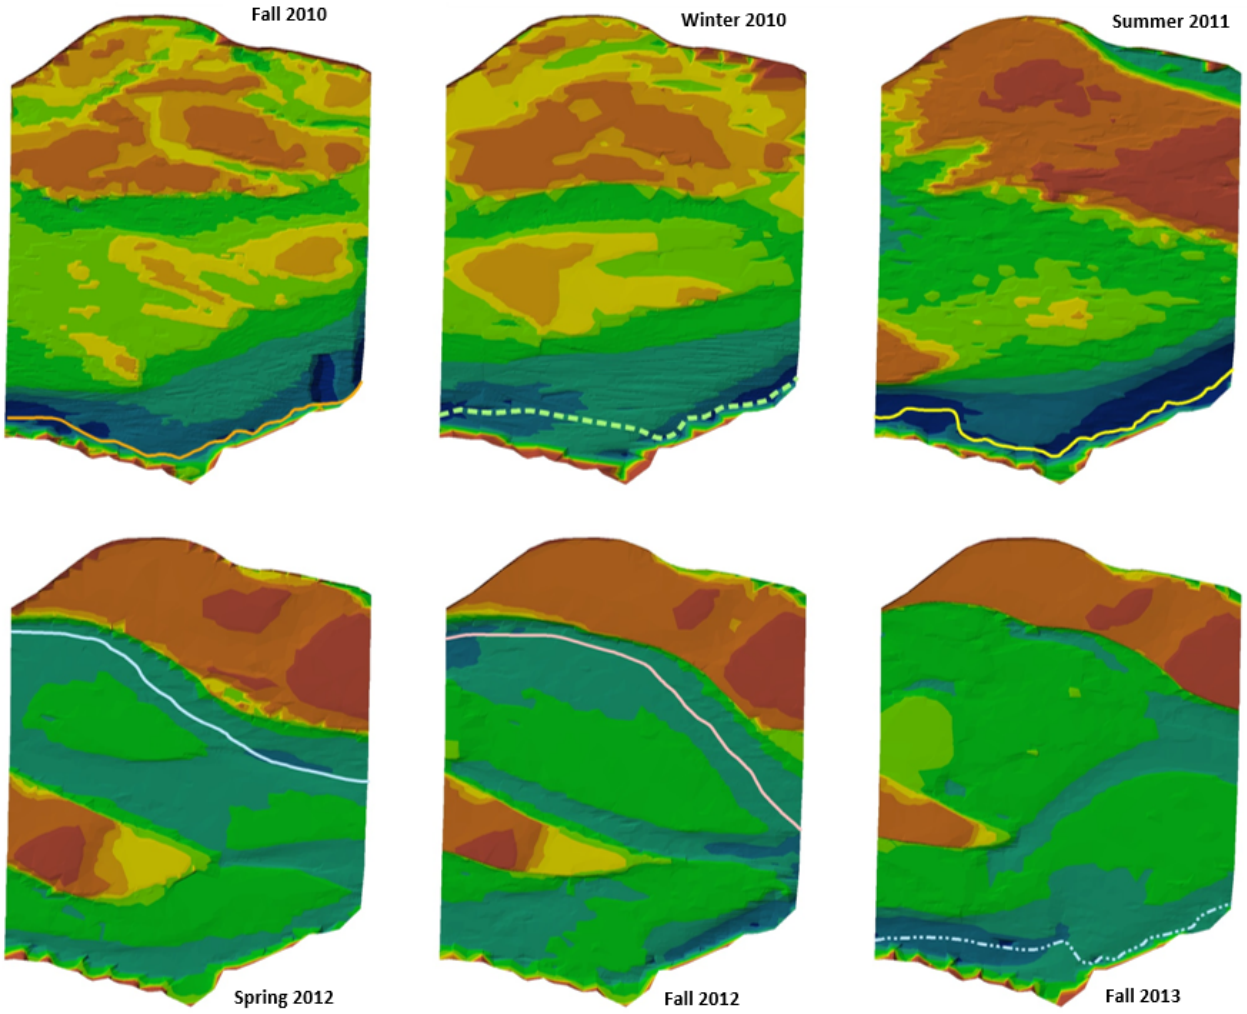

Figure 7 Thalweg Locations for Each Season Surveyed – Site 761

Sandbar Growth and Decay: A major question in the 2003 BiOp Amendment is whether a flow of 60,000 cfs for 60 days will produce sandbars within the study reach. Although the study data do not provide a definitive answer to this question, some observations can be made. The high releases from Gavins Point Dam in 2010 were on the order of 45,000 cfs. Tributary flows, particularly from the James River (RM 800), helped to increase the total flow through the project reach during the fall 2010 survey period. Flows peaked above 63,000 cfs on 4 August 2010, exceeding 50,000 cfs through mid-August and from the beginning of September through mid-November. Although these flows were much higher than normal flows, they were too small to create significant ESH area. In contrast, the 2011 flows were much higher than 60,000 cfs, and greatly increased ESH area.

Every significant sandbar-building flood event affects future building events. If the 60,000 cfs flow would have occurred in 2010 for a longer duration, it may have created more significant sandbar habitat. The current remaining sandbars were formed by large flows and many remain above the 10-percent flow level. If the 60,000 cfs flow occurred today, it may not act as a building event because it could erode the existing high-elevation sandbars rather than form new sandbars.

Relative shear stress over a sandbar and/or adjacent to a sandbar is a good indicator of whether the sandbar would be eroded away by the time of the next survey. Typically, initiation of particle movement is modeled with the Shields method. Inversely, low shear stresses indicate depositional areas. Using this approach and assuming a 0.4 mm median particle size, deposition is assumed to occur for shear stresses of approximately 0.005 lb/ft^2 or lower, under normal flow conditions. This appears to be appropriate for determining sandbar persistence for the lower flow periods, but not necessarily for the higher flows.

The location of the thalweg versus the location of major sandbars has a strong correlation to the sandbar decay rate. In periods when the thalweg was close to the major sandbar(s), the decay rate was significantly higher. As the thalweg moved away from the sandbars (e.g., toward one of the banklines), the decay rate was lower. Based on the survey data, wind erosion was not a significant factor in sandbar decay following the 2011 flood.

The study also examined correlations between sandbar growth and two-dimensional hydraulic model results at Site 795 (see Figure 8 for an example of the results). For the highest flows, there was a zone with highly transient sandbars. Surveyed sandbars within this zone represent snapshots in time, with bed material that is continuously moving, depositing, and eroding. The highly transient sandbars did not persist after the floodwaters receded. As expected, sandbars were more likely to persist in areas of reduced shear stress, velocity, and depth.

There was an average flow depth of 3.0 feet above the sandbars created between fall and winter 2010. This depth increased to 12.5 feet for sandbar area formed between summer and fall 2011. The rate of sandbar erosion following the 2011 flood was directly related to sandbar area. Sites with the largest sandbars generally eroded the quickest (based on the percent decrease in area between fall 2011 and spring 2012).

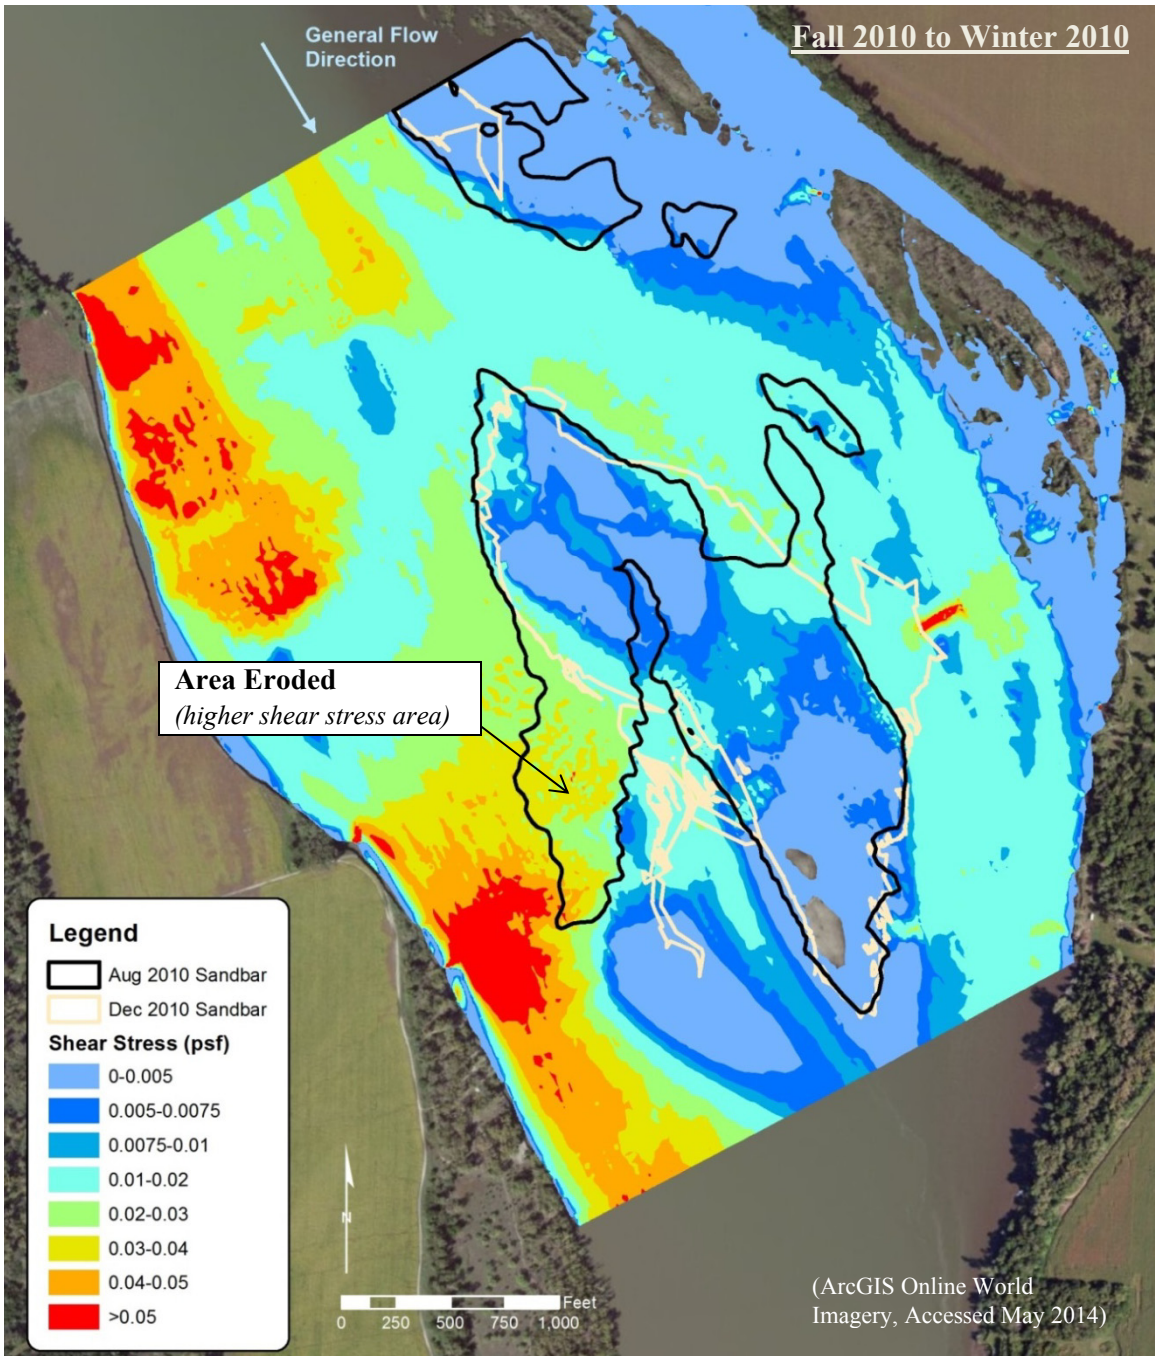

Figure 8 Computed Shear Stress (Fall 2010 at 52,000 cfs) – Sandbar Decay

Sandbar formation is a dynamic sediment transport process. Figure 9 compares the 90-percent sandbars at Site 795 for all survey periods. This figure shows where the sandbars are highly transient versus areas where the sandbars are relatively persistent. The surveyed sandbars, especially within the highly transient zone, represent snapshots in time of bed material that is continuously moving, depositing, and eroding. Moreover, these highly transient sandbars did not persist after the floodwaters receded. As expected, sandbars are more likely to persist in areas of reduced shear stress, velocity, and depth.

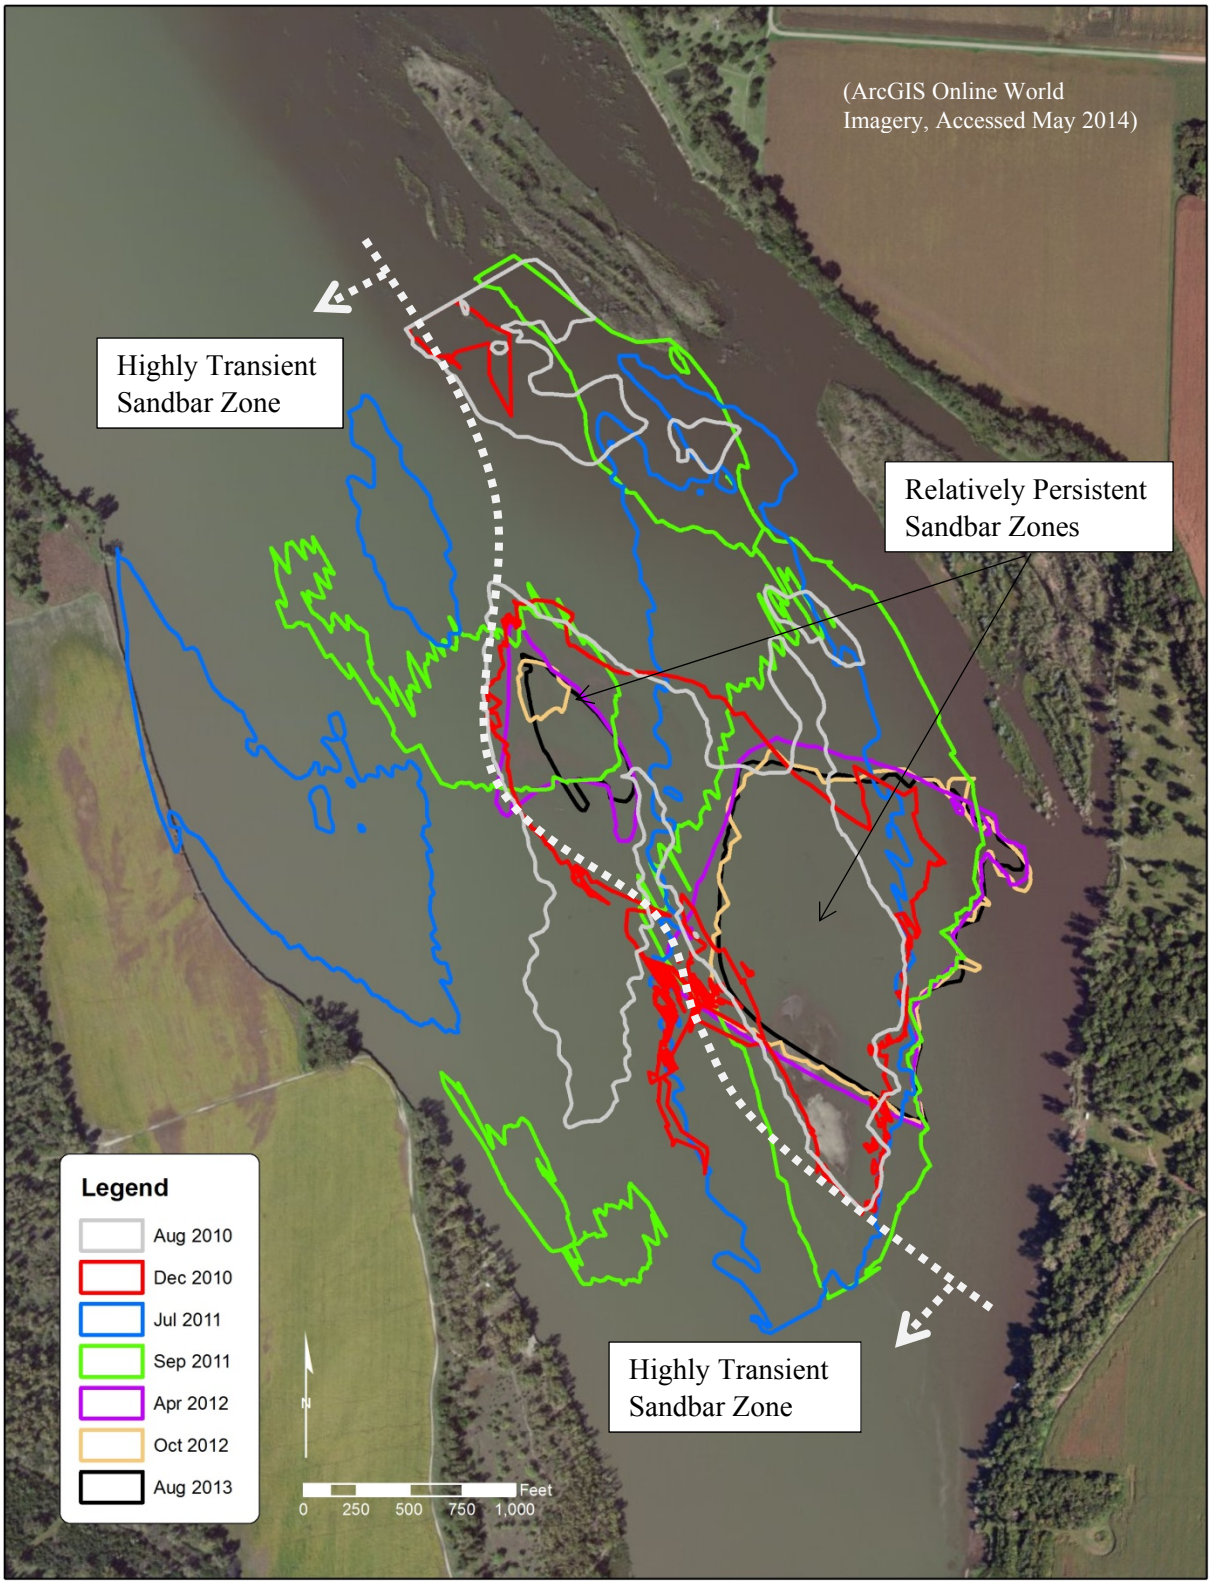

Figure 9 Sandbars (90% flow level) at Site 795 – All Survey Periods

Sandbar Area Projections: The total sandbar area at each site was projected 10 years into the future (see Figure 10 for an example) based on the observed sandbar growth/decay, thalweg location, site characteristics, and engineering judgment. In particular, the variability of the thalweg and its most recent surveyed location were strongly correlated to the sandbar projections. Projected decay of the 90-percent flow level sandbar area was the greatest at Site 770 and the least at sites 793 and 795. The location of the thalweg during the study period, as well as the overall site width, had a direct impact on the sandbar projections. For comparison, USACE (2011) indicates that the projected life expectancy of a constructed sandbar is 5 to 10 years. This is dependent on rates of erosion and vegetation encroachment, as well as flows and potential ice jams or thalweg shifts. The lifespan of a sandbar may be extended through maintenance activities such as vegetation removal and reshaping.

Abstract: The availability of quality spawning habitat within the San Joaquin River downstream of Friant Dam (Reach 1A) is crucial for successful reintroduction and sustained population of Chinook salmon. Several uncertainties exist as to the suitability of existing spawning habitat within Reach 1A and how sediment transport may affect efforts aimed at improving spawning and incubation habitat. Multiple studies are currently underway or have been completed to help identify the quality of the hyporheic environment as it relates to successful spawning and fry emergence, including evaluations of water quality within the hyporheic zone (DO, water temperature, fine sediment accumulation), egg survival, mesohabitat, bed material size and mobility, scour and deposition, and channel morphology changes associated with alteration to the flow regime. In addition, bedload and suspended load monitoring have been conducted within the reach since 2010.

Critical to identification of potential spawning areas are the bed material and hydraulic conditions within the reach during probable spawning periods of spring-run and fall-run Chinook salmon. This current study combines bed material characterization efforts with two-dimensional hydraulic modeling results to identify areas considered potentially suitable spawning habitat based upon depth and velocity requirements. The suitability of the potential spawning habitat is evaluated with GIS parameterization of substrate and hydraulic conditions, and correlation of surveyed redds, substrate, and hydraulic conditions are examined and quantified.

INTRODUCTION

The San Joaquin River Restoration Program (SJRRP) aims to "restore and maintain fish populations in good condition in the main stem of the San Joaquin River below Friant Dam to the confluence of the Merced River, including naturally-reproducing and self-sustaining populations of salmon and other fish." The SJRRP Fisheries Management Plan identifies spawning and incubation as a life stage to be supported for successful completion of the salmon life cycle.

SJRRP's current understanding of the system is that sufficient availability and quality of spawning habitat within Reach 1A of the San Joaquin River is imperative to sustaining a population of Chinook salmon (*Oncorhynchus tshawytscha*). Multiple studies are currently underway or have been completed to help identify the quality of the surface water and hyporheic environments as they relate to successful spawning and fry emergence (current efforts summarized in Section 3.2 of 2014 Monitoring and Analysis Plan; SJRRP, 2013a). These include efforts to evaluate water quality within the hyporheic zone (DO [Reclamation, 2012a], water temperature effects [Reclamation, 2012a], fine sediment accumulation [SJRRP, 2010a; SJRRP, 2013b]), egg survival (SJRRP, 2012), mesohabitat characterization (SJRRP, 2010b), spawning habitat use by transported fall-run Chinook (SJRRP, 2011; SJRRP, 2013c), bed material size and mobility (Tetra Tech, 2012a,b; SJRRP, 2012; SJRRP, 2013d), scour and deposition (SJRRP, 2011), and channel morphology changes associated with alteration to the flow regime (SJRRP, 2011; SJRRP, 2012; SJRRP, 2013e). In addition, bedload and suspended load monitoring have been conducted within the reach since 2010 (Graham, Mathews & Associates, 2012; Reclamation, 2014a). Most recently, spatial characterization of hydraulic conditions within Reach 1A was completed through two-dimensional hydraulic modeling across a wide range of flows (Reclamation, 2014b), and continuous facies mapping of the bed material was completed within the low-flow channel (SJRRP, 2014b).

The purpose of this current study is to initially characterize potential spawning locations within Reach1A of the San Joaquin River from Friant Dam to Highway 99 (HW99) based upon suitable hydraulics, bed material, and surface water temperature (figure 1). These potential areas will then analyzed for patterns of correlation and compared with mapped spawning redds within the reach over the past 2 years. This effort is part of a larger study to characterize suitability of spawning and incubation habitat based on physical, biological, and chemical criteria.

POTENTIAL SPAWNING HABITAT QUANTITY

Requirements for spawning Chinook salmon evaluated in this initial assessment of potential spawning habitat area include hydraulic conditions, substrate, and surface water temperature. Multiple other aspects of spawning habitat quality may impact where a fish chooses to spawn and are only briefly discussed within this paper. However, we recognize the importance of many additional variables influencing spawning habitat quality and ultimately on the incubation habitat provided for successful emergence. These are anticipated to be incorporated into future analyses.

With respect to hydraulic conditions for spawning Chinook, water depth must be sufficient to cover the fish during spawning, and velocity must be adequate to flush finer particles downstream during the process of red construction, but not so great that eggs do not remain in the egg pocket or adults have to expend too much energy holding position in the water column (SJRRP, 2014a). The SJJRP Spawning and Incubation Subgroup reviewed habitat suitability indices (HSI) from studies on the Tuolumne, Stanislaus (Aceituno, 1990, 1993), and Merced (Gard, 1997) Rivers (all tributaries to the San Joaquin River) and suggested the criteria for suitable spawning depths for the San Joaquin River to be between 0.7 and 3.7 feet (ft) and velocities between 0.8 and 3.4 ft/s. These values correspond to the criteria from the Stanislaus River and encompass the ranges for all three rivers, thereby providing the greatest flexibility for evaluation on the San Joaquin River.

Chinook salmon generally select larger substrate to spawn in than other Pacific salmon species. Suitable spawning gravel consists of a mixture of particle sizes from sands to cobbles, with a median diameter (D50) of 2.5 to 5 cm (SJRRP, 2010c). A review of reported spawning substrate in Central Valley System suggests that the preferred substrate size ranges between 2.5 and 10 cm in diameter, and some studies indicate spawning in substrate up to 30 cm in diameter (SJRRP, 2010c). Substrate requirements for spawning are highly correlated to fish size with large fish capable of using larger substrate materials than small fish (SJRRP, 2014a) to build a redd. Moir and Pasternack (2010) found that Chinook often utilize coarser substrate when higher velocities are present. Fine sediment within the system has a large influence on the incubation habitat once the eggs are laid (Tappel and Bjornn, 1983). However, the presence and influence of fine sediment on egg survival is a topic currently under investigation, the results of which will be incorporated into future designation of suitable incubation habitat.

Chinook salmon have specific water temperature requirements before and during spawning in order to survive and deposit their eggs (SJRRP, 2014a). Surface water temperatures for successful spawning and incubation are illustrated in table 1. The critical temperature range defines the range over which a fish shows definite signs of thermal stress (Elliot, 1981).

Table 1 Temperature Requirements for Spawning and Incubation (from SJRRP, 2010).

	Spawning	**Incubation and Emergence**
Optimal	≤ 57 °F (13.9 °C)	≤ 55 °F (13 °C)
Critical	60-62.9 °F (15.6-17°C)	58-60 °F (14.4-15.6°C)
Lethal	≥62.6 °F (17 °C)	≥62.6 °F (17 °C)

Two-dimensional Hydraulic Modeling: Two-dimensional hydraulic models of Reach 1A of the San Joaquin River were developed and calibrated using SRH-2D (Reclamation, 2008) to spatially characterize hydraulic conditions throughout the reach as a tool for predicting the availability of spawning habitat (Reclamation, 2014b). For computational efficiency, the reach was modeled in two sections: the first is from Friant Dam (Mile Post (MP) 267) downstream to Highway 41 (HW41) Bridge (MP 255) and is referred to as Reach1A_01, and the second extends from HW41 downstream to Highway 99 (HW99) Bridge (MP 243) and is referred to as Reach1A_02.

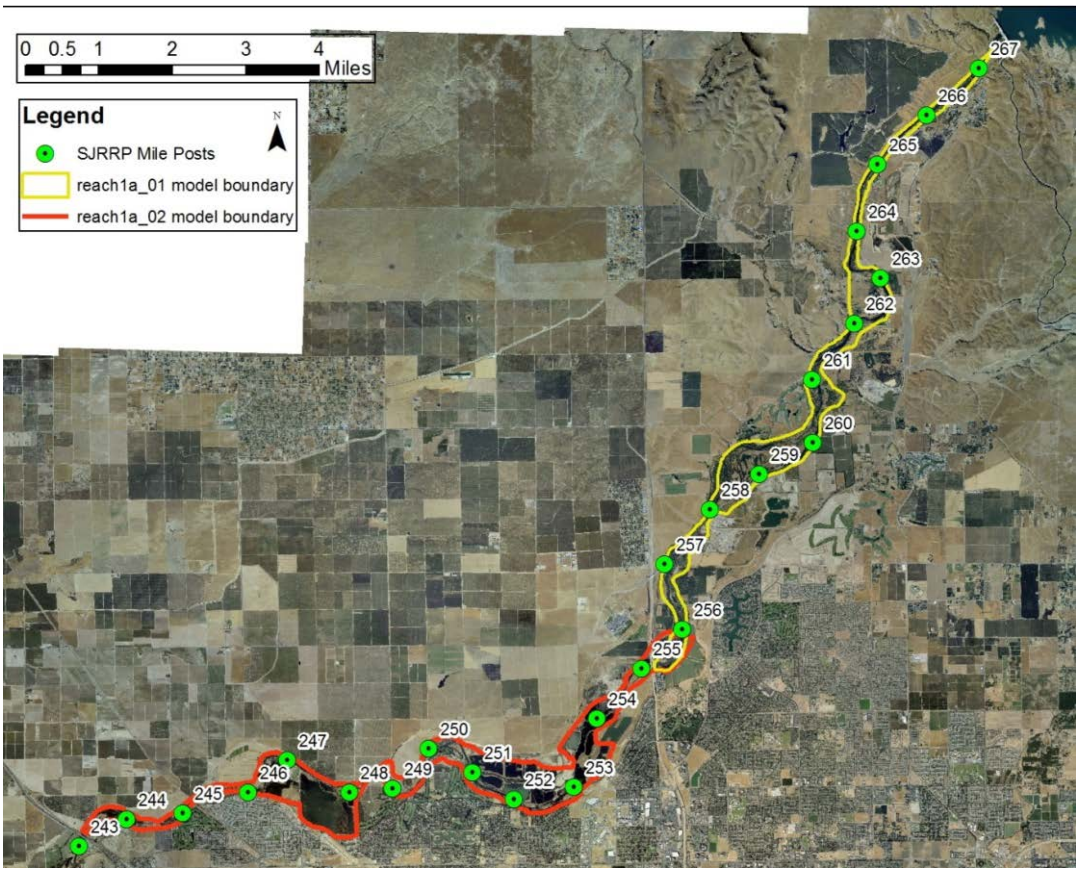

Figure 1 Map of modeled reaches. Reach 1A_01 extends from Friant Dam (MP 267.5 to HW41 (MP 255) and Reach 1A_02 extends from HW41 (MP 255) to HW99 (MP 243) for a total reach length of 24.5 river miles.

The mesh for each subreach generally consisted of rectangular cells to represent the main channel and most side channels and triangular cells to represent the floodplain. Within the channel, rectangular cell sizes ranged between 5-10 ft laterally and 20-30 ft longitudinally. The final grids were comprised of approximately 117,000 cells within the Reach 1A_01 model and 138,000 cells within the Reach 1A_02 model. Terrain data for Reach 1A are a compilation of ground-based survey points and photogrammetry collected in 1998, combined with in-channel bathymetry collected by boat using SONAR in 2009. The final topographic models for each subreach were created in State Plane CA III, NAVD88 ft. Flows modeled to date were based upon the availability of calibration data and range from 270 cfs to 7,650 cfs. Rating curves developed from measured flows and water surface elevations at HW 41 and HW 99 served as the downstream boundary conditions for each model.

Hydraulic roughness (Manning's *n*) is defined at each cell in a computational mesh. Initial roughness values were delineated based on zones of vegetation density and land use from 2007 aerial photographs (MEI, 2000; DWR, 2010). Roughness zones were modified in some areas to better reflect current conditions based upon 2011 aerial photos and to improve calibration with initial model results. Final computational meshes for model Reach 1A_01 and Reach 1A_02 consist of 8 roughness categories (table 2).

Model calibration was conducted for both subreaches using available water surface elevation and flow measurements. In-channel calibration was performed first to define roughness within the channel, and then a subsequent calibration effort was conducted to define roughness within the floodplain. Calibration was performed by varying roughness in model simulations to determine the best match to measured water surface elevations (table 2). The goal of the model calibration was to predict water surface elevations with a root mean squared error (RMSE) of less than 0.5 ft.

Table 2 Calibrated roughness values for SRH-2D hydraulic simulations.

Land Use Type	**Reach1A_01**	**Reach1A_02**
Channel Bed	0.04	0.04
Off-Channel Open Water	0.04	0.045
In-channel Riffles/Rough areas	0.065	0.065
Open /Bare Ground/ Scattered Brush	0.045	0.068
Scattered Trees	0.06	0.09
Medium Density Trees/Brush	0.08	0.12
Dense Trees/ Brush	0.1	0.15
Agriculture	0.045	0.055

Depth and velocity data were processed for 350 cfs in each reach to determine areas meeting spawning habitat hydraulic criteria. This discharge was selected as representative of the flow present during Spring-run and Fall-run Chinook spawning based upon the flow release schedule from Friant Dam into Reach 1A as specified in the Stipulation of Settlement (NRDC v. Rodgers, 2006). The spawning habitat hydraulic criteria were provided by the San Joaquin River Spawning and Incubation Subgroup and represent the depth and velocity ranges considered suitable on the Stanislaus River. Areas meeting the criteria for depths ranging between 0.7 and 3.7 feet and velocities ranging between 0.8 and 3.4 ft/s were delineated as polygons within GIS and determined as potentially suitable for spawning based on hydraulic conditions.

Bed Material Characterization: Bed material sampling has been conducted throughout Reach 1A of the San Joaquin River numerous times over the last 20 years using multiple sampling techniques to meet a variety of project goals. To most efficiently evaluate bed material for spawning habitat, a spatially continuous map of bed material was necessary. Facies maps provide an opportunity to capture spatial variability of the sediment comprising a channel bed through delineation of boundaries between notably different areas of bed material. Facies mapping was initially completed within Reach 1A in 2002, but only encompassed the first 12.3 miles downstream from Friant Dam (Stillwater Sciences, 2003), and several locations may have experienced local areas of change within the last 10 years. As such, during the summer of 2013, an effort was undertaken to update and expand upon the initial facies mapping to reflect current conditions of the river bed and to help characterize areas with suitable bed material for Chinook spawning.

In both the 2002 and 2013 mapping efforts, the Buffington and Montgomery (1999) mapping technique was adapted with slight variations between the two years. This is a hierarchical classification system of each facies according to the three most prevalent gain classes (i.e. silt, sand, gravel, cobble, and boulder) and sub-divided according to a classification based on phi-size class (very fine, fine, medium, coarse, very coarse). For example, 'sandy gravel' indicates that the most prevalent grain class is gravel but there are significant amounts of sand. Facies mapping was conducted by floating the river by kayak, delineating areas of bed material change, and visually identifying the facies classification. Simultaneously, pebble counts were performed in areas where no previous volumetric or pebble count samples had been collected. The maps and all sediment data were transferred to GIS.

An analysis was completed to associate a range of gradations with each facies category based upon pebble count data collected over the last 20 years. However, the results indicated that the pebble count data alone were not sufficient to differentiate between the coarse-scale facies categories. In addition, the pebble count data alone were incapable of differentiating between spawnable and non-spawnable facies categories because the resulting range of gradations for each facies where pebble counts were performed covered the preferred range of diameters for spawning. In other words, the results suggested that every facies category with one or multiple pebble counts contained suitable substrate for spawning. Another complication was that many facies categories, such as those over bedrock or in silt, contained no pebble count data.

Surface Water Temperature: The SJRRP has determined that water temperature is likely a limiting factor for each life history stage of Chinook salmon in the San Joaquin River, particularly in the warmest and driest years

(CDFW, 2012). As part of the SJRRP, a water temperature monitoring system was developed to better understand the longitudinal distribution of water temperature and aid in successful management of flow releases during critical salmon life-stages. With respect to salmon spawning, surface water temperature is a key factor influencing adult salmon behavior and survival during late summer and fall (August through December). Twenty water temperature monitoring locations are present within Reach 1 to help identify the spatial distribution of the potential spawning areas based upon known temperature limitations for Chinook salmon. Data collected at these sites within the last several years suggest that in general, the closer the site is to Friant Dam, the more suitable the water temperatures are during the critical spawning period. In 2011 it was observed that the closer the site was to the dam, the greater the number of days temperatures were below critical (14.4 ℃) and lethal (15.6 ℃) temperature thresholds for spawning and incubation; however, due to releases from the dam (>13℃) being greater than the optimal temperature (13℃) and cooler air temperature in late fall, more days met optimal temperature conditions further downstream than just below the dam (figure 2).

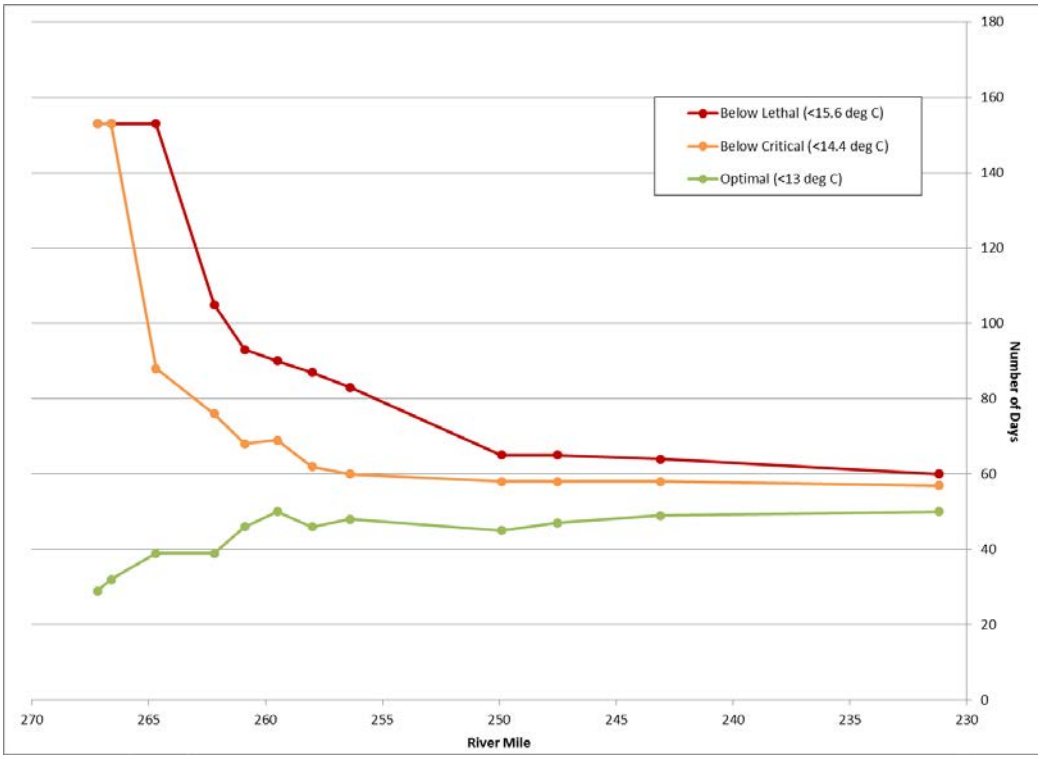

Figure 2 Number of days during expected spawning and incubation period (August through December, 2011) that water temperature was below objectives for incubation and emergence (SJRRP, 2010c).

Spring-run Chinook historically spawned in the San Joaquin River between late August and October, and Fall-run Chinook still spawn within tributaries to the San Joaquin River from October through December, peaking in early to mid-November. Based on this timing, water temperature monitoring indicates that Fall-run Chinook may not be limited by surface water temperatures during spawning within Reach 1A (figure 3). However, Spring-run spawning may be restricted to the first 10 miles downstream from Friant Dam.

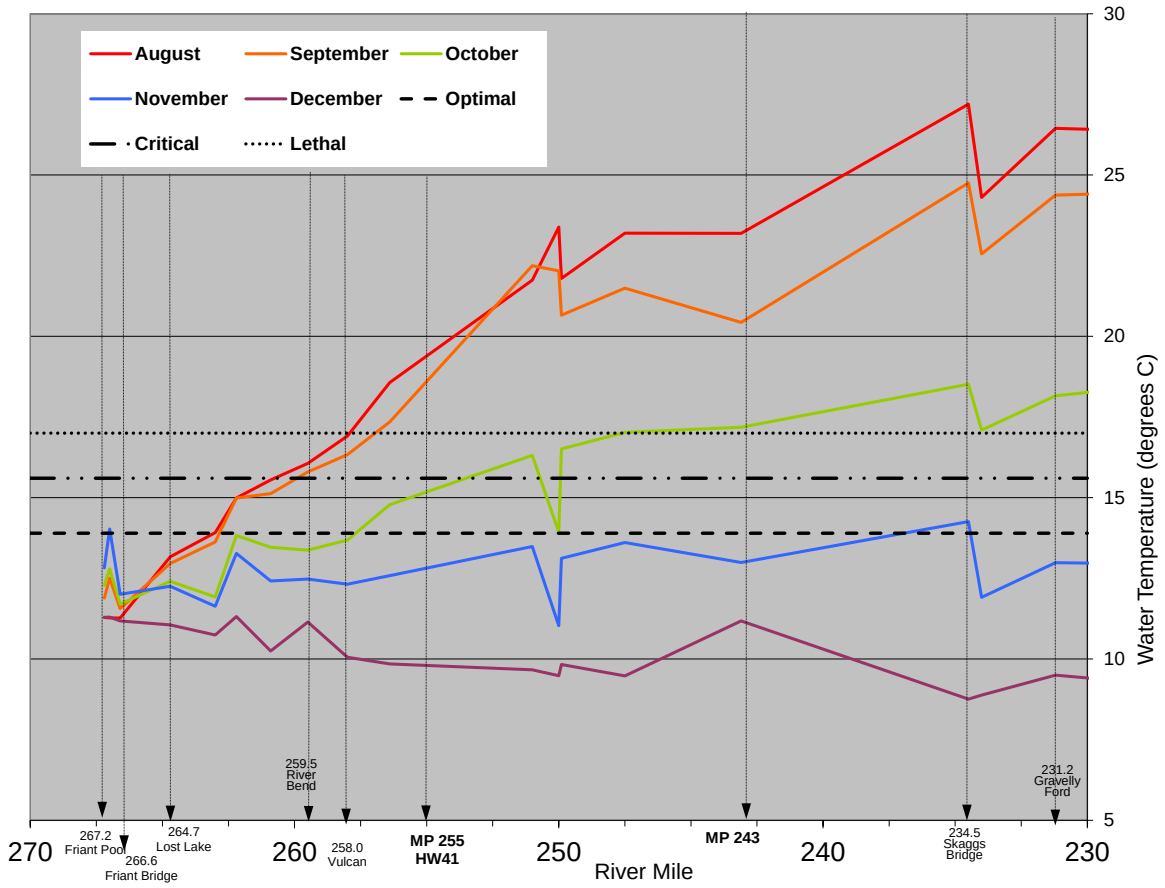

Figure 3 Monthly average stream temperatures for the period of record along with the optimal, critical, and lethal temperature ranges for spawning. The period of record differs slightly for each gage and therefore some points may represent longer time frames than others.

RESULTS OF ANALYSIS

The total modeled area encompassed over 12,000 acres (ac) (table 3). At a discharge of 350 cfs, 1,090 ac of the channel were inundated with depths greater than 0.1 feet. However, only 80 ac were determined to be potentially suitable for spawning based upon hydraulic conditions (0.7 to 3.7 ft depth and 0.8 and 3.4 ft/s velocities), indicating that only 7.4% of the total inundated area was determined to be suitable for spawning based upon hydraulic conditions alone. Inundated areas and areas of suitable hydraulic conditions were also compared with facies mapping to determine the existence of correlations between hydraulics and substrate. An example illustration of the delineation of mapped features is shown in figure 4. Inundated areas with facies designations were evaluated by dominant substrate type (figure 5). The majority of inundated area (excluding gravel pits, side channels, overbank areas, and channel margins) was comprised of sand (59%), while gravel and cobble represented a combined 36% of inundated area. The area deemed suitable based upon hydraulic conditions within each dominant substrate type is depicted in figure 6. Hydraulically suitable conditions were most common in gravel and cobble-dominated substrate, representing a total of 78% of the area (58.3 acres) identified as suitable. Twenty percent of the area with suitable hydraulic conditions was within substrate dominated by sand based upon the facies mapping.

Table 3 Modeled and inundated areas based on two-dimensional modeling results compared with the area meeting the depth and velocity criteria for spawning for each reach and also combined. Results presented are in acres.

	Area (Acres)		
	Reach1A_01	**Reach 1A_02**	**Total Combined**
Modeled Area	5,375	6,627	12,002
Inundated Area	293	797	1,090
Area Meeting Depth and Velocity Criteria for Spawning	44	36	80

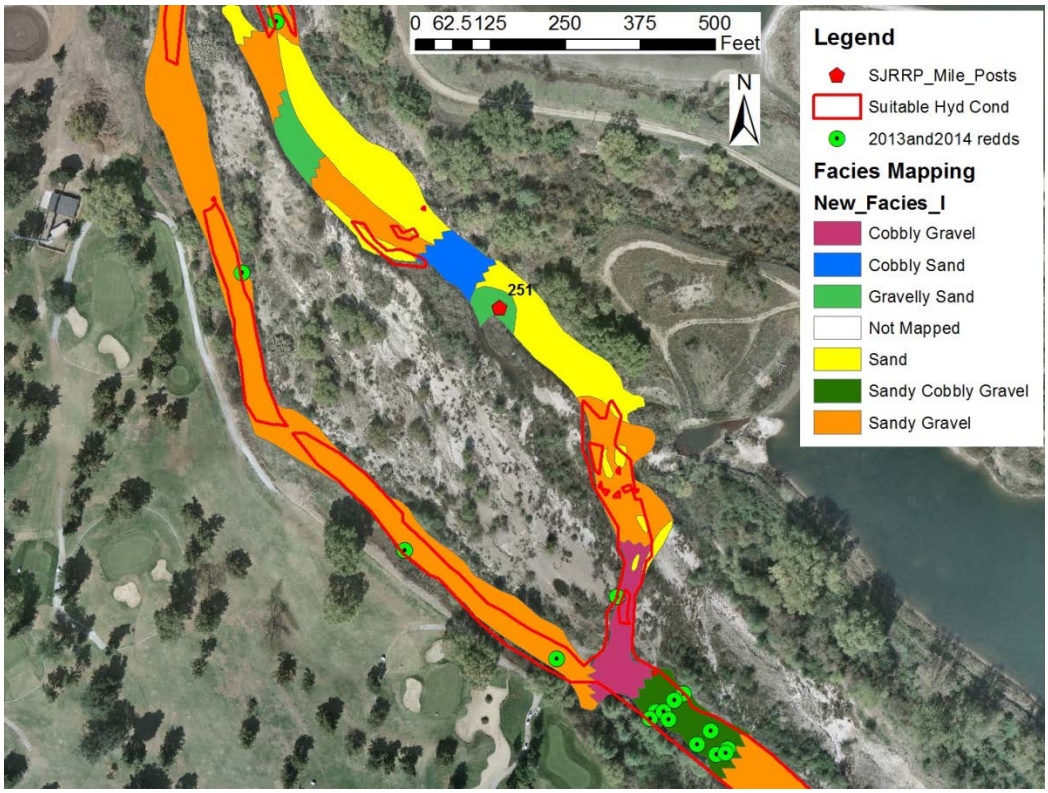

Figure 4 Example map of the delineation of redd locations, suitable hydraulic condition polygons, and facies categories near MP 251.

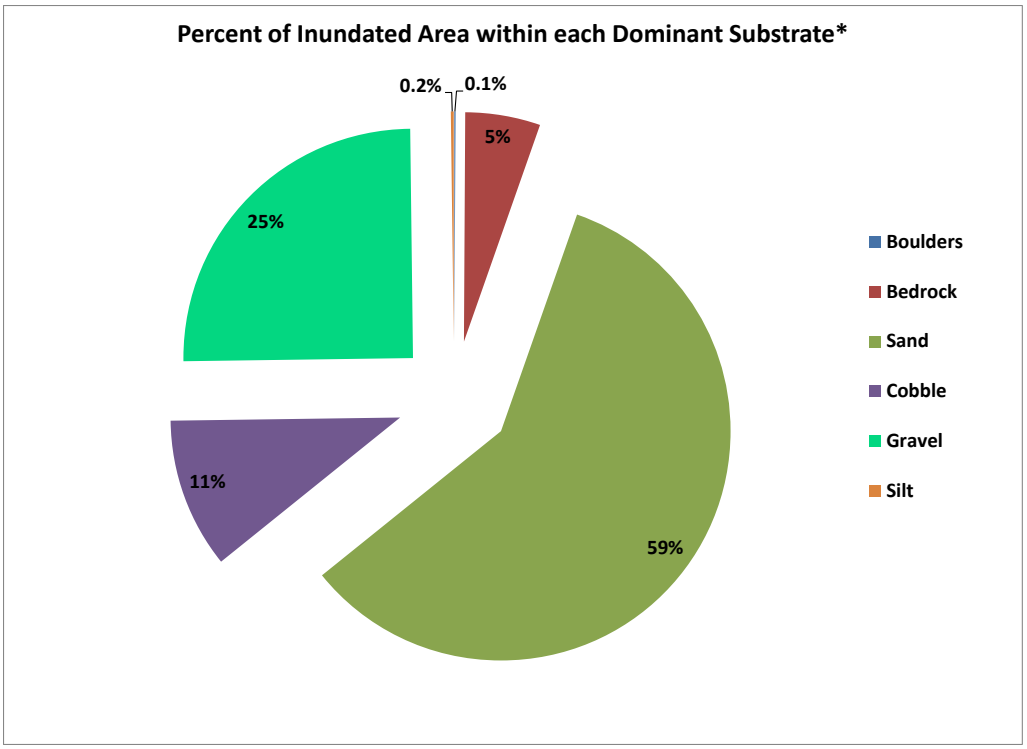

Figure 5 Percent of inundated area within each dominant substrate. *This analysis excludes inundated areas that did not have facies characterization, such as gravel pits, side channels, and channel margins.

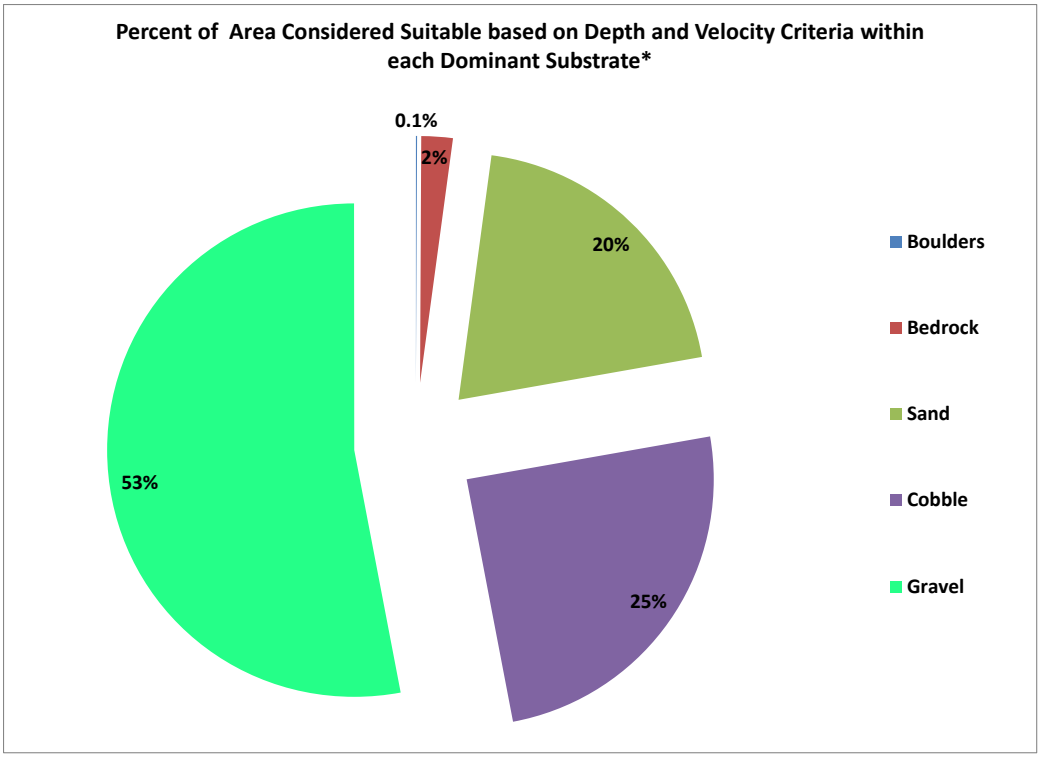

Figure 6 Percent of area with suitable hydraulic conditions within each dominant substrate type. *This analysis excludes suitable areas that did not overlap with facies characterizations, such as those in side channels and along channel margins.

There were 130 redds surveyed within the reach between Friant Dam and HW99 (figure 1) during 2013 and 2014 combined. There were an additional 22 redds surveyed just at or downstream from HW99 that were not included in the analysis because they were not located within the longitudinal extent of the mapped facies and two-dimensional modeling boundary. An analysis was done to identify which type of substrate the fish selected to spawn in based upon the facies mapping. The distribution of spawning within dominant substrate is shown in figure 7. Ten of the 130 redds were located outside of the mapped facies areas in areas identified as islands or channel margins above the low flow channel. Of the remaining 120 redds, the salmon overwhelmingly selected to spawn in facies with a gravel- (84 redds, 70%) or cobble-dominated (23 redds, 19%) substrate. However, several still chose to spawn in facies mapped as being dominated by sand or bedrock. This could be due to the presence of patches of gravel and cobble within larger generalized areas of mapped substrate.

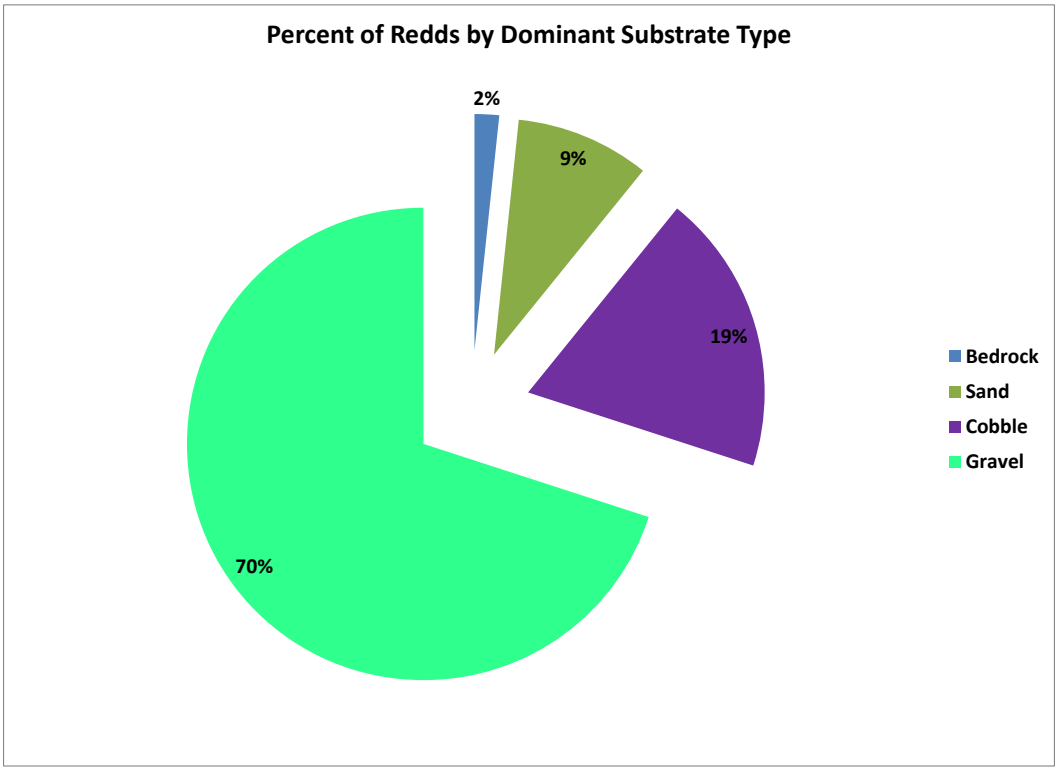

Figure 7 Percent of the occurrence of redds by dominant substrate type out of 120 redds.

Of the 130 redds within the reach, 96 of them (74%) were located within an area with suitable hydraulic conditions based upon two-dimensional modeling results; 123 (95%) were located within 15 feet of an area with suitable hydraulic conditions. It should be recalled that the numerical model grid within the channel was typically comprised of quadrilaterals ranging in size between 5-10 ft by 20-30 ft.

An investigation was completed to determine the association between those 96 redds within suitable hydraulic conditions and the dominant substrate type. Three of the redds were not located in a mapped facies as they were all constructed at the very edge of the low flow channel boundary. The results show little variation from the results of all 130 redds illustrated in figure 7, which is expected because most all the redds were located within the area defined as hydraulically suitable. A final statistical evaluation was performed using Jacob's electivity analysis to determine the preference of salmon to place redds within each dominant substrate type and within hydraulically suitable areas. Jacob's index was measured using the following formula:

$$D = (r - p)/(r + p - 2rp)$$

Where r represents the proportion of habitat used; p represents the proportion of habitat available, and D varies from -1 to 1, indicating a degree of preference for each habitat type (Hamann et al., 2014). A value of -1 indicates strong avoidance; a value of +1 indicates strong preference, and values approaching 0 suggest that the habitat is used in

proportion to its availability in the environment. The results and interpretation of the analysis are presented in table 4 and table 5.

Table 4 Results of electivity analysis indicating the degree of association of redds with hydraulic conditions.

	Jacob's Index	Interpretation
Hydraulically Suitable Area	0.9	Strong Preference
Non-hydraulically Suitable Area	-0.9	Strong Avoidance

Table 5 Results of electivity analysis indicating the degree of association of redds with dominant substrate type.

Dominant Substrate	Jacob's Index in total inundated area with mapped facies	Jacob's Index in hydraulically suitable area	Jacob's Index in non-hydraulically suitable area	Interpretation
Boulders	-1.0	-1.0	-1.0	Strong Avoidance
Bedrock	-0.5	-0.7	-0.2	Avoidance
Sand	-0.9	-0.9	-0.9	Strong Avoidance
Cobble	0.3	0.4	0.2	Mild Preference
Gravel	0.7	0.7	0.8	Preference
Silt	-1.0	-1.0	-1.0	Strong Avoidance
Cobble and Gravel	0.9	0.9	0.9	Strong Preference

CONCLUSIONS

Results of this effort provide supportive evidence for characterizing spawning habitat using hydraulic information gained from two-dimensional modeling and from substrate characterization. Based upon the hydraulic modeling effort, only 7.4% of the total inundated area was determined to be suitable for spawning. However, 74% of the redds surveyed within the last 2 years were located within these areas, and 95% were within 15 feet of these areas. These data suggest a strong correlation between the hydraulic conditions determined to be suitable for spawning using depth and velocity and between locations selected by salmon for redd construction. The results may also indicate that the current grid resolution captures the preferred spawning locations to within +/- 15 feet because the cell sizes within the channel were typically 5-10 ft wide by 20-30 ft long to limit model simulation time. A refined model at select locations may assist in further refining localized spawning preferences. However, the results also point towards the possible use of a buffer zone of approximately 15 feet around areas deemed suitable when a coarser-scale model is necessary to capture long reaches.

Redd data analyses reveal that salmon tend to spawn in gravel and cobble more frequently than other substrate. However, some fish selected to spawn in facies dominated by sand substrate. This may be partially attributed to the detail of the facies mapping. A benefit of the facies mapping is the ability to map long reaches of channel within a relatively short time frame. Patches of gravel and cobble are often present along channel margins or locally within the channel and may not be captured in the facies mapping. Refined mapping within mapped facies dominated by sands may improve the correlation between large substrate and redd construction location. Another possible explanation may be that salmon are less concerned with substrate than other factors when searching for a location to spawn, and the substrate is more important to defining incubation habitat and egg survival. Data from this effort could be used to develop preference curves for substrate for spawning salmon, in which sand and boulder substrate receive lower values than cobble and gravel substrates.

Examination of the dominant substrate within areas determined to be suitable for spawning based upon hydraulic conditions shows that even though gravel and cobble only represent a combined 36% of the total inundated area with mapped facies, 78% of the suitable hydraulic conditions are within gravel- and cobble- dominated substrate.

Similarly, the 96 redds within suitable hydraulic conditions were located in gravel- and cobble-dominated substrate 89% of the time. These data along with Jacob's electivity analysis results demonstrate a strong preference for redd sites to be located in suitable hydraulic conditions and in gravel- and cobble- dominated substrates. Clear correlations exists between substrate and suitable conditions for spawning, between redd sites and hydraulically suitable conditions, and between redd sites and gravel- and cobble-dominated substrate. From a common understanding of physical processes with the respect to the influence of hydraulic conditions on sediment transport and resultant substrate, the data from this exercise suggest that both hydraulic conditions and substrate are important in redd sites selection.

Finally, water temperature was also reviewed in this study to evaluate how it may limit the area considered suitable for spawning. Results suggest that water temperature may not limit spawning for Fall-run Chinook in most years because the temperatures, while not optimal, are below lethal in October, November, and December from Friant Dam downstream to HW 99 (~MP 243). However, the water temperatures may limit Spring-run Chinook spawning to the first 10 miles downstream from Friant Dam. These first 10 miles of the entire 24.5 mile reach encompasses 36.2 acres of suitable spawning habitat based upon depth and velocity, which represents 45% of the total suitable spawning area within Reach 1A.

STUDY DIRECTION

This current study presents a small fraction of the analysis necessary to eventually define the availability and quality of spawning and incubation habitat within Reach 1A. However, this step is important in determining that two-dimensional modeling results and substrate can indeed be used to help quantify available suitable spawning habitat. Additional analyses are planned to determine the applicability of mesohabitat maps in delineating potentially suitable spawning habitat. In addition to the reach-scale two-dimensional hydraulic modeling, finer-scale modeling of several riffles within Reach 1A is planned to identify the sensitivity of model results to refined topographic information and mesh resolution.

The quality of spawning and incubation habitat will be further distinguished through incorporation of findings from studies characterizing the hyporheic environment (DO, toxicity, temperature), vegetation and cover mapping, sediment mobility, substrate permeability, fine sediment accumulation within redds, egg survival, and escapement. One of the greatest challenges anticipated from this effort is the extrapolation of localized findings within one or several redds or riffle to the entire Reach 1A.

The ultimate goal of the larger-scale endeavor is the capability to predict the quantity and location of habitat meeting the needs of Chinook salmon to successfully complete their life cycle through spawning and incubation. Once the abundance or scarcity of suitable spawning and incubation habitat is determined based upon the anticipated fish use of the system, the limiting factors can be identified, and any means necessary to improve those conditions and the locations in need of improvement will be definable.

ACKNOWLEDGEMENTS

The authors of the paper express gratitude to all SJRRP members for their efforts in collecting and analyzing data related to spawning and incubation habitat that was used for this study. Erica Meyers was responsible for maintaining and evaluating the water temperature data as it relates to spawning and incubation, and Andy Shriver significantly contributed to the collection and GIS translation of the facies characterization. We are grateful to the SJRRP for continuing to support spawning habitat investigations, and appreciate the continued input by members of the Spawning and Incubation Subgroup.

EARLY WARNINGS AND LONG-TERM CHANGES: APPLICATION OF CONTINUOUS TURBIDITY MONITORING TO PROTECT AN ENDANGERED FISH SPECIES DURING CONSTRUCTION OF A LARGE-SCALE FLOOD-REDUCTION EFFORT

John D. Jastram, Hydrologist, US Geological Survey, Richmond, VA, jdjastra@usgs.gov;
Douglas L. Moyer, Hydrologist, US Geological Survey, Richmond, VA, dlmoyer@usgs.gov;
Kenneth E. Hyer, Hydrologist, US Geological Survey, Richmond, VA, kenhyer@usgs.gov

Flooding of the Roanoke River has caused substantial damage in the City of Roanoke, Virginia, over the past century. With over $1 billion worth of property at risk from potential flood damage, the City of Roanoke partnered with the U.S. Army Corps of Engineers (USACE) to construct the Roanoke River Flood Reduction Project (RRFRP) in an effort to reduce flooding impacts within the City. Construction of the RRFRP was complicated by concern that construction-related increases in sediment transport would potentially harm the endangered Roanoke logperch (*Percina rex*).

In early 2005, approximately coincident with the beginning of RRFRP construction, the U.S. Geological Survey (USGS) Virginia Water Science Center (VAWSC) partnered with the USACE to initiate a monitoring program using continuous turbidity monitoring stations and suspended-sediment sampling to assess changes in sediment transport through the affected reach and to provide a real-time warning system for potential impacts from sediment releases on logperch habitat. Specifically, the objectives were to:

a) Detect short- term changes in suspended-sediment transport during construction of the RRFRP in near real-time; and to
b) Assess spatial and temporal trends in suspended-sediment transport in the affected section of the Roanoke River.

This suspended-sediment monitoring program was conducted in synchrony with complementary monitoring programs focused on assessing geomorphological change and logperch community structure during construction of the RRFRP. These complementary programs were conducted by the VAWSC and the USGS Virginia Cooperative Fish and Wildlife Research Unit at Virginia Polytechnic and State University, respectively.

Continuous turbidity monitors were deployed at multiple locations along the construction reach for various time periods. These deployments were located, spatially and temporally, such that active construction reaches were closely bracketed with a monitor near the upstream and downstream extents of active construction to monitor flow into and out of the active construction reach – construction reaches were limited to 4,000 linear feet, progressing upstream. Continuous turbidity monitors also were deployed at the upstream and downstream extent of the RRFRP for the duration of the RRFRP, and suspended-sediment sampling was conducted at these benchmark stations throughout the period of study (2005-2012).

During the study, and particularly during active construction phases, differences between upstream and downstream turbidity measurements were tracked daily by construction managers

to identify potential inputs of sediment from construction activities. With instruments monitoring the water flowing into and out of active construction reaches, an input potentially attributed to the RRFRP would be expected to generate an increased turbidity response at the outflow location as compared to turbidity at the inflow location. In the event of such a pattern, further data exploration utilizing other measured water-quality parameters would be conducted, and, if warranted, a site visit would be conducted to rule out instrument fouling or other malfunction as the cause of the observed pattern. Upon completion of the construction activities, cumulative distribution frequencies (CDFs) were plotted by construction phase to evaluate discrepancies in turbidity between the inflow and outflow monitors to assess whether changes in the turbidity regime occurred that were indicative of RRFRP activities altering sediment transport.

The relation between turbidity and SSC was determined, and potential changes in this relation over time and/or space were explored, using multiple linear regression. Site-specific simple linear regression (SLR) models were developed using SSC and corresponding turbidity measurements from the discrete sampling activities at the two benchmark stations. Determination of change in the turbidity-SSC relation over time was accomplished by adding a time term to the turbidity-SSC model and evaluating the significance of time in the model. Evaluation of whether the turbidity-SSC relation varied between the benchmark stations was accomplished using Analysis of Covariance (ANCOVA), in which indicator variables were added to the turbidity-SSC SLR to determine significance of location within a pooled model calibrated using data from both stations.

Results of the analysis of turbidity distributions by construction phase indicated that turbidity generally increased in the downstream direction throughout the overall study reach and that turbidity was highly variable throughout the period of the study. No evidence of RRFRP induced sediment transport was apparent in the CDFs, though this analysis was limited at times because of the lack of pre-construction monitoring for some phases.

Turbidity was an effective surrogate for suspended sediment at the two benchmark sites, as indicated by the strong statistical significance of turbidity in the models ($p < 0.0001$) and high coefficients of variation ($R^2 = 0.95$) in each of the site-specific regressions. These regression models remained static over the period of study, as evidenced by the lack of significance of a time term in the regressions, indicating that the turbidity-sediment relation was not changing over time. Additionally, these models were static spatially, as no significant difference was detected between the two stations using the ANCOVA – a single model was statistically indistinguishable from site-specific models.

The results of the temporal and spatial analysis of the turbidity-SSC regressions provide further evidence that the RRFRP did not induce sediment transport within the study reach. Increases in local contributions to suspended-sediment transport would be expected to alter sediment characteristics such as color, organic content, and size-distributions, which would result in changes in the turbidity-SSC relation. Further, these changes would only be apparent at the downstream site receiving water from the construction reach, yet no significant difference between the two stations was detected.

The results of this monitoring and analysis program indicate that no detectable changes in suspended-sediment transport occurred in association with RRFRP construction, suggesting that the construction activities did not have deleterious effects on logperch habitat. These findings are consistent with findings of the complementary geomorphological and logperch community monitoring programs.

SHORTCOMINGS OF TWO-PARAMETER POWER FUNCTIONS FOR FITTING BEDLOAD RATING CURVES

David Gaeuman, Geomorphologist, Trinity River Restoration Program, Weaverville, CA, (530) 623-1813, dgaeuman@usbr.gov

INTRODUCTION

The capacity to estimate the sediment loads of streams is a key component of numerous types of geomorphic investigations (Andrews, 1986; Inman and Jenkins, 1999; Singer and Dunne, 2001; Syvitski et al., 2005; Klonsky and Vogel, 2011). Sediment loads at defined locations along a stream are frequently calculated with empirical sediment rating curves developed by statistically fitting the parameters of a transport model to a set of paired water discharge and sediment transport measurements.

Various transport models can be fit to sediment transport and stream flow data. Whether a particular model is appropriate depends on the purpose of the rating curve. Often, the purpose of fitting a rating relation is simply to estimate sediment loads. In cases where transport computations are confined to interpolated values within the range of observed discharges, the form of the fitted equation and the values of the fitted parameters may be of little importance. However, the use of incorrect functional models can lead to large errors when extrapolation beyond the observed range of discharges is required (Glysson, 1987). Moreover, sediment rating curve parameters are also sometimes used to investigate the transport process by inferring relationships between the fitted parameters and physical attributes of the system (Asselman, 2000; Barry et al., 2004; Gaeuman, 2010). Where extrapolation is required or when parameter values are to be assigned physical meaning, the use of appropriate fitting procedures and a functional form that accurately represents the transport process are critical.

Perhaps the most common transport model used for this purpose is a simple 2-parameter power function:

$$Q_s = aQ^b \qquad (1)$$

where Q_s is the sediment transport rate, Q is the water discharge, and a and b are parameters. This method may serve as a reasonable approximation for the relationship between flow and suspended sediment transport, but it provides an unrealistic representation of coarse bedload transport. The existence of a threshold for sediment entrainment below which coarse sediment is immobile is a fundamental concept in bedload transport theory. Such a threshold can be accommodated by fitting bedload transport data with a shifted power function in which a discharge threshold required for the initiation of sediment transport (Q_c) is subtracted from Q:

$$\begin{aligned} Q_s &= a(Q - Q_c)^b \qquad for\ Q_c > Q \\ Q_s &= 0 \qquad\qquad\quad otherwise \end{aligned} \qquad (2)$$

This 3-parameter transport model is analogous to numerous sediment transport equations (e.g. Meyer-Peter and Müller 1948) that express the sediment transport rate as a function of the excess

dimensionless shear stress exceeding a critical value defined by the Shields number. Inclusion of Q_c in the rating relation accounts for the behavior of coarse bedload fractions that remain motionless at small discharge levels. Where the data show that no such threshold exists, Q_c can take a value of zero, thereby reducing (2) to a standard two-parameter power function.
Although equation (2) offers a more flexible and realistic representation of the bedload transport process, a large proportion of investigators prefer to base their analyses on the simpler two-parameter model. Given the popularity of the simple power function for representing bedload transport, it is prudent to consider the effect arbitrarily forcing Q_c to zero has on the quality of the fitted rating curve. This paper presents a numerical experiment demonstrating that incorrectly ignoring non-zero values of Q_c can produce gross errors in the fitted values of both *a* and *b*. The significance of those errors for various rating curve applications is discussed and demonstrated using bedload measurements collected in the field.

EXAMPLE USING SYNTHETIC DATA

The potential impact of inappropriately imposing a two-parameter power function on a system where a non-zero entrainment threshold exists is demonstrated by fitting synthetic data drawn from a hypothetical rating curve defined by equation (2) with *a*, *b*, and Q_c set to 0.1, 2, and 1.5 m^3/s. Eleven paired Q-Q_s data points spanning a range of Q from 1.53 to 3 m^3/s were drawn from the curve. No error was added to the computed values of Q_s, so the 11 data points matched their parent curve exactly. Those data were then fit with a 2-parameter power function given by equation (1) using the linear regression functionality in Microsoft Excel, which implements linear least squares with log transformed data. As illustrated in Figure 1, that procedure results in a poor fit that deviates markedly from the actual parent curve used to generate the data. The value of the fitted exponent *b* of 9.31 is 4.66 times larger than the actual value of 2, and the value of the fitted coefficient is 5 orders of magnitude too small. These results are typical – in general, incorrectly forcing Q_c to zero invariably results in overestimation of *b* and, for datasets in which Q is predominantly greater than unity, underestimation of *a*.

The magnitude of the errors depends to a large extent on how much greater the values of Q in the dataset are than Q_c. For the example of Figure 1, the data used to fit the power function spans a range of Q between 1.02 times Q_c and $2Q_c$. If the range of Q used to fit the curve is limited to $1.02Q_c$ to $1.9Q_c$ while holding all other conditions constant, the estimated value of *b* increases to 9.86, or 4.93 times the correct value, and the estimated value of *a* is further reduced to 0.000013.

These errors in the parameter estimates can produce substantial errors in sediment loads computed with equation (1), although the nature and magnitude of the errors will depend on the characteristics of the hydrograph the rating curve is applied to. It is clear from Figure 1 that the 2-parameter fit to the data will under-predict transport rates associated with discharges near the center of the data range (e.g., the transport rate computed for 2 m^3/s with the 2-parameter curve is just 44 percent of the correct value). The potential for overestimation of transport rate at discharges beyond the range of the sample data, however, is a more significant problem. Although sediment rating curves should, in principle, be based on sample data spanning the full range of the flows they will be applied to, that is not always possible. Sampling at the highest discharges may be impractical for numerous reasons, including safety considerations, equipment limitations, lack of funds, or time constraints. Large flow events often remain unsampled, such

that load estimates for those events must be based on measurements obtained at relatively small discharges.

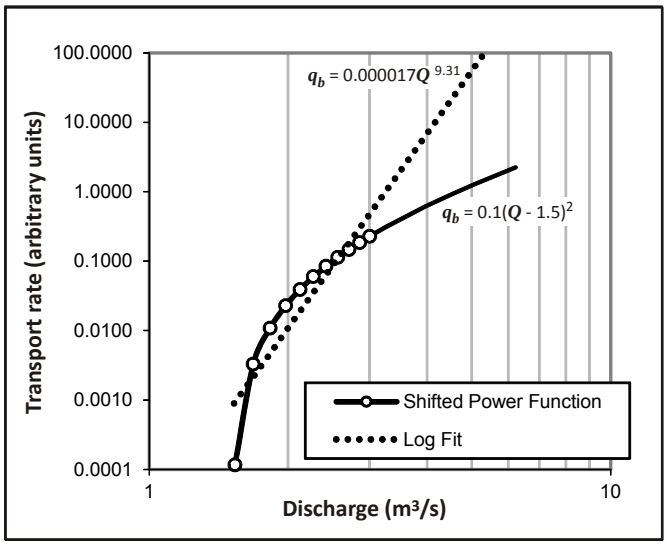

Figure 1 Comparison between a shifted power function [equation (2)] with known parameters and a fitted curve based on a 2-parameter power function [equation (1)] with parameters fit by ordinary least squares. The data points drawn from the shifted power function used in the fitting operations are indicated by the open circles.

The magnitude of the potential errors caused by extrapolating a 2-parameter rating curve beyond the range of the data is illustrated using the synthetic hydrograph shown in Figure 2. That hydrograph starts at 1.5 m^3/s (equal to Q_c) and rises at a steady rate of 0.15 m^3/s per day for 20 days to a peak of 4.5 m^3/s ($3Q_c$). The peak is maintained for 3 days, after which flow recedes at an exponential rate of 1.5 percent per day for 71 days.

At $3Q_c$ and 3 days, neither the magnitude nor the duration of the peak is extraordinary, and the mean discharge over the full hydrograph (2.8 m^3/s) is within the range of the transport data. Nonetheless, greatly overestimated transport rates at the higher discharges produces large errors in the total computed load. The 2-parameter rating curve based on data spanning 1 to 2 times Q_c (Figure 1) produces an estimated transport rate for 4.5 m^3/s that is 23 times larger than the correct value and a total load for the full hydrograph that is 10.2 times too large. If the 2-parameter rating curve based on transport data spanning 1 to 1.9 times Q_c is used, the maximum transport rate is 40 times too large and the total load is overestimated by a factor of 17.

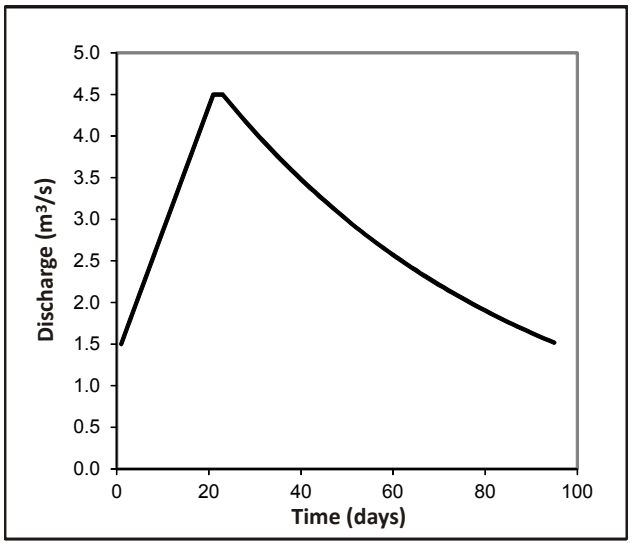

Figure 2 Synthetic hydrograph used to demonstrate the effect of extrapolating a 2-parameter rating curve to higher discharges when estimating total sediment loads.

EXAMPLE USING FIELD DATA

The data presented in this section consists of 18 bedload transport samples collected in Rush Creek, a tributary to the Trinity River in northern California, in water years 2004 and 2005 (Figure 3). These bedload samples were obtained at discharges ranging from 3.4 to 13.4 m^3/s, which slightly exceeds the stream's mean annual daily maximum flow of 11.6 m^3/s, based on 10 years of available record (water years 2004-2013, USGS 11525530 Rush Creek near Lewiston, CA). The annual mean flow in the creek over the same 10-year period is 1.2 m^3/s.

When fitted with a rating curve of the form given by equation (2), these data yielded estimates of a, b, and Q_c of 1.243, 2.415, and 1.8 m^3/s, respectively, whereas fitting these same measurements with a 2-parameter power function produced estimates of a and b of 0.0798 and 3.422. As with the previous example, forcing Q_c to equal zero by imposing equation (1) substantially increased the estimated value of b (by 42 percent in this example) and decreased the estimated value of a by orders of magnitude.

Elevations in the Rush Creek watershed range from about 540 m above sea level at the confluence with the Trinity River to more than 2200 m at the creek's headwaters in the Trinity Alps. Consequently, relatively long-duration flood events can occur during the spring snowmelt, but the largest floods tend to be brief events associated with intense winter storms that produce heavy rain in the lower elevations and rain-on-snow higher in the mountains. Acquiring sediment transport samples over the full range of flows therefore requires the ability to quickly mobilize a sampling crew during the relatively sudden and short-duration peaks that occur during winter storms.

In the case of the 2004 and 2005 Rush Creek data presented here, neither the instantaneous peak discharge nor a discharge equaling the maximum daily mean were sampled. Both maxima were attained during a storm on February 17, 2004 when the instantaneous peak flow reached 54.9

m^3/s and the daily mean flow was determined to be 25.7 m^3/s. Although an attempt was made to collect bedload samples during that storm, none were obtained until the following day (February 18) when discharge was between 13.4 and 10.7 m^3/s (Figure 4). Thus, computing the total sediment load for any time period that includes water year 2004 requires extrapolation beyond the range of the measured data.

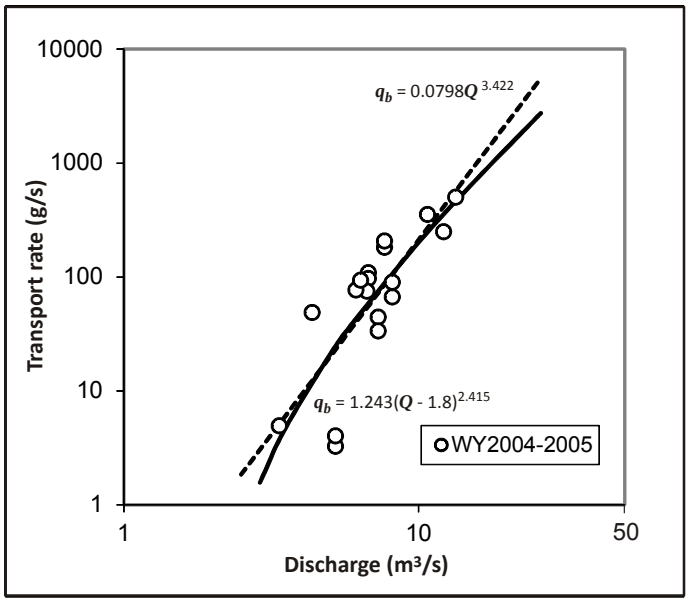

Figure 3 Comparison between a 3-parameter rating relation incorporating an entrainment threshold and a 2-parameter power function fit to bedload data collected in Rush Creek.

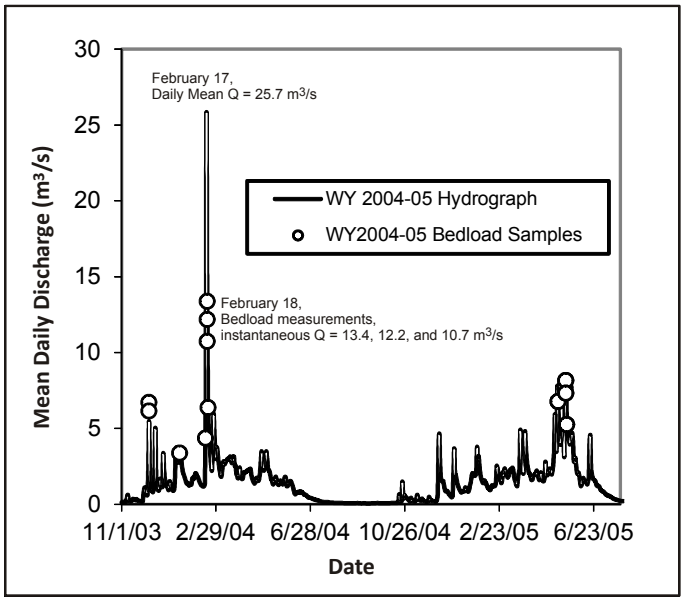

Figure 4 Daily mean discharge in Rush Creek in water years 2004 and 2005. Open circles indicate days on which bedload samples were acquired and the corresponding discharges.

Application of the 3-parameter rating relation based on equation (2) to the daily mean flows recorded for Rush Creek in water year 2004 results in a total bed sediment load of 305 metric tons, whereas application of the 2-parameter curve fit the same data yield a total load of 560 metric tons. Thus, omission of Q_c from the rating relations developed from Rush Creek bedload samples increases the total estimated bed sediment load for the year by a factor of more than 1.8. The increase would be even larger if the instantaneous peak, which was more than twice as large as the daily mean, had been considered in the analysis. It is also worth pointing out that the nearly 2-fold overestimation of the load described here arises from a hydrological record containing just one day on which the daily mean flow exceeded the range of measurements. It seems reasonable to suppose that, in some instances, it may be necessary to compute loads from hydrological records that exceed the range of sediment transport measurements on multiple days.

IMPLICATIONS FOR INTERPRETING TRANSPORT PROCESSES

Several previous authors have attempted to link variability in bedload rating curve parameters to differences in site conditions and the physical processes involved in bedload transport (Emmett and Wolman, 2001; Barry et al., 2004; Bunte et al., 2006). According to Barry et al. (2004), variations in b at different stream locations are inversely proportional to q^*, the measure of relative substrate armoring introduced by Dietrich et al. (1989). Similarly, Bunte et al. (2006) reported an inverse correlation of b with armoring as expressed by the ratio of the surface to subsurface median particle sizes, as well as a positive correlation with stream width.

Given that both of these studies used 2-parameter rating curves, it seems likely that the reported variations in b are related to differences in the relative magnitudes of Q_c at the various sampling locations as much as any other factor. That is, use of a 2-parameter rating curve should be expected to produce larger values of the exponent b for sample data sets associated with smaller values of Q_U/Q_c, where Q_U represents the upper limit of the range of the discharges sampled. The reported correlations between b and measures of substrate armoring and channel geometry may arise simply because those measures co-vary with Q_c. This interpretation is consistent with the observations of Emmett and Wolman (2001), who noted a positive correlation between b and the median and 90^{th}-percentile bed surface particle sizes and suggested that delayed onset of bedload mobility (i.e., a larger Q_c) due to the presence of a coarse armor layer on the streambed causes the rating relation to steepen (i.e., increase in b). If correct, the interpretation offered here implies that the value of b obtained from equation (1) may depend on attributes of the sampling effort, such as the range of discharges over which bedload samples were obtained, as much as any physical attributes of the stream.

Statistical relationships have also been reported between values of the coefficient a and certain physical parameters. Barry et al. (2004) observed an inverse correlation between a and drainage basin area, and attributed it to a proportionality between a and the ratio of sediment transport rate and stream discharge. Of five statistical relationships between a and physical parameters related to stream substrate or geometry reported by Bunte et al. (2006), three (bankfull width, basin area, and bankfull discharge) involve inverse relationships with alternative measures of stream scale. Similarly, Syvitski et al. (2000) found an inverse correlation between a and long-term mean discharge, although that study considered fine suspended sediment transport rather than bedload.

The tendency for a to decrease with increasing stream size, however, requires no geomorphic interpretation. It is simply a mathematical consequence of using a power function to model the rating relation. A generic power function equivalent to equation (1) can be written:

$$Y = aX^{b} \qquad (3)$$

Here, the substitution of X and Y for Q and Q_c is intended to emphasize the fact that the mathematical properties of the equation are independent of any geomorphic considerations. Solving for a yields:

$$a = Y/X^{b} \qquad (4)$$

It is clear from equation (4) that a is inversely proportional to X^b, such that, for constant Y, a must decrease whenever X increases, regardless of what X represents. It can also be seen that the magnitude of the decrease in a for a given change is X is greatly magnified by an increase in b, provided X is greater than unity. In general, any increase in b will cause a disproportionately large change in a, and will amplify the effect of increasing or decreasing X.

CONCLUSIONS

Sediment rating curves are commonly developed by fitting transport data to a simple 2-parameter power function that implicitly incorporates an assumption that sediment transport persists at all discharge levels. This assumption may be valid for the transport of fine suspended sediment, but is an unrealistic representation of coarse bedload transport, which generally ceases at discharges below a non-zero threshold (Q_c). The existence of such a threshold can be accommodated by fitting the transport data to a 3-parameter power function in which an entrainment threshold is subtracted from the measured water discharge.

Numerical experiments demonstrate that inappropriately fitting sediment transport data with a 2-parameter power function can result in large errors in both parameter estimates. Fitting the 2-parameters model to synthetic data with discharges ranging from Q_c to $2Q_c$ produced estimates of the exponent, b, between 4 and 5 time larger than the correct value, and estimates of the coefficient, a, that are orders of magnitude too small. Application of the resulting rating curves to a hypothetical hydrograph showed that these parameter errors can propagate to large errors in estimated sediment loads, particularly if extrapolation beyond the range of the measured data is required. In a similar analysis of bedload transport and stream flow data collected in a California stream, the value of b determined with a 2-parameter rating curve exceeded the value of b determined with a 3-parameter transport model by 42 percent. The estimated annual load based on the 2-parameter model and daily stream flow data is 80 percent larger than the annual load estimated with the 3-parameter model.

In general, forcing Q_c to zero by fitting bedload data with a 2-parameter power function exaggerates the value of the b. The degree to which b is exaggerated increases as the ratio of Q_c to the range of discharges sampled increases. The value of a scales in proportion to $1/Q^b$. Consequently, errors in b can lead to disproportionately large errors in a, depending on the range of discharges in the sample data. Overall, distortion of these parameter values caused by

improperly forcing Q_c to zero undermine efforts to interpret the physical meaning of variability in rating curve parameter values. Statistical relationships between rating curve parameters and various physical attributes of streams described in the literature may actually reflect spurious correlations related to the selection of physical metrics that co-vary with Q_c or to mathematical properties of the power function model.

EXTENDED ABSTRACT

The emphasis of this paper is a methodology for the selection of total bed material sediment transport relations and although only 4 transport functions are presented, it is applicable for analysis of any sediment transport function. Based upon analysis of over 8,000 measurements from flumes and rivers, the data are partitioned into dimensionless grain size intervals. The methodology then requires the development of a weighting function by taking the ratio of the measured versus the predicted sediment transport concentrations and determining the accuracy and precision of the ratio within the dimensionless grain size interval for each sediment transport function. Within each dimensionless grain size interval, four dimensionless parameters, dimensionless grain size, relative depth, grain Froude number, and dimensionless Stream Power, are computed based upon the data and dimensionless number that produces the best overall statistical results for the four transport functions is selected. The statistical results for each transport function, using the best dimensionless number within the dimensionless grain size interval, are used to select the best function.

The methodology determines not only the ranking of sediment transport methods for a given river situation, but also indicates if the methods have high to low applicability. This method can then be used to select an appropriate sediment transport method dynamically in a sediment transport model over time and space. However, to illustrate the methodology, four total bed material sand transport relations are used in this presentation. The transport relations are: Ackers and White (1973), Brownlie (1981a), Engelund and Hansen (1967), and Yang (1973).

TWO-DIMENSIONAL POISSONIAN HOMOGENEOUS MODEL FOR SUSPENDED SEDIMENT AND POLLUTANT MOVEMENTS IN OPEN-CHANNEL FLOW

Geraldo Wilson Júnior, Docteur d'Etat, COPPE/Federal University of Rio de Janeiro-UFRJ, Rio de Janeiro, Brazil, jrwilsong@gmail.com

Cid da Silva Garcia Monteiro, D.Sc., Modelling Methods and Geophysic Computational Laboratory-LAMEMO/UFRJ, Rio de Janeiro, Brazil, csgm25@yahoo.com.br

Abstract: When classic equations are used to study the sediment movements in open-channel flows, some problems appear, relating to: (i) the non-linearity of the equations, (ii) the complexity of the liquid and solid interactions and (iii) the unawareness of the liquid and solid movement's changes. The Random Theory avoids such problems and proposes a kinematic analysis of the flow and solid particles movements, exploiting, simultaneously, the open flux turbulent characteristics. The two-dimensional suspended sediment or pollutant trajectories $\omega(x,z,t)$ result from the combination of two 1-D chronological displacements series in the *i = 1, 3* senses, intercalated with periods of time when the grain does not move in these senses. These two series are interdependent. When the one-dimensional series are described by Homogeneous Poissonian Random Process, the resultant two-dimensional model is also Homogeneous Poissonian, defined by four mobility density functions, which characterize the particles' movement. The objectives of this work are: (i) to present the longitudinal and vertical two-dimensional Random Process Model; (ii) to calibrate and validate it, using radiotracers data from laboratory channels experiments; (iii) to show that the Random Theory may be applied to evaluate the 2-D sediment and pollutant movements in open-channel flows, for instantaneous and continuous injections conditions. To validate the model, data obtained from radioactive applications in a prismatic channel 12.0 m long, 0.40 m width and 0.60 m height of the *Central Hydraulic Laboratory of France – LCHF* were used. They have showed that the 2-D Random Process may describe, with precision, the suspended movement of fine sediment particles and/or contaminants in open channel flows, whatever kind of immersion may be.

INTRODUCTION

The bed and suspended load movements of sediments and contaminant particles in open channel flows characterize stochastic process, where the elementary events are the single grains' trajectories. They are dependent of the liquid phase turbulent structure, or in other words, of the hydrodynamic process. The trajectories or achievements of the single particle or of the group of particles can be analyzed by Lagrangean or Spatial and Eulerian or Temporal Descriptions and by the Random Processes Theory. Two stochastic processes are considered:

$$\vec{R}(t,\omega)=\left[X(t,\omega),Y(t,\omega),Z(t,\omega)\right]=X_{ti}(\omega);\ i=1,2,3 \tag{1}$$

that characterizes the evolution of the particle's position vector as a function of time, which longitudinal, lateral and vertical components are $X(t,\omega)$, $Y(t,\omega)$ and $Z(t,\omega)$, respectively. The second 3D stochastic process:

$$T(x,y,z,\omega)=\left[T(x,\omega),T(y,\omega),T(z,\omega)\right]=T_{xi}(\omega);\ i=1,2,3 \tag{2}$$

characterizes the particle's passing time by the point of coordinates (x,y,z).

$T(x,\omega)$, $T(y,\omega)$ and $T(z,\omega)$ represent the times spent by the particle to travel the distances *0x*, *0y* and *0z*, respectively. ω represents the trajectory or the sediment particle achievements, as presented in Figure 1, following. $X_{ti}(\omega)$ and $T_{xi}(\omega)$ processes can be defined by their Probability Distribution Functions:

$$F_t(x_i)=P\left\{X_i(t,\omega)\le x_i\right\};\ x_i\ge 0;\ i=1,2,3 \tag{3}$$

$$Q_{xi}(t)=P\left\{T(x_i,\omega)\le t\right\};\ t\ge 0;\ i=1,2,3 \tag{4}$$

which are related to each other by Todorovic´'s Equation (5) (Todorovic´ *et al.*, 1966; Wilson-Jr., 1987):

$$F_t(x_i) = 1 - Q_{xi}(t); \quad i=1,2,3 \tag{5}$$

They had shown that the Probability Distribution Function of these random processes can be expressed in terms of two pairs of Approximate Functions $F_{t1}(x_i)$ and $F_{t2}(x_i)$; $Q_{x1i}(t)$ and $Q_{x2i}(t)$; $i = 1,2,3$, respectively, such that:

$$0 \le F_{t1i}(x_i) \le F_{ti}(x_i) \le F_{t2i}(x_i) \le 1; \quad i=1,2,3 \tag{6}$$

$$0 \le Q_{x2i}(t) \le Q_{xi}(t) \le Q_{x1i}(t) \le 1; \quad i=1,2,3 \tag{7}$$

In each direction, e. g. in the longitudinal direction $0x_{i=1}$, where $x_i = x_1 = x$, the Approximate Distribution Functions $F_{tj}(x)$ and $Q_{xj}(t)$, $j = 1,2$ can be explained as functions of two new stochastic processes $G_n^{0,x}$ and $E_n^{0,t}$ from the same elementary events ω:

$$G_n^{0,x} = \{\mu_{0,x} = n\} \tag{8}$$

which represents the medium number of grain displacements, $\mu_{0,x}$ over the distance $[0, x]$, and,

$$E_n^{0,t} = \{\eta_{0,t} = n\} \tag{9}$$

the medium number of grain displacements, $\eta_{0,t}$ over the time period $[0, t]$.

$G_n^{0,x}$ and $E_n^{0,t}$ are Markovian Processes with similar properties. So, for the set $G_n^{0,x}$, it has:

$$\left\{\begin{array}{l} P\{G_1^{x,x+\Delta x} | G_k^{0,x}\} = \lambda_2(x,k)\Delta x + \vartheta(\Delta x) \\ P\{G_\nu^{x,x+\Delta x} | G_k^{0,x}\} = \vartheta(\Delta x) \quad \nu \ge 2 \\ P\{G_0^{x,x+\Delta x} | G_k^{0,x}\} = 1 - \lambda_2(x,k)\Delta x + \vartheta(\Delta x) \\ P\{G_0^{0,0}\} = 1 \end{array}\right\} \qquad \Delta x \to 0 \tag{10}$$

where $\vartheta(\Delta x)$ is a grain first order infinitesimal displacement distance.

The $G_n^{0,x}$ and $E_n^{0,t}$ occurrence probabilities are solutions of the system of equations derived from these properties:

$$\left\{\begin{array}{l} \dfrac{\partial}{\partial x} P\{G_k^{0,x}\} = \lambda_2(x,k-1) P\{G_{k-1}^{0,x}\} - \lambda_2(x,k) P\{G_k^{0,x}\} \\ \dfrac{\partial}{\partial x} P\{G_0^{0,x}\} = -\lambda_2(x,0) P\{G_0^{0,x}\} \end{array}\right. \tag{11}$$

with the following initial conditions:

$$x = 0 \begin{cases} P\{G_0^{0,x}\} = 1 \\ P\{G_k^{0,x}\} = 0; \; k \ge 1 \end{cases} \tag{12}$$

Similar analytical expressions to the Equations (10), (11) and (12) are obtained for the $E_n^{0,t}$ process. The solution of these differential equations yields the probability laws for the numbers of displacements in time and spatial intervals.

Two functions $\lambda_1(t,n)$ and $\lambda_2(x,n)$ appear, which describe the sediment particle mobility, in time and in that particular direction $x_{i=1} = x_1 \approx x$. Considering the three directions of the orthogonal axes $0xi$, $i = 1, 2, 3$, three pairs of Mobility Functions $\lambda_{1i}(t,n)$ and $\lambda_{2i}(x_i,n)$ are obtained, which describe the sediment grains 3D movements, in time and space. In each x_i direction it has been:

$$\begin{cases} \lambda_{1i}(t,n_i) = \lim_{\Delta t \to 0} \dfrac{P\left\{E_{1i}^{t,t+\Delta t} \middle| E_{n_i}^{0,t}\right\}}{\Delta t} \\ \lambda_{2i}(x_i,n_i) = \lim_{\Delta x_i \to 0} \dfrac{P\left\{G_{1i}^{x_i,x_i+\Delta x_i} \middle| G_{n_i}^{0,x_i}\right\}}{\Delta t} \end{cases} \qquad i = 1,2,3 \qquad (13)$$

PARTICLES' RANDOM TRAJECTORIES

The particle's trajectory ω results from the combination of three chronological displacement series: (i) an alternate series of longitudinal displacements in the direction of the flow, with intercalated periods of time when the particle ceases to progress in this sense; (ii) an alternate series of vertical displacements in the direction of gravity , with intercalated periods when the particle ceases to decant; (iii) a series of lateral displacements, with intercalated periods when the particle ceases to move laterally, as shown in Figures 1 and 2 (Wilson-Jr., 2004). One can observe that: (1) when the particle ceases to progress in the direction of flow, it can be decanting or moving laterally, (2) when it ceases to decant, it can be moving in the longitudinal or lateral directions, (3) when it ceases to progress towards one of the walls, it can be decanting or moving in the longitudinal direction. In this manner, the three series are interdependent and should be considered together.

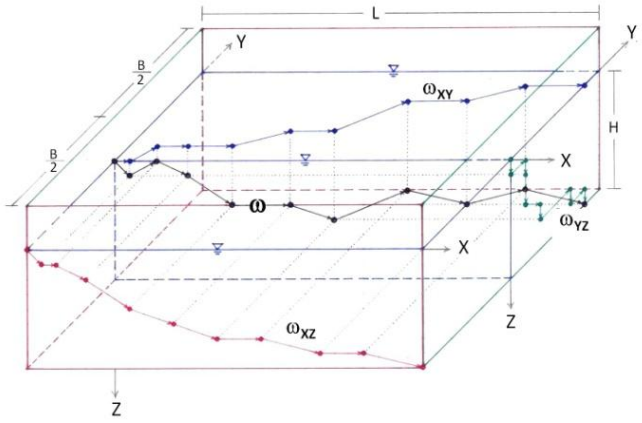

Figure 1. Sediment particle trajectory and its components in open channel flow (Wilson-Jr., 2004)

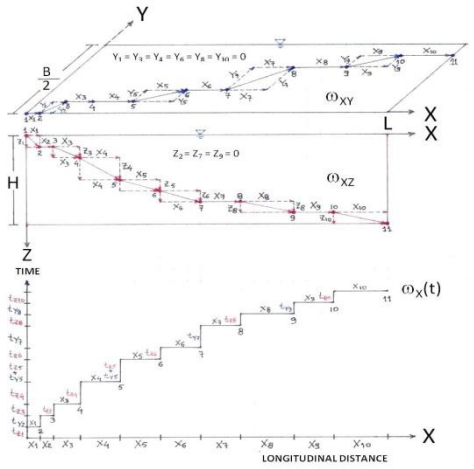

Figure 2. Particle trajectories on the horizontal ω_{XY} and vertical ω_{XZ} plans and longitudinal chronological series ω_X (*t*) (Wilson-Jr., 2004)

As positive longitudinal and vertical displacements are predominant these random series are more appropriate to describe the particle movements than the series of lateral displacements, where the negative movement (opposite to the direction of one of the walls) no can be neglected. Thus, the 2D resulting Random Processes that characterize the Lagrangean and Eulerian Descriptions, become respectively equal to:

$$\vec{R}(t,\omega) = \left[X(t,\omega), Z(t,\omega)\right] = X_{ti}(\omega); \qquad i=1,3 \qquad (14)$$

$$T(x,z,\omega) = \left[T(x,\omega), T(z,\omega)\right] = T_{xi}(\omega); \qquad i=1,3 \qquad (15)$$

OBJECTIVES

General Objectives

The general purpose of this work includes the study of Lagrangean and Eulerian Descriptions of bed and in suspension sediments and contaminants particles' movements and cases of instantaneous and continuous immersion of these particles in open channel flows, using the Theory of Random Process.

Specific Objectives

In particular, it is intended: (i) show that the Theory of Random Process accurately describe the 2D movements,

longitudinal and vertical, of sediment and pollutants in open channel flows; (ii) present the 2-D Poissonian models of sediments and contaminants in longitudinal and vertical suspension movements; (iii) highlight the importance of Temporal and Spatial Intensity Mobility Functions in the definition of random models, as well as in calibration and validation of 2D models, with data obtained in laboratory channels and nature.

3-D LAGRANGEAN RANDOM PROCESS

To better illustrate the ω trajectories of the particles, it will adopt Lagrangean Description of the Random Processes $X_{ti}(\omega)$, $i = 1,2,3$; shown in Figure 2.

Probability Density Function $f_t(x, y, z)$

Conceding the mutual independence of the Random Processes $X_{ti}(\omega)$, $i = 1,2,3$; the Probability Distribution Function of the particles' position with respect to time can be simplified, and be described by the general equation (Sayre and Conover, 1967; Wilson-Jr., 1987, 2004):

$$F_t(x,y,z) = \sum_{n=0}^{\infty} P\left\{ \sum_{j=0}^{N(t)} X_j \le x,\ \sum_{j=0}^{N(t)} Y_j \le y,\ \sum_{j=0}^{N(t)} Z_j \le z,\ N(t) = n \right\} \tag{16}$$

where $N(t)$ represents the number of particle displacements in time interval $[0,t]$. Thus, the Probability Density Function of the position of the particle in time t, is given by:

$$f_t(x,y,z) = \frac{\partial^3 F_t(x,y,z)}{\partial x \partial y \partial z} = f_t(x)\, f_t(y) f_t(z) P\left\{ \sum_{n=0}^{\infty} N(t) = n \right\} = f_t(x)\, f_t(y) f_t(z) \tag{17}$$

The pairs of Mobility Functions $\lambda_{1i}(t,n)$ and $\lambda_{2i}(x_i,n)$, $i = 1,2,3$; also called Particle Kinematic Change Functions, characterize the particles temporal and spatial movements, respectively (Wilson-Jr., 1987; Monteiro, 2004; Wilson-Jr. and Monteiro, 2013). When the probability of the grains' displacements, in time and distance intervals $[t,\ t+\Delta t]$ and $[x,\ x+\Delta x]$, Δt and Δx tending to zero, are independents of time, particle position and previous displacements, i.e., independents of the sediment particle history, the particle movement is called <u>*out of memory*</u>. In this case, the Mobility Functions are positive constants and the Density Probability Functions $f_t(x_i)$, $i = 1, 2, 3$ are described by Homogeneous Poissonian Random Processes (Wilson-Jr., 1987). For the 3D model results:

$$0.0 \le f_{t1}(x_i) \le f_t(x_i) \le f_{t2}(x_i) \le 1.0 \tag{18}$$

$$\begin{cases} f_{t1}(x_i) = \lambda_{2i}\, e^{-\lambda_{1i} t - \lambda_{2i} x_i} \displaystyle\sum_{k=0}^{\infty} \frac{(\lambda_{1i} t)^k}{k!} \frac{(\lambda_{2i} x)^k}{k!} \\ f_{t2}(x_i) = \lambda_{2i}\, e^{-\lambda_{1i} t - \lambda_{2i} x_i} \displaystyle\sum_{k=0}^{\infty} \frac{(\lambda_{1i} t)^{k+1}}{(k+1)!} \frac{(\lambda_{2i} x)^k}{k!} \end{cases} \qquad i = 1, 2, 3 \tag{19}$$

For any kind of sediment and/or pollutant immersion, if there is no loss or gain of particles in the course of time and distance, the total volume occupied by the particles is preserved after immersion time t_d. That is, it has been:

$$M_t = \int_{x=0}^{\infty} \int_{y=0}^{\infty} \int_{z=0}^{\infty} f_t(x,y,z)\, dx\, dy\, dz = 1; \quad t \ge t_d \ge 0 \tag{20}$$

To illustrate the performance of the 3D model components, plots of the probability density functions for some values of the mobility functions λ_{1i} and λ_{2i}, $i = 1,2,3$, are presented in Figures 3, 4 and 5 (Wilson-Jr., 2004). The mobility values are obtained by comparing the experimental and theoretical variations of the particles' position moments as function of time, and/or of the particles' passing time moments through cross sections. T^{-1} and L^{-1} in the figures correspond to the units of λ_{1i} and λ_{2i}, $i = 1,2,3$, that is, the inverse of time and length units, respectively.

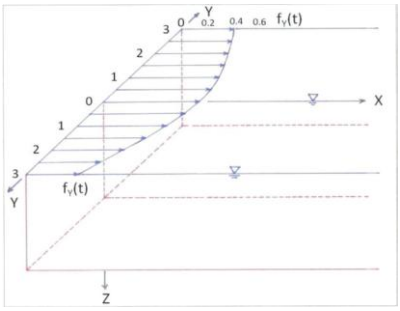

Figure 3. Probability density function of lateral displacements in time. ($\lambda_{1y} = 0.07T^{-1}$; $\lambda_{2y} = 0.90L^{-1}$)

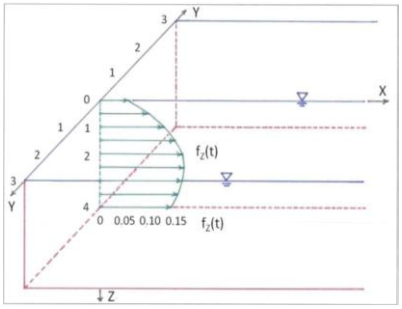

Figure 4. Probability density function of vertical displacements in time. ($\lambda_{1z} = 0.15T^{-1}$; $\lambda_{2z} = 1.15L^{-1}$)

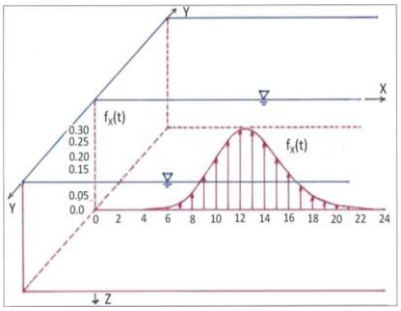

Figure 5. Probability density function of longitudinal displacements in time. ($\lambda_{1x} = 0.15T^{-1}$; $\lambda_{2x} = 3.50L^{-1}$)

To determine Probability Density Functions $f_t(x)$, $f_t(y)$ and $f_t(z)$, the software PAICON (***P**rocessos **A**leatórios com Injeção **I**nstantânea e **CON**tínua*) was used, implemented in *Delphi language* from *Inprise Corporation* (Monteiro and Wilson-Jr., 2002; Monteiro, 2004). These curves are fitted to the experimental results of projects on sediment and pollutants' transport and dispersion with the use of tracers: radioactive, fluorescents or chemicals, among others. In the Figure 6 is shown the points of the Rhodamine-B transit curve through a River *Loire*'s cross section and the upper and lower theoretical probability density approximate curves $q_{xj}(t), j = 1,2$, adjusted with the use of the PAICON Program (Monteiro and Wilson-Jr., 2003). The tracer application technique known as Double Labelling Method (*Méthode de Double Marquage*) was used. Simultaneous labelings and injections of water and fine sediments (special type named *schlam*) with Rhodamine-B and Au^{198}, respectively, allowed a comparative study of sediment and fluid transfer properties, in the segment between *Grangent* and *Villerest* Dams, on the River *Loire* (Tola *et al.*, 1981; Wilson-Jr., 1987).

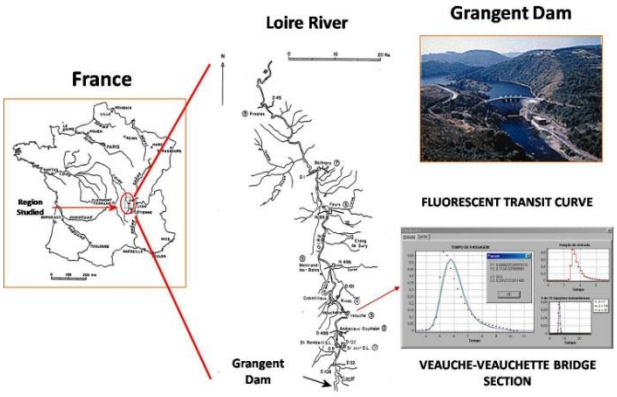

Figure 6. Rhodamine-B transit curve through the *Veauche-Veauchette* Bridge section, on the River *Loire* (Tola *et al*., 1981; Monteiro and Wilson-Jr., 2003)

Intensity of Particle Mobility Functions

The Mobility Functions λ_{1i} and λ_{2i}, $i = 1,2,3$, defined by Equations (13) appeared from the analytical development of Random Processes $X_{ti}(\omega)$ and $T_{xi}(\omega)$ to explain sediment mobility in each direction i and on the instant t. Different models can be obtained from the mathematical expressions that define these mobility functions, which should consider the sediment and/or contaminant particle characteristics, as well the hydrodynamic properties. The general expressions for λ_{1i} and λ_{2i}, $i = 1,2,3$, obtained by Vukmirovic´(1975) and Wilson-Jr. (1987, 2012) consider the mobility of the particles as a function of time, of the distances traveled in one direction and of its past performance in time (n) and distance (k), in each direction (i):

$$\begin{cases} \lambda_{1i}(t,n) = \lambda_{1i}(t)\,\lambda_{2i}(n) \\ \lambda_{2i}(x_i,k) = \lambda_{2i}(x_i)\,\lambda_{2i}(k) \end{cases} \qquad i = 1, 2, 3 \qquad (21)$$

$$\begin{cases} \lambda_{1i}(t,n) = \lambda_{1i} = const. \\ \lambda_{2i}(x_i,k) = \lambda_{2i} = const. \end{cases} \qquad i = 1, 2, 3 \qquad (22)$$

where: λ_{1i} is the particle mobility factor in a given time t in the direction i; and
λ_{2i} the particle mobility factor in a certain position x_i in the direction i.

2-D HOMOGENEOUS LAGRANGEAN RANDOM POISSONIAN PROCESSES

For these cases the grain mobility functions in the longitudinal and vertical directions assume constant values in accordance with Equation (22), or simply:

$$\text{for } i = 1 = x \Rightarrow \begin{cases} \lambda_{11} = \lambda_{1x} = const_{11} \\ \lambda_{21} = \lambda_{2x} = const_{21} \end{cases} \tag{23}$$

$$\text{for } i = 3 = z \Rightarrow \begin{cases} \lambda_{13} = \lambda_{1z} = const_{13} \\ \lambda_{23} = \lambda_{2z} = const_{23} \end{cases} \tag{24}$$

Some of the main statistical properties that characterize the 2-D Homogeneous Lagrangean Random Process $X_t(x,z)$, for cases of **instantaneous** and **continuous immersions**, are analytically described by the following equations (Monteiro, 2004; Wilson-Jr. and Monteiro, 2004):

Instantaneous Immersion Case

Probability density function $f_t(x,z)$

$$0.0 \le f_{t1}(x,z) \le f_t(x,z) \le f_{t2}(x,z) \le 1.0 \tag{25}$$

$$\begin{cases} f_{t1}(x,z) = \lambda_{21}\,\lambda_{23}\, e^{-\lambda_{11}t-\lambda_{21}x}\, e^{-\lambda_{13}t-\lambda_{23}z} \sum_{n=0}^{\infty}\sum_{k=0}^{\infty} \dfrac{(\lambda_{11}t)^n}{n!}\dfrac{(\lambda_{21}x)^n}{n!}\dfrac{(\lambda_{13}t)^k}{k!}\dfrac{(\lambda_{23}z)^k}{k!} \\ f_{t2}(x,z) = \lambda_{21}\,\lambda_{23}\, e^{-\lambda_{11}t-\lambda_{21}x}\, e^{-\lambda_{13}t-\lambda_{23}z} \sum_{n=0}^{\infty}\sum_{k=0}^{\infty} \dfrac{(\lambda_{11}t)^{n+1}}{(n+1)!}\dfrac{(\lambda_{21}x)^n}{n!}\dfrac{(\lambda_{13}t)^{k+1}}{(k+1)!}\dfrac{(\lambda_{23}z)^k}{k!} \end{cases} \tag{26}$$

Probability distribution function $F_t(x,z)$

$$0.0 \le F_{t1}(x,z) \le F_t(x,z) \le F_{t2}(x,z) \le 1.0 \tag{27}$$

$$\begin{cases} F_{t1}(x,z) = e^{-\lambda_{11}t-\lambda_{21}x}\, e^{-\lambda_{13}t-\lambda_{23}z} \sum_{n=0}^{\infty}\sum_{k=n}^{\infty} \dfrac{(\lambda_{11}t)^n}{n!}\dfrac{(\lambda_{21}x)^k}{k!} \sum_{m=0}^{\infty}\sum_{p=m}^{\infty} \dfrac{(\lambda_{13}t)^m}{m!}\dfrac{(\lambda_{23}z)^p}{p!} \\ F_{t2}(x,z) = e^{-\lambda_{11}t-\lambda_{21}x}\, e^{-\lambda_{13}t-\lambda_{23}z} \sum_{n=0}^{\infty}\sum_{k=n}^{\infty} \dfrac{(\lambda_{11}t)^{n+1}}{(n+1)!}\dfrac{(\lambda_{21}x)^k}{k!} \sum_{m=0}^{\infty}\sum_{p=m}^{\infty} \dfrac{(\lambda_{13}t)^{m+1}}{(m+1)!}\dfrac{(\lambda_{23}z)^p}{p!} \end{cases} \tag{28}$$

Median position of particles $M_t(x,z)$

$$M_{t1}(x,z)_{Inst.} \le M_t(x,z)_{Inst.} \le M_{t2}(x,z)_{Inst.} \tag{29}$$

$$\begin{cases} M_{xz1}(t)_{Inst.} = E\left[F_{t1}(x,z)\right] = \dfrac{1}{\lambda_{21}\,\lambda_{23}}\left[\lambda_{11}\,\lambda_{13}\,t^2 + (\lambda_{11}+\lambda_{13})t + 1\right] \\ M_{xz2}(t)_{Inst.} = E\left[F_{t2}(x,z)\right] = \dfrac{\lambda_{11}\,\lambda_{13}}{\lambda_{21}\,\lambda_{23}}\,t \end{cases} \tag{30}$$

Variance of the particles' positions $\left[S^2_{xzj}(t)\right]_{Inst.}$

$$\left[S^2_{xz1}(t)\right]_{Inst.} \le \left[S^2_{xz}(t)\right]_{Inst.} \le \left[S^2_{xz2}(t)\right]_{Inst.} \tag{31}$$

$$\begin{cases} \left[S^2_{xz1}(t)\right]_{Inst.} = \dfrac{2\lambda_{11}\lambda_{13}(\lambda_{11}+\lambda_{13})t^3+\left[(\lambda_{11}+\lambda_{13})^2+10\,\lambda_{11}\lambda_{13}\right]t^2+6(\lambda_{11}+\lambda_{13})t+3}{(\lambda_{21})^2(\lambda_{23})^2} \\ \left[S^2_{xz2}(t)\right]_{Inst.} = \dfrac{2\lambda_{11}\lambda_{13}(\lambda_{11}+\lambda_{13})t^3+2\lambda_{11}\lambda_{13}t^2}{(\lambda_{21})^2(\lambda_{23})^2} \end{cases} \tag{32}$$

Continuous Immersion Case

This case consists of a uniform injection, laterally distributed in the free surface at the channel's upstream extremity during a period of time t_d, as illustrated in Figures 7 and 8. In the experiments conducted at the LCHF (*Laboratoire Central d'Hydraulique de France*), t_d varied from 7.0 to 13.0 minutes (Wilson-Jr., 1987).

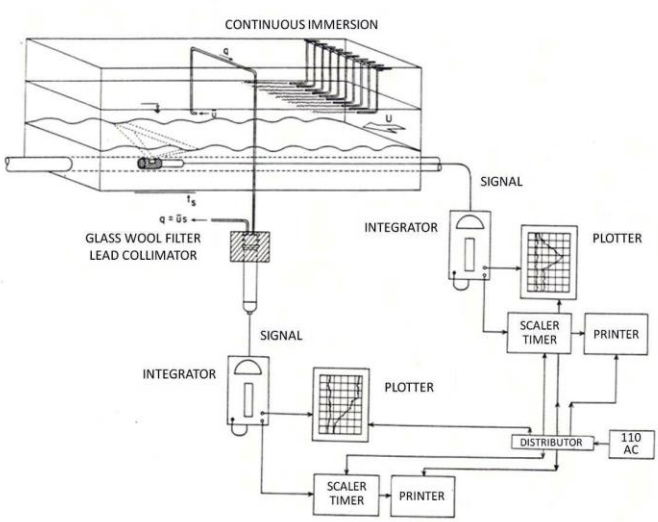

Figure 7. Immersion and detection system of bed and suspended movements of fine sediments in laboratory channel (Wilson-Jr., 1987)

Figure 8. Continuous immersion of fine sediments on the free surface of LCHF's channel

In the following equations $t_o \geq t_d$ represents the period of time of continuous recording of tracer's passage by the sampling points. To shorten the text, only the statistical properties related to the upper approximate probability density function of the 2-D Homogeneous Lagrangean Random Processes $X_{ti}(\omega)$, $i = 1,3$ will be presented.

Probability density function $h_{to}(x,z)$

$$h_{to}(x,z) = \frac{1}{t_d}\int_0^{t_d} f_{t_o-\tau}(x)\, f_{t_o-\tau}(z)\, d\tau \tag{33}$$

For the 2-D Poissonian Random Process, the upper approximate probability density function $h_{to2}(x,z)$ becomes:

$$h_{to2}(x,z) = \frac{1}{t_d}\int_0^{t_d} \lambda_{21}\, e^{-\lambda_{21}x}\, e^{-\lambda_{11}(t_o-\tau)} \sum_{n=0}^{\infty}\left\{\frac{\left[\lambda_{11}(t_o-\tau)\right]^{n+1}}{(n+1)!}\frac{(\lambda_{21}x)^n}{n!}\right\}\times \lambda_{23}\, e^{-\lambda_{23}z}\, e^{-\lambda_{13}(t_o-\tau)} \sum_{n=0}^{\infty}\left\{\frac{\left[\lambda_{13}(t_o-\tau)\right]^{n+1}}{(n+1)!}\frac{(\lambda_{23}x)^n}{n!}\right\} d\tau \tag{34}$$

Probability distribution function $H_{to}(x,z)$

$$H_{to}(x,z) = \frac{1}{t_d}\int_0^{t_d} F_{t_o-\tau}(x)\, F_{t_o-\tau}(z)\, d\tau \tag{35}$$

The distribution functions $F_{to\text{-}\tau}(x)$ and $F_{to\text{-}\tau}(z)$ are obtained from the 1-D models approximate equations in the longitudinal and vertical directions, respectively, that is, from the 1-D Homogeneous Poissonian equations system, in the *i = 1, 3* directions, with instantaneous immersions (Monteiro, 2004):

$$0.0 \le F_{t1}(x_i) \le F_t(x_i) \le F_{t2}(x_i) \le 1.0 \tag{36}$$

$$\begin{cases} F_{t1}(x_i) = e^{-\lambda_{1i} t - \lambda_{2i} x_i} \sum_{\nu=0}^{\infty} \sum_{k=\nu+1}^{\infty} \frac{(\lambda_{1i} t)^{\nu}}{\nu!} \frac{(\lambda_{2i} x_i)^{k}}{k!} \\ F_{t2}(x_i) = e^{-\lambda_{1i} t - \lambda_{2i} x_i} \sum_{\nu=0}^{\infty} \sum_{k=\nu}^{\infty} \frac{(\lambda_{1i} t)^{\nu}}{\nu!} \frac{(\lambda_{2i} x_i)^{k}}{k!} \end{cases} \tag{37}$$

Thus, for the Upper Approximate Probability Distribution Function $F_{(to\text{-}\tau)2}(x_i)$, *i = 1,3*, it has been:

$$F_{(t_o-\tau)2}(x_i) = e^{-\lambda_{1i}(t_o-\tau) - \lambda_{2i} x_i} \sum_{\nu=0}^{\infty} \sum_{k=\nu}^{\infty} \frac{[\lambda_{1i}(t_o-\tau)]^{\nu}}{\nu!} \frac{(\lambda_{2i} x_i)^{k}}{k!} \qquad i = 1,3 \tag{38}$$

Average position of the particles

The average position of the particles is given by the first-order moment, defined by:

$$\left[M^1_{xz}(t_o)\right]_{Cont.} = \frac{1}{t_d} \int_0^{t_d} M^1_x(t_o-\tau)\, M^1_z(t_o-\tau)\, d\tau \tag{39}$$

which can be estimated by two approximate first order moments, such that:

$$\left[M^1_{xz1}(t_o)\right]_{Cont.} \le \left[M^1_{xz}(t_o)\right]_{Cont.} \le \left[M^1_{xz2}(t_o)\right]_{Cont.} \tag{40}$$

Combining Equations 28, 29, 30, 39 and 40, one obtains the approximate expressions of the average position of the particles. The upper approximation is given by:

$$\left[M^1_{xz2}(t_o)\right]_{Cont.} = \frac{\lambda_{11}\,\lambda_{13}}{\lambda_{21}\,\lambda_{23}} \left(t_o^2 - t_o\, t_d + \frac{t_d^2}{3} \right) \tag{41}$$

Variance of the particles' position

Similarly, one can obtain the approximate expressions of the second order moment and of the Variance from the following definitions:

$$\left[M^2_{xz}(t_o)\right]_{Cont.} = \frac{1}{t_d} \int_0^{t_d} M^2_x(t_o-\tau)\, M^2_z(t_o-\tau)\, d\tau \tag{42}$$

$$\left[S^2_{xz}(t_o)\right]_{Cont.} = \left[M^2_{xz}(t_o)\right]_{Cont.} - \left[M^1_{xz}(t_o)\right]^2_{Cont.} \tag{43}$$

SUSPENDED SEDIMENT MOVEMENTS IN LABORATORY OPEN CHANNEL

An original experimental device was developed for the study of bed and suspended load with vertical transfers in a LCHF's channel 12.0 m long having a rectangular cross section 0.40 m wide by 0.60 m deep (Wilson-Jr., 1987). The lateral walls are made of glass, allowing for visual observations of bed configurations evolutions and the following of injections of sediments labeled with tracers. The channel was adapted, as schematized in Figure 7, such that hydraulic and sedimentologic measurements could be performed simultaneously with conventional methods.

Among several hydraulic and sedimentologic measurements performed, the following are highlighted: (i) the 3-D liquid velocities field; (ii) transport and dispersion of bed load particles; (iii) the vertical and transversal concentration profiles of suspended sediments continuously injected in the open surface of the channel, during time intervals; and (iv) the temporal and specific evolutions of the sediments deposited in the channel bed.

Examples of vertical profiles of cohesive and non-cohesive sediment concentration obtained in cross sections of the channel are presented in Figures 9 and 10, while examples of similar theoretical curves obtained from the probability density functions $f_t(x,z)$ are shown in Figure 11.

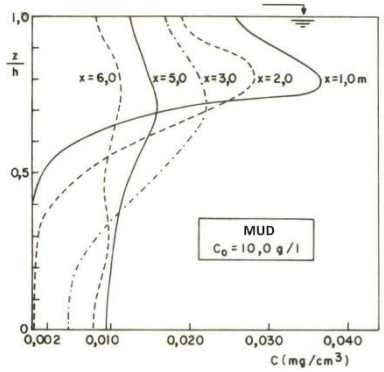

Figure 9. Vertical profiles of suspended cohesive sediment concentration across fixed section (Wilson-Jr., 1987)

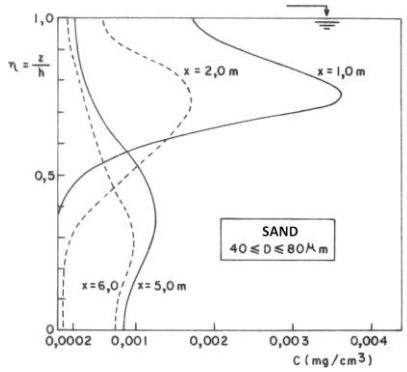

Figure 10. Vertical profiles of suspended non cohesive sediment concentration across fixed section (Wilson-Jr., 1987)

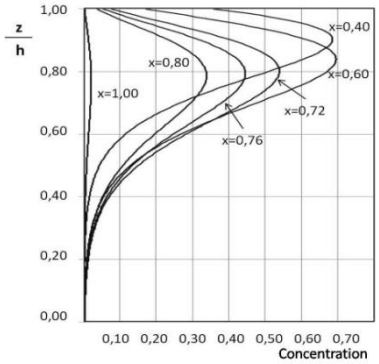

Figure 11. Theoretical vertical profiles of suspended cohesive sediment concentration across fixed section.

The comparison of these theoretical and experimental curves indicate that the 2D Random Models are so promising as the 1D models that the authors have been applied in laboratory channels and nature, in projects and investigations of Civil and Environmental Engineering.

SUSPENDED SEDIMENT MOVEMENTS RESULTS

Mendes and Wilson-Jr. (1998), Wilson-Jr. and Monteiro (2004) showed that the Homogeneous One-dimensional Poissonian Models described precisely the sediment and pollutant passage time through open channel cross sections. Data from experiments performed in Brazil and France consisting on the instantaneous immersion of tracers in suspension an upstream section and on the determination of the transit time's curves through some downstream cross sections were used for the 1-D applications using the PAICON-1D software. Some of these applications are highlighted in Wilson-Jr. and Monteiro (2004, 2013).

For the implementation of 2-D Poissonian models, the PAICON program was restructured to include the two-dimensional case and modern techniques of graphic outputs. This PAICON-2D version calculates the values of the approximate probability density and distribution functions of the Lagrangean and Eulerian descriptions, to estimated or experimentally obtained values of the λ_{11}; λ_{13}; λ_{21} and λ_{23} Mobility Functions.

To calibrate and validate the 2D Random Models is necessary to determine the values of these functions in the directions: longitudinal (λ_{11} and λ_{21}) and vertical (λ_{13} and λ_{23}). They are determined by the probability density functions moments of first and second order in each direction and by the longitudinal and vertical mean velocity of the particles, namely by Equations (44) to (47), following (Wilson-Jr. and Monteiro, 2013).

Temporal and spatial mobility of the particles in the x_i; i=1,3 directions

$$\begin{cases} \lambda_{1x_i} = \lim_{\Delta t \to 0} \dfrac{P\left\{E_{1x_i}^{t,t+\Delta t}\right\}}{\Delta t} \\ \lambda_{2x_i} = \lim_{\Delta x_i \to 0} \dfrac{P\left\{G_{1x}^{x_i,x_i+\Delta x_i}\right\}}{\Delta x_i} \end{cases} \qquad i = 1,3 \tag{44}$$

Longitudinal and vertical mean positions of a group of particles

$$\begin{cases} X_m(t) = \dfrac{\lambda_{1x}}{\lambda_{2x}} t = \dfrac{\lambda_{11}}{\lambda_{21}} t \\ Z_m(t) = \dfrac{\lambda_{1z}}{\lambda_{2z}} t = \dfrac{\lambda_{13}}{\lambda_{23}} t \end{cases} \tag{45}$$

Variances of the longitudinal and vertical positions of a group of particles

$$S_j^2(t) = 2\frac{\lambda_{1j}}{\lambda_{2j}^2}t \qquad j = x, z \text{ ou } j = 1, 3 \qquad (46)$$

Longitudinal and vertical mean velocities of a group of particles

$$U_j = \frac{\lambda_{1j}}{\lambda_{2j}} \qquad j = x, z \text{ ou } j = 1, 3 \qquad (47)$$

Each pair of values of the Mobility Functions describes the sediment grain movement in one direction. The results of the evolution in time of their approximate superior probability density function are shown in Figures 12 and 13.

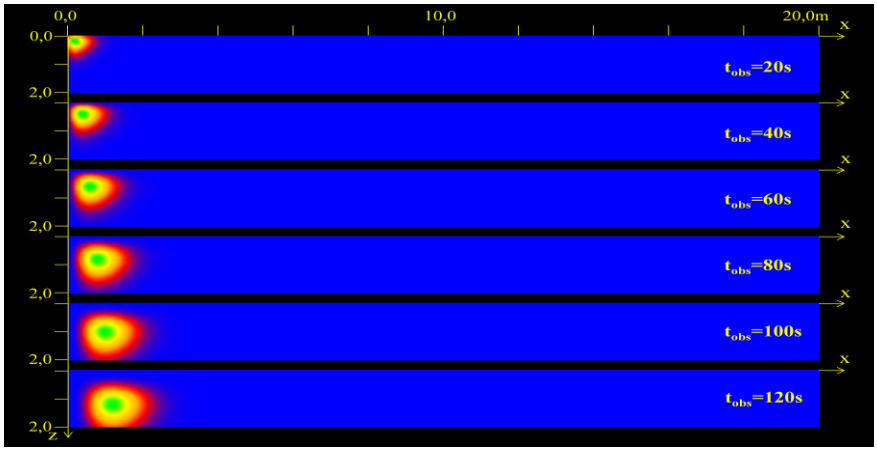

Figure 12. Cloud of sediments due to an instantaneous immersion at the free surface: case of equal longitudinal and vertical mobility.
($\lambda_{1x} = \lambda_{1z} = 0.10\ s^{-1}$; $\lambda_{2x} = \lambda_{2z} = 10.0\ m^{-1}$; $U_x = U_z = 0.01\ m\ s^{-1}$)

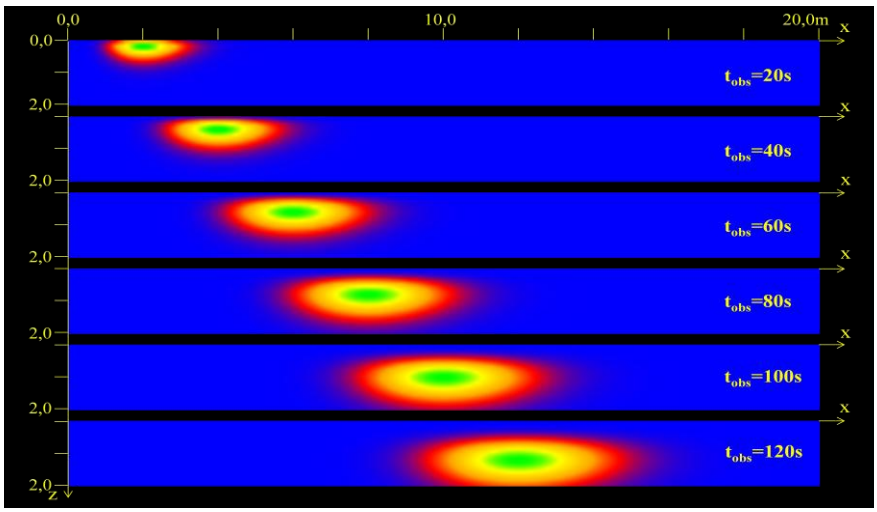

Figure 13. Cloud of sediments due to an instantaneous immersion at the free surface: in which case longitudinal mobility is greater than the vertical.
($\lambda_{1x} = 1.0\ s^{-1}$; $\lambda_{1z} = 0.10\ s^{-1}$; $\lambda_{2x} = \lambda_{2z} = 10.0\ m^{-1}$; $U_x = 0.10\ m\ s^{-1}$; $U_z = 0.01\ m\ s^{-1}$)

Their values are proportional to the concentration of sediment in suspension injected instantly to the free surface of a section located at the upstream extremity of the flow, for the cases where: (i) longitudinal and vertical mobility are equal; (ii) in the case of fine sediment which longitudinal mobility is about one order of magnitude higher than its vertical mobility or settling velocity. Similar studies were considered in the case of a continuous immersion for a time $[0, t_d]$ for t_d equal to 120 seconds. They are shown in Figures 14 and 15.

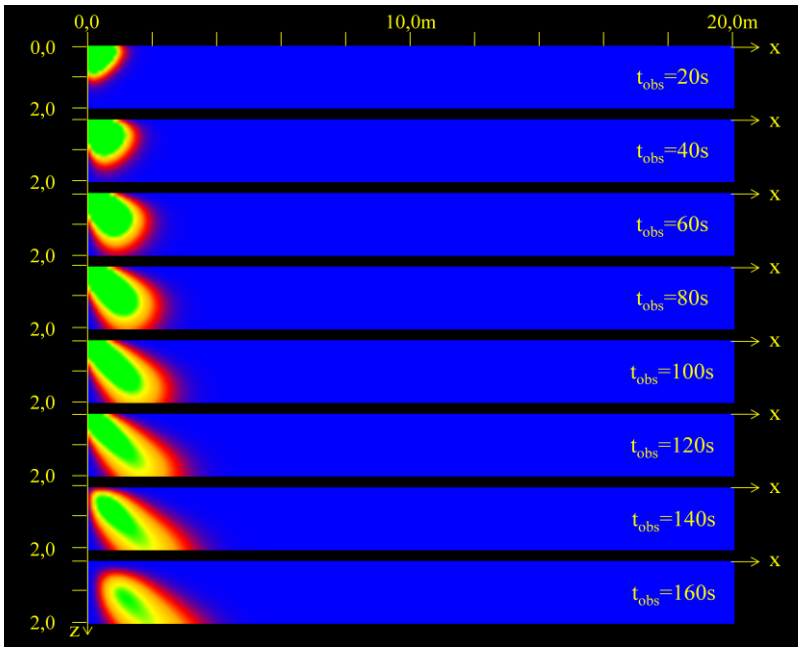

Figure 14. Plume of sediments due to continuous immersion at the free surface during the time interval $[0, t_d]$: case of equal longitudinal and vertical mobility. ($\lambda_{1x} = \lambda_{1z} = 0.20$ s^{-1}; $\lambda_{2x} = \lambda_{2z} = 10.0$ m^{-1}; $t_d = 120$ s; $U_x = U_z = 0.02$ m s^{-1})

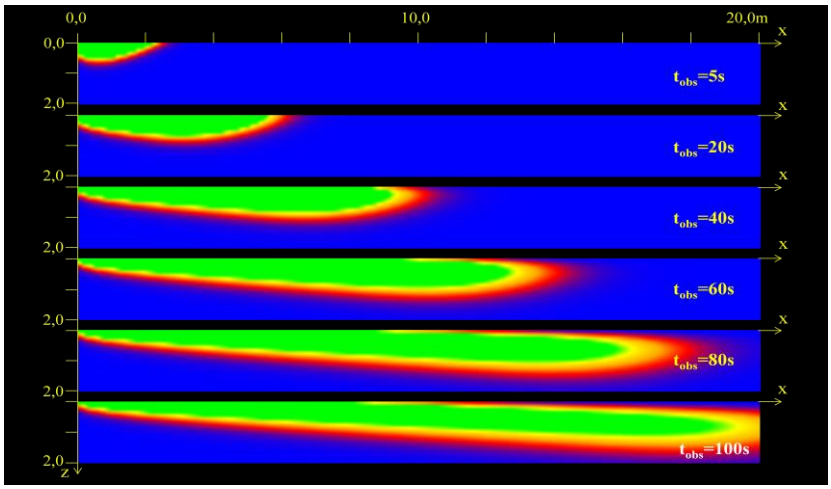

Figure 15. Plume of sediments due to continuous immersion at the free surface during the time interval $[0, t_d]$: in which longitudinal mobility is greater than the vertical. ($\lambda_{1x} = 2.0$ s^{-1}; $\lambda_{1z} = 0.10$ s^{-1}; $\lambda_{2x} = \lambda_{2z} = 10.0$ m^{-1}; $U_x = 0.20$, $U_z = 0.01$ m s^{-1})

CONCLUSIONS AND RECOMMENDATIONS

The Random Theory has shown that the trajectory ω of the particle results from the combination of two chronologic series of movement periods: (i) an alternate series of longitudinal downstream steps intercalated by time periods when the particle does not move in this sense, and (ii) an alternate series of fall vertical steps intercalated by time periods when the grain does not move vertically. These series are defined by the Mobility Functions: $\lambda_{x1}(t,n)$, $\lambda_{z1}(t,n)$, $\lambda_{t2}(x,n)$ and $\lambda_{t2}(z,n)$, which analytical expressions characterize the particles random movements.

It has been shown that the Random Process Theory is very enveloping, in such way that the diffusion dispersion Fickian classical equations of suspended sediment and pollutant movements are particular random process cases, characterized by constant values of the mobility functions, or in other words, by Homogeneous Poissonian Models.

When the sizes and concentrations of the sediment grains are reduced (fine sand, clays, and mud mixtures with concentrations lower than 150 mg/l), the solid particles behave as those of the fluid and the 1-D suspended movement can be described by 1-D Homogeneous Poissonian Models. This results is not surprising, since for large values of x and t, the Poissonian Model approaches the Gaussian Model, classical solution of the Diffusion-Dispersion equation.

When the grain mobility is not constant, more complexes models are generated, combining longitudinal and vertical non-homogeneous Poissonian and non-Poissonian models. Mobility Functions obtained in open channel flows, with grain of sediment labeled with radiotracers, permit the determination of the Mobility Functions and to adjust and validate the resultant random models.

Two research lines are opened: (i) the study of sediment and/or pollutant movement described by Mobility Functions that vary with time, distance and number of displacements performed in time and space, that is, performed by particles *with memory*; (ii) a description of the sediment movement by 2-D and 3-D processes. For these courses, a collection of data on sediment and pollutant movement obtained in laboratory channel and in nature with use of radioactive, dyes and chemical tracers is available for the use of this powerful Theory of Random Processes.

The authors express their sincere gratitude to PENO/COPPE/UFRJ, CAPES, FAPERJ and CNPq for the institutional support received, without which, the realization of this work would not have been possible.

ESTIMATION OF SUSPENDED-SEDIMENT AND NUTRIENT FLUXES AND ASSOCIATED TRENDS ACROSS THE CHESAPEAKE BAY WATERSHED

EXTENDED ABSTRACT

Douglas L. Moyer, Hydrologist, U.S. Geological Survey, Richmond, Virginia, dlmoyer@usgs.gov; Jeffrey G. Chanat, Hydrologist, U.S. Geological Survey, Richmond, Virginia, jchanat@usgs.gov; Kenneth E. Hyer, Hydrologist, U.S. Geological Survey, Richmond, Virginia, kenhyer@usgs.gov; Michael J. Langland, Hydrologist, U.S. Geological Survey, New Cumberland, Pennsylvania, langland@usgs.gov; Joel D. Blomquist, Hydrologist, U.S. Geological Survey, Baltimore, Maryland, jdblomqu@usgs.gov

Chesapeake Bay is the largest of the Nation's estuaries and one of the most ecologically productive in the world. Excessive transport of suspended sediment and nutrients from the Chesapeake Bay watershed has had a detrimental effect on the habitat available to the living resources throughout the entire bay. Considerable effort has been taken by the Chesapeake Bay Program (CBP), comprised of Federal, State, and local governments, academic institutions, and non-profit organizations to reduce the amount of suspended-sediment and nutrients delivered annually to the bay. In 2010, the Environmental Protection Agency mandated the development of a total maximum daily load for the bay watershed as part of continued effort to reduce suspended-sediment and nutrient delivery to the bay. Improvement is expected in bay habitat as measured by improvements in water clarity, submerged aquatic vegetation, and dissolved oxygen. The CBP supports the operation of the CBP Nontidal Monitoring Network, which is a 120-station monitoring network, in the bay watershed. Data from this network are used to monitor current water-quality (suspended sediment and nutrients) conditions and track how these conditions change over time. Suspended-sediment and nutrient fluxes and changes in fluxes over time are key indicators that water resource managers use to assess the progress being made towards improving the structure and function of the bay ecosystem.

The U.S. Geological Survey (USGS), as a partner of the CBP, is responsible for the estimation of suspended-sediment and nutrient fluxes at all CBP Nontidal Monitoring Network stations as well as quantifying long- and short-term changes in suspended-sediment and nutrient fluxes. This flux and trend information is essential to the CBP to (1) assess progress made towards meeting water-quality goals, (2) efficiently allocate resources to areas of the watershed with degrading water-quality conditions, and (3) forecast conditions in the estuary for upcoming critical periods. The USGS ensures the integrity of the observed suspended-sediment and nutrient flux results by meeting three objectives:

1) Provide training for and evaluation of agencies monitoring water-quality conditions across the 120-station CBP Nontidal Monitoring Network to verify that all agencies are monitoring the full range of hydrologic conditions, while utilizing depth- and width-integrating isokinetic sampling techniques;

2) Evaluate and improve the statistical tools used to estimate fluxes and trends; and

3) Assess the quality of the observed water-quality data used to drive the statistical analyses to ensure that the flux and trend results are as accurate and defensible as possible.

The U.S. Geological Survey serves as the technical lead for the collection of suspended-sediment and nutrient data, across the CBP Nontidal Monitoring Network. They are responsible for ultimately ensuring that monitoring data are comparable from station-to-station and are appropriate for generating representative observed suspended-sediment and nutrient fluxes. Historically, our CBP monitoring partners (i.e. State agencies and River Basin Commissions) collected suspended-sediment and nutrient samples on a monthly basis by collecting a single grab sample from the centroid of flow. These samples were typically part of a larger ambient water-quality monitoring program. However, these monitoring techniques are not sufficient for the determination of suspended-sediment and nutrient fluxes because they do not capture the vertical and/or horizontal heterogeneity that often exists during high-flow conditions. The USGS, working with each of the CBP monitoring partners, added two critical sampling elements required for a monitoring station to be included in the CBP Nontidal Monitoring Network: targeted storm-flow monitoring and sample collection using isokinetically collected width- and depth-integrating techniques. The USGS annually evaluates how well each monitoring partner has represented water-quality conditions across the full range of each site's flow regime. Additionally, routine field audits are performed of all CBP monitoring agencies to ensure that monitoring is being performed consistently.

The U.S. Geological Survey annually estimates the total monthly and annual fluxes of suspended sediment and nutrients at each nontidal monitoring station as well as estimates the extent to which these fluxes are changing over time. Historically, USGS utilized a multiple-regression approach (ESTIMATOR) (Cohn and others, 1989) to estimate daily suspended-sediment and nutrient concentrations based on daily streamflow, time, and season. Two shortcomings of this historical approach were (1) the functional form of the ESTIMATOR model forces the relation between concentration and discharge to be linear or quadratic which makes ESTIMATOR susceptible to considerable over- or under- prediction of flux at stations that exhibit sigmoidal (s- shape) relations between concentration and discharge; and (2) the inability of ESTIMATOR to determine trends in flux estimates which the CBP require to directly measure progress towards reducing suspended-sediment and nutrient delivery to the bay.

The U.S. Geological Survey recently completed an evaluation of a new approach used to estimate suspended-sediment and nutrient fluxes and associated trends in fluxes, to address the shortcomings of the ESTIMATOR model. This new approach, Weighted Regression on Time, Discharge, and Season (WRTDS) is similar to ESTIMATOR in that it estimates daily concentrations based on daily streamflow, time, and season; however, instead of predefining the relation between concentration and flow as only linear or quadratic, WRTDS allows the relation between concentration and streamflow to be more flexible (Hirsch and others, 2010). The greatest effect of using WRTDS for flux estimates is an overall reduction in flux bias (the tendency to over- or under-predict observed flux) compared to flux estimates from ESTIMATOR (Moyer and others, 2012; Hirsch, 2014). Additionally, WRTDS allows for direct determination of trends in monthly and annual fluxes which provides CBP managers

more relevant information regarding how much annual fluxes of suspended-sediment and nutrients have changed (Moyer and others, 2012).

The U.S. Geological Survey routinely reviews the water-quality record, for each nontidal monitoring station, for the presence of non-environmental heterogeneities that may bias resulting flux and trend estimates. Causes for these heterogeneities typically fall into three categories, which are: (1) inconsistent storm sampling whereby targeted storm sample collection is added to a fixed-frequency monitoring record (2) changes in analytical laboratory censoring levels, and (3) changing analytical laboratory procedures (e.g. switching from total suspended solids to suspended-sediment concentration analysis). Using subsampling experiments on densely- sampled records, the USGS is characterizing the potential effects of the first of these heterogeneities in water-quality records. Preliminary experiments indicate that inconsistent storm sampling can result in deviations in estimated annual fluxes on the order of +/- 10 percent for dissolved inorganic nitrogen, +/- 15 percent for total phosphorus, and +/- 30 percent for suspended sediment, relative to a temporally homogenous baseline dataset containing both monthly and targeted storm samples. The USGS has developed simple screening-level indicators to identify which records may have been collected using inconsistent storm sampling methods. The analysis of the potential effects of inconsistent storm sampling can serve as a model for quantifying the effects of the other methodological heterogeneities listed above, and help to assure the quality of USGS and CBP monitoring partners' water-quality records, and the resulting flux and trend estimates provided to the CBP.

The U.S. Geological Survey is currently pursuing future enhancements to implemented data-collection and data- analysis techniques that will continue to reduce uncertainty in and improve the accuracy of each nontidal monitoring station's suspended-sediment and nutrient flux estimates and associated trends in estimated fluxes. Data-collection enhancements include: (1) continuous *in situ* monitoring of water-quality field parameters including pH, specific conductance, dissolved oxygen, turbidity, and water temperature; (2) use of those continuous water-quality parameters as surrogates for estimating suspended-sediment and/or nutrient fluxes, and (3) continuous *in situ* monitoring of dissolved nutrients (i.e. nitrate and orthophosphorus). Jastram and others (2009) demonstrated that suspended-sediment and nutrient fluxes, estimated using continuous *in situ* water-quality field parameters, exhibited reduced uncertainty when compared to suspended- sediment and nutrient fluxes estimated using streamflow. Data-analysis enhancements include: (1) utilization of continuous observed water-quality field parameters, for the estimation of suspended-sediment and nutrient fluxes, and (2) development of a weighted-regression approach similar to WRTDS that allows for the estimation of concentrations and fluxes at sub- daily time intervals, which is essential for small (~ less than 100 square miles) flashy watersheds.

These steps taken by the U.S. Geological Survey help to ensure that the most appropriate monitoring and analysis techniques are being used to support the determination of suspended-sediment and nutrient fluxes and associated trends in flux across the bay watershed. These steps also serve to distinguish the CBP Nontidal Monitoring Network as one of the most robust water-quality monitoring networks in the Nation.

INTRODUCTION

As time passes, reservoirs storing water also continue to fill with sediment, causing storage loss, reducing water supply reliability, and impacting infrastructure, particularly marinas, boat ramps, outlet works, turbines, and water intakes. In addition, reservoir deltas may extend upstream from the full reservoir pool and increase the frequency of flooding. The release of clear water downstream from the dam can lead to channel degradation. Sedimentation will also reduce the surface area available for recreation. The rate of reservoir sedimentation varies across the world and is very site specific, ranging from an average annual storage loss of 2.3 percent in China to 0.2 percent in North America (Garcia et al., 2008). The traditional approach in the design of federal dams in the United States was to construct the outlet works intake structure to be above the predicted reservoir sediment level at the dam during the first 50 to 100 years of operation, thereby allocating space in the bottom of the reservoir for sediment. However, reservoir sediment accumulation affects all levels of the reservoir (Utah Division of Water Resources, 2010), affecting all storage allocations by use (e.g. Conservation, Multi-Use, or Flood Pool). Under traditional dam building approaches, future generations will have to take some action after the sediment design life is reached, which could include dredging, sediment flushing, or dam decommissioning. However, the cost or feasibility of these measures was not determined.

In the field of natural resources management in the United States, there is recently more attention on reservoir sedimentation by managers, engineers, and scientists. For example, there is the recent resolution proposed by the Subcommittee on Sedimentation (SOS) to the Advisory Committee on Water Information (ACWI), who represents the interests of water-information users and professionals in advising the Federal Government on Federal water-information programs and their effectiveness in meeting the Nation's water-information needs (www.acwi.org):

> "Continued sedimentation threatens the project benefits for many of the Nation's reservoirs. The SOS encourages all Federal agencies to develop long-term reservoir sediment-management plans for the reservoirs that they own or manage by 2030. These management plans should include either the implementation of sustainable sediment-management practices or eventual retirement of the reservoir. Sustainable reservoir sediment-management practices are practices that enable continued reservoir function by reducing reservoir sedimentation and/or removing sediments through mechanisms that are functionally, environmentally, and economically feasible. The costs for implementing either sustainable sediment management practices or retirement plans are likely to be substantial, and sustainable methods to pay for these activities should also be identified.
>
> Federal agencies are encouraged to start developing sustainable reservoir sediment-management plans now for one or two reservoirs per year on a pilot basis. From this experience, interagency technical guidelines will be developed for preparing sustainable reservoir-sedimentation plans."

This technical report provides information beginning the development of guidelines for the formulation of reservoir sustainability plans for the effective management of inflowing sediment loads and in-situ deposits.

METHODS

This technical document summarizes key information from a Reclamation Science and Technology (S&T) Program research report (Reclamation, 2015), which provides addition details in the development of guidelines for the formulation of reservoir sustainability plans. Two key questions were set at the beginning of the research process, along with further pertinent information as the research progressed:

1. What is the process for developing a plan and strategy for the managing sediment inflow and deposition in Reclamation reservoirs? Sedimentation occurs at all reservoirs at various rates and sedimentation eventually impacts reservoir facilities and storage capacity. Taking a proactive approach to managing reservoir sediment provides the best chance for extending the useful life of any reservoir.

A sediment management plan must address the social, environmental, technical, economic, and legal challenges. With guidance adapted from Utah Division of Water Resources (2010) and Garcia et al. (2008), the following broad and general steps are provided to develop a reservoir sustainability plan. Not all steps are mandatory and some steps can occur concurrently:

   a. Determine the magnitude of the sediment problem
   b. Define preliminary sediment management options
   c. Define stakeholders and constraints
   d. Assess feasibility and economic viability of options
   e. Develop and implement a sediment management plan
   f. Monitor and revise plan if necessary

2. What is the best method for identifying which Reclamation reservoirs present the highest risk for experiencing adverse operational impacts and pose the greatest need for implementing an appropriate sustainability plan? Many Reclamation reservoirs in multiple Regions have experienced operational challenges due to sedimentation. Early identification of sediment related problems and proactive implementation of a customized sustainability plan are vital components in the preservation of a dam or reservoir's ability to meet Reclamation's mission.

The best way to determine the rate and extent of the reservoir sedimentation begin with direct surveys. However, the vast majority of Reclamation's reservoirs haven't even been surveyed since dam closure. Other indirect methods are available to estimate the amount of storage loss and determine which reservoirs have the greatest sedimentation problems.

Further guidance on the steps in developing a reservoir sustainability (or any other sediment sustainability) management plan and methods on quantifying reservoir impacts are detailed in further sections. This document details the preliminary steps in terms of what sustainable reservoir sediment management options are available in formulating a reservoir sustainability plan.

There is a wealth of knowledge giving detailed options available in addressing the problems of reservoir sedimentation. Garcia et al (2008) provides a good general discussion on reservoir sedimentation and sediment management options. Morris and Fan (1998) and Basson and Rooseboom (1997) both provide the most comprehensive information on sediment management in reservoirs. This research is intended to only reference the options as part of the guidelines for formulating reservoir sustainability plans.

a. Determine the Magnitude of the Problem:

The second question asked in the research effort was: what is the best method for identifying which Reclamation reservoirs present the highest risk for experiencing adverse operational impacts and pose the greatest need for implementing an appropriate sustainability plan?

As the saying goes, "one cannot manage what they cannot measure." The best method, or in this case methods, of determining the magnitude of the problem are direct measurements. As mentioned in the summary, there are two direct ways to measure storage loss and the potential of sediment problems in a reservoir:

1. Performing a repeat hydrographic survey of the reservoir, and;
2. Sediment flux measurements upstream and downstream of the reservoir.

Chapter 9 in Reclamation's Erosion and Sedimentation Manual (Reclamation, 2006) provides guidance on the performance of reservoir surveys. Prior to the development of modern measurement techniques with Global Positioning System (GPS) and acoustic depth sounding equipment, early reservoir surveys were performed along range lines (cross sections), where the station and depth were directly measured from a boat. With modern techniques, the entire reservoir can be surveyed and contour maps can be developed. The comparison of reservoir

survey data collected using entirely different methods can result in high uncertainty. Therefore, to reduce uncertainty in the estimate and distribution of reservoir storage loss, more frequent reservoir surveys are needed to accurately measure the rate of reservoir sedimentation.

Sediment flux measurements entail the continuous or repeated measurement of suspended sediment loads and bed load sediments both upstream and downstream of a reservoir, where then by conservation of mass, the amount of sediment depositing in the reservoir, or the storage lost, is estimated. Flux measurements, however, give only a storage loss estimate, and do not provide a measurement of sedimentation near important features (e.g. marinas, boat ramps, outlet works and water intakes).

Sediment flux measurements generally require more continuous monitoring and therefore more resources than periodic reservoir surveys. However, in combination, both provide a robust estimation of the timing and rate of reservoir sedimentation, including the properties of incoming and outgoing sediments (e.g. particle size).

Chapter 9 in Reclamation (2006) notes that the frequency of reservoir surveys should depend on the estimated rate of reservoir sediment accumulation, along with the current operation and maintenance plan.

Generally, the availability of funding limits the performance of direct measurements by reservoir survey and/or sediment flux measurements. At a lesser cost, the potential impacts of reservoir sediment to important features (e.g. outlet works, water intakes, boat ramps) can be evaluated with a reconnaissance survey, where a profile of the reservoir is rapidly surveyed to determine priorities.

At lesser cost but with greater uncertainty, there are several indirect methods are available to estimate the amount of storage loss and determine which reservoirs pose the greatest of impacts. Prior to the implementation of using indirect methods to determine sedimentation rate, one can define reservoirs that are offstream and possibly those in a series that have may have reduced sedimentation rates. These reservoirs generally have a low likelihood of impacts due to reservoir sedimentation.

On the other end of the spectrum, according to Basson and Rooseboom (1997) and Dendy et al. (1973), reservoirs with small storage/runoff ratios in relatively small catchments in semi-arid areas with high sediment yield ratios are highly vulnerable to reservoir sedimentation.

As far as indirect computations, the simplest method to determine reservoir storage loss and potential impacts at a given reservoir is to extrapolate storage loss or sediment yield rates from other nearby surveyed reservoirs in RESSED which are in similar hydrologic/geologic areas.

Next, a more detailed and process intensive way to estimate reservoir storage loss rates is the use of Geographic Information System (GIS) analyses. Several methods are listed, from least to most detailed:

1. Compute the regional rate of storage loss, for example by applying a regional regression equation. For example, extrapolate from other nearby reservoirs or by Hydrologic Unit Code (HUC). Another example is the 3W Model (Minear and Kondolf, 2009), which is a reservoir sedimentation prediction model that accounts for regional sediment yields, changing trap efficiencies over time in reservoirs, and the passing of sediment between a series of reservoirs.
2. Perform detailed watershed sediment yield estimates with GIS information. Several models/methods are available, such as the Watershed Erosion Prediction Project (WEPP) model (http://www.ars.usda.gov/News/docs.htm?docid=10621)

Additional Site Specific Data:

For a given site, once preliminary information is gained and there are potential sediment impacts that confirm the need for development of a sustainable sediment management plan, additional site-specific data should be collected. A reservoir survey should be performed if one was not recently collected. Next, a study should be performed of the composition of sediments that are flowing into and possibly out of the reservoir, and of sediments that may have already deposited in the reservoir. This study would include fluvial sediment sampling of the river above and below the reservoir, and in-situ sediment sampling of reservoir deposits.

In some cases, the presence of any contaminants above background concentrations will need to be determined prior to the implementation of any sediment management options. An inventory of upstream and downstream infrastructure in and near the reservoir which may be impacted by sediments and/or any changes to the reservoir and dam is necessary.

Depending on the availability of data, a more detailed hydrologic study may be necessary to better understand the timing and volume of inflows into the reservoir as part of developing any further sediment management options. In addition, data describing the operations of the reservoir is necessary.

Once preliminary information and rates of sedimentation are identified for a reservoir, the next step is to determine when sedimentation will impact key features.

Estimating Reservoir Life:
Once storage loss rates are calculated, various methods are available to determine the amount of time until reservoir sedimentation affects the design function of a reservoir. One traditional way is estimating the reservoir life, or the time until the usable storage pool completely fills with sediment, presumably followed by the abandonment of the structure (Garcia et al., 2008). However, sediment problems will arise well before the reservoir completely fills with sediment (Garcia et al, 2008) and reservoir life should not be viewed in such a manner. Some reservoirs experience problems with storage loss as little as 6% (Loehlein, 1999; Garcia et al.,2008). Reservoir sedimentation will become a serious problem when an important structure or key feature (e.g. outlet works, water intake, and boat marina) are buried, clogged, or abraded by sediments. An empirical method to estimate when sediment levels reach key features is to spatially estimate the sediment distribution in a reservoir based on methods from Reclamation (1982) and Reclamation (1962). Without direct measurement of sedimentation patterns, the spatial distribution of sediment may have high uncertainty.

According to Garcia et al. (2008), the "life" of a reservoir is better described based on the three distinct stages:

1. Continuous Sediment Trapping
2. Partial Sediment Balance
3. Full Sediment Balance

Most large reservoirs worldwide are operated in Stage 1, continuously trapping sediment. Only a few reservoirs worldwide have been designed to achieve Stage 3, which is the ultimate goal in formulating a sediment management plan for a reservoir. By achieving a Full Sediment Balance between upstream and downstream points of the reservoir, additional reservoir storage is no longer lost.

The time when sediment will reach key structures can be estimated by extrapolation from measurements, numerical modeling, or physical modeling. In addition, GIS analyses can be used to evaluate the complex bathymetry of reservoirs (e.g. Reclamation, 2012). Generally, analyzing profiles of repeat surveys, and estimating either the rate of delta progression for an upstream feature, such as a marina, or estimating the rate of bottomset delta growth near dam intakes are means to estimating when sediment problems will affect these particular facilities.

One useful way to determine the relative impact of the arrival of sediments to infrastructure at a dam is comparing the hydrologic size (Reservoir Capacity/Mean Annual Runoff), K_w, and the reservoir capacity to sediment inflow (Reservoir Capacity/Mean Annual Sediment Yield), K_t, of a particular facility to other facilities in an inventory.

Figure 1 presents this empirical diagram, derived from Basson and Rooseboom (1997), which is also a means to understand ways to manage reservoir sedimentation. The larger the hydrologic size (K_w) of the reservoir, the more important carry over storage into multiple years becomes for the facility. Data needs for this method are:

1. Total Reservoir Capacity
2. Mean Annual Sediment Yield
3. Mean Annual Runoff

In general, the farther a particular reservoir is toward the bottom left quadrant of Figure 1, the sooner that reservoir sediments will impact infrastructure located near the dam. For example, in Reclamation's inventory of dams, Black

Canyon, Guernsey, Paonia, and Lake Sumner are reservoirs near the bottom and left of the diagram. Currently, all these facilities pass measurable amounts of sediment through their respective outlet works facilities. The former Lake McMillan was nearly filled with sediment and replaced with the larger Brantley Dam, inundating the structure. An important feature to Figure 1 is that as time passes and reservoirs fill with sediment (decrease in storage), their plotting position moves toward the bottom left quadrant.

Figure 1 also presents three potential sediment management options: flushing, sluicing, and storage/dredging. The ranges of these preliminary options are taken from Basson and Rooseboom (1997), and are based on empirical data from Chinese and South African reservoirs. At the most bottom-left, flushing, is defined as drawing down the water level to re-entrain previously deposited sediments and to remove these sediments from the reservoir through bottom outlets. In the middle, sluicing, is defined as an operation technique whereby sediment-laden inflows are passed through the reservoir before the sediment particles can settle, thereby reducing the sediment trap efficiency of the reservoir, and maintaining reservoir storage capacity. The storage or "dredging" option is defined as inflowing sediment is stored in the reservoir and mechanical means are necessary to maintain or possibly regain storage, with the exception that the venting of turbid density currents is a possible sediment management option for reservoirs in this category. The majority of Reclamation reservoirs in RESSED fall into the "dredging" category. These potential sediment management options, along with several others, are presented in more detail in the following section.

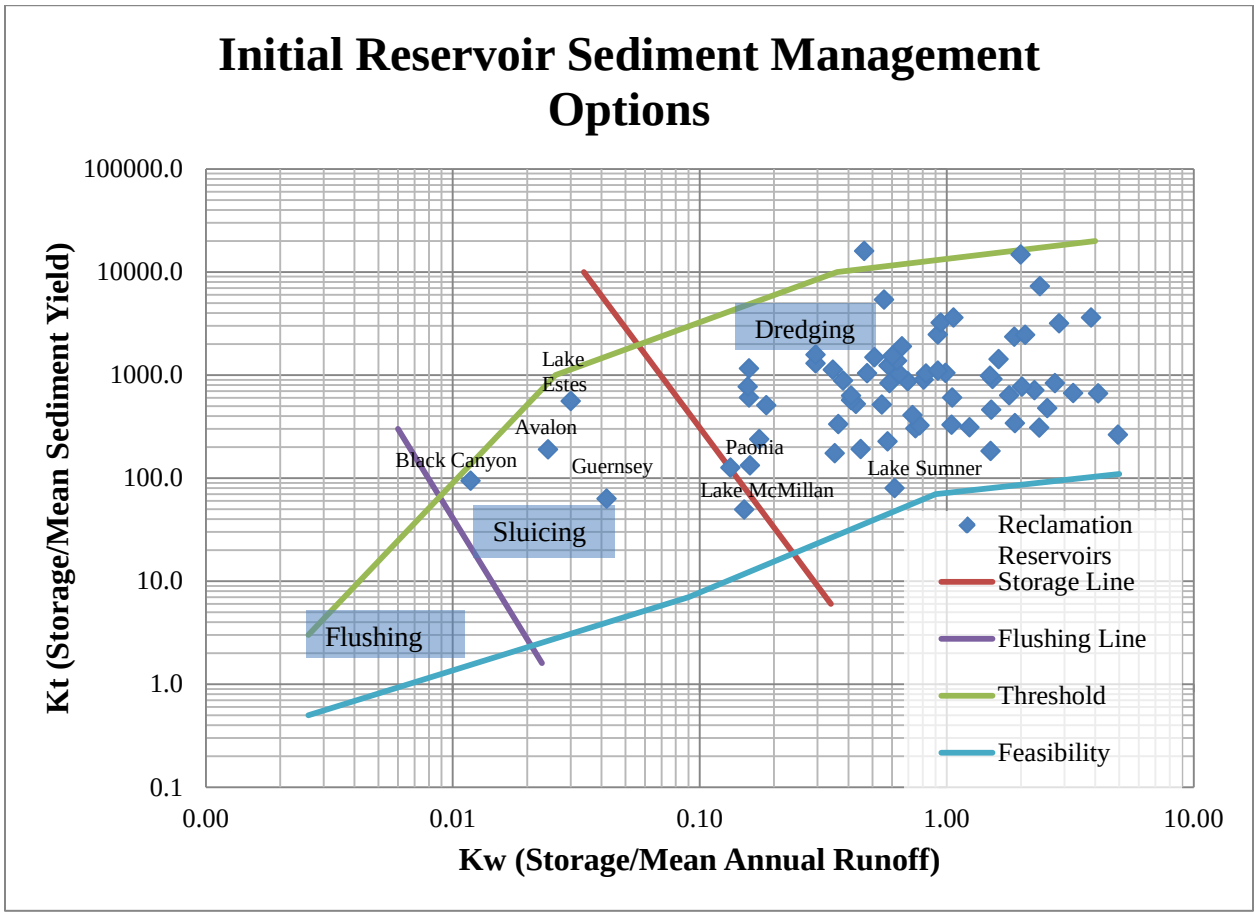

Figure 1. Diagram Adapted from Basson and Rooseboom (1997) for Determining Relative Reservoir Impact and Preliminary Reservoir Sediment Management Options

Necessity of a Sediment Management Plan:
Sediment management plans for achieving reservoir sustainability at Reclamation facilities are currently developed on a reactive basis for reservoirs which are already experiencing impacts from reservoir sedimentation. Currently, no programmatic-level allocation of resources is in place at Reclamation for proactive, comprehensive, sustainable sediment management of facilities. However, in addition to the SOS resolution promoting the development of sediment management plans, there is the push within other organizations at International (e.g. China and South Africa), Federal (e.g. U.S. Army Corps of Engineers), and State (e.g. California, Utah, Kansas, and Texas) levels that are in the process of systematically developing and implementing reservoir sustainability plans for reservoirs.

Whether sediment management planning of reservoirs is performed programmatically or at an ad-hoc basis, in the likeliest case of limited funding, prioritization is necessary to determine the reservoirs that may need to implement a sustainable sediment management plan.

Basson and Rooseboom (1997) provided general guidance for South African reservoirs relative to other reservoirs quantified using the index presented in Figure 1. According to their guidance, if the relative storage loss rate, K_t is less than 50, the reservoir sedimentation problem is considered serious, meaning sediment management actions need to be taken.

Comparing Reclamation's surveyed inventory, only the former Lake McMillan falls below a K_t value of 50. It is important to note that this inventory does not include any reservoirs which have not been surveyed. If the criterion were set to a value K_t less than 300, this would encompass most reservoirs with already known sediment issues, which are 13 of the 83 surveyed Reclamation reservoirs (16%) in RESSED. These facilities would have initial priority in following the guidelines developed in this document to formulate a sustainable sediment management plan. Other prioritization schemes to determine the necessity of a sediment management plan or dam decommissioning may involve the quantification of the time until sediments reach key features, and the quantification of the loss of benefits as a result of plugging, burial, and/or abrasion of pertinent features which provide benefits.

Eventually, all reservoirs need to be managed sustainably to provide benefits for future generations or decommissioned. The process is envisioned that a continued development of sustainable sediment management plans would occur for most Reclamation reservoirs that have inflowing sediments or a decommissioning plan would be put in place.

b. <u>Define Preliminary Sediment Management Options:</u>
With the development of relative reservoir impact and the unveiling of preliminary potential sediment management options presented in Figure 1, this section provides more detail of potential sustainable reservoir sediment management options/methods that have been applied to other reservoirs worldwide. All reservoir sediment management methods can be put into three different categories (Garcia et al, 2008; Kondolf et al, 2014):

1. Reduce Sediment Delivery (Watershed Management)
2. Prevent Sediment Deposition (Route Sediments through or around Storage)
3. Increase or Recover Volume (Removal of Deposited Sediments)

Figure 2 shows a variety of sediment management techniques placed into the three above categories by Kondolf et al. (2014). The exception within the three categories is raising a dam to increase storage, which does not fully deal with the management of incoming sediments, but extends the reservoir life by the creation of more storage.
There can be instances where a combination of methods from the above categories is necessary to maintain reservoir capacity and achieve reservoir sustainability.

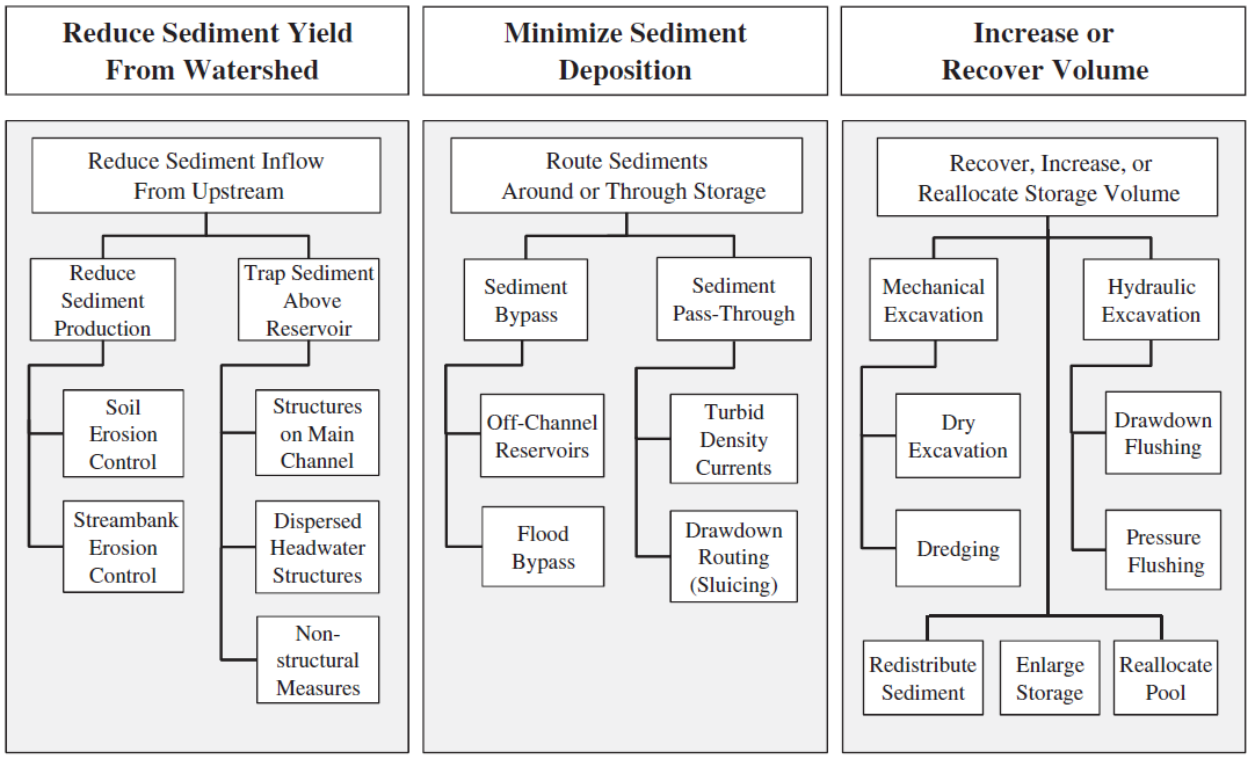

Figure 2. Diagram of Sediment Management Options for Reservoir Sustainability (taken from Kondolf et al. 2014)

The majority of sustainable sediment management options which are applicable to Reclamation's Mission are focused within the second and third categories presented in Figure 2. The first category, watershed management, is to reduce the amount of sediments entering there reservoir (thereby reducing sediment yield) would require involvement with other federal agencies, such as the U.S. Forest Service, Bureau of Land Management, State, County, and City resource managers, and private landowners.

Watershed management options include the control of land use practices; such as grazing, mining, logging, and land development. Other structural options include the development of land terracing, check dams, erosion control structures, and sediment basins in tributaries. A unique method is warping, which is the release of sediment laden flows on agricultural land to filter out sediments and return clearer flows back to the river.

The second category involves reducing sediment deposition of sediments flowing into a reservoir. This would either entail designing features to bypass sediment either through or around the reservoir. Included is the construction of bypass features in the reservoir, which may be an open channel, tunnel, or pipeline to divert sediment-laden flows from upstream end of the reservoir and discharge the flows downstream of the dam. Other means of reducing sediment deposition is to allow sediment-laden flows to pass-through the reservoir, either by allowing turbid density currents to pass through outlet works structures while the reservoir is full, or by drawing down the reservoir before the arrival of sediment-laden flows to keep flow velocities high enough through the reservoir and outlet works to pass sediment. Another option is this category includes the development of offstream reservoirs, where sediment-laden flows pass downstream, and clear water flows are diverted from the river to the reservoir.

The third category involves methods to remove deposited sediments. The first subcategory is hydraulic removal, where either the reservoir is drawn down, allowing flow velocities to increase near outlet works structures in order to erode previously deposited sediments (drawdown flushing), or by opening the outlet works gates and to not allow the reservoir to completely draw down, but rely on velocities near the structure to flush sediments through the gates (pressure flushing). The second subcategory is mechanical removal of sediments, which is by either dredging deposited sediments while storage remains near full in the reservoir or by dry excavation with construction equipment when the reservoir is drawn down.

Dredging is the most common sediment management method for reservoirs located in regions where carry over storage through multi-year droughts is paramount, and the reservoir cannot be drawn down. Dredging is typically more expensive than operational sediment management techniques (flushing or sluicing) to pass sediment downstream of the dam, and typically only occurs locally around structures due to the expense. Basson and Rooseboom (1997) noted that dredging is generally more expensive than creating new storage (e.g. dam raise), but that technology has narrowed the gap in cost. The most typical type of dredgers are cutter-suction and bucket-wheel types for reservoir depths less than 30 meters. If the reservoir is short enough in distance (e.g. less than 4km), a hydrosuction type of dredge is the most economical dredging option. Electric powered dredging is cheaper than diesel-powered when electricity is readily available nearby. The disposal cost of sediment is a major factor when estimating the cost of dredging as a sediment management option for reservoir sustainability. The dredging of reservoirs to maintain storage capacity is less expensive than dredging for navigation because the shape of the excavation area is not nearly as important and there is less movement and downtime with reservoir dredging.

Basson and Rooseboom (1997) and Morris and Fan (1998) both provide comprehensive information on the dredging of reservoirs for sediment management.

Timing of Methods:
Recovering decades of storage lost to sedimentation may be cost prohibitive. However, long-term dredging of the average annual sediment load may be economically viable, especially when compared to the long-term costs of no action and reservoir retirement.

The timing of reservoir sediment management methods is generally determined on a site-specific basis. For example, the method of sluicing requires drawdown of the reservoir before the arrival of the snowmelt or flood season in order to pass the initial sediment-laden flows and then capture the clear water flows at the end of the flood season for storage and use during drier periods of the year. Dredging may need to occur while the reservoir is or nearly at full pool for the dredger to access and remove deposited sediments. Nonetheless, dredging could occur at different locations depending on the reservoir level, where depths ranging from 30 to 50 feet are targeted. Over the longer term, sediment management methods may occur annually or periodically (e.g. biennial, decadal), depending on the rate of inflowing sediments and other site constraints.

c. Define Stakeholders and Constraints:

The majority of dams and reservoirs will have a unique combination of site specific constraints. Critical to the identification of site constraints is the involvement of all stakeholders that benefit or may be impacted by the implementation of sediment management methods for reservoir sustainability. The determination of unique and potentially conflicting requirements on a given reservoir or set of reservoirs is necessary prior to further development and implementation of any reservoir sediment management methods within a plan. The general types of constraints to identify as part of developing a sustainable reservoir sediment management plan are:

a. Physical Constraints
    a. Dam Height
    b. Storage Volume
    c. Reservoir Length and Width
    d. Hydrology
    e. Geology
    f. Spatial sediment distribution
    g. Sediment grain size
b. Operational Constraints
    a. Allocation of Use
    b. Carryover Storage
c. Economic Constraints
    a. Loss of Revenue
    b. Reduction of Benefits

c. Costs of retirement under the no action alternative

d. Environmental Constraints
   i. Downstream Impacts
      1. Infrastructure
      2. Water Quality
      3. Reversal of channel degradation
      4. Permitting
      5. Other reservoirs
   ii. Upstream Impacts
      1. Reversal of channel aggradation
   iii. Contaminants

e. Other Constraints

In most cases, the implementation of a reservoir sustainability plan will cause a reduction in benefits in the short-term, with the tradeoff that the reduced benefits will be available on a sustainable basis. Some stakeholders will potentially lose some short term benefits in order to sustainably manage a reservoir. Ultimately, however, all benefits would be lost to all stakeholders if the reservoir fills with sediment and the dam must be decommissioned at great expense to future generations.

d. <u>Assess Feasibility and Economic Viability of Options:</u>

The economics, or in other words, the associated costs relative to the associated benefits over the life of the reservoir, ultimately drive whether to finance sediment management methods to manage a reservoir sustainably. Traditional design and economic analyses do not appropriately take into account the long-term costs or benefits to achieve reservoir sustainability (Garcia et al., 2008). The long-term loss of benefits for agricultural, municipal, industrial, recreational, and other uses due to the loss in reservoir storage due to reservoir sedimentation must be accounted for in comparison to the long-term costs of maintaining the associated benefits the facility provides, in addition to the cost of decommissioning the dam or the creation of additional storage once reservoir sedimentation problems have become too severe.

The goal of making a resource, in this case the water storage a reservoir provides, sustainable or renewable requires a change from the traditional economic concept of time discounting a reservoir's value, which ignores the potential loss of benefits to future generations. A life cycle approach must be developed, where either the reservoir is managed as an exhaustible resource with a sinking fund to pay for the decommissioning of the dam and the development of new storage, or to manage the resource sustainably, such as using the RESCON (REServoir CONServation) approach (Palmieri et al, 2003).

As best stated in Garcia et al. (2008), the RESCON methodology proceeds in three stages:

1. Determine which methods of sediment management are technically feasible;
2. Determine which alternatives are more desirable based on an economic analysis;
3. Incorporate environmental and social factors to select the best course of action for sediment management.

The RESCON approach is applicable to proposed or existing dams and reservoirs to develop a preliminary assessment of sustainable sediment management alternatives, and to compare the alternatives to the alternative of allowing the reservoir to fill up with sediment and the ensuing course of dam decommissioning (Garcia et al., 2008). The RESCON approach accounts for major benefits and costs over the complete project life-cycle and, in particular, acknowledges the concept of *intergenerational equity*, which is the concept of taking into account the economic, social, and environmental cost and benefits of all future generations. Making a reservoir a sustainable, rather than an exhaustible resource, promotes intergenerational equity (Annandale, 2013). Additional information regarding the performance of the RESCON approach as part of determining sustainable sediment management options for a reservoir can be referenced in Palmieri et al (2003).

Environmental Considerations:
In order to achieve reservoir sustainability, a change in the operation and maintenance of the reservoir may be required. It is then necessary to consider the environmental consequences, and to minimize any impacts that are potentially detrimental. For example, some sediment management methods require the passing of sediments downstream of the reservoir. The release of high sediment concentrations from a reservoir can pose serious impacts to downstream aquatic environments, infrastructure, and recreation (Utah Division of Water Resources, 2010). However, high sediment concentrations could be of benefit to fisheries and geomorphic features reliant on higher sediment concentrations (e.g. cover and sandbar development), such as the case in many Southwestern United States Rivers (e.g. Colorado River in the Grand Canyon). Federal laws and agencies are in place to enforce the law of the land where, in the case of the United States, relatively strict water quality standards are in place to protect environmental resources. Determination of water quality impacts from reservoir sediments and any potential contaminants must be analyzed to minimize adverse environmental impacts and to comply with various laws, such as the National Environmental Protection Act, Clean Water Act, and the Endangered Species Act (Utah Division of Water Resources, 2010). Sources providing more information on sediment impacts and regulatory requirements include Sedimentation Engineering (Garcia et al., 2008) and Managing Sediment in Utah's Reservoirs (Utah Division of Water Resources, 2010).

e. Develop and Implement a Sediment Management Plan:

Based on the potential feasible sustainable sediment management methods that are determined in combination with the RESCON approach, water quality requirements, and any other unique site-specific constraints, a detailed consensus-based reservoir sustainability plan can be developed and implemented for the reservoir. The reservoir sustainability plan itself would detail any changes involving the dam and reservoir, which would include a combination of a monitoring plan of incoming, depositing, and passing sediments, the change in operational and maintenance procedures, the design and construction of new infrastructure to pass sediments, a periodic dredging plan, agreements of funding, and coordination with other stakeholders public and private.

f. Monitor and Revise Plan if Necessary:

As with the management of any resource, continued monitoring of reservoir sediments is necessary to track whether the implemented sediment management options are performing as predicted or not. If a particular sediment management method is not sustainably maintaining the storage of a reservoir, the plan may need to be revised to meet the criteria of sustainability. This revision of the plan may require one or more of the previous steps outlined in this document.

CONCLUSION AND SUMMARY

This technical paper details the general steps and guidance that could be followed in developing a reservoir sustainability plan (Reclamation, 2015). The dam owner and investigator(s) should not only follow these general guidelines, but should refer to other guidelines and case studies that are widely available and referenced throughout this document, such as Utah Division of Water Resources (2010), Garcia et al. (2008), Morris and Fan (1998), and Basson and Rooseboom (1997). Development of reservoir sustainability plans for reservoirs will be no less site-specific and unique as the site conditions and operations that each dam and reservoir inherently encompasses. The reservoir sustainability guidelines outlined in this document are:

a. Determine the magnitude of the sediment problem
b. Define preliminary sediment management options
c. Define stakeholders and constraints
d. Assess feasibility and economic viability of options
e. Develop and implement a sediment management plan
f. Monitor and revise plan if necessary

Findings from the research in Reclamation (2015), pertinent to Reclamation's inventory of dams and reservoirs, recommends the development of additional Geographic Information System (GIS) data that includes the storage capacity, drainage area, mean annual inflow, and mean annual sediment yield for all Reclamation reservoirs. This data would be valuable in further determining the relative impact of reservoir sedimentation in all Reclamation reservoirs, short of a comprehensive reservoir survey program for all Reclamation reservoirs. Additional reservoir sedimentation distribution tools can be refined and developed to estimate the spatial and temporal impacts of reservoir sedimentation to important features. Other prioritization schemes to determine the necessity of a sediment management plan or dam decommissioning may be necessary. These decision-making schemes may involve the quantification of the time until sediments reach key features, and the quantification of the loss of benefits as a result of plugging, burial, and/or abrasion of pertinent features which provide benefits.

AN INVENTORY OF SEDIMENTATION IN HAWAII'S RESERVOIRS USING MIXED METHODS

Kim Falinski, Research Assistant, University of Hawaii at Manoa, Water Resources Research Center, Honolulu, HI 96822, falinski@hawaii.edu; David Penn, Project Coordinator, Pacific Cooperative Studies Unit, University of Hawaii at Manoa, Honolulu HI 96822, dpenn@hawaii.edu

Abstract: Hawaii's reservoirs face increasing scrutiny due to heightened dam safety and flood control concerns, growing water demands, and uncertain water pollution effects. In order to promote long term reservoir sustainability, it is vital that we improve our understanding of reservoir capacity loss due to sedimentation. We collected, organized, and analyzed existing physical data about reservoirs located on the main Hawaiian Islands, and interviewed reservoir managers throughout the state about storage capacity and sedimentation processes. Results showed that although sedimentation of Hawaii's reservoirs is rarely measured and poorly documented, it is a serious concern and the accurate measurement of reservoir sedimentation is a challenge for proper reservoir management. We grouped reservoirs into five different management types —federal, state, county, private agriculture and private development – and found that management practices and reservoir maintenance differed significantly between these groups. Sedimentation, in some cases, was significant enough to lead to dry reservoirs conditions. However, unlike in other parts of the world where reservoir sedimentation can be directly correlated with watershed erosion practices, most reservoirs in Hawaii are off-stream impoundments, fed by stream diversions and irrigation systems that are far from the watersheds above the reservoir. Existing engineering surveys focus on the structural integrity and safety of dams, few surveys address capacity loss. We suggest that the use of dual-frequency bathymetric surveying equipment would provide accurate assessments of reservoir depths, and recommend a cooperative effort to systematically conduct statewide surveys. Reservoirs in Hawaii are a significant resource for adaptive and sustainable water supply, conservation, and flood control, and as such the maintenance, including assessment and removal of sediments, is an important consideration for water use and development on each island.

INTRODUCTION

Worldwide, sedimentation is a leading causes of reduced capacity in small reservoirs (Wang and Hu, 2009). Global water use is rising with population and development, while long-term water availability is declining, posing challenges for resource managers. Water needs and constraints in Hawaii follow this pattern (Water Resources Associates, 2003; Bassiouni and Oki, 2013). With a rapidly growing population, increasing development, and the forecasted establishment of a diversified agricultural sector, Hawaiian resource planners and managers must carefully consider how to meet growing water demand while balancing human welfare, economic impact, and ecological sustainability. Reduced reservoir storage capacity has real economic costs, including less available water, higher maintenance costs (i.e. dredging), greater risk of dam breach, less capacity to reduce flooding and capture sediments, and lower potential for electricity generation (Hawaii Department of Agriculture, 2010; Randle et al., 2013).

In addition to providing water capacity, small reservoirs are also effective sediment retention basins that positively impact downstream water quality (Liu et al., 2014). Small reservoirs also increase water availability and reduce the peak flow of storm runoff (Deitch et al., 2013). Aquatic ecosystems can benefit from small dams that reduce the amount of sediment and nutrients carried in surface runoff (Verstraeten and Prosser, 2008). The ability to retain sediment is especially important for Hawaii where very small watersheds (often < 20 km^2) are directly connected to coastal waters that are highly valued for their coral reef systems and recreation use capacity. Sedimentation on the reef is considered to be a primarily driver of the ecosystem's decline in Hawaii (Jokiel et al., 2014).

Reservoir sedimentation data is used widely to better understand the relative contribution of watershed characteristics to sediment and nutrient export (Verstraeten et al., 2003). Modeling approaches that calculate annual sediment yield based on land use, such as InVEST and N-SPECT, are limited by a lack of validation data. For Pacific high islands such as Hawaii and Guam, the particular watershed physical characteristics and land use and management actions that dominate sediment export remain unclear (Nakama, 1992; Hoover and Mackenzie, 2009; Storlazzi et al., 2009). Additional sediment export data would help to calibrate and validate sediment export models for developing watershed-scale conclusions. Reservoir accumulation provides data that integrates physical and human processes over longer periods of time than most in-situ sampling efforts can achieve.

Regardless of whether reservoir sedimentation data are used to describe changes in water storage capacity or to better understand watershed processes that contribute to sediment export, an understanding of reservoir sedimentation processes is critical to surface water management (Angulo et al., 2011; Ignatius and Jones, 2014). The United States Geological Survey (USGS) maintains nation-wide information about reservoir sedimentation for the Reservoir Sedimentation Database (RESSED, http://water.usgs.gov/osw/ressed/). However, the RESSED database currently does not currently contain any records for Hawaii reservoirs.

Therefore, the objectives of our research were to (1) analyze existing Hawaii reservoir data for trends that could be related to reservoir sedimentation, and to (2) conduct semi-structured interviews with the reservoir managers and owners to augment and explain archival information and available reservoir records.

BACKGROUND

The Hawaiian island chain, located in the north central Pacific Ocean, has a total land area of 16,636 km^2. The formation of the volcanic islands created high, steep, rain-catching ridges and dikes that confine freshwater in basal and high level aquifers. The islands have few natural freshwater lakes, 376 perennial streams (providing more than half the irrigation water statewide), and nearly all water for domestic and industrial use is obtained from groundwater supplies (Tribble, 2008). Flashy streams in short watersheds prevent streams from storing sediment in floodplains. Streams supply more than 50% of irrigation water in Hawaii, which is often stored in reservoirs (Oki, 2003).

The sugar industry was a major driver of Hawaii's economy from the mid-1800s until the mid-1900s. The first successful sugarcane plantation began on Kauai in 1835. As the forests were cut down to create more land for sugar, records indicate that the amount of rainfall decreased, as well (MacLennan, 2007). Ambitious irrigation ditch systems were created to bring water from higher elevations to the plantations, and reservoirs were used to store that water. The major irrigation systems include the Pioneer Mill irrigation system in west Maui, the Waimea irrigation system on Hawaii Island, and the East Kauai irrigation system in Kauai (Wilcox, 1996). The sugar industry began to falter in the 1930s, and continued to decline into the 1940s and 1950s, when pineapple rose in prominence as a cash crop. Pineapple was farmed commercially in the islands until the late 1990s to early 2000s, when industrial farms stopped production. Land use changes (urbanization) in the last century led to decreases in overall water demand but increases in potable water demand. Climate change impacts may create conditions that are drier in some areas, and wetter in others, that could change vegetation patterns and the frequency and intensity of large storm events leading to more erosion into reservoirs (Timm and Diaz, 2009).

Agriculture in many parts of the islands depends on a steady irrigation supply, yet Hawaii's 140 largest reservoirs that store water for irrigation are currently being breached and decommissioned at a rapid rate. This is due to a variety of factors, including (1) tighter dam safety regulations that took effect following the 2006 Kaloko dam break, (2) the risk of structural instability due to age, construction, and deferred maintenance, (3) the loss of storage and operational capacity caused by sedimentation, debris accumulation, and clogging of inlet and outlet structures; and (4) the lack of paying customers for reservoir-based water service. Figure 1 shows the location, size and use type for DLNR-regulated reservoirs in Hawaii. Reservoir water use was valued at $436 million by the US Department of Agriculture in 2003. The Hawaii Dam Safety Act, which determined that the landowner was responsible for the maintenance of reservoirs on their land, was passed in 1987. On March 16, 2006, the Kaloko reservoir on northeastern Kauai broke during heavy rains, killing seven people (Godbey, 2007). The Dam Safety Act was updated in 2007 to more closely supervise the safety of the remaining reservoirs (Hawaii State Legislature, 2007).

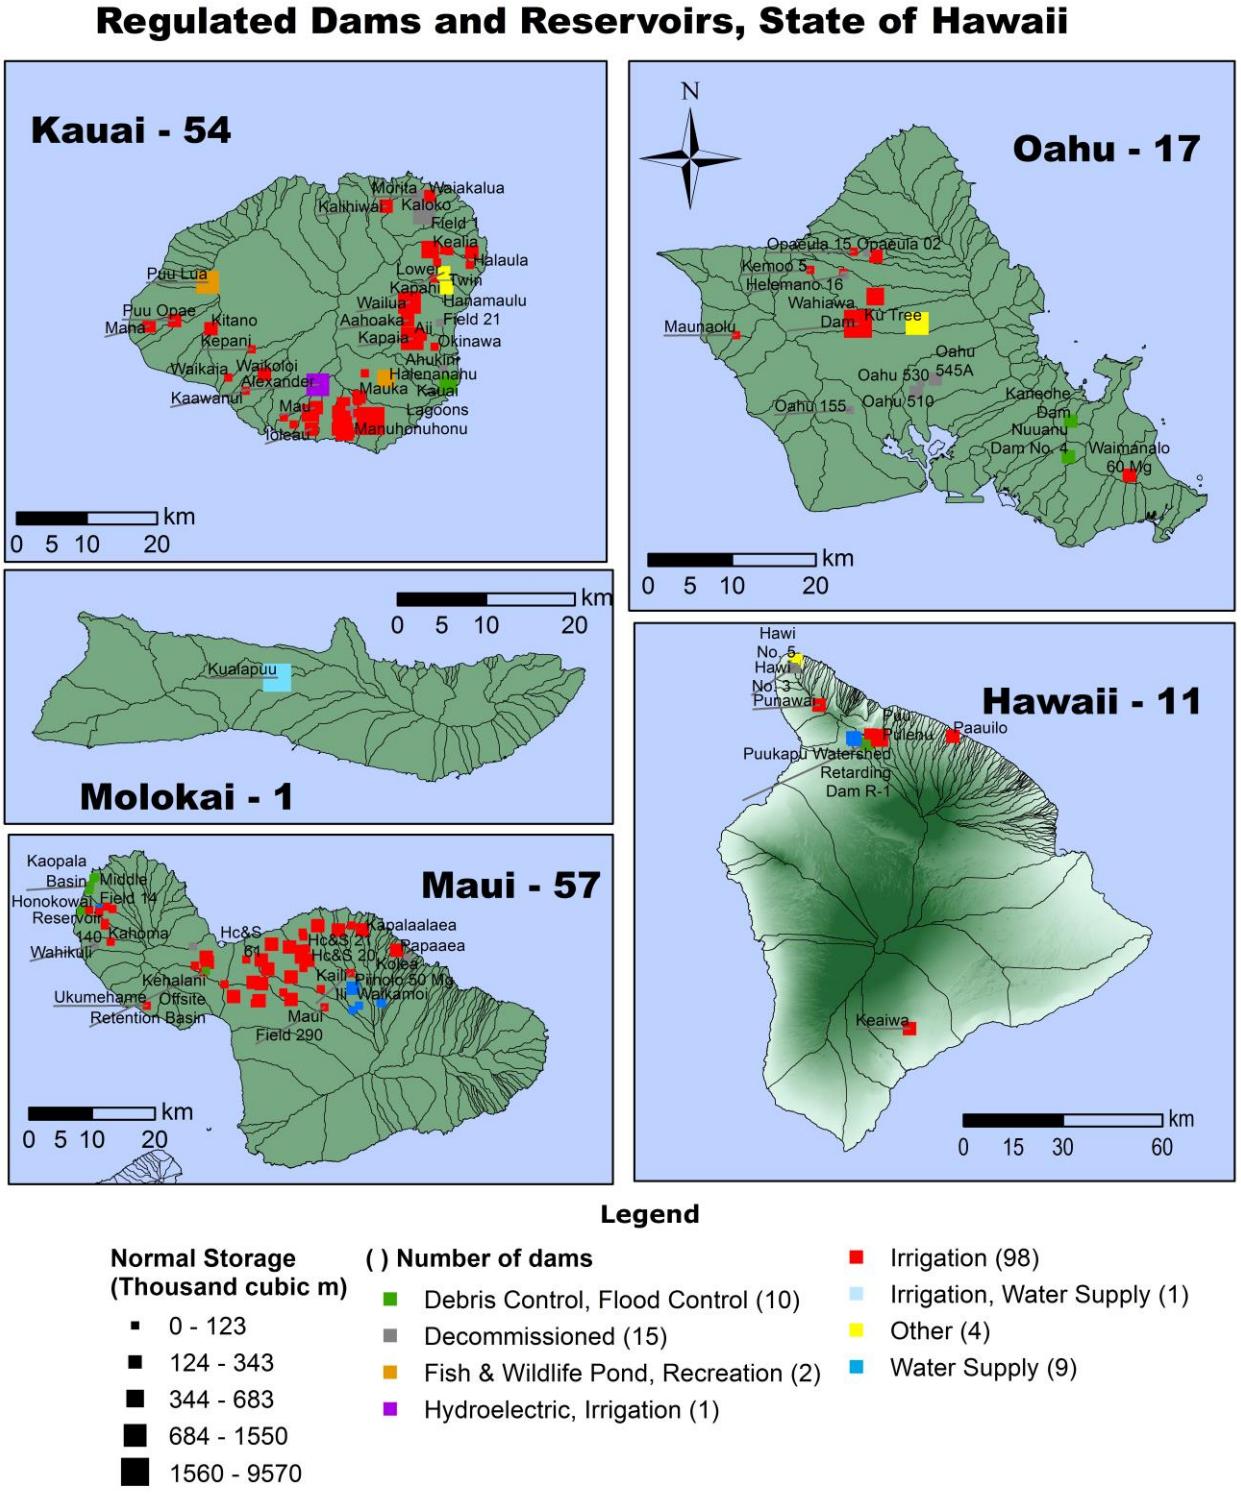

Figure 1 Reservoirs classified by use type. The total number of reservoirs in the Hawaii Dam Safety database (as of March 2013) is listed next to the island name. Some reservoirs have since been decommissioned. GIS data made available from the State of Hawaii Office of Planning, the Coastal Geology group at University of Hawaii at Manoa and the Department of Land and Natural Resource Dam Safety program.

METHODOLOGY

Data Acquisition

We obtained permission from the U.S. Army Corps of Engineers to access the National Inventory of Dams (NID) via its secure online portal. At an initial meeting with the staff of the State of Hawaii Dam Safety Program (HDSP), we obtained similar permission to access the HDSP inventory. The NID and HDSP contain about the size, capacity, spillway characteristics, year built, and ownership of most of the 140 regulated reservoirs in Hawaii. Management types in the databases were further classified by owner into five categories: Federal, State, Local, Private-Agriculture and Private-Development (defined as private owners who manage three reservoirs or less by a single private owner).

With the federal and state inventories as our foundation, we conducted literature searches and gathered references that document reservoir-specific physical characteristics (e.g., geotechnical investigations, dam safety inspections, emergency action plans, and environmental assessments). We collected the HDSP reports to the legislature from 2007 to 2015 describing changes in the dam status (Dam and Reservoir Safety Program, 2011) and private reports on selected reservoirs, obtained with the permission of reservoir owners and the cooperation of reservoir authors. Additionally, we used remote sensing products including 2011 World View 2 (1m resolution) to determine whether a reservoir was being maintained dry or not dry, and compared these results to other sources.

To house this information, we created a database in Microsoft Access that mimics the structure of the national RESSED database for data input, and combined and cross-checked the data from both the NID and HDSP databases with the RESSED fields. Lastly, we added fields that are not part of the official RESSED structure, yet allow for more detailed analysis of the dataset, including operational water level, excavation history, and level of sedimentation.

Interviews with Reservoir Owners

Using the HDSP inventory, we contacted the 42 dam owners and operators, covering the 140 reservoirs in the HDSP inventory, to participate in our project. The survey instrument used in the follow-up phone and on-site interviews is presented in Table 1. The survey was designed to locate and acquire existing information, and to provide a semi-structured opportunity for reservoir managers to describe possible problems related to sediment accretion and mitigation efforts. After the interview was conducted, we summarized open-ended responses into themes (Wengraf, 2001). Interviewees are not identified by name in this report, and information provided about specific reservoirs was acquired through public records.

Table 1. Survey instrument for Hawaii's regulated reservoir owners and managers.

	Question	Answer format
1	When was the last time your reservoir(s) was (have been) surveyed/measured?	Year
2	Original plans available?	Yes/no
3	As-built drawings available?	Yes/no
4	How many times has it been surveyed?	Number
4a	Who did the survey?	Name
4b	What method?	Acoustic, bathymetric survey, sediment sampling,
4c	How much did it cost?	Number
5	Why did you do it?	Open
6	What will you do with the results?	Open
7	Are you willing to share those results with us?	Yes/no
8	What is your level of interest in conducting new surveys/measurements in order to find out how much the reservoir has filled in with sediment? (1–5)	Scale (1–5)
9	Is sedimentation a significant issue in the reservoirs you manage?	Open
10	What mitigation efforts have you used to prevent additional sediment?	Open

	build-up?	
11	What are your incentives for continuing to use/maintain the reservoir?	Open
12	Would you like to continue to talk with us and help us gather more information on reservoir sedimentation in Hawaii?	Yes/No

Between April and August 2013 we visited publicly and privately owned reservoirs on the islands of Oahu, Maui, and Hawaii, and gathered other information through email and phone calls. The primary purpose of the site visits was to visually survey and assess the extent of reservoir sedimentation and to gather otherwise unavailable copies of documents describing sedimentation. Through extensive collaboration with the Hawaii Department of Agriculture we obtained particularly significant information about a number of reservoirs.

RESULTS

Although there were 140 regulated reservoirs in the state of Hawaii as of 2013, only one is documented sufficiently to populate the record fields required by the national RESSED database: Kaneohe reservoir, Oahu (see Wong (2001)). Of the 25 regulated dams removed statewide since the program began, most of the removals were initiated after the 2006 Kaloko dam disaster and the 2007 regulatory response (11 on Oahu, 3 on Maui, 5 on Hawaii and 4 on Kauai). Seven reservoirs that were local or state owned had partial information that could be provided to the RESSED database, including Nuuanu Dam and Kalihiwai Reservoir (Aqua Technex, 2009) have bathymetric surveys. We identified recent engineering studies for 34 reservoirs that were conducted for dam safety compliance purposes, many involving dam breach, removal or undersizing. Our research indicated that each reservoir has a unique history of maintenance, sediment build-up and water use, and that to acquire sedimentation data for specific reservoirs requires a detailed, recorded history of how it was managed and operated in the past. Evidence is mostly anecdotal, and the types of documents typically did not include formal sedimentation surveys. The most complete datasets are associated with public works reservoirs and reservoirs owned by large corporations. During this investigation, we found that many irrigation systems are spatially disconnected from the watersheds that provide the system water.

Data Analysis of Reservoirs in Hawaii

Hawaii's reservoirs have the capacity to store 44.6 million cubic meters (11,800 Mgal) of water at normal levels, with the majority of the capacity (43%) located on Kauai (Table 1). Statewide, most reservoirs are used for irrigation purposes (80%), as seen in Table 2, and only 10 reservoirs are purposed for municipal water supply. Categorical analysis made some calculations difficult, especially when reservoirs were listed with multiple uses (this occurred in 26 out of 140 dams). An example is Alexander reservoir in Kauai, used for both hydroelectric power generation and for irrigation. Multiple uses of reservoir water allow for multiple benefits to the hydrologic systems.

Table 1 Storage capacity by island.

	Normal Storage (thousand m^3)	Maximum Storage (thousand m^3)	Percent of total capacity
Hawaii	1532	3681	3%
Kauai	19184	33872	43%
Maui	5362	8349	12%
Molokai	5261	6269	12%
Oahu	13325	25655	30%
Total	44665	77825	57

Compared to other worldwide locations where significant information for watershed sedimentation processes are collected from sediment deposition rates, 80% of the reservoirs used for irrigation in Hawaii often have water delivered far from the reservoir, or only a portion of the stream is used to supply the reservoir. These off-stream, and sometimes off-ditch reservoirs do not offer enough information to be able to discern larger watershed processes, but are still relevant to understanding the loss of capacity due to sedimentation.

Only Kualapu'u reservoir on Molokai is used for both irrigation and water supply, and its normal operating level is kept close to capacity. In general, we found that the reservoirs were only kept close to capacity when used for water supply (80% of max) or for fish and wildlife ponds (97% of max) (Table 2). The operating level for irrigation reservoirs, which represent 80% of all reservoir use averages at 67% capacity. The one hydroelectric dam that is currently regulated in Hawaii operates at 42% maximum storage capacity. However, conversations with the owner indicate that sediments are problematic and contribute to reduced storage level. Although 64% of the reservoirs are considered small in size, 74% of the capacity is provided by intermediate sized reservoirs (n = 49)[1].

Table 2 Data for reservoirs use type across the Hawaiian Islands.

Reservoir Type	Normal Storage (thousand m^3)	Max Storage (thousand m^3)	Number of Reservoirs	Percent of Total	Percent Capacity	High or Proposed High (%)+
Debris control	191	773	5	4	25	100
Flood control	1298	13791	11	8	9	91
Fish and wildlife pond	1771	1826	3	2	97	67
Recreation	2456	12184	7	5	20	100
Hydroelectric	1320	3133	1	1	42	100
Irrigation	38957	58164	112	80	67	88
Water supply	6297	7876	10	7	80	80
Other	4188	5653	17	12	74	82

+ Hazard classification refers to the design of the dam spillway relative to the probable maximum inflow flood

The majority (by number) (70%) are reservoirs are owned in part by private owners, including large farms (56%) and a diverse array of owners, including small farms, housing developments and recreation and tourism facilities (14%) (Figure 2). The Private-Development group is more likely to be using the reservoirs for development or other urban reservoir uses, including for aesthetic reasons. Unlike the private and agriculture owners, smaller private owners are less likely to have the resources to repair or excavate reservoirs.

[1] The National Inventory of Dams specifies small reservoirs as less than 1,000 ac-ft (1,233,481 m^3) and greater than 50 ac-ft (61,674 m^3); intermediate reservoirs are between 1,000 ac-ft (1,233,481 m^3) and 50,000 ac-ft, (61,674,092 m^3) and large reservoirs are greater than 50,000 ac-ft. Academic literature generally considers small reservoirs to be less than 100,000 m^3.

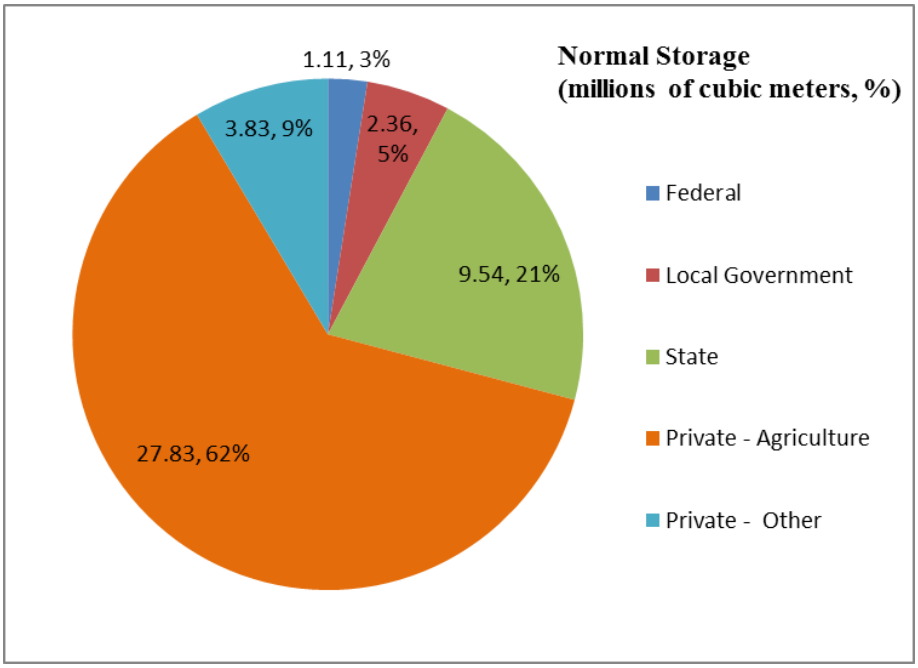

Figure 2: Storage capacity of Hawaii's reservoir by management type

Figure 3 presents the cumulative age of reservoirs for the four counties of Hawaii. Many of Hawaii's reservoirs are approaching 100 years old. The rate of reservoir building slowed considerably after 1920, and no new reservoirs were built before and after World War II (1935-1951), or between 1958 and 1965. With the exception of Kualapu'u on Molokai, finished in 1969, reservoir size too declined over time, by about 4800 m^3 per year, on average. Kualapu'u, as a large reservoir, was created during the water engineering boom post-1950 that was seen nationwide. The results are more striking if you consider the many reservoirs that were built and decommissioned from use before the Hawaii Dam Safety Program was established in 1987, known today only through archival records.

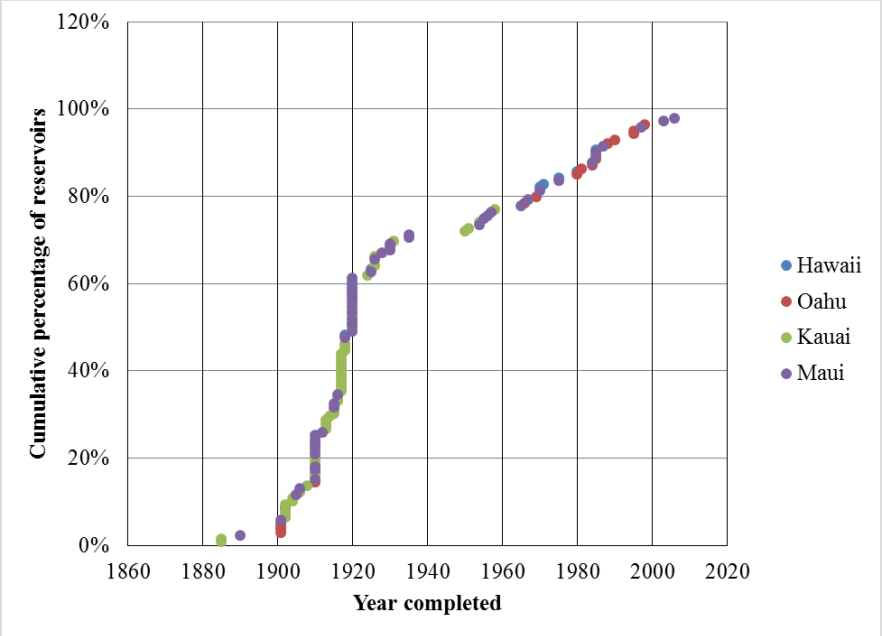

Figure 3. Age distribution of reservoirs by county, State of of Hawaii. Note that nearly 60% of the reservoirs were completed by 1920. The most recent dams have been constructed for flood prevention and sediment retention.

Interviews with Reservoir Owners

Table 3 indicates that most reservoir managers have experienced some level of sedimentation issue with their reservoir, and that others have developed methods to mitigate the effects of sediment build-up.

Table 3 Summary of survey responses by owner type.

	Federal	State	Local Government	Private-Agriculture	Private-Other	Total
Number of owners	1	4	6	9	15	35
Number responded to survey	1	3	3	5	10	22
Mean interest level (1-5)	5	4	5	5	3.4	

Interviews and field visits suggest that sedimentation is not the primary issue for compliance with safety regulations; dams are vulnerable to aging infrastructure. As a result of the new regulations after the Kaloko reservoir breach, many owners are shifting towards decommissioning their reservoirs. Historically, Private-Agriculture reservoirs were maintained through public-private partnerships, but lack of finances and demand combined with a more robust dam safety regulatory structure led to their disuse. Individuals, trusts, and smaller business associations that generally managed only one or two reservoirs (private/other) are facing greater struggles to understand and comply with the new dam safety regulations, and some have made significant investments in engineering studies to substantiate their position with dam safety regulators (see for instance Kalihiwai homeowners, County of Honolulu Board of Water Supply).

Notably, many former and current large agricultural land owners with multiple reservoirs employed a single point person to manage all the reservoirs. These managers made few written records available, but shared their institutional knowledge and expertise. Larger agriculture owners acknowledged sedimentation as a fact of life, actively used reservoirs as detention basins, and implemented schedules for dredging accumulated sediments. It appears that this group may be an important source of formal records, and represents some of the most useful sites for field surveys of sedimentation rates.

Another theme that emerged from the conversations was that there are at least 300–400 unregulated dams with no reporting requirements that would otherwise provide information to facilitate the achievement of watershed research objectives. Not surprisingly, there is a trend towards taking a regulated reservoir and converting it to a smaller non-regulated reservoir. Increasingly, watershed management plans are suggesting that smaller dams (often smaller than the regulated limit), including gabion dams, be used as retention basins to mitigate sedimentation into coastal waters (for instance, the Ala Wai Watershed Management Plan (2013) and the Lanai Community Plan (2014)). The longevity of these structures and their ability to withstand flood events remains unclear.

Many of the interviewees perceived that there is an ideal method for removing sediment from a reservoir. Current practice is to drain the reservoir, which may take several weeks, and then manually remove sediment using backhoes and other mechanical equipment. If the reservoir was not originally designed to allow access for these types of vehicles, then the sediment must be removed manually. This was done recently at Waikoloa Reservoir No. 2 on Hawaii Island, which suffered earthquake damage in 2006. Private agricultural companies have the heavy earth moving and forming equipment available, and can also divert water to allow the reservoir to be dredged. The dredge spoils can be then placed on land. If the landowner does not have a use for the excavated sediment, transport and disposal pose additional challenges. Material including sediment-sorbed contaminants may prevent movement of the sediments to other properties or landfills.

Reservoirs that are operated and maintained for public water use consider sediment in their maintenance costs. For instance at the Waikoloa reservoirs, sediments are removed through flocculation processes (requiring flocculant additives), and the water is treated in sedimentation basins. The sediments must periodically be dredged and treated per Department of Health requirements.

The interviews and government document research found that many owners and operators conduct new investigations to support dam removal and compliance with newly revised dam safety regulations. These investigations (often by consulting companies) typically do not include measurement of reservoir bathymetry and determination of base elevation and changes in bed elevation over time, thereby neglecting possible capacity loss to sedimentation. Investigations consist primarily performing of structural analyses and presenting recommendations for maintaining the reservoir in a safe condition.

Interviewees suggested that while the sugarcane plantations frequently dredged out small reservoirs to retain full capacity, large reservoirs were not usually dredged unless sediment and debris blocked the reservoir inlets. In most case, sedimentation is not the only limitation to water capacity. Most of the aging reservoirs require the installation of new-HDPE style liners (or equivalent) to prevent seepage, as well as vegetation removal and structural improvements for earthen embankments that have degraded over time. Maintenance of dilapidated spillway, pump systems and removing vegetation are the primary modifications that need permits.

Another theme that emerged from the interviews, specifically with larger agricultural managers, was the use of reservoirs (both regulated and non-regulated) for fire mitigation. . It is estimated that 0.5% of the total state land area burns each year (Hawaii Wildfire Management Organization 2014), and fire is recognized as a major threat to native species in remaining forest lands (Conry, 2010). Interviewees, especially managers of agricultural lands that had gone fallow, indicated that reservoirs were often used by local and state agencies to combat wildfire. Previously, plantation and ranch personnel served as fire wardens, but changing land use practices reduced the amount of people willing and knowledgeable to serve in this role. In combination with the reduction of reservoirs operating at capacity, reduced capacity from sedimentation presents a significant threat.

Erosion of irrigation channels is a concern that is separate from normally modeled hillslope processes, yet one that was mentioned by participants. The ditch system that once fed reservoirs today diverts water directly into streams, including Honokowai and Wahikuli Streams on Maui (Department of Land and Natural Resources, 2011) and streams in the Upper Kapaa region on Kauai. In other subtropical islands, many off-stream reservoirs that are fed by irrigation ditches, sedimentation is not a significant issue (Morris, 2010). Others, such as the Lower Hamakua ditch, reported an approximate one-foot depth of sediment build-up when it was refurbished in 2004. For the Maunawili ditch system on Oahu leading to Waimanalo Reservoir, interviews revealed that hired workers manually clean the ditches of silt and debris on a daily basis. Because many of the reservoirs are off-stream, they are often disconnected from the watershed-scale hydrologic processes. Sedimentation in the reservoir is still evident, although minimal, from the degradation of the channel leading into the reservoir.

Many reservoir managers (n=14) reported that the use of their reservoirs changed over time. For some managers, reducing the size of the reservoir below the regulatory limit was a solution more amenable than creating a new reservoir or maintaining the old reservoir at regulatory size. Other managers maintain their reservoir in a dry state, yet keep the reservoir in the system for possible future use or until it can be breached (for example, Manuhonuhonu reservoir, Kauai). Private-Development managers consider the reservoir that is now amongst homes and golf courses as an aesthetic asset, and the homeowners association or builder adopts the responsibility of maintaining the reservoir and the safety documents (for example, Kauai Lagoons, Kauai). These reservoirs are often still considered for irrigation use, flood control or other use in the database, but are providing a new ecosystem service to residents within their viewshed.

Two reservoirs on Oahu are notable for providing different uses than originally intended. Wahiawa reservoir, otherwise known as Lake Wilson, is a state recreation area known for its bass fishing. It also provides the important function of flood mitigation of the Kaukonaua streams leading to populated Haleiwa. As one of the largest reservoirs, no study has ascertained its current bathymetry, although it is assumed that sedimentation has reduced its capacity. Nuuanu Dam No 4, also used for flood protection, is currently being dredged (R.M. Towill Corporation, 2013). A bathymetry was completed in 2010, acknowledging that sediments had reduced capacity. Neither reservoir was originally designed for flood control. Similarly, the reservoirs build in west Maui in the 1980s for debris control (Honokowai Structure #8, Mahinahina, Kahana, and more) today are being used to capture sediment, yet their design does not permit efficient trapping of sediments during larger storms.

DISCUSSION

The level of information available for bed elevation and other sediment-related reservoir characteristics varies widely. It would take considerable effort (beyond the resources of the current project) to track down reasonably complete information about each reservoir. We determined that bed elevation is not routinely included in reservoir inventories, databases, and documents. In some cases, bed elevation may be derived from existing inventory data about dam height, site elevation, and reservoir depth (which by itself must generally be derived from reservoir surface area and storage capacity). However, initial estimates of original bed elevation are available for reservoirs national program investigations in the 1970s, which include area-capacity curves that indicate a base elevation at which storage capacity is zero (Harding-Lawson Associates, 1978).

No new reservoirs have been built since 2006, and a majority of the reservoirs built in the last three decades were built on Maui for a distinctly different purpose: to prevent debris from getting to the coral reef ecosystem offshore. Figure 3 represents only the ages of the reservoirs that are currently in the database; archival research indicates that many more reservoirs existed pre-1950 that were removed from use before the Dam Safety program was created. Similar with the responses of larger agricultural managers today, sugarcane-era documents support that reservoir building and maintenance occupied a significant amount of workers time. Lacking this maintenance, sedimentation of reservoir and degradation of irrigation ditches will continue to be a problem. Future research is needed to identify and employ efficient sediment removal methods that meet environmental protection requirements.

Funding is a critical issue for all aspects of reservoir sustainability. In 2014, Hawaii voters approved a legislatively referred amendment to the state constitution that authorizes the state to issue special purpose revenue bonds and use the proceeds from the bonds to offer loans to qualifying dam and reservoir owners to improve their facilities to protect public safety and provide significant benefits to the general public as important water resources (Hawaii State Legislature, 2014d). In addition, the state budget typically includes line items for generic reservoir safety improvements in state-owned irrigation systems and for specified capital improvements particular public reservoirs.

For example, the current biennium budget (July 2013-June 2015) includes $9 million for land acquisition, design, and construction for statewide reservoir safety improvements (deemed necessary to qualify for federal aid financing and/or reimbursement) and $7 million for compliance-related improvements to three specific reservoirs (Hawaii State Legislature, 2014a). However, the legislature did not approve separate measures that proposed to spend an additional $1.8 million for dam rehabilitation and remediation at a different public reservoir (Hawaii State Legislature, 2014b), and to require that a state agency prepare all studies to determine the safe removal or retirement of a dam or reservoir upon the request of a homeowner association or homeowner of property where a dam or reservoir is situated (Hawaii State Legislature, 2014c).

Re-developing agriculture in Hawaii will require reliable access to water for irrigation. Yet, the overall number of reservoirs in the state of Hawaii is in a steady decline. Irrigation reservoirs, which make up a majority of the reservoirs, have been decommissioned in the last five years at a disproportionately high rate, yet it was determined that sedimentation is not the highest concern of reservoir managers. Many reservoirs act like sediment retention basins, and prevent sediments from delivery and transport to coastal waters, thereby preventing possible water quality problems. The State of Hawaii may not have sufficient resources and interest to support the development and implementation of extensive reservoir sustainability measures. It remains to be seen how many more dams will be removed due to safety concerns and economic constraints. However, sediment deposition in reservoirs is an ongoing problem, and leaving issues unaddressed until problems become acute leads to costly, ineffective solutions.

CONCLUSION

The reservoirs of Hawaii serve multiple purposes – they are essential for irrigation, provide a safety net for water supply, offer possible provide habitat for aquatic ecosystems and perform as fire mitigation, flood and sediment controls. Our findings indicate that many reservoir managers consider sedimentation an operational concern, and that the current bathymetric data available does not allow for reliable estimates of watershed-scale sediment export processes. The database information analyzed here presents only part of the story, as there are many smaller reservoirs that are not regulated that serve important water capacity, fire prevention, flood regulation and sediment retention services. Quantifying actual reservoir storage capacity and the costs of restoring capacity lost to sedimentation are important considerations for water supply planning, as are detailed assessments of relationships

between stream diversions, ditch flows, reservoir storage, stream baseflows, and the achievement of instream flow objectives.

ACKNOWLEDGEMENTS

We would like to thank the USGS for providing support for this study under project number 2012HI370B. We are also grateful to the DLNR Dam Safety office, the Hawaii DOA, the Honolulu Board of Water Supply, and all of the interviewees for providing opportunities for collaboration.

Abstract

The removal of Elwha Dam and Glines Canyon Dam in Washington State has caused considerable sediment release to the lower reach of Elwha River. A reliable sediment transport model is needed for predicting post-dam removal sediment transport. This presentation reports the verification of SRH2D model for simulating fluvial sediment transport processes during the 1994 Lake Mills drawdown experiment on the Elwha River. SRH2D model is a depth-averaged two-dimensional model for flow and sediment transport in alluvial rivers developed by the Bureau of Reclamation. The experiment drawdown was performed in April 1994 by gradually lowering the Lake level by 18 feet over one week period. Flow discharge, cross sectional data, and sediment size distributions were collected at the reservoir reach during the experiment. This study simulated flow hydrodynamic and sediment transport during the experimental drawdown. The simulation used surveyed cross section data to reconstruct the lake bathymetry. Surveyed flow discharge and sediment load are used as the upstream boundary conditions for flow and sediment. Observed lake level in the reservoir was the downstream boundary condition. Multiple simulation runs using different sediment transport formulas, computational meshes, and various Manning's roughness are compared with field surveyed data. Results showed the importance of initial channel bathymetry, non-equilibrium sediment transport, locally induced turbulence, and bank erosion for simulating the morphodynamic processes of reservoir sedimentation delta. Additionally, the simulation results also demonstrated the applicability of SRH2D model in simulating complex sediment transport processes.

1 Introduction

The objective of this study is to simulate fluvial processes during the 1994 Lake Mills drawdown experiment in the Elwha River, Washington. The experiment drawdown was performed in April 1994 by gradually lowering the Lake level by 18 feet over one week period. Flow

discharge, cross sectional data, and sediment size distribution were collected at the reservoir reach during the drawdown experiment (Childers *et al.* 2000). This study simulated the experimental drawdown using SRH2D model and compared the simulated results of cross sectional changes with measurements. SRH-2D, Sedimentation and River Hydraulics – Two Dimensional model, is two-dimensional hydraulic, sediment, temperature, and vegetation model for river systems developed at the Bureau of Reclamation (BOR 2008). We conducted two series of simulations: one is to use the measured data to extract cross sections, and then test the sensitivities of modeling results to meshes, roughness coefficient, various sediment transport formulas, and different methods of adaptive lengths; the other is to use a refined mesh with many breaklines to pre-define the channel flow.

2 Model Set-up

2.1 Computational Grid

The simulation domain is the Lake Mills reservoir reach covering the reservoir delta from Section 3 to Section 17 as shown in Fig.1 and 2. The simulation boundary including the left and right banks is obtained from the boundaries of measured cross sections. The bathymetry in the simulated reach is interpolated using the surveyed bed elevation at each cross sections in 1994.

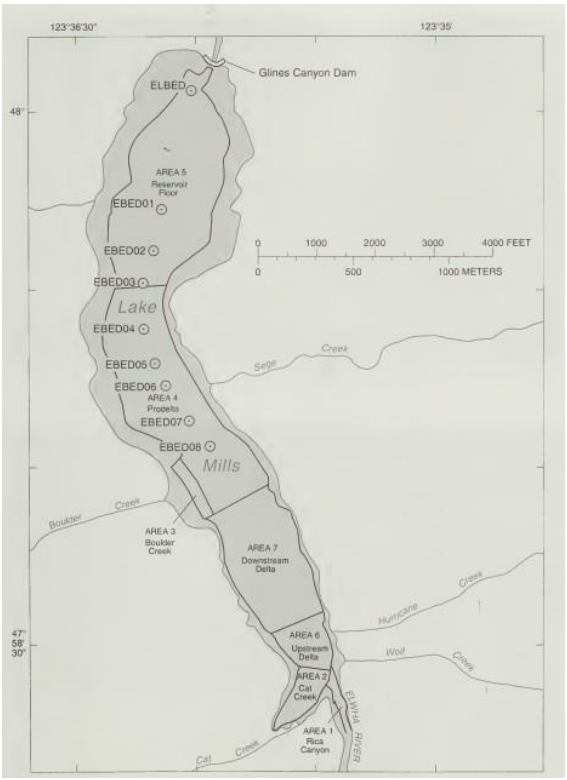

Fig.1 Location of the simulation reach.

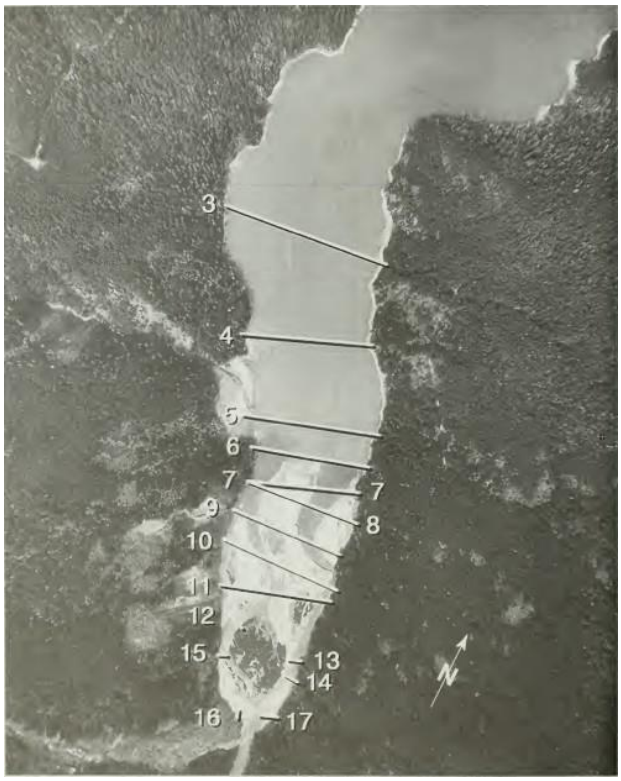

Fig.2 Location of surveyed cross sections

The simulation domain is the Lake Mills reservoir reach covering the reservoir delta from Section 3 to Section 17 as shown in Fig.2. The simulation boundary including left and right banks

is obtained from the boundaries of measured cross sections at April 8th. All other measured data points on the delta from USGS GIS shape files are also used (Fig.3a). The bathymetry in the simulated reach is interpolated using the surveyed cross sections and all other measured points on the delta. The measured data points in the tables of USGS report is based on the local coordinates. Conversions are needed to change the elevations to the NAD88 datum. The local elevation was added 0.9 ft to the NGVD29 system, and added 3.625 ft to the NAD88 datum. Therefore, the recorded elevations in the USGS report were added 4.525 ft to the NAD88 datum. The initial bed bathymetry showed two small side channels near both banks (Fig.3b). Cross sections, 16 and 17, are used as the inlets. This study used an improved quadrilateral mesh, shown in Fig.3c, to accommodate the complex geometry of the delta channels at the beginning of the drawdown experiment.

2.2 Simulation Data

Stream flow data were collected at five sites. Stream flow data were collected at five sites. Daily flows at ELWW, a gaging station that was established just a few weeks prior to the beginning of the drawdown experiment. The stream flow discharge (Fig.4a) at ELWW gauge is used. The measured discharge is divided into two parts: one part is 40% of the total discharge at the cross section #16, and the rest is at the cross section #17. Both suspended and bed load sediment discharges measured at ELWW gauge (Fig.4b) are used as sediment upstream boundary condition.
