JFIC2015

PROCEEDINGS OF THE

JOINT FEDERAL INTERAGENCY CONFERENCE 2015

Proceedings of papers of the
5th Federal Interagency Hydrologic Modeling Conference
and the 10th Federal Interagency Sedimentation
Conference
Reno, NV, April 19 – 23, 2015

The first Federal Interagency Sedimentation Conference (FISC) was held in 1947. Since then, they have been sponsored by the ACWI Subcommittee on Sedimentation (SOS) and held in 1963, 1976, 1986, 1991, 1996, 2001, 2006, and 2010. The Subcommittee on Hydrology (SOH) held their first Federal Interagency Workshop, "Hydrologic Modeling Demands for the 90s" in Fort Collins, Colorado, in 1993. That workshop was limited to Federal participants. Subsequent to that workshop, the SOH decided to hold a broader series of conferences and to open them to all interested parties. Federal Interagency Hydrologic Modeling Conferences were held in 1998, 2002, 2006, and 2010, and covered models addressing surface water quality and quantity issues.

These conferences have been well-attended, and together have produced over 2,100 technical papers. Combined, the Joint Conferences provide engineers and scientists the opportunity to discuss recent accomplishments in the physical, chemical, and biological aspects of sedimentation, and the development and use of hydrologic models addressing surface water quality and quantity issues. As a continuation of these conferences, SEDHYD again provides an interdisciplinary mix of scientists and managers from government agencies, academia, and the business community to present their recent accomplishments and progress in research and on technical developments related to sedimentation processes and the impact of sediment on the environment.

The Joint Conference follows a mixed set of formats including formal technical presentations, poster sessions, field trips, short courses, and model demonstrations. The Joint Conference is also hosting a ***student*** paper competition for cash prizes.

The Joint Conference is being held at the Peppermill Hotel and Resort, Reno, Nevada, USA. Reno is situated in a high desert just east of the beautiful Sierra Nevada. It lies on the western edge of the Great Basin, at an elevation of about 4,400 feet (1,300 m) above sea level. The downtown area (along with Sparks) occupies a valley informally known as Truckee Meadows. The area offers spectacular desert landscapes and ecosystems, as well as numerous indoor and outdoor recreational opportunities.

Joint Federal Interagency Conference

Joint Conference Chair:	G. Douglas Glysson, US Geological Survey (ret.)
Operations Chair:	Paula Makar, US Bureau of Reclamation
Technical Program Coordinator:	Jerry Bernard, USDA NRCS (ret.)
Proceedings Coordinator:	Mark Strudley, NOAA National Weather Service
Poster/Demo Coordinator:	Jennifer Bountry, US Bureau of Reclamation
Registration:	Darren Nezamfar, US Army Corps of Engineers
Exhibits:	Mark Landers, US Geological Survey
Short Course Coordinator:	Jeff Bradley, ASCE
Computer-A/V Coordinator:	Jeff Harris, US Army Corps of Engineers (ret.)
Field Trip Coordinator:	Victor Hom, NOAA
Student Program:	Amanda Cox, Saint Louis University
ACWI-SOS Chair:	Amanda Cox, Saint Louis University
ACWI-SOH Chair:	Victor Hom, NOAA

10th FISC

Chair:	Tim Randle, US Bureau of Reclamation
Technical Program Chair:	Marie Garsjo, US Geological Survey (ret.)

5th FIHMC

Chair:	Jerry Webb, US Army Corps of Engineers
Technical Program Chair:	Claudia Hoeft, USDA NRCS

The Federal Interagency Subcommittees on Hydrology (SOH) and Sedimentation (SOS), under the Advisory Committee on Water Information (ACWI).

Subcommittee Organizations

American Forests
American Society of Civil Engineers (ASCE)
Association of State Floodplain Managers
Bureau of Land Management (BLM)
Bureau of Reclamation (USBR)
Colorado Water Resources Research Institute CWRRI)
Defenders of Property Rights
U.S. Army Corps of Engineers (USACE)
Electric Power Research Institute (EPRI)
Federal Emergency Management Agency (FEMA)
Federal Energy Regulatory Commission (FERC)
Federal Highway Administration (FHwA)
National Aeronautics and Space Administration (NASA)
National Hydrologic Warning Council
National Park Service (NPS)
National Science Foundation (NSF)
NOAA-National Weather Service (NWS)
Office of Surface Mining (OSM)
U.S. Environmental Protection Agency (USEPA)
U.S. Geological Survey (USGS)
Universities Council on Water Research (UCOWR)
USDA-Agricultural Research Service (ARS)
USDA-Forest Service (FS)
USDA-Natural Resources Conservation Service (NRCS)

Suggested Citation:
In Proceedings of the 3rd Joint Federal Interagency Conference (10th Federal Interagency Sedimentation Conference and 5th Federal Interagency Hydrologic Modeling Conference), April 19 – 23, 2015, Reno, Nevada.

JFIC2015

TABLE OF CONTENTS

1D Stream Restoration 1

1E Climate Change, Variability, and Impact 1

1F Flood Hydrology 1

2A Sediment Yield and Transport Modeling 2

2B Surrogates of Sediment, Optical

2C Physical Measurement and Modeling 1

Release of the USGS Sediment Data Portal
Casey Lee and Meredith Warren

Electronic Notes Application for On-Site Recording and Storage of U.S. Geological Survey Fluvial-Sediment Data
Julio A. Oms, Dianne Lopez-Trujillo, John R. Gray, Kenneth A. Skach, and Francisco Granado-Santos

Characterizing and Simulating Sediment Loads and Transport in the Lower Part of the San Antonio River Basin
J. Ryan Banta, Darwin J. Ockerman, Cassi L. Crow, and Stephen P. Opsahl

2D Stream Restoration 2

Development of a Velocity-Based Quantitative Design Methodology for Bendway Weirs
Nathan Holste

Performance of Log Crib Walls for Bluff Stabilization
Ben Lee, Marty Melchior, Andy Selle, and Ben Swanson

Rock Check Structures for Restoration of Headwaters
Jon Fripp and Richard Weber

Riparian and Channel Changes Along the Trinity River Below Lewiston Dam, California, 1980 to 2011
Jennifer Curtis

2E Climate Change, Variability, and Impact 2

Reservoir Sustainability: Evaluation of Climate Change and Sedimentation Impacts to Reservoir Water Management Operations at Coralville Dam, Iowa
Kevin J. Landwehr and Gregory S. Karlovits

Using an Integrated Surface Water-Groundwater Flow Model for Evaluating the Hydrologic Impacts of Historic and Potential Future Dry Periods on Simulated Water Budgets in the Santa Rosa Plain Watershed, Northern California
Joseph A. Hevesi, Linda R. Woolfenden, and Tracy Nishikawa

Collaboration on Climate Change Analysis in the Pacific Northwest
James D. Barton

ADHydro: Quasi-3D HIgh Performance Hydrological Model
Fred L. Ogden, Wencong Lai, and Robert C. Steinke

2F Flood Hydrology 2

SToRM: A Model for 2D Environmental Hydraulics
Francisco J.M. Simões

Hydraulic Modeling of Truckee Canal Alluvial Fans using SRH-2D
Rebecca Kallio, Joseph Wright, and Victoria Sankovich-Bhals

Model Integration for Real-Time Flood Forecasting Inundation Mapping for Nashville Tributaries *
William Charley

Evaluating Physical Models of Dam Removal Against Results from Condit, Marmot, and Elwha for Process Driven Sediment Transport and Channel Bed Response
Joanna Crowe Curran

3A Sediment Yield and Transport Modeling 3

Mount St. Helens Update: Recent Trends, Understandings and Projects to Manage Debris Avalanche Sediments
Chris Nygaard and Paul Sclafani

Forecasting Long-Term Sediment Yield from the Upper North Fork Toutle River, Mount St. Helens, Washington State
Tim Meadows, Colin Thorne, Nick Mount, and Tom Coulthard

Mount St. Helens Long Term Sediment Management Alternative Analysis
Paul Sclafani and Chris Nygaard

Two Dimensional Numerical Modelling of Hyperconcentrated Flows
Jianchun Huang, Yong Lai, and Kuowei Wu

3B Surrogates of Sediment 1

Sediment-Generated Noise (SGN): Comparison with Physical Bedload Measurements in a Small Semi-arid Watershed
James R. Rigby, Roger A. Kuhnle, Bradley T. Goodwiller, Mary H. Nichols, Wayne O. Carpenter, Daniel G. Wren, and James P. Chambers

Sediment-Generated Noise (SGN): Laboratory Determination of Measurement Volume
Daniel G. Wren, Bradley T. Goodwiller, J. R. Rigby, Wayne O. Carpenter, Roger A. Kuhnle, and James P. Chambers

Design and Implementation of a Field Deployable Passive Acoustic Bedload-Monitoring Surrogate
Bradley T. Goodwiller, Daniel G. Wren, J. R. Rigby, Wayne O. Carpenter, James P. Chambers, Roger A. Kuhnle, and Robert C. Hilldale

Continuous Bedload Measurement on the Elwha River Using Impact Plates: Installation and Calibration
Robert C. Hilldale

3C Physical Measurement and Modeling 2

USGS Training of Sediment Data Collection Techniques
Gary P. Johnson, John R. Gray, Kurt Spicer, and Mark Landers

3D Stream Restoration 3

3E Restoring and Sustaining River Environments 1

3F Flood Hydrology 3

Performance of Suspended Sediment Concentration in Two Distinctive Lower Mississippi River Hydrographs
Tzenge-huey (Jerry) Shih and Dave Ramirez

4A Sediment Yield and Transport Modeling 4

Sediment Modeling on the Lower Yellowstone River at Intake Dam
Curtis J. Miller, Daniel B. Pridal, and Christopher J. Svendsen

Sedimentation Analysis of the Yellowstone River at Intake Diversion Dam
Mike Sixta, Blair Greimann, and Kent Collins

Inaccuracies in Sediment Budgets Arising from Estimations of Tributary Sediment Inputs: An Example from a Monitoring Network on the Southern Colorado Plateau
Ronald E. Griffiths and David J. Topping

User-interactive Sediment Budgets in a Browser: A Web Application for River Science and Management
David Sibley, David J. Topping, Megan Hines, and Bradley Garner

4B Surrogates of Bedload 2

Update on ISSDOTv2 Method of Measuring Bedload Transport Using Time Sequenced Bathymetric Data
David Abraham, Tate McAlpin, David May, Thad Pratt, and John Shelley

Distinguishing Bed-load and Bed-material-load Fluxes with Repeat Bathymetric Data
Brandon McElroy and David Abraham

Using Hydrophones as a Surrogate Sediment Monitoring Technique to Detect Temporal and Spatial Variability in Bedload Sediment Transport
Mathieu Marineau, J. Toby Minear, and Scott Wright

Evaluation of Multiple-Frequency, Active and Passive Acoustics as Surrogates for Bedload Transport
Molly Wood, Ryan Fosness, Greg Pachman, Mark Lorang, and Diego Tonolla

4C Physical Measurement and Modeling 3

Bed Sediment Characterization of the Mississippi River, Grafton, Illinois to Head of Passes, November 2013
Roger Gaines and Anthony M. Priestas

Drought, Low Water, and Dredging of the Middle Mississippi River in 2012
David C. Gordon and Michael T. Rodgers

Missouri River 2011 Extreme Flood – Channel Response Evaluation and Observations
Chris Svendsen and Daniel Pridal

4D Stream Restoration 4

Rapid, Quantitative Analysis of the Cost Effectiveness of Streambank Protection Measures Using the Bank-Stability and Toe Erosion Model (BSTEM)
Natasha Bankhead and Andrew Simon

Streambank Erosion: Developing Recession Rates Based on Condition Class and Flow Stage Characteristics
W. Barry Southerland and Lisa J. French

Vegetation Calibration in a Sediment Transport Model of the Middle Rio Grande
David Varyu and Lisa Fotherby

Removing Invasive Plants from the Mojave River, An Erosive Inland Desert River System in Southern California
Gregory Norris and Julia Grim

4E Restoring and Sustaining River Environments 2

Estimation of Suspended Sediment and Total Mercury Loads and Application of Flow-Adjusted Trend Analyses to Assess Floodplain Restoration, Carson River, Nevada
Carl E. Thodal, Eric Morway, and Karen A. Thomas

Missouri River Habitat Project Design, Performance, and Aspects of the 2011 Flood
Daniel Pridal

Evaluation of Levee Setbacks as a Sustainable Solution Along the Missouri River
Tony D. Krause, Kelly Baxter, David J. Crane, and Randall L. Behm

PIANC Working with Nature Concept: Development of the 3 Meter Navigation Channel on the Middle Mississippi River *
Robert Davinroy

4F Hydroecological Modeling 1

Hydrodynamic Modeling to Evaluate the Influence of Constructed Side-Channel Habitat on Larval Drift of Pallid Sturgeon in the Lower Missouri River
Susannah O. Erwin and Robert B. Jacobson

Impact of Precipitation Uncertainty on SWAT Model Performance
Milo Anderson, Yongping Yuan, and Ronald L. Bingner

Modeling Interactions of Flow and Vegetation for Improved Riverine System Management
Daniel Dombroski, Blair Greimann, Yong Lai, Victor Huang, Lisa Fotherby, Mark Stone and Li Chen

5A Sediment Yield and Transport Modeling 5

Sand Bar Volume Model: Improving Modeled Sand Bar Response in Marble Canyon
David Varyu, Blair Greimann, Nate Bradley, and Kendra Russell

Processes Limiting Depth of Arroyo Incision: Examples from the Rio Puerco, New Mexico
Eleanor Griffin and Jonathan Friedman

Estimating Flow Concentration and Sediment Redistribution in Shrub-Dominated Rangeland Communities
Sayjro Kossi Nouwakpo, Mark Weltz, Kenneth McGwire, and Colleen G. Rossi

Temperature Simulation of a Reach of the Methow River near Winthrop, Washington
Jianchun Huang and Jennifer Bountry

5B Surrogates of Sediment, Acoustics 1

Physically Based Method for Measuring Suspended-Sediment Concentration and Grain Size Using Multi-Frequency Arrays of Single-Frequency Acoustic-Doppler Profilers
David J. Topping, Scott A. Wright, Ronald E. Griffiths, and David J. Dean

Research and Methods Development in the Sediment Acoustic Leadership Team *
Mark Landers

Surrogate Analysis and Index Development (SAID) and Real-Time Dissemination
Marian Domanski, Timothy Straub, Molly Wood, Mark Landers, Gary Wall, and Steven Brady

5C Physical Measurement and Modeling 4

Effective Particle Sizes of Cohesive Sediment in a North Mississippi Stream
Roger Kuhnle and Daniel Wren

Suspended-Sediment Concentrations, Loads, Total Suspended Solids and Particle-Size Fractions in Minnesota, 2007-2011
Christopher A. Ellison, Brett E. Savage, and Gregory D. Johnson

Coarse Particulate Organic Matter Transport in Two Rocky Mountain Streams: Measurements, Transport Dynamics, Annual loads, and Yields
Kristin Bunte, Kurt W. Swingle, Jens M. Turowski, Steven R. Abt, and Daniel A. Cenderelli

Sediment Budgets, Transport, and Depositional Trends in a Large Tidal Delta
Tara L. Morgan-King and Scott A. Wright

5D Fluvial Geomorphology 1

The Study of Most Probable Mean Daily Bankfull Runoff Volumes in Small Watersheds dominated by Convective/Frontal Channel-Forming Events and the Co-incident Inner Berm Channel
Thomas J. Garday

5E Post Fire Analyses and Restoration 1

5F Hydroecological Modeling 2

6A Sediment Yield and Transport Modeling 6

The Upper Bound of Abutment Scour Defined by Selected Laboratory and Field Data
Stephen T. Benedict

Baffle-Post Structures for Flow and Bed-Sediment Control in Open Channels
Caroline Ubing, Robert Ettema, and Christopher Thornton

6B Surrogates of Sediment, Acoustics 2

Suspended-Sediment Transport and Storage: a Demonstration of Acoustic Methods in the Evaluation of Reservoir Management Strategies for a Small Water-Supply Reservoir in Western Colorado
Cory A. Williams, Rodney J. Richards, and Kent Collins

Ultrasonic Measurements of Suspended Sediment Concentrations at Harris Bayou
Wayne Carpenter, Daniel Wren, Bradley Goodwiller, James Chambers, Thomas Kajdan, Cristiane Surbeck, and Roger Kuhnle

Studying Surrogates to Estimate Suspended Sediment Concentrations on the Missouri River at Nebraska City, NE
Jon F. Nania

Hydroacoustic Signatures of Colorado Riverbed Sediments in Marble and Grand Canyons Using Multibeam Sonar
Daniel Buscombe, Paul E. Grams, Matt A. Kaplinski, Robert Tusso, and David M. Rubin

6C Physical Measurement and Modeling 5

Application of Cross-Plot Analysis on Francis Levee Site Using Time Lapse SRT and ERT
Leti Wodajo, Craig Hickey, and Chung Song

A Simplified Bathymetric Survey System Using a Modified Sounder GPS
Theodore L. Huscher and David Griffith

Subsurface Hydrologic Effects on Sediment Deposition
Zhaoxia Li, Sayjro Nouwakpo, and Chi-hua Huang

Representativeness of Soil Samples Collected to Assess Mining-Related Contamination of Flood Plains in Southeast Kansas
Kyle Juracek

6D Fluvial Geomorphology 2

Morphological Evolution of Fluvial and Estuarine Segment Flows
Geraldo Wilson Junior and Mario Grüne de Souza e Silva

Flow Energy and Bedload-Transport Efficiency: The Froude Number as a Metric for Bedload Transport Rates
Andrew Simon and Michael Singer

Effects of Upstream Sediment Supply and Flow Rate on the Initiation and Topographic Evolution of Sandbars in Laboratory and Numerical Channels
Paul J. Kinzel, Brandy L. Logan, and Jonathan M. Nelson

Reconciliation of Flux-based and Morphologic-based Sediment Budgets
Paul E. Grams, Daniel Buscombe, David J. Topping, Joseph E. Hazel, Jr., and Matt Kaplinski

6E Post Fire Analyses and Restoration 2

Predicting and Comparing Measured Bulking and Peak Discharge Using Multiple Methods for Post-Fire Hydrologic and Sedimentation Analysis on the "Dump Fire" in Saratoga Springs, Utah
Nathaniel Todea

Stream Restoration Within a Confined Space : A Case Study on the Middle Rio Grande
Jonathan AuBuchon and Chi Bui

The Application of WARSSS for a Watershed-Based Sediment Budget and Post-Fire Stream Restoration: The Hayman Fire, Trail Creek Watershed, Colorado
David Rosgen, Darcie Frantila Geenen, and Brandon Rosgen

6F Hydroecological Modeling 3

Hybrid Hydraulic Modeling of River-Training Structures in Sinuous Channels
S. Michael Scurlock, Amanda L. Cox, Drew C. Baird, Christopher I. Thornton, and Steven R. Abt

Modeling Flow Complexity with In-Stream Structures: A Semi-Automatic Approach *
Yong Lai

Space-Time Substitution in a Stream Evolution Model Integrating Habitat and Ecosystem Benefits
Brian Cluer and Colin Thorne

Composite Modeling of the Halfway Wash Fish Barrier
Mike Sixta, Kendra Russell, and Leslie Hanna

7A Sediment Yield and Transport Modeling 7

Coupled Sediment Yield and Sediment Transport Modeling to support Waterway Navigation Planning in Northeast Brazil
Calvin T. Creech, Rafael Brito Siquiera, James P. Selegean, Carol Miller, and Pedro Cunha

Sediment Dynamics on River Networks: Incorporating Sources, Stores, and Sinks from a Sediment Budget into a Network-Modeling Framework
Jonathan A. Czuba, Efi Foufoula-Georgiou, Karen B. Gran, Patrick Belmont, and Peter Wilcock

Constructing a Near-Continuous Suspended-Sediment Budget Using Acoustic Instrumentation on the Rio Grande in Big Bend National Park, USA
David J. Dean, David J. Topping, Ronald Griffiths, Thomas A. Sabol, John C. Schmidt, and Jeffrey Bennett

Development and Analysis of Suspended Sediment Rating Curves for the Kalamazoo River from Marshall to Morrow Dam, Michigan
David T. Soong, Christopher J. Hoard, Faith A. Fitzpatrick, and Ronald B. Zelt

An Inventory of Sedimentation in Hawaii's Reservoirs Using Mixed Methods
Kim Falinski and David Penn

Simulations of Lake Mills Drawdown Experiment Using SRH2D Model
Jennifer G. Duan, Lei Liu, and Chunshui Yu

Numerical Modeling of Isleta Diversion Dam Gate Operation Hydraulics to Minimize Sediment Effects
Drew Baird and Michael Sixta

8D Fluvial Geomorphology 4

Geomorphic Change in the Limitrophe Reach of the Colorado River in Response to the 2014 Delta Pulse Flow, United States and Mexico
Erich R. Mueller, John C. Schmidt, David J. Topping, and Paul E. Grams

Basin-Scale Geomorphology and Sediment Transport Analysis for the Mouse/Souris River Enhanced Flood Protection Plan
Peter Hinck, Benjamin Sheets, Miguel Wong, and Amy Anderson

Suspended Sediment Transport Through a Large Fluvial-Tidal Channel Network
Scott A. Wright and Tara L. Morgan

Bedload Database and Prediction Performance
Rollin H. Hotchkiss and Darren D. Hinton

8E Modeling of Major River Systems 1

The Analysis of Modeled and Satellite Great Lakes Snow Water Equivalent Data and Incorporating Near Real-Time Estimates into Water Level Forecasting
James W. Lewis, Carrie M. Vuyovich, and Steven F. Daly

Hydraulic Modeling and Mapping of the Yellowstone River to Support Cumulative Effects Assessment
Laurel J. Hamilton, Kevin K. Adams, Megan A. Splattstoesser, and Roger L. Kay

The Colorado River Basin Water Supply and Demand Study: Modeling to Support a Robust Planning Framework
Alan Butler, Carly Jerla, Ken Nowak, Jim Prairie, Bill Oakley, Neil Wilson, and Edie Zagona

Truckee-Carson RiverWare© Planning Model Description and Applications
Heather Gacek, Thomas Scott, and Shane Coors

8F Management and Decision-Making Models 1

Real-Time Water Control Decision Support with CWMS 3.0 *
William Charley

Utilizing Probabilistic Forecasts for Colorado River Reservoir Operations: Decision Making and Risk Management
Anthony Powell, Daniel Bunk, Shana Tighi, Katrina Grantz, and Shane Coors

Pipeline Stream Crossings – a Risk-Based Approach to Minimize Aquatic Impacts
Janine Castro, Anne MacDonald, Erin Lynch, and Colin Thorne

Multi-Objective Modeling in RiverWare for USACE-SWD
John Daylor, David Neumann, Edith Zagona, and Jennifer Steffen

9A Sediment Yield and Transport Modeling 9

Channel and Bank Stability of the Burnett River in the Aftermath of the 2011 and 2013 Floods: Implications for Sediment Delivery to the Great Barrier Reef
Andrew Simon, Natasha Bankhead, and Peter Wilson

Sediment Diversion Efficiency, Lessons from Mississippi River Models
Ronald Heath, Gary Brown, and Jeremy Sharp

Preliminary Results for Calculating Salinity and Sediment Loading for Runoff in the Upper Colorado River Basin
Erik Cadaret, Robert Blank, Kenneth McGwire, Sayjro K. Nouwakpo, Colleen G. Rossi, Mark Weltz, Todd Adams, Alice Boizet, Sandra Li, Tye Morgan, and Jacob Phillips

Continuous Vertical Sorting Model in a One-Dimensional Sediment Transport Model, SRH-1D
Sean Kimbrel, Blair Greimann, and Victor Huang

9B Dam Removal/Rehabilitation 1

Bankfull Width Controls on Riffle-Pool Morphology Under Conditions of Increased Sediment Supply Field Observations During the Elwha River Dam Removal Project
Andrew K. Brew, Jacob A. Morgan, and Peter A. Nelson

Scour and Subsequent Repair at Lock and Dam 25
Timothy Lauth, David Gordon, Matthew Rector, and William Moeller

Geomorphic Adjustments on the Upper Missouri River in Response to Dam Management and Flooding
Katherine Skalak, Edward Schenk, Adam Benthem, Cliff Hupp, Joel Galloway, and Rochelle Nustad

Elwha PlaneCam, Affordable Near-Real-Time Orthoimagery and Digital Elevation Models in Support of Adaptive Sediment Management and Modeling During Elwha and Glines Canyon Dam Removal
Andrew Ritchie, Jennifer A. Bountry, and Timothy J. Randle

9C Reservoir Sedimentation and Sustainability 3

Collection and Interpretation of Reservoir Data to Support Sustainable Use
Gregory L. Morris

Unsteady Flow and Sediment Modeling in a Large Reservoir Using HEC-RAS 5.0
John Shelley, Stanford Gibson, and Aaron Williams

Developing a Sediment Management Plan for Paonia Reservoir
Kent Collins and Sean Kimbrel

Rio Grande and Cochiti Reservoir Sedimentation Issues: Are There Sustainable Solutions?
Charles M. Davis, C. Bahner, Darrel E. Eidson, and Stanford Gibson

9D Fluvial Geomorphology 5

Proposed Diversion Works in Rivers that Show Significantly Less Morphodynamic Activity Than Expected *
Miguel Wong

A Review of the Lower Mississippi River Potamology Program
David S. Biedenharn, John H. Brooks, Roger A. Gaines, Barbara A. Kleiss, Charles F. Pinkard, and Wayne A. Stroupe

Gravel Deposits on Lower Mississippi River Sandbars
Richard McComas and C. Fred Pinkard

Sediment and Carbon Sequestration in the Atchafalaya River Basin, Louisiana
Cliff R. Hupp, Daniel E. Kroes, Edward R. Schenk, and Gregory B. Noe

9E Modeling of Major River Systems 2

Mississippi River Model
Edmund M. Howe

Current and Historical Sediment Loads in the Lower Mississippi River
Colin Thorne, Kevin Knuuti, Oliver Harmar, Chester Watson, Nick Clifford, and David Biedenharn

Saint-Venant Modeling for Large River Basins – Challenges and Data Needs
Ben R. Hodges, Frank Liu, and Alfredo Hijar

Synthetic Bathymetry Method Development, Validation and Application to five Pacific Northwest Rivers
Zachary P. Corum, Travis D. Ball, and Matthew J. Hubbard

9F Management and Decision-Making Models 2

Problems and Prospects of SWAT Model Application on an Arid/Semi-arid Watershed in Arizona
Yongping Yuan, Wenming Nie, and Emily Sanders

The KINEROS2 – AGWA Suite of Modeling Tools
David C. Goodrich, Carl L. Unkrich, Yoganand Korgaonkar, Shea Burns, Jeff Kennedy, Gabriel Sidman, Brian Scott Sheppard, Mariano Hernandez, Phil Guertin, Scott N. Miller, William Kepner, Phil Heilman, and Mark Nearing

Representing Green Infrastructure Management Techniques in Arid and Semi-arid Regions: Software Implementation and Demonstration Using the AGWA/KINEROS2 Watershed Model
Yoganand Korgaonkar, I. Shea Burns, Jane Barlow, D. Phillip Guertin, Carl Unkrich, David C. Goodrich, and William Kepner

Integrated Modeling Approach for Fate and Transport of Submerged Oil and Oil-Particle Aggregates in a Freshwater Riverine Environment
Faith A. Fitzpatrick, Rex Johnson, Zhenduo Zhu, David Waterman, Richard D. McCulloch, Earl J. Hayter, Marcelo H. Garcia, Michel Boufadel, Timothy Dekker, Jacob S. Hassan, and Kenneth Lee

Models/Demos

2D Hydrologic Modeling using the Gridded Surface Subsurface Hydrologic Analysis (GSSHA) model and the Watershed Modeling System (WMS) *
Christopher Smemoe

Demonstration of the Capabilities of the KINEROS2 – AGWA 3.0 Suite of Modeling Tools
I. Shea Burns, Carl L. Unkrich, David C. Goodrich, Yoganand Korgaonkar, Jeff Kennedy, Gabriel Sidman, Brian Scott Sheppard, Mariano Hernandez, Phil Guertin, William Kepner, Phil Heilman, and Mark Nearing

Demonstration of the Water Erosion Prediction Project (WEPP) Internet Interfaces and Web Services
Jim Frankenberger, Dennis Flanaga, Bill Elliot, and Eric Theller

Hydrologic Modeling System (HEC-HMS) Model Demonstration *
William Scharffenberg

Modeling of a Non-Physical Fish Barrier, Demonstration
Marcela Politano, Ezequiel martin, Yong Lai, Merlynn Bender, and Dave Smith

River Analysis System (HEC-RAS) Model Demonstration *
Gary W. Brunner

RiverWare Demonstration
David Neumann and Edie Zagona

RVR Meander – A Toolbox for River Meander Planform Design and Evaluation
Eddy J. Langendoen, Davide Motta, Jorge D. Abad, Marcelo H. Garcia, Roberto Fernandez, and Nils Oberg

WinDAM B & C Earthen Embankment Overtopping and Internal Erosion Analysis Software Computer Demonstration
Karl Visser, Ronald D. Tejral, and Mitchell L. Neilsen

WinTR-20 Software Computer Demonstration
Quan D. Quan, William H. Merkel, and Helen Fox Moody

Posters

2011 Morganza Control Structure Tail Bay Scour Development and Sediiment Distribution
Tzenge-huey Shih and Suchen Chien

An Approximation of the Sediment Budget for the Tombigbee River and the Mobile River Basins
John J. Ramirez-Avila, William McAnally, and Sandra L. Ortega-Achury

Analyzing Streambank Erosion Using LIDAR *
Gary Trent Snellings

Assessment of Fire Impacts on Hydrology and Erosion Using Field Experiments and the Rangeland Hydrology and Erosion Model *
C. Jason Williams

Computation of Continuous Suspended-Sediment Concentration Records related to a Short-Term Drawdown of Fall Creek Lake, Upper Willamette Basin, Oregon *
Heather Bragg

Continuous Loosening and Transport of Sediment Deposition *
Yannick Ratke

Continuous Turbidity Monitoring as a Tool for Evaluating Suspended Sediment Loading in the Middle Truskee River and Tributaries, Placer and Nevada Counties, California
Brian Hastings, David Shaw, Stefan Schuster, and Beth Christman

Creation and Maintenance of Dynamic Channels: Lessons Learned from the Large-Scale Restoration of a Regulated River *
Susannah Erwin

Effects of Bedload Sampler Netting Properties on Hydraulic and Sampling Efficiency
Kristin Bunte, Kurt W. Swingle, Steven R. Abt, and Daniel A. Cenderelli

Estimating Sediment Yield on Disturbed Rangeland Using the Rangeland Hydrology and Erosion Model (RHEM) *

Abstract: One-dimensional sediment-transport models historically simulate vertical channel adjustment, raising or lowering cross-section node elevations to simulate erosion or deposition. This approach does not account for bank erosion processes including toe scour and mass failure. In many systems lateral channel adjustments can be as important – or more important – than vertical bed changes. There is also important feedback between incision, deposition, toe scour, and bank-failure processes. Each process can depend on the others. Additionally, bank-derived sediments can affect downstream processes and impact downstream projects, depositing in flood damage reduction channels, silting natural or engineered spawning substrates, or filling downstream reservoirs. Therefore, to account for these processes and feedback between them, the USDA-ARS Bank Stability and Toe Erosion Model (BSTEM) has been integrated with the sediment transport methods in HEC-RAS 5.0.

BSTEM is a physically based bank-erosion model that accounts for hydraulic, toe erosion and bank-failure processes in homogeneous or layered banks. It computes toe-erosion by subdividing flow segments in the near bank zone to compute a vertical distribution of boundary shear stresses and calculates a critical failure plane through layered bank sediments, failing the bank and adjusting the cross section when driving forces exceed resisting forces.

Because of their complementary features, river modelers often run HEC-RAS and BSTEM iteratively, in tandem, simulating toe scour and bank failure with BSTEM and computing water surface elevations, simulating bed change and routing bed and bank-derived sediment with HEC-RAS. To provide a more efficient, integrated modeling framework and continuous simulation of potential bed and bank-erosion loadings, HEC-RAS and BSTEM have been coupled, automating the feedbacks between hydraulic, bed, toe, and bank processes. BSTEM uses HEC-RAS hydraulics to determine water surface elevations and to compute the vertical distribution of shear stresses along the bank surface, and evaluates if cross section deposition or erosion simulated by HEC-RAS sediment transport exacerbates or improves bank stability. If BSTEM computes failure, HEC-RAS updates the cross section to reflect the new bank geometry and adds the sediment mass of the failed layers (by particle-size class) to the transport model, routing it downstream. This paper will describe the model integration, and present an example application and model validation.

Keywords: Sediment modeling, Bank Failure, Toe Erosion, HEC-RAS, BSTEM

INTRODUCTION

The USDA ARS – Bank Stability and Toe Erosion Model (BSTEM) simulates two major stream bank erosion processes:

1. Bank Failure: A geotechnical model that evaluates bank stability by computing failure planes through the bank to determine if the driving forces exceed the resisting forces, and selecting the 'critical failure plane,' with the lowest factor of safety.

2. Toe Scour: A lateral erosion model that computes a shear distribution between the water surface and bank toe and simulates lateral hydraulic scour in this zone.

HEC-RAS sediment transport simulates a third processes:

3. Channel Erosion or Deposition: Vertical adjustment of the channel portion of the cross section in response to erosion or deposition.

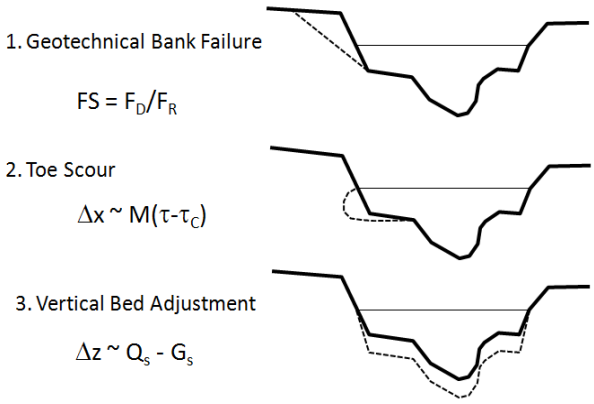

Figure 1 The three processes coupled in the integration of the USDA-ARS BSTEM model and HEC-RAS, including bank and toe-erosion processes from BSTEM and vertical adjustment (and sediment routing) from HEC-RAS, where FS=factor of safety, F_D=driving forces, F_R=resisting forces, Δx=lateral bank change, M=erodibility, τ=shear stress, τ_c=critical shear stress, Δz=vertical bed change, Q_s=sediment supply, and G_s=sediment capacity.

However, these three processes interact. Vertical change can stabilize toes or steepen banks, accelerating or preventing bank failures. Bank scour and failure add sediment to the stream, affecting sediment continuity and downstream deposition or erosion while decreasing available shear stress for a given discharge. To simulate these processes simultaneously, and to capture the interactions and feedbacks between them, USDA-ARS BSTEM algorithms were incorporated into the HEC-RAS sediment-transport algorithms.

METHODOLOGY

Exhaustive presentation of the processes, equations and algorithms that compose USDA-ARS BSTEM and HEC-RAS sediment transport are outside of the scope of this paper. A separate document accompanies the HEC-RAS 5.0 (USACE, 2015), documenting the methodology in detail. However, it is important to summarize the model approach to the three main processes:

1. Bank Failure Methods

The USDA-ARS Bank Stability and Toe Erosion Model (BSTEM) computes the critical linear failure plane through layered bank materials. It uses either the method of slices (Langendoen and Simon, 2008) or the horizontal layer method (Simon et al., 2000) to compute a factor of safety for multiple failure planes, starting at several elevations along the bank and extending through the bank at multiple angles. At each time step specified, a "bracket and Brent" optimization algorithm (Teukolsky et al., 2007) converges on the critical failure-plane angle at each bank intersection point within a few iterations and

selects the failure plane with the lowest factor of safety as the 'critical failure plane'. If BSTEM computes a factor of safety less than 1.0, HEC-RAS fails the bank, introducing the failure block mass into the sediment routing model as a sediment source. HEC-RAS also updates the cross section to compute future hydraulics based on the new, wider, cross-section geometry. The geotechnical model can compute failure planes through homogeneous banks or 'soil layers,' stratified materials with distinct vertical variation in soil properties. The method of slices can also compute tension cracks, which decrease failure plane length, usually removing more resisting forces than driving forces, decreasing the factor of safety and increasing bank-failure frequency.

The geotechnical algorithms are very sensitive to pore-water pressure. Positive and negative pore-water pressures are computed from groundwater elevation and the relation between hydrostatic pressures in the bank and the confining hydrostatic forces from the water in the channel. Groundwater elevation can be specified in HEC-RAS or computed dynamically, in response to rising and falling water-surface elevations in the channel, with a simple 'bank reservoir' groundwater model.

2. Toe Scour Methods

The BSTEM toe erosion model (Simon et al., 2011) moved specified cross section nodes normal to the bank surface. HEC-RAS moves nodes laterally to keep nodes from eroding below the bed elevation. The toe scour methods use cohesive equations if ≥20% (an adjustable threshold) of the layer is silt and clay and cohesionless methods if the fine content is lower than the threshold. Cohesive scour uses a simple excess shear equation emphasizing site specific soil parameters (critical shear stress and erodibility [k in cm^3/N-s or ft^3/lbf-s]). However, neither laboratory nor field methods reliably measure cohesionless erodibilities, so the cohesionless methods apply transport functions. Applying bed transport equations to well graded (poorly sorted) bank sediment (especially with substantial silt or clay content, but not enough to trigger the cohesive equations) can pose sorting problems and often over predicts scour. Bed sorting algorithms and theory (Gibson and Piper, 2007) are not directly applicable. The development team is experimenting with alternate bank sorting methodologies to model these processes.

Both cohesive and cohesionless toe scour methods compute lateral adjustment based on local bank shear at each cross section node. HEC-RAS is a one-dimensional model, which computes a single, cross section average bed shear for each time step. Bank shear stress is maximum at the bed, decreasing up the bank towards the water surface, so applying the average bed shear to all bank nodes overpredicts scour. BSTEM accounts for this, computing shear at each inundated bank node with a radial shear distribution, based on the ratio of the hydraulic radius of the local radial flow zone to the hydraulic radius of the bank (Simon et al., 2011).

Unlike stand alone, USDA-ARS versions of BSTEM (Simon et al., 2011), toe scour algorithms in HEC-RAS cannot currently simulate overhanging banks. If a node scours past the node above it, which is common since shear stress is higher at deeper nodes or material is more erodible, HEC-RAS shears the bank vertically, scouring the higher node to match station of the node below it. This is a technical limitation (HEC-RAS requires monotonically increasing cross section stations) but translates into the physical assumption that cantilever failure will make overhanging banks vertical.

3. Bed Change Methods

HEC-RAS added sediment transport calculations in version 4.0, (Gibson et al., 2006), applying sediment transport functions, bed mixing algorithms, and temporal limiters to compute a sediment balance at each control volume, then adjusting wetted cross section nodes vertically, raising them in response to erosion and dropping them in response to deposition. These capabilities leveraged the full suite of steady flow hydraulic analysis in those earlier versions of HEC-RAS (e.g. ineffective flow areas, inline structures,

flow dependent roughness, etc…) and HEC-RAS 5.0 integrates sediment transport capabilities with unsteady flow (Gibson and Boyd, 2014, Shelley et al. 2015) and powerful features associated with that modeling environment (e.g. lateral structures, flow splits, operational rules).

MODEL INTEGRATION

HEC-RAS 5.0 includes the USDA-ARS Bank Stability and Toe Erosion Model (BSTEM) interface as an optional third tab in the sediment editor (Figure 2). The model requires users to designate the 'bank' portion of the cross section, the nodes that can scour laterally and the zone where failures can start, between the bank 'toe' and 'edge' stations. It also requires a ground water elevation which will either remain static for the entire simulation or initializes the dynamic groundwater model. Finally, BSTEM requires soil properties for each bank layer.

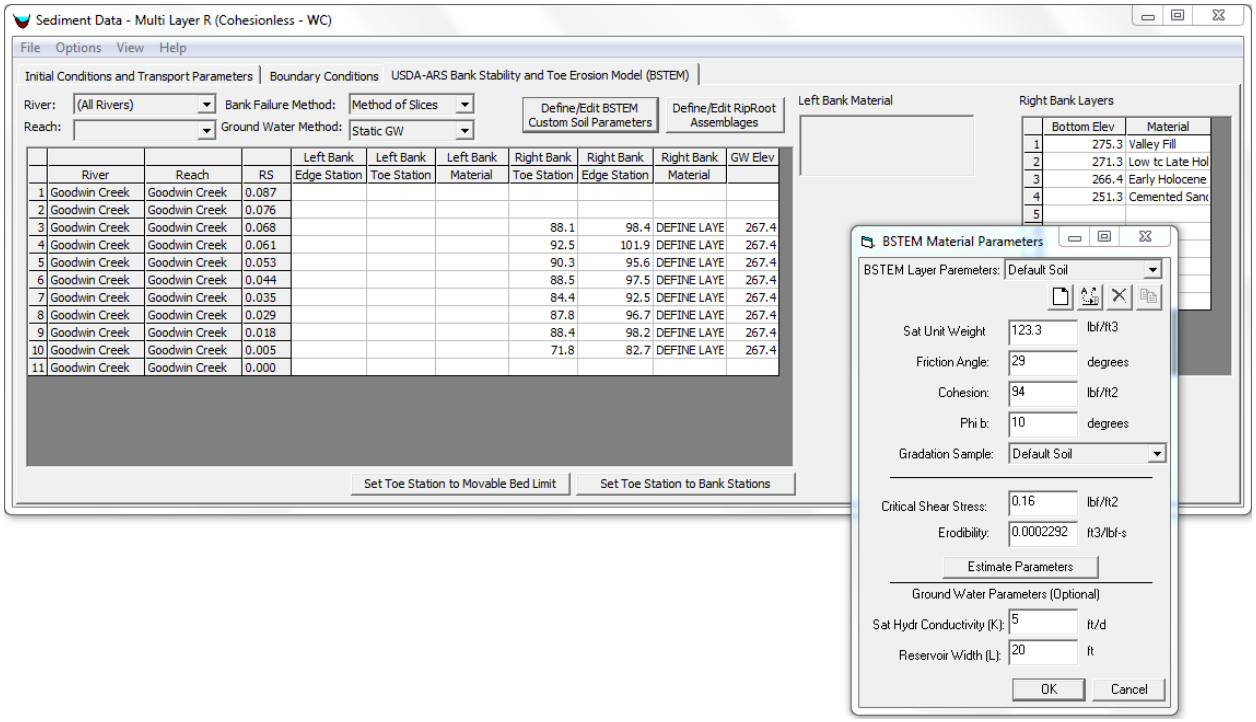

Figure 2 USDA-ARS Bank Stability and Toe Erosion Model (BSTEM) interface in HEC-RAS including the soil parameter interface and an example of soil layer definition.

Defining soil parameters is the most data intensive part of using the BSTEM algorithms. Each soil layer requires classical geotechnical parameters (unit weight, friction angle, cohesion, and bulk unit weight), ϕ^b (representing the rate of increasing apparent cohesion with increasing matric suction), and hydraulic scour parameters (critical shear and erodibility). The model can be very sensitive to these parameters, particularly *k* where values can span orders of magnitude, making them highly site specific. Therefore, HEC-RAS included three methods of increasing complexity, to specify soil properties and negotiate the trade-off between data collection costs and parameter uncertainty. First, HEC-RAS included 16 default parameters from the BSTEM database, regression estimates based on decades of USDA-ARS measurements and modeling. Computing bank erosion in an HEC-RAS sediment model can be as simple as defining bank toe and edge stations, defining a groundwater elevation, and selecting the closest soil type from a default drop down list. However, because these parameters are so site specific, defining customized soil parameters (Figure 2) is recommended. HEC-RAS populates the soil type drop down list with customized soils as well as the default types. Finally, users can specify soil stratigraphy, selecting

the layer contact elevation and either a default or customized soil type for each layer (the method used in Figure 2 and the example application below).

The model can also be sensitive to the toe station parameter. The USDA-ARS BSTEM toe station and the HEC-RAS movable bed limits should generally be the same node, to avoid immobile cross section nodes or double counting scour. HEC-RAS includes a button to copy the movable bed limits to the BSTEM toes, to keep them consistent. If these nodes coincide, channel nodes move vertically and bank nodes move laterally, with the toe/movable bed limit node tracking both degrees of freedom. HEC-RAS also includes an option that deposits (but doesn't erode) outside the movable bed limits, allowing bank stations to move laterally and vertically in one direction.

Bank failure computations can increase sediment simulation run times by as much as an order of magnitude if BSTEM runs for both banks of every cross section at every computation increment. However, HEC-RAS only computes bank processes for banks with BSTEM data, allowing users to analyze particular reaches or stretches. Additionally, the model computes bank failure at every computational increment by default, but can often provide the same results computing on a coarser temporal scale. Users can reduce run times by increasing the number of time steps between bank computations, reducing run times dramatically. HEC is actively working on methods to optimize searches, detect and skip unnecessary computations, and find other opportunities to reduce run times further.

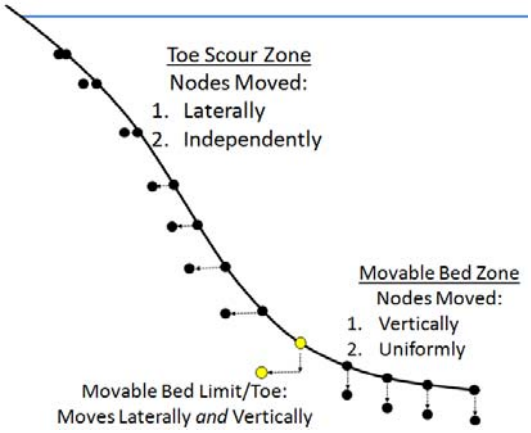

Figure 3 Differences between toe scour and bed change node updates in the coupled HEC-RAS/BSTEM model.

BSTEM algorithms are tied to the sediment transport module in HEC-RAS, requiring a sediment model to perform a dynamic bank-migration analysis. However, bank mechanics can be isolated from bed mechanics by defining the sediment transport parameters but setting the cross section(s) to 'pass through nodes.' A pass through cross section with BSTEM parameters will only adjust the cross section according to the BSTEM processes.

EXAMPLE APPLICATION

The USDA-ARS bank-process models are often tested and validated on Goodwin Creek (Simon et al., 2000; Langendoen and Simon, 2008; Lai et al., 2014), a carefully instrumented research reach in northern Mississippi with detailed hydrologic, groundwater and bank migration time-series data. ARS has measured flow on both major reach tributaries continuously since October 1981, recording flow each time stage changes by a small increment, providing a reliable, high resolution, upstream boundary condition. Up to eleven fixed cross sections were surveyed 51 times, between February 1996, and a bank stabilization project in 2007 (as well as six times since the project), recording up to 8 m of bank migration (Simon et al., 2000; 2008; 2011). The reach also has distinct stratigraphy, with four easily distinguished soil layers, each with detailed soil parameter and erodibility data from extensive borehole shear and jet tests. The soil property measurements, the temporal resolution of the boundary condition and bank migration time series, and the magnitude of the lateral bank scour and failure make Goodwin Creek an ideal site to test the coupled HEC-RAS/BSTEM model.

The initial, 1996 cross sections were used to build the HEC-RAS model and three customized soils were entered in the HEC-RAS Soil Property data base. Cross section "Toe" and "Top of Bank" nodes were

carefully identified and the "Define Layers" option (Figure 2) was selected for each cross section, populating each with the same four-soil-stratigraphy: a cemented sand and gravel conglomerate on the bottom, an early Holocene cohesive soil, a late Holocene cohesive soil, covered with valley fill.

Validation is a wrought concept with unhelpfully broad semantic range in model development (Oreskes et al, 1994; Rykiel, 1996; Gibson, 2013). In this case, 'validation' simply means an exercise to increase user confidence that the algorithms in the HEC-RAS/BSTEM coupling behave as designed by comparing them to field data and other models.

Since this was a model validation, rather than a project calibration, we adopted the parameters from the successful CONCEPTS model in Langendoen and Simon (2008) without adjustment. Langendoen and Simon (2008) adjusted the erodibility and critical shear of the toe material at the outside of a bend to compensate increased shear stresses produced by the three-dimensional flow that the 1D model ignores. The HEC-RAS validation adopted this approach and these parameters.

The toe material in Goodwin Creek is a cemented conglomerate, which controls the stream morphology and the rate of bank recession. The conglomerate has a relatively low fine content (1.4% finer than 63 μm) but has cohesive properties, amenable to jet tests and cohesive erodibity equations. However, since BSTEM uses cohesionless equations, by default, if the layer is less than 20% fine-grained material, the model was run with both the cohesionless approach and with the cohesive, erodibility approach used in Langendoen and Simon (2008) (by dropping the "% fine for cohesionless approach" factor to zero).

The Goodwin Creek analysis was run through the period (Mar 1996 – Feb 2001) replicated by Langendoen and Simon (2008) and then extended to include subsequent migration until the banks were modified as part of a bank-stabilization project in March 2006.

RESULTS

Cohesive model results are plotted with seven, measured, right-bank surveys for two representative, cross sections on Goodwin Creek in Figure 4 (XS6 and XS7, two mid-reach cross sections from Langendoen and Simon, 2008) . The location and shape of the final model cross section approximately matched the observations, estimating total bank migration and computing tension cracks where observed. The tension cracks in the prototype are longer than those the model computed. Langendoen and Simon (2008) customized the tension crack, specifying the observed crack length, but customized crack length is not available in HEC-RAS 5.0. Despite these minor differences, the results suggest the following: First, they represent a code verification step for the HEC-RAS/BSTEM model, demonstrating that it replicates prototype behavior and other model results. Second, results validate the Langendoen and Simon (2008) calibration (based on 1996-2001 measurements), demonstrating that their parameterization performed well outside of its calibrated time window (e.g. 2001-2007).

Select cross sections are plotted in Figure 4. Including all 51 repeated cross-sections would make the plot too dense to evaluate model results. It is still useful to evaluate the model against all measured data, however. Therefore all prototype measurements were plotted with the model results by interpolating the lateral migration time series at five reference elevations in Figure 5. The cross-section stations for lower elevations migrate more gradually in both the prototype and the model, as the toe consistently scours. Bank-failure events expand the higher elevations more episodically. The high bank processes track the observed stations better than the toe scour processes for both cross sections. The model also simulates more retreat at XS6 early in the time series and less later, matching the final migration but not matching intermediate steps. However, given the complexity of the processes and the uncertainty in the data, the spatial and temporal agreement for XS7 is excellent and XS6 is acceptable for most purposes.

Finally, the relative contribution of bank sediment is plotted in Figure 6, differentiating between hydraulic (toe scour) and geotechnical (mass failure) processes. Bank failure contributes almost an order of magnitude more sediment (205.6 tonnes) than toe scour (25.6 tonnes), but the rate of the former is correlated with the rate of hydraulic toe erosion, as expected. Both processes slow as the simulation progresses (a phenomenon also observed in the prototype data in Figure 5). Flows in the first two years were higher than the rest of the simulation, but model results also indicate process feedbacks. Widening cross sections and depositing upstream sediment decrease boundary shear stress and, therefore slow toe erosion and consequently, bank failure rates and overall migration.

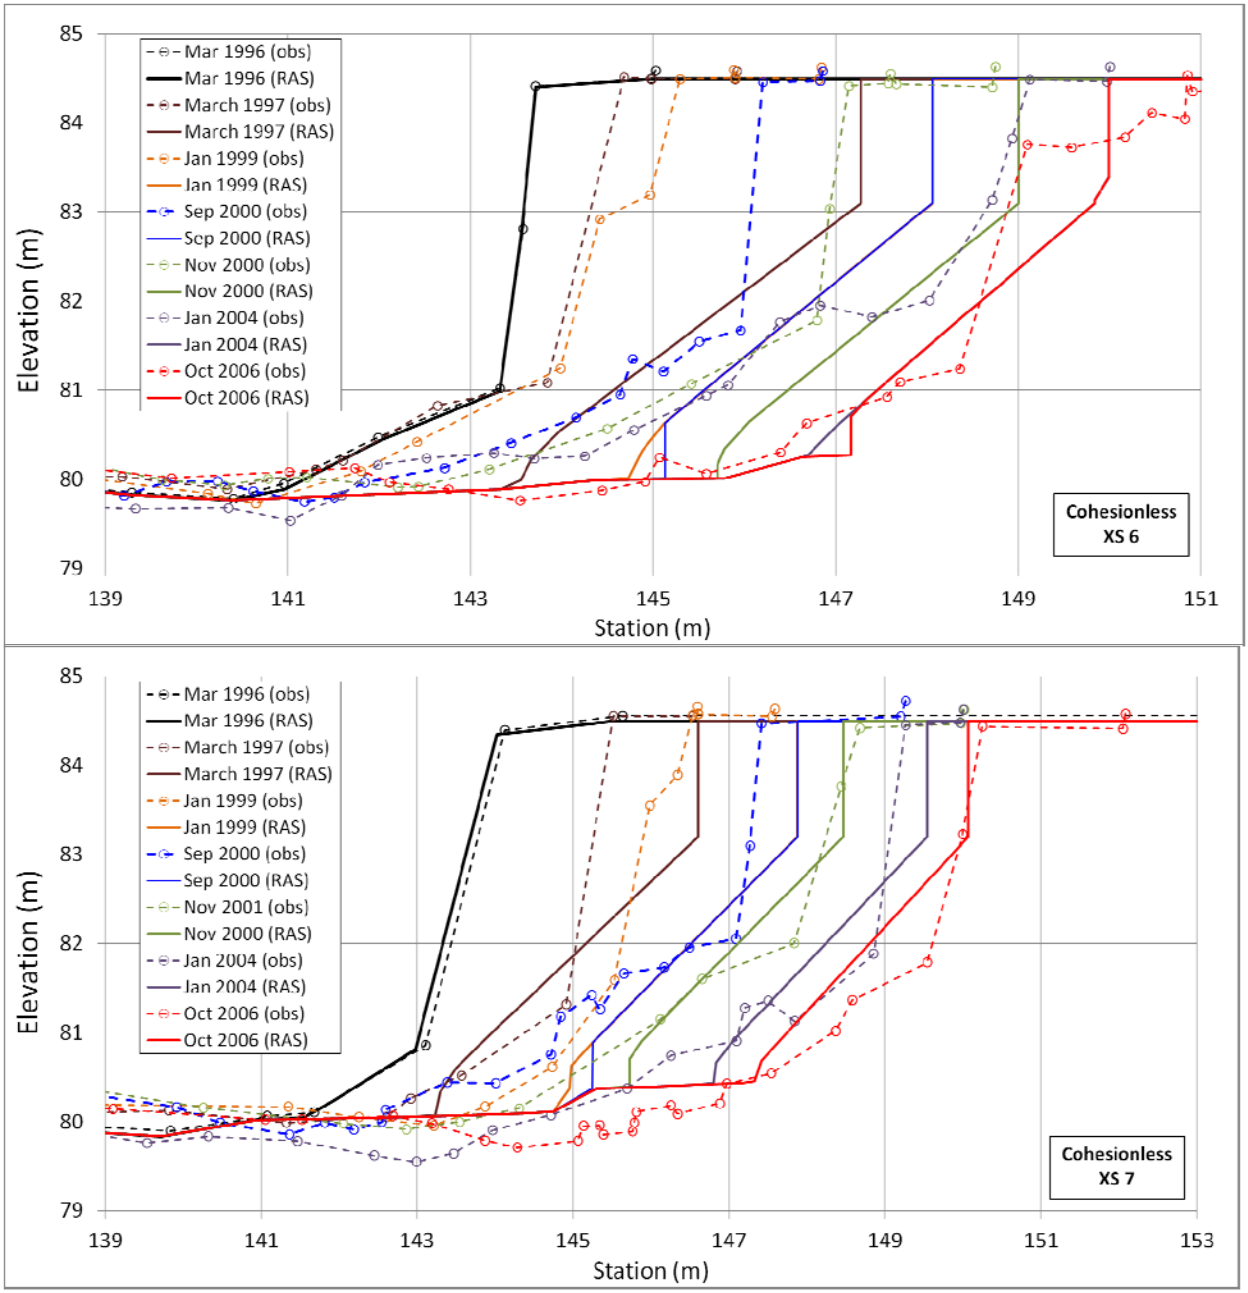

Figure 4 Select Goodwin Creek repeated right bank surveys at the two central cross sections with HEC-RAS/BSTEM cross section migration.

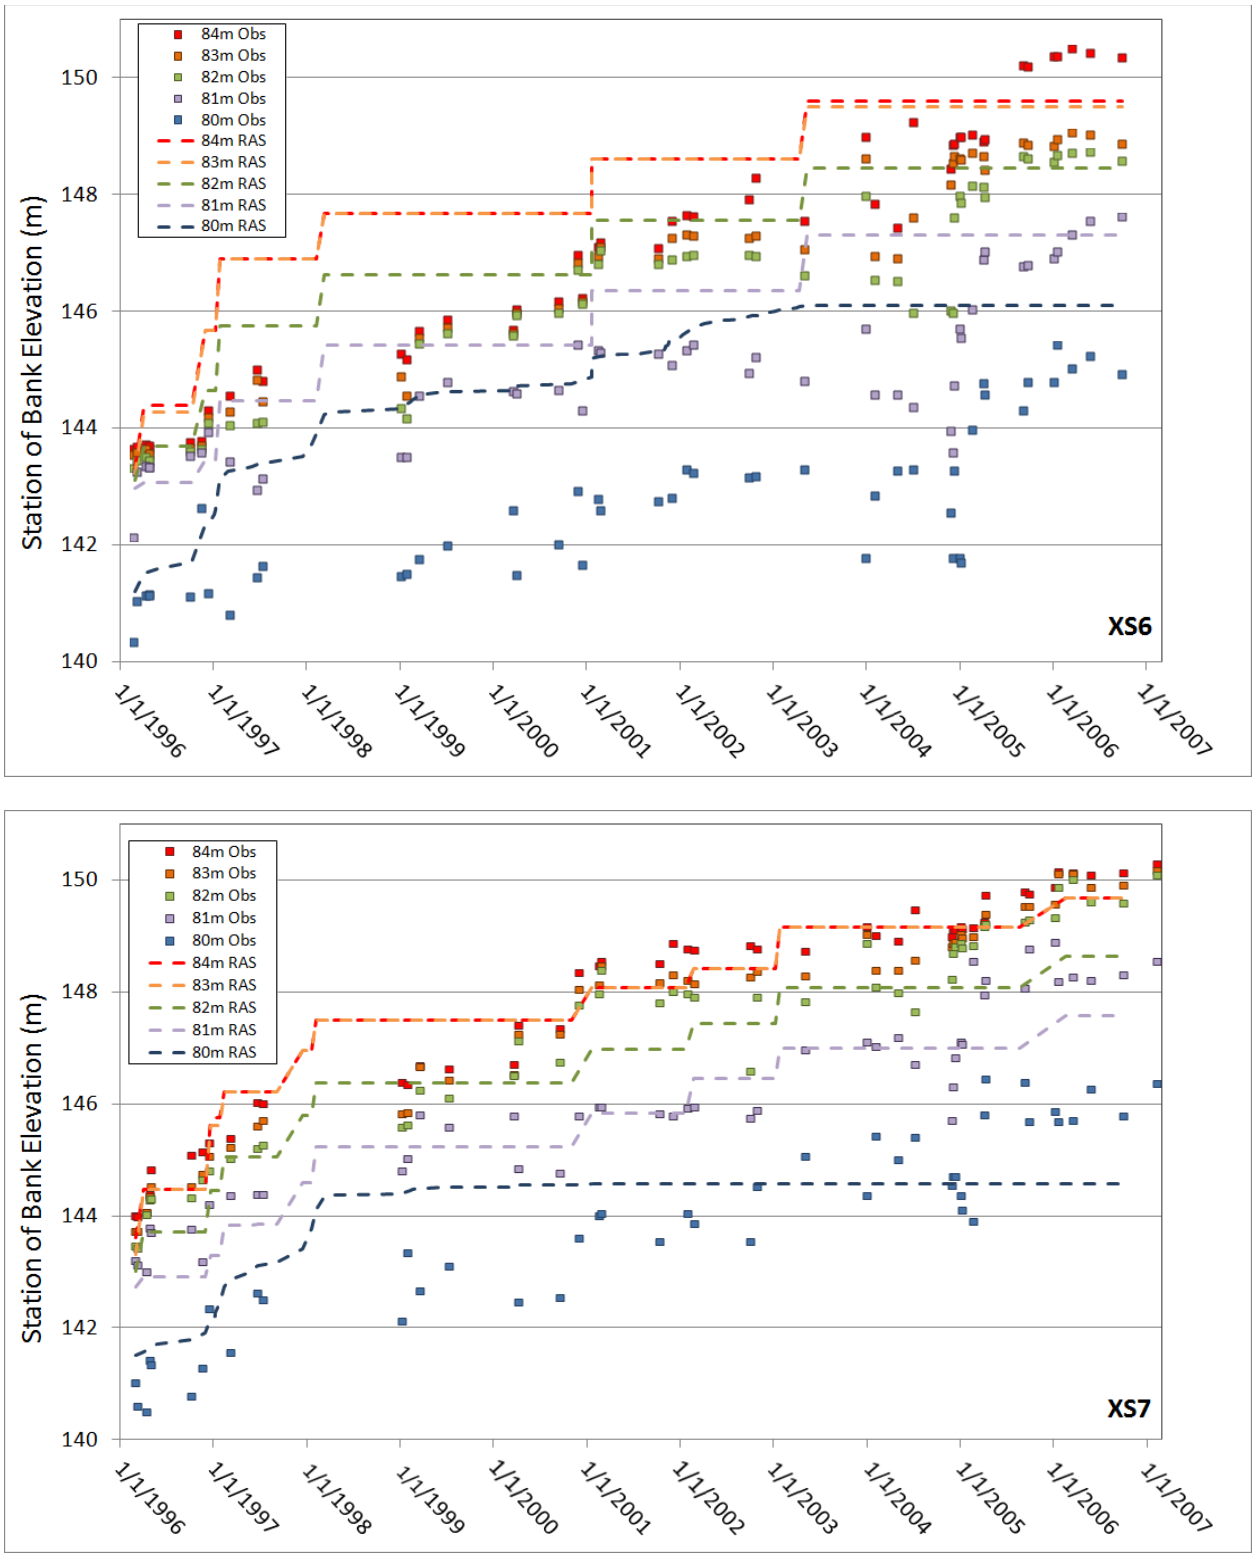

Figure 5 The lateral migration of the right bank of cross sections 6 and 7 (from Figure 4) at five different elevations. The HEC-RAS/BSTEM continuous simulation results are plotted with stations interpolated at the five elevations from all surveys between March 1996 and October 2006.

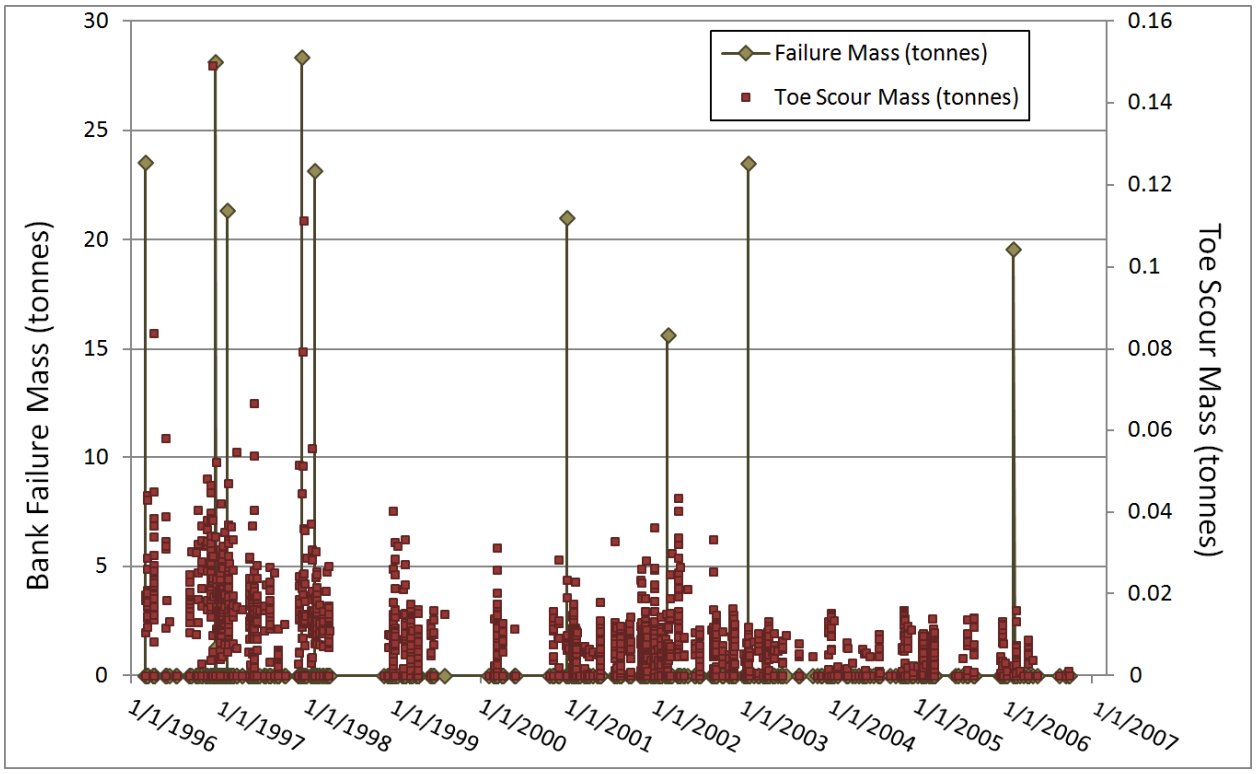

Figure 6 Time series of toe scour and bank failure contributions from the cohesive simulation for XS7 above. The toe scour contribution dropped over time as the channel widened and the ten failures contributed almost an order of magnitude more sediment over the simulation.

The cohesive model results reported above were based on excellent soil and flow data and model parameters that are not only based on copious, careful measurements, but already calibrated by Langendoen and Simon (2008). The cohesionless toe scour prediction in the coupled HEC-RAS/BSTEM code with the transport equations have over predicted scour in most model applications to date, often dramatically. Hundreds of feet of bank migration are not uncommon with some transport functions. Therefore, whether the data-driven cohesive or equation-driven cohesionless method is used, calibration (e.g. comparison to repeated cross sections or historic aerial photographs) is still essential. Additionally, the authors are experimenting with bank 'mixing algorithms' that apply transport-capacity calculations to clast-sized bank materials.

Despite these limitations, the cohesionless methods successfully bracketed prototype migration. Wilcock and Crowe (2003) seemed the most appropriate transport function *a priori*, with its surficial transport formulation (building mixing processes into the equation) and its bimodal flexibility. This method under predicted migration by 30 to 50%, (Figure 7) indicating that the transport equation performed as intended, mainly missing cementation effects in the toe conglomerate, which it was not designed to capture. Alternately, Engelund and Hansen (1972) over predicted bank migration by 50 to 100% (Figure 8). The range of results between the best fit equations underlines the importance of site specific data, but the cohesionless methods bounded the results.

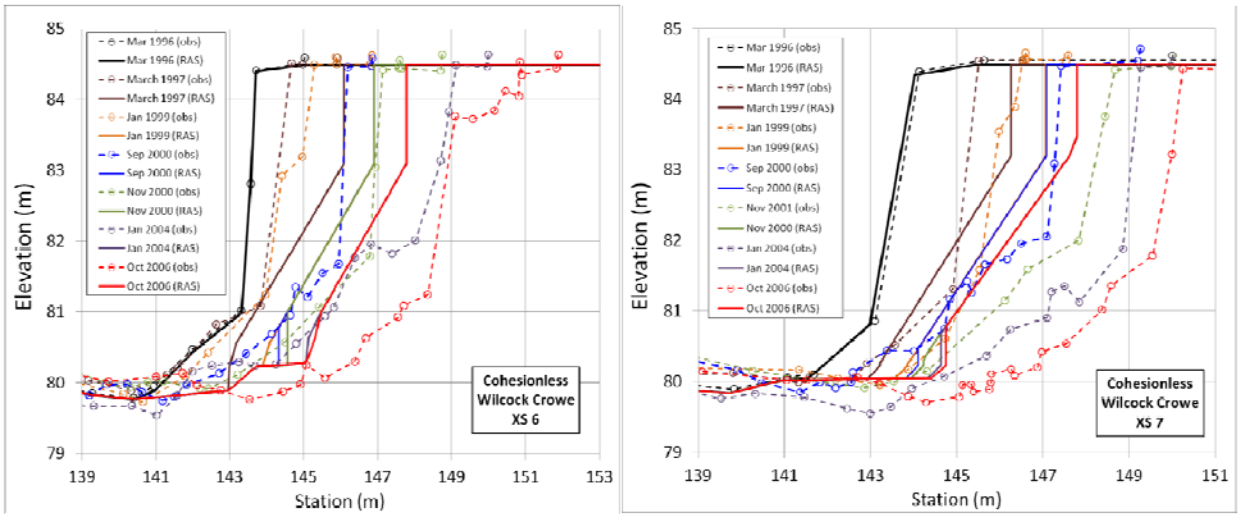

Figure 7 Measured cross sections from Figure 3 and simulated cross sections, computed with cohesionless methods base on the Wilcock and Crowe (2003) transport equation.

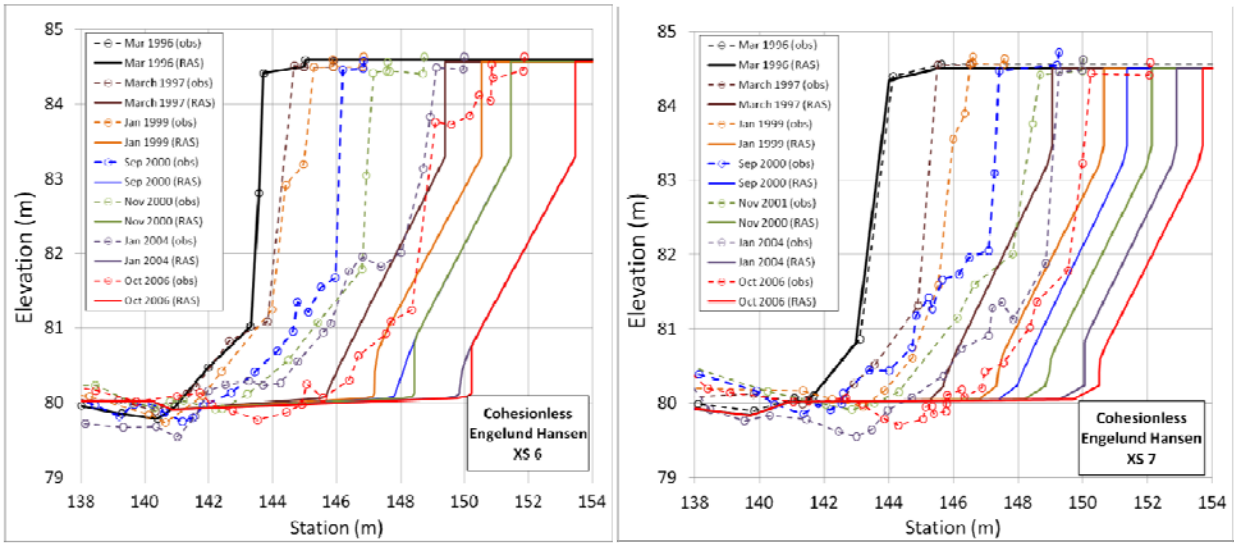

Figure 8 Measured cross sections from Figure 3 and simulated cross sections, computed with cohesionless methods base on the Engelund Hansen transport equation.

CONCLUSION

The USDA-ARS Bank Stability and Toe Erosion Model (BSTEM) has been integrated into HEC-RAS. The joint model simulates coupled bed and bank processes, and the feedbacks between vertical bed erosion and deposition, lateral toe scour, and geotechnical bank stability. Bank migration at Goodwin Creek, Mississippi was simulated with the coupled model using the parameters and benchmarks in Langendoen and Simon (2008), and then continued for five years beyond. The coupled HEC-RAS/BSTEM model performed well, replicating the calibration and demonstrating its subsequent robustness. HEC-RAS 5.0 includes these capabilities, making them broadly available.

Acknowledgements: The integration of HEC-RAS and the USDA-ARS Bank Stability and Toe Erosion Model (BSTEM) has been a substantial undertaking including multiple contributors in the USACE, the private sector, other Federal agencies, and international interests. Andrew Simon (PhD - Cardno, formerly of USDA-ARS) partnered with HEC to initiate, envision and facilitate the integration. Eddy Langendoen (PhD - USDA-ARS) provided essential technical support and advice throughout the process. The integration utilized code developed by Andrea Curini, (MSc. - URS, formerly of USDA-ARS), Robert Thomas (PhD - University of Leeds, formerly of University of Tennessee) and Yong Lai (PhD - USBR), funded by the Bureau of Reclamation and the Taiwanese Water Resources Agency, with input from Yavuz Ozeren (PhD - University of Mississippi). John Shelly (PhD – USACE-Kansas City) and Paul Boyd (PhD - USACE-Omaha) provided District guidance and feedback on the development. Stanford Gibson (PhD - HEC) and Steve Piper (RMA) worked on the integrated HEC-RAS code. Funding for the development, troubleshooting, and documentation of the integrated HEC-RAS/BSTEM product has come from multiple sources including two USACE R&D Programs (Regional Sediment Management and Flood & Coastal Storm Damage Reduction), the Australian Rivers Institute, and the Missouri River Recovery Program. Imaan Taghavi (UC Davis) tested the combined code, running simulations and analyzing the results plotted in this paper.

HEC-RAS Sediment Transport Simulation of Three Reservoirs in the Lower Susquehanna River Basin, Pennsylvania and Maryland

Michael Langland, Hydrologist, US Geological Survey, Pennsylvania Water Science Center, New Cumberland, PA, langland@usgs.gov

Abstract

The U.S. Environmental Protection Agency (USEPA) recently (2010) listed the nation's largest estuary, the Chesapeake Bay, as impaired and established sediment and nutrient load allocations for the six states and the District of Columbia waters draining into the Bay. The Susquehanna River is the largest tributary to the Chesapeake Bay and transports about one-half of the freshwater and substantial amounts of sediment, nitrogen, and phosphorus. The loads transported by the Susquehanna River to the Bay are affected by the deposition of sediment and nutrients behind three large hydroelectric dams on the Lower Susquehanna River in Pennsylvania and Maryland. The three consecutive reservoirs (Lake Clarke, Lake Aldred, and Conowingo Reservoir) formed behind the three dams (Safe Harbor, Holtwood, and Conowingo) involve nearly 32 miles of the river and have a combined design capacity of 510,000 acre-feet at their normal pool elevations.

Previous studies by Ott and others (1991), Hainly and others, (1995), Reed and Hoffman (1996), Langland and Hainly (1997), Langland (2009), Hirsch (2012) and Gomez and Sullivan (2012) have indicated the two upstream reservoirs have minimal sediment storage capacity and have been in a "dynamic equilibrium" with respect to sediment transport since the 1950's. The most downstream reservoir (Conowingo) is nearly at sediment storage capacity and transitioning to a "dynamic equilibrium" state. Dynamic equilibrium implies there will be no change in long-term (decades) sediment retention resulting from the loss of storage capacity, however short-term (years) deposition and erosion cycles will continue. When capacity is reached, increased flow velocities through the reservoirs will result in less time for transported sediments to deposit resulting in increased sediment loads to receiving waters, including the Chesapeake Bay.

In order to simulate the sediment transport out of the reservoir system and into the lower Susquehanna (2008-11), the U.S. Geological Survey (USGS), in cooperation with the U.S. Army Corps of Engineers (USCOE) and the Lower Susquehanna River Watershed Assessment Team (LSWA, a consortium of Federal, State, and private organizations), completed the development of a one-dimensional (1-D) model (HEC-RAS). The USGS constructed new geometric and hydraulic boundaries to align with previous bathymetric cross sections. USGS also constructed sediment transport curves and utilized historical bathymetric data, existing sediment core samples, particle–size and sheer stress data, and current (2008-2011) hydrology and load information to help calibrate the model.

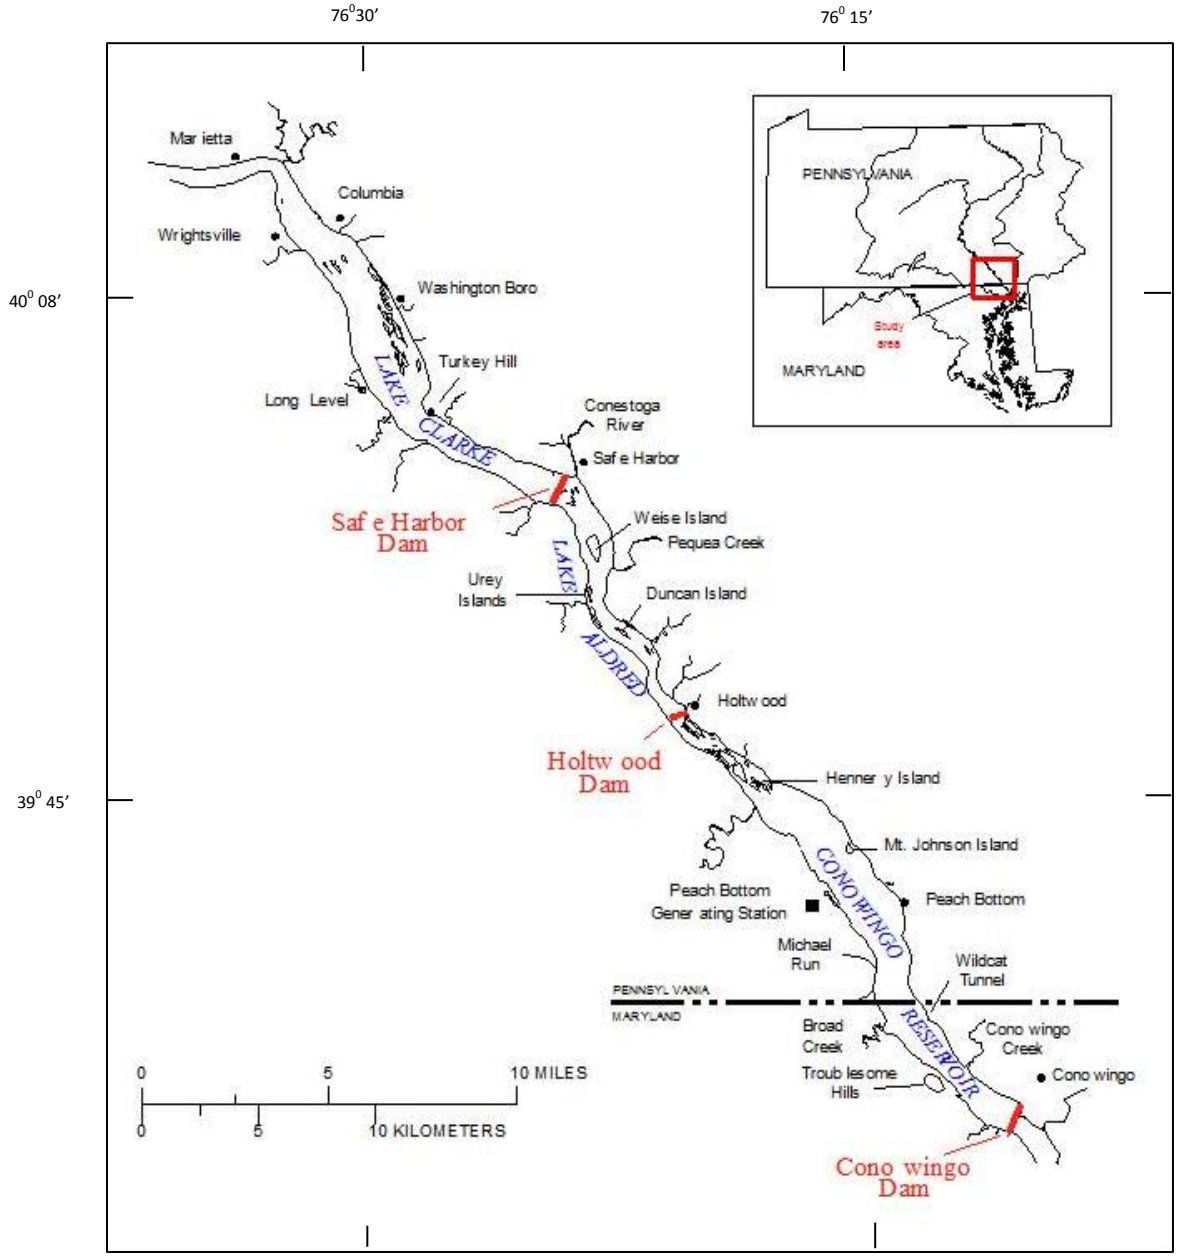

Figure 1 Location of three Hydroelectric Dams and associated reservoirs in the Lower Susquehanna River, Pennsylvania.

The 4-year simulation period was generally normal (10 percent above or below the long-term mean streamflow) for 2 of the 4 years, and above and below normal the other 2 years. In addition, a flood event that produced the second highest daily mean streamflow since 1968 occurred in September 2011. Numerous model iterations of the model were performed and checked to determine bed movement, bed shear, estimated sediment loads, particle size transport, and energy dispersion. During model development, it became apparent that the HEC-RAS model

did moderately well at simulating reservoir deposition over the 4-year simulation period (figure 2A) but did not represent the increased sediment loads from scour during the large storm event that occurred during the simulation period (September 2011). To simulate erosion (scour), two model parameters (fall velocity and bed sorting method) were changed to predict increased sediment loads from larger storm events (figure 2B).

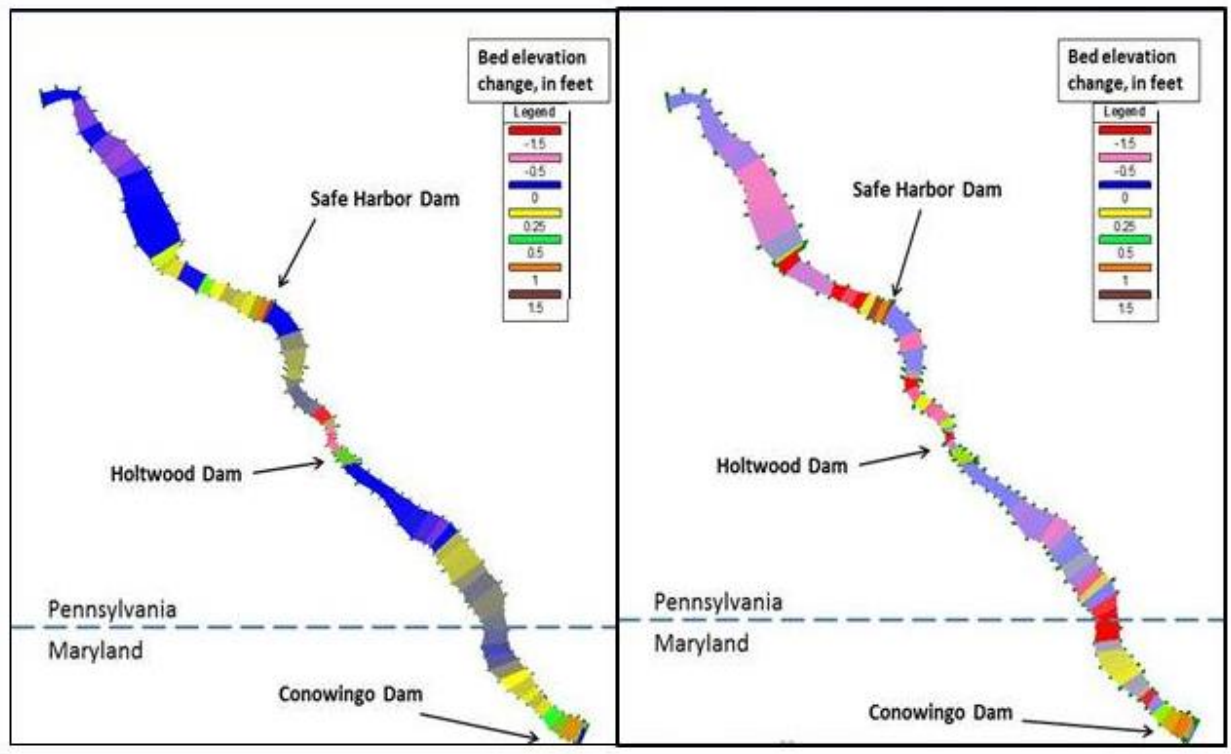

Figure 2 Changes in bed elevation using a HEC-RAS depositional model (A-left), and changes in bed elevation using a HEC-RAS scour model (B-right) for simulation period 2008-2011.

Overall, the two models (deposition and scour) allowed for a range in uncertainty and generally simulated the deposition or scour to about one-half of the expected sediment when compared to estimates from bathymetric change and load results. Lower than expected load estimates were attributed to three likely reasons. First, the HEC-RAC model is limited to simulating either sediment deposition or removal, not both, along a single transect. Comparisons of the 2008 and 2011 bathymetry data showed within individual transects where sediment was both deposited and removed. Second, the modeled "fall velocity" of the fines was about two times lower than literature values and 2-D model runs performed by the USACE. Third, the 1-D model allows one shear stress value when laboratory stress studies on the sediment core data indicate an eight-fold range in variability.

EVALUATING SUSTAINABLE SEDIMENT MANAGEMENT ALTERNATIVES FOR LEWIS AND CLARK LAKE

Paul M. Boyd, Ph.D. P.E, Hydraulic Engineer, U.S. Army Corps of Engineers, Omaha, NE, paul.m.boyd@usace.army.mil; Stanford Gibson Ph.D., Hydraulic Engineer, U.S. Army Corps of Engineers, Hydrologic Engineering Center, Davis. CA, Stanford.gibson@usace.army.mil

Abstract

The Missouri River Recovery Program initiated the Lewis and Clark Lake Sediment Management Study (LCLSMS) to evaluate sediment flushing scenarios at Lewis and Clark Lake/Gavins Point Dam near Yankton, South Dakota. Phase I of the report examined large discharges for short durations, and was published in April 2013. Phase II utilized new features in HEC-RAS (e.g. unsteady sediment transport and bank erosion modeling) to develop an updated reservoir model to examine additional scenarios. The second phase considered in-channel discharges of varying durations to estimate delta progression, evaluate dam and spillway modifications, and predict sediment delivery through Gavins Point Dam.

This paper describes the application of these new tools to the reservoir model and a downstream model to assess impacts of the predicted sediment discharge. Results of the modeled scenarios are summarized and conclusions made about the effectiveness of using HEC-RAS for reservoir modeling.

INTRODUCTION

The deposition of hydraulically transported sediments occurs in all flow impoundments, whether they are constructed or naturally occurring. Sedimentation occurs when flow velocities drop below the threshold required for transport. This deposition can cause an impediment to flow and an eventually redirection of flow. This usually occurs when the impoundment is completely or nearly full of sediment. If left in the current flow regime, Lewis and Clark Lake will eventually fill with sediment, albeit more than 150 years in the future according to current projections.

Lewis and Clark Lake is impounded by Gavins Point Dam on the Missouri River. Its existing uses would be severely compromised if the reservoir is allowed to fill with sediment. The reservoir is operated for flood risk reduction, hydropower, navigation, recreation, water supply, water quality, fish and wildlife, and irrigation. The Lewis and Clark Lake Sediment Management Study is evaluating a wide variety of scenarios for managing the reservoir and the sediment within it to continue to provide the intended benefits.

Lewis and Clark Lake

Lewis and Clark Lake was formed by the closure of Gavins Point Dam in 1955. The dam is located at river mile 811.1 (RM 811.1), approximately five miles upstream of Yankton, South Dakota, on the Missouri River as shown in Figure 1. Gavins Point Dam is one of six mainstem dams on the upper Missouri that are operated by the Northwestern Division of the U.S. Army Corps of Engineers. The Missouri River dams and reservoirs provide significant benefits to the nearly 15 million people that reside in the states through which it flows.

Figure 1 Lewis and Clark Lake behind Gavins Point Dam

Lewis and Clark Lake reached its full water surface elevation of 1208 feet (NGVD 1929) in early 1957 and has been managed with water elevations between 1206 feet and 1210 feet (NGVD 1929) ever since. When closed, the lake extended to approximately RM 836, creating an open-water lake that was approximately 25 miles long.

Since closure, sediment surveys have been performed approximately every decade to determine the amount of sediment deposition and changes in the reservoir's storage capacity. These surveys have indicated that approximately 2,600 acre-feet of sediment have been deposited per year below elevation 1210 feet (NGVD 1929) through the 2011 surveys (USACE, 2013a). In the reach between Gavins Point Dam and Fort Randall Dam at RM 880, sediment is delivered from tributaries including the Niobrara River, Ponca Creek, and Bazile Creek, as well as from the banks and bed of the river upstream. Figure 2 shows the two largest deltas in the river reach. Additional sediments are deposited in the overbanks of the river and in the Niobrara River delta at RM 844, yielding a total sediment input into the reach in excess of the volume below the 1210-foot threshold.

Figure 2 Niobrara River Delta (left) and Lewis and Clark Lake Delta (right)

The deposition of sediments in the Lewis and Clark Lake delta has effectively shortened the length of the lake over the past 50 years. Currently, the open reach of the lake extends to near RM 826, a distance of 15 miles of open lake. The migration of the delta appears from visual observations to be approximately 500 to 600 feet per year, although the deposition rate has remained fairly constant over the past 50 years (USACE, 2011).

The migration of the delta both up- and down-river reduces the storage capacity of the reservoir. The initial capacity of the lake was 575,000 acre-feet below the 1210-foot elevation, and the 1995 capacity was 470,000 acre-feet, which is a storage loss of approximately 18.5 percent. Storage loss was updated with the 2011 surveys for this project. These surveys indicated the total storage loss at the 1210-foot elevation was 26 percent (USACE, 2013).

THE LEWIS AND CLARK LAKE SEDIMENT MANAGEMENT STUDY (LCLSMS)

The LCLSMS was developed to examine the engineering viability of moving the sediments deposited behind Gavins Point Dam into the river downstream of the reservoir. In the 2003 amended Biological Opinion (BiOp) for the Missouri River, the U.S. Fish and Wildlife Service stated *"The Corps shall research and develop a way to restore the dynamic equilibrium of sediment transport and associated turbidity in river reaches downstream of Fort Peck, Garrison, Ft. Randall, and Gavins Point Dams. Sediment bypass around large dams is feasible (Singh and Durgunoglu, 1991). Bed degradation below dams and head cutting at the mouths of tributaries might be addressed with grade control structures. Weir notches at grade control structures would allow for fish passage to the tributaries. Because of the large sediment deposition zone at the upper end of Lewis and Clark Lake and its proximity to Gavins Point Dam, Gavins Point may provide the best opportunity for a pilot study (USFWS 2003)."*

Initial consideration of using flows through the reservoir to transport sediment was not strongly supported. Additional research on the reservoir system in the Lewis and Clark Lake reach showed that there is the possibility that sediments can be transported through Lewis and Clark Lake (Engineering and Hydrosystems, 2002). A number of different flow and stage

scenarios have been suggested by this research. With the recommendation for a study at Gavins Point Dam through the BiOp, and proof of concept provided by the 2002 study by E&H, the LCLSMS was initiated in 2005.

Project Goals

The LCLSMS is an engineering viability study. As defined, the study will deal only with the physical processes of hydraulic flow, and sediment erosion, transport, and deposition. Environmental, economic, political, and quality of life issues will not be considered in the scope of this study. The project goals are to:

- Determine the hydraulic capacity to transport sediment in and below Lewis and Clark Lake
- Develop estimated final reservoir geometries as a result of flow alternatives
- Determine downstream sediment transport capacity and possible deposition zones
- Develop a test flow to mimic the hydraulic alternative most likely to result in the desired outcome
- Protect existing project infrastructure

Since the study began, it has grown to include two modeling phases to evaluate hydraulic drawdown flushing, a modeling effort to examine the future depletion of available sediments below the dam, and a cost analysis of dredging alternatives.

LCLSMS Activities

Phase I – Using GSTARS-HTC to Examine High Flow Single Events

The LCLSMS project began with the development of the project plan and scope of work for modifying GSTARS3 by Colorado State University's Hydroscience and Training Center (HTC) in 2005. Award of the work to develop GSTARS-HTC signaled the beginning of the project in late 2005. This effort was considered Phase I, and was completed in 2012.

Phase II – Using HEC-RAS to Examine Repeated Flow Events

Based on the results of Phase I and stakeholder feedback, the Missouri River Recovery Program (MRRP) chose to continue the study by expanding it to include more flow scenarios and examine the impacts of repeated events into the future. This phase also included the transition to the HEC-RAS one-dimensional model for analysis (HEC-RAS v.5.0). This phase began in latter 2011 and is expected to be completed by the fall of 2015.

Projection of Future Conditions below Gavins Point Dam

In coordination with the Emergent Sandbar Habitat (ESH) Program, the LCLSMS expanded the study to include an analysis of future sediment availability in the reach below Gavins Point Dam in 2012. It is expected to be completed in the fall of 2015.

Cost Analysis of Dredging Alternatives for Lewis and Clark Lake

Dredging is a common management action for rivers, lakes, and harbors. Many stakeholders have inquired about the Corps' ability to dredge Lewis and Clark Lake and the magnitude of the effort needed to maintain the current reservoir capacity. The study has teamed with the Corps of Engineers Research and Development Centers (ERDC) Dredging Operations Technical Support

Program (DOTS) (http://el.erdc.usace.army.mil/dots/) to consider three dredging configurations for Lewis and Clark Lake. The dredging alternatives study was begun in mid-2013 and is expected to be completed by the fall of 2015.

ANALYSIS AND RESULTS

Phase I Results

Two numerical sediment transport models were developed to predict the movement of sediment through and below Gavins Point Dam. The Lewis and Clark Lake Model used the GSTARS-HTC (USACE, 2013b) code to predict sediment transport through the Missouri River delta and past the spillway at Gavins Point Dam. The model extends from Fort Randall Dam (RM 880) to Gavins Point Dam (RM 811). The model for the reach from Gavins Point Dam to Sioux City, Iowa (RM 730) used HEC-RAS to route the flow and sediment output from the reservoir model through the recreational river reach below the dam, and deliver it to the downstream navigation channel.

Five flushing scenarios were developed based on guidance from a flushing-reconnaissance report (Engineering and Hydrosystems Inc, 2002) that recommended very high river flows for short durations. Flow scenarios varied from 88,000 to 176,000 cfs, with the peak flow lasting up to seven days.

The largest event was also simulated with a section of the Gavins Point Dam spillway lowered by ten feet to increase the energy available to move sediment. For the study analysis, all flows were released through the spillway at Gavins Point Dam to avoid sending sediment through the powerhouse. All the scenarios included draining Lewis and Clark Lake (to increase effectiveness), increasing discharge at Fort Randall Dam upstream to the peak flow, maintaining the flow for the flush duration, and reducing the flow as the reservoir refills.

All the flushing scenarios predicted transport of silt and clay size particles through the dam. In the cases of the high flow and modified spillway, the model predicted very high sediment concentrations and total mass of sediment transported. Each scenario also predicted the redistribution of sand-size particles throughout the delta and bottom of Lewis and Clark Lake. However, due to the length of the reservoir and the location of the spillway gates, which are 20 feet above the lake bottom, almost no sand passed through the spillway for any scenario. Only the flushing scenario with 176,000 cfs and the modified spillway gates, when sediment concentrations were the highest, predicted 0.07% of the mass of sediment passing the spillway as sand; the remaining 99.93% was silt and clay (USACE, 2013c).

While these high-flow, short-duration scenarios did not predict the delivery of enough sand to support sandbar habitat below the dam, a number of conclusions indicate that there may be scenarios not modeled in this study that would hold promise. Study results are summarized as:

- All the modeled scenarios showed erosion of delta deposits and redistribution of sand within the reservoir, with much of the sand settling in the deepest area of the lake. Repeated flushing events may result in better sediment transport to the downstream channel once the deeper areas are filled in.

- Modifying the spillway resulted in a significant increase in sediment transport. The modification of the spillway or inclusion of low-elevation outlets in the dam structure could greatly increase flushing efficiency.
- The spillway crest elevation above the reservoir bottom prevents complete draining of the reservoir through the spillway, resulting in a sediment trap at the face of the dam. As the delta migrates closer to the dam, transport of sand to the face of the dam will increase during any flushing event. Therefore, flushing effectiveness will increase in the future.
- The downstream model predicted minor aggradation of the channel only with the highest sediment discharge from the dam. Since the sediment in the dam discharge was comprised of silts and clays, most were transported through the reach and into the navigation channel.

These conclusions directly led to the development of Phase II and the inclusion of longer and more varied management scenarios. All the documents associated with the Phase I and Phase II modeling studies are available at http://moriverrecovery.usace.army.mil/mrrp/f?p=136:155:2604171657024::NO::PIS_ID:28.

Phase II Analysis - Using HEC-RAS to Examine Repeated Flow Events

Stakeholder feedback and additional questions from other Federal agencies prompted the MRRP to expand the LCLSMS study to include flushing scenarios that limited flow to the bank-full condition coupled with a long term view to sediment management.

Table 1 Gavin's Point Dam and Lewis and Clark Lake Advantages and Challenges to Alternative Sediment Management (USACE, 2015)

Advantages	Challenges
Gavins Point is the most downstream dam of the Missouri cascade and immediately upstream of the target reach to increase sand load.	Eighteen miles of open water between the current sediment delta and the dam.
Relatively small reservoir for the Missouri River.	The dam has no low-level outlets. So even when drained, the reservoir has a standing pool and multiple miles of open water between the delta and the structure.
Niobrara River delivers a substantial sand load 33 miles upstream of the dam.	There are social and policy constraints on the releases that can be made from Gavins Point dam.
Fort Randall Dam allows managers the flexibility to specify an optimal inflowing hydrograph with unusual precision.	
The impoundment volume of the upstream Missouri cascade removes the standard refilling uncertainties associated with sediment management draw downs in other systems.	

Morris and Fan (1998) defined the classical taxonomy of passive reservoir sediment management alternatives, including: flushing, sluicing, bypass, and turbidity currents. It is still very difficult to predict, model, or manage turbidity currents, and bypass solutions that are not part of the

original design are almost always prohibitively expensive, making flushing and sluicing the two main passive options.

The reservoir model was constructed using a developmental version of HEC-RAS 5.0. HEC-RAS was selected primarily for institutional and transparency reasons. Since the Omaha District has constructed 1D hydraulic models of this system with HEC-RAS, it was advantageous to use HEC-RAS for the sediment modeling. Keeping the sediment model in the same modeling platform as the hydraulic analyses leverages District data and expertise. However, Omaha and HEC identified several limitations of the release version of HEC-RAS 4.1 that complicated flushing analyses in this system. Therefore, this analysis integrated project modeling with software development to implement new methods in HEC-RAS and apply them to the Lewis and Clark Lake analysis.

The scenarios to be modeled were vetted through stakeholder and local and Federal agency feedback. While the list is not all-inclusive, it does cover most of the commonly considered management modifications for reservoir flushing. Many of these scenarios would require significant investment in the project infrastructure. However, any cost comparisons should include the cost of lost benefits due to sedimentation. Table 2 summarizes the scenarios modeled in the HEC-RAS Lewis and Clark Lake model.

Table 2 Phase II HEC-RAS Model Flow Scenarios

Scenario	Flushing Flow (cfs)	Flushing Duration	Other
II-1	None	None	No Action – 53 year projection to determine delta progression through 2064
II-2	60,000	7 days	Base alternative – single drawdown flushing event
II-3	60,000	7 days	Scenario II-2 with 2064 geometry
II-4	60,000	7 days	Seven spillway gate inverts lowered to 1,170 feet
II-5	30,000	7 days	Half magnitude version of II-2
II-6a	60,000	7 days	Low Elevation Tunnels (invert 1,157 feet)
II-6b	30,000	7 days	Low Elevation Tunnels (invert 1,157 feet)
II-7a	180,000	~8 days	Repeat of Scenario I-1 from Phase I
II-7b	88,000	~10 days	Repeat of Scenario I-2 from Phase I
II-8	30,000	7 day repeating	Annual flushing event through 2064
II-9	30,000	7 day repeating	Annual flushing event with longitudinal revetment through 2064
II-10	30,000	7 days	Annual flushing event with dredging 675 tons per day during flush through 2064

The model was calibrated from 1955-2012 to water surface profiles, bed volume change, and grain size distributions. All the scenarios were run in HEC-RAS 5.0, and a short summary of results follows.

Scenarios II-1 and II-3 were compared to determine if there would be an increase in flushing efficiency if the delta were closer to the dam. While results showed that sediment delivery during the event was higher with the future delta conditions, it was not appreciably so.

The highest increases in sediment delivery downstream of Gavin Point Dam were seen in scenarios where physical modifications were made to the dam or reservoir infrastructure. Figure 3 shows the five low-level tunnels simulated in scenario II-6. They are placed below the spillway gates and would allow for nearly complete dewatering of the reservoir to a run-of-river condition, which is ideal for drawdown flushing.

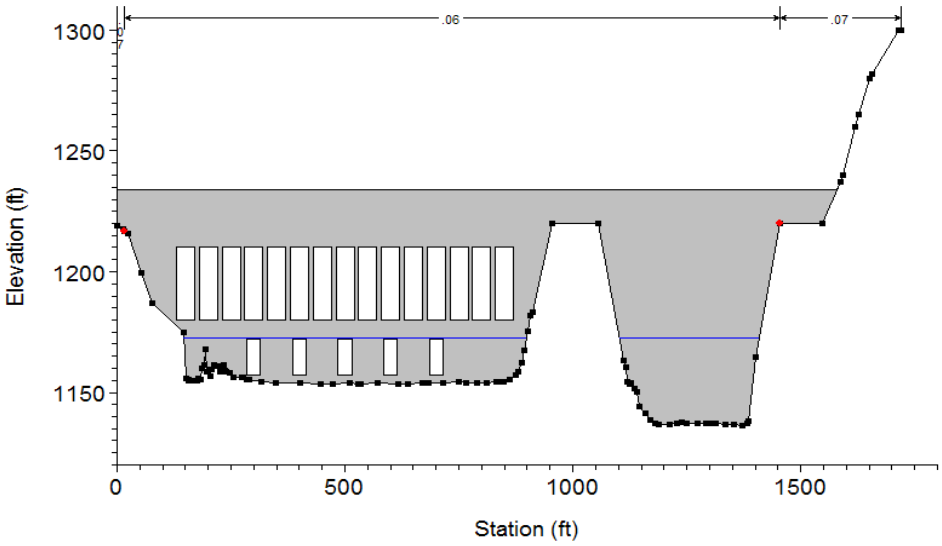

Figure 3 Low level outlets added to Gavin's Point Dam for Scenario II-6.

In both cases (II-6a and 6b) the low level outlets drained the reservoir more effectively, which reduced the total event duration by decreasing the draining time and almost eliminating the transition phase required to reach an equilibrium run-of-river flow. Local bed change was computed for Scenario II-6a and 6b and is shown in figure 4.

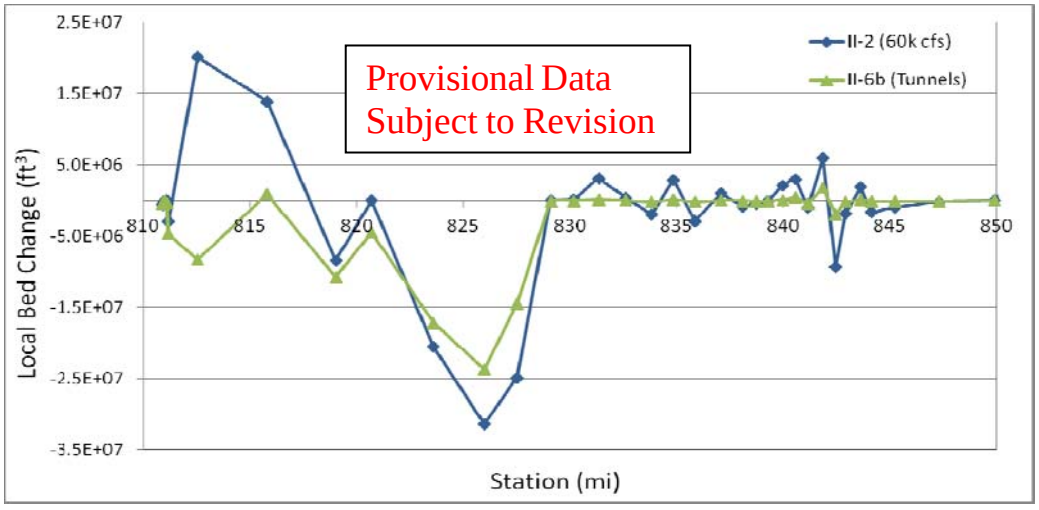

Figure 4 Seven day, 60,000 cfs sluicing event with and without low-level outlet tunnels.

The low level gates flush sediment because they decreased trap efficiency (or increased pass thorough efficiency). In both cases, the low-level outlet models passed most or all of the sediment scoured from the delta and even scoured some pool deposits on the way to the outlets. Scenario II-6 flushes more sediment of every size class than the other scenarios. But more importantly, it flushes sand. In fact, the 30,000 cfs version of Scenario II-6 releases more than half of the 60,000 cfs volume of each size class and orders of magnitude more sand than any of the other higher flow scenarios.

Scenario II-9 included an underwater revetment that would be approximately 15 feet below the water surface at full pool. It would be exposed during drawdown to channelize flows on the south bank of the reservoir, increasing flow velocity and transporting sand-size sediments to the spillway. Figure 5 lays out the approximate location of the revetment.

Figure 5 Approximate alignment of modeled revetment.

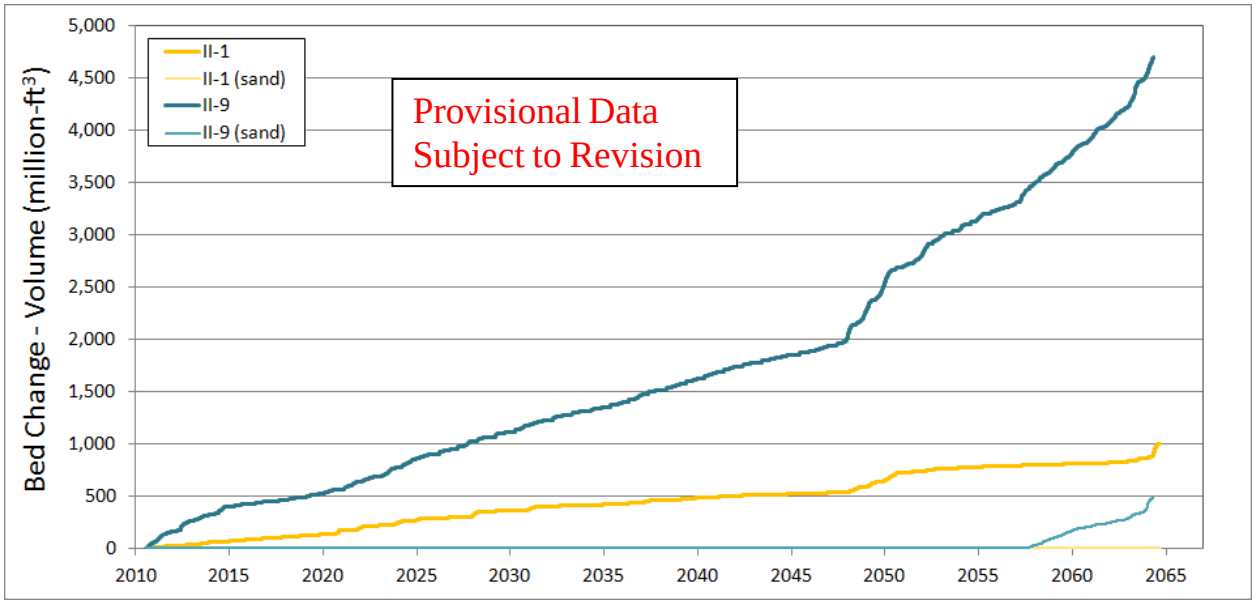

Figure 6 Time series of sediment released from Gavin's Point dam for Scenario II-1 (no action) and II-9 (revetment and flush), including total release and the sand component.

Figure 6 shows a comparison of scenarios II-1 and II-9. Scenario II-9 included two management alternatives, a drawdown flush and the revetment. A sensitivity analysis suggests that most of the value in this alternative comes from the revetment and that the reservoir may start passing sand before 2065 with just the revetment.

Modeling a Drawdown Flush on the Niobrara River

In August 2014, USACE Omaha and HEC began a joint project to model a scheduled drawdown flushing event at Spencer Dam on the Niobrara River. This project is intended to determine the uncertainty associated with using HEC-RAS to model a reservoir drawdown flush in a sand-bed river system. The results will be used to improve the LCLSMS Phase II reservoir model. The Spencer Dam flush study is supported by the Corps' Regional Sediment Management (RSM) Program.

Projection of Future Conditions Below Gavins Point Dam

The reach of the Missouri River directly below Gavins Point Dam has been historically significant as nesting habitat for the Interior Least Tern and Piping Plover. These shore birds rely on bare sandbars to forage and provide clear lines of sight to identify predators.

The construction of dams on the Missouri River has resulted in the loss of nearly 100% of the sediment load from the upper river into this reach. Without sufficient sediment load, the bed and banks of the river have degraded, resulting in channel armoring, bank erosion, and the loss of emergent sandbar habitat for these and other birds.

The question has often been raised as to when, under the current management regime, the reach will effective run out of available sand in the bed and banks. This would seriously inhibit the ability to build sandbars through any means, whether with designed flows or through traditional construction methods.

USACE Omaha is developing a HEC-RAS 5.0 model with WEST Consultants, Inc. to examine future sediment erosion and project bed armoring and bank erosion over the next 100 years. In addition, the model will test the threshold for the projected sediment loads required to prevent future degradation. Finally, the model will be tested with varying discharges to observe what sandbar building can be expected in the future. The analysis and the completed report are expected by the end of 2015.

Cost Analysis of Dredging Alternatives for Lewis and Clark Lake

Coker et al. (2009) suggested a sediment management plan for Lewis and Clark Lake that includes yet undeveloped autonomous vehicles for material movement. While the Corps does not current have any technology of this design, the agency has considerable experience in traditional sediment movement methods including mechanical movement and hydraulic dredging.

The LCLSMS has teamed with ERDC and the Corps' New Orleans District to develop practical cost estimates for three systems for moving sediment from the Lewis and Clark Lake delta to the Missouri River directly below Gavins Point Dam. These three systems are:

- Mechanical excavation with barge transport
- Staged dredging
- Single line dredging with booster pump

Each of these systems is being analyzed with production rates varying from 10,000 to 30,000 tons per day of sediment delivered.

The ability to discharge sediment below the dam is dependent upon the river's ability to transport this sediment without incurring significant aggradation. To address this concern the number of days per season where discharge is above thresholds is being evaluated. The cost analysis is ongoing, and a report is expected with the release of the Phase II modeling reports.

FUTURE ACTIVITES

There are four ongoing research efforts within the greater LCLSMS. Each of these will add to the original, single-event drawdown flushing analysis in phase I, and give a more complete view of possible management actions that could be considered in the future. However, these studies all deal with the existing sediment in the system and do not examine ways to reduce sediment delivery to the reservoir. While sediment delivery from upstream on the Missouri River has been significantly reduced due to the mainstem dam system, tributaries, primarily the Niobrara River, continue to be the major contributor to the delta sediments at Lewis and Clark Lake. The influence of the tributary sediment delivery warrants further examination.

The results presented in this paper should be considered provisional and subject to change. Once the Spencer Dam flushing model and analysis are complete, minor modifications may be made to the Lewis and Clark Lake model before publication.

However, there are some actions that clearly result in increased sediment transport when compared to the current infrastructure and management regime. These include lowering of spillway gates, low-level tunnels, and prioritizing flow to improve flushing efficiency. These are all techniques that have been included in dam designs over the past half century, but not originally included in the design of Gavins Point Dam.

The Corps intends to complete the LCLSMS in 2015 and provide all the associated reports via the MRRP website page at: http://moriverrecovery.usace.army.mil/mrrp/f?p=136:155:2604171657024::NO::PIS_ID:28.

MODELING BED DEGRADATION OF A LARGE, SAND-BED RIVER WITH IN-CHANNEL MINING WITH HEC-RAS 5.0

John Shelley, Ph.D., P.E., U.S. Army Corps of Engineers, Kansas City District, john.shelley@usace.army.mil; Stanford Gibson, Ph.D., U.S. Army Corps of Engineers, Hydrologic Engineering Center, stanford.gibson@usace.army.mil.

INTRODUCTION

The Missouri River is a large, regulated, sand-bed river. Over the past several decades, large stretches of the lower Missouri River have degraded with bed elevations dropping as much as 7 ft (USACE, 2009a). Bed degradation on the lower Missouri River has already cost Federal, State, and local entities over a hundred million dollars in emergency slope protection, bridge pier stabilization, and water intake retrofitting. To analyze and find solutions to this problem, the U.S. Army Corps of Engineers, with support from local stakeholders, developed a one-dimensional mobile-bed hydraulic/sediment model for 165 miles of the lower Missouri River using HEC-RAS 5.0. The modeling effort utilized features new to HEC-RAS 5.0, including specification of sediment load and gradation via a DSS file and new commercial dredging features. The model calibrated, reproducing historic bed volume changes, water surface elevations and channel velocities. This paper documents novel aspects of this modeling effort. More information on the full range of model inputs and choices can be found in USACE (2014).

MODEL OVERVIEW

USACE engineers developed a one-dimensional, quasi-unsteady HEC-RAS 5.0 sediment model (USACE, 2015, Gibson et al., 2006) to predict future degradation and to screen and evaluate potential solutions. The model starts ten miles upstream from the St. Joseph, Missouri USGS gaging station and ends near the Waverly, Missouri USGS gaging station. The downstream boundary is a historically stable location on the river. The model contains 303 cross-sections which span approximately 165 river miles of the Missouri River, with six to twelve cross-sections per river bend. The model was built with 1994 bathymetry and run forward to November of 2011. Figure 1 provides a schematic of the model network with river miles, major tributaries, channel cross-sections, and USGS gages located.

Channel roughness was assigned as Manning ‘n’ values in four horizontally-varied regions: the active channel, the channel with sill influence, the channel with dike influence, and the floodplain. At very high flows, the roughness for the active bed decreases as the bed transitions from dunes to plane bed. Bedform amplitude changes were verified using multi-beam bathymetric surveys, as seen in Figure 2. Dunes which dominate normal flows (67,000 cfs on May 27, 2010) transition to a planar transport regime at higher flows (196,000 cfs on June 28, 2011) during the 2011 flood.

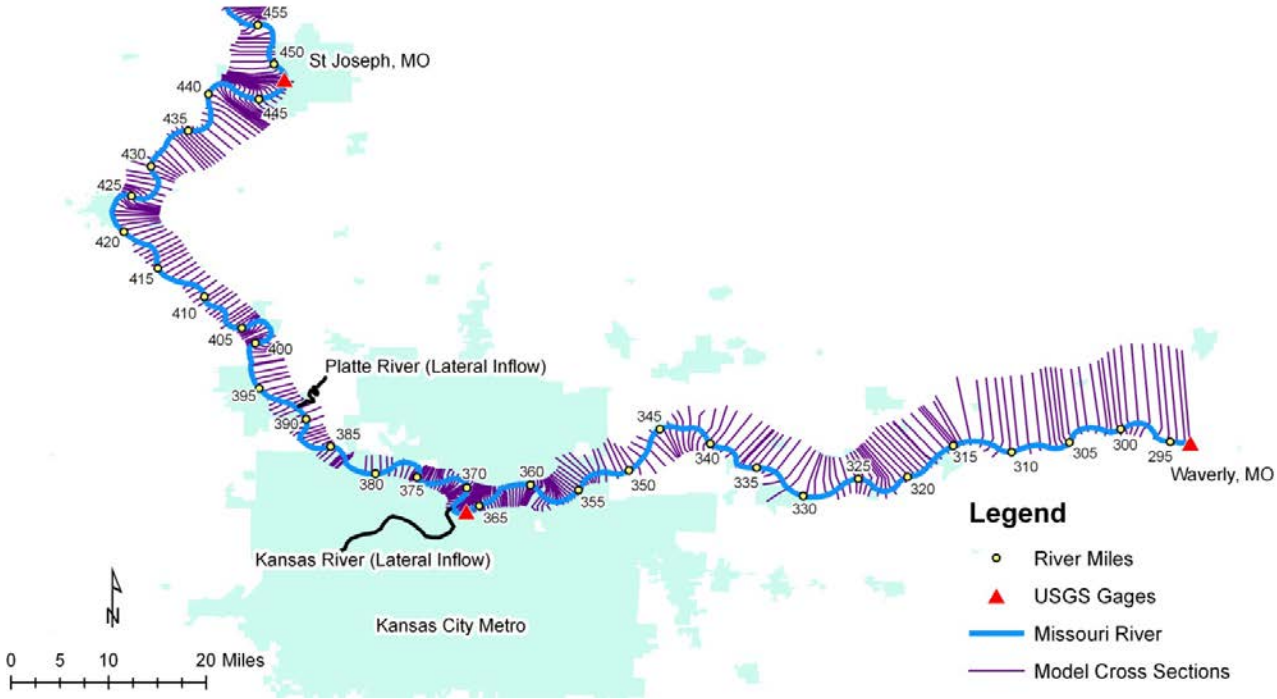

Figure 1 Model Schematic.

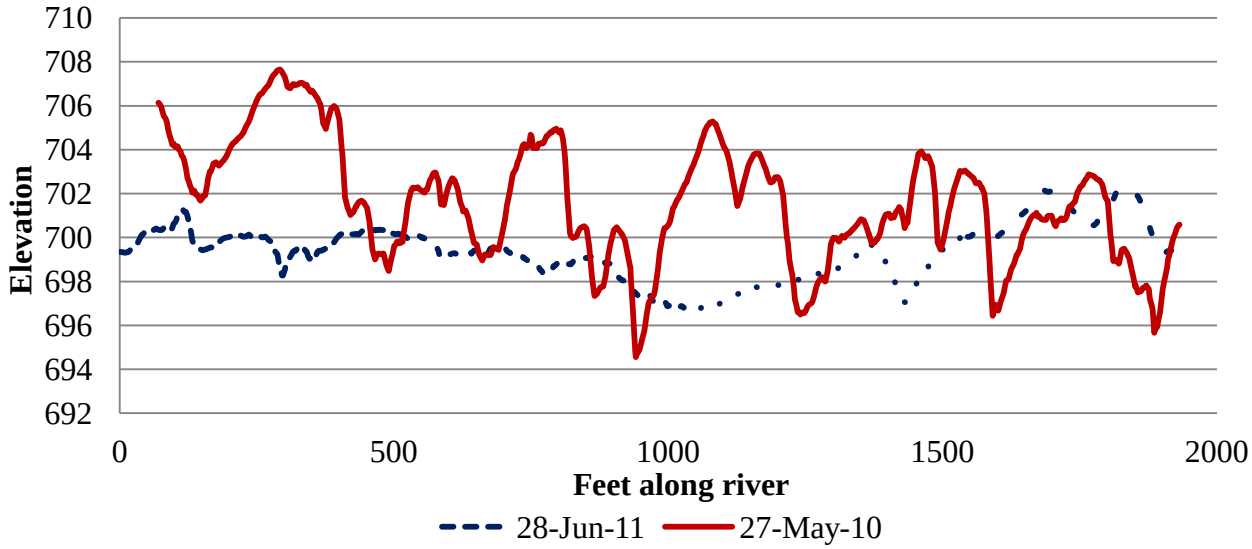

Figure 2 Flatter bedforms during flood flows just upstream of the Kansas River confluence.

The Brownlie bed roughness predictor (Brownlie, 1983), a new feature included in HEC-RAS 5.0 (Gibson, 2013) was evaluated for use in this model. Although this roughness predictor was developed for large sand rivers with bed forms that shift regimes, it over predicted roughness at high flows and under predicted roughness at low flows at the Kansas City gage. An 'n' value of 0.028 calibrated well with observed stages at the Kansas City gage for moderate and high flows,

but the highest flows calibrated to a lower 'n' value. This flow dependence was modeled using the flow-roughness factor in HEC-RAS.

NEW HEC-RAS FEATURES

DSS-TIME SERIES FOR SEDIMENT

HEC-RAS 4.1 included three sediment load options at upstream model boundaries: Equilibrium Load, Rating Curves, and Sediment Load Series. None of these options provided sufficient flexibility to specify loads with gradations that vary over time. On the Missouri River, a second flow-load-gradation relationship was required to model the unique supply-limited sediment loading of the historic 2011 flood. During the 2011 flood, the mainstem dams released tremendous volumes of relatively clear water while the watershed downstream from the dams contributed very little due to drought conditions.

HEC-RAS 5.0 includes a fourth sediment load option, Sediment Load Series by DSS, which was flexible enough to accommodate non-stationary loads and gradations with some pre-processing. HEC-Data Storage System (DSS) is the base that HEC-RAS and other HEC models use for input, and output time series, and to pass data between models (USACE, 2009b). In HEC-RAS 5.0, the DSS Sediment Load Series boundary condition reads a DSS sediment mass time series for each grain class.

In the degradation model, the sediment load series for each grain class were computed in Excel using the following formula:

$$Qs_i = Qbed * Pbed_i + Qsus * Psus_i$$

where Qs_i = the daily sediment load input for grain class size i, in tons

Qbed = the daily bed material load, in tons

$Pbed_i$ = the proportion of bed material corresponding to grain size i

Qsus = the daily suspended sediment load, in tons

$Psus_i$ = the proportion of suspended sediment load corresponding to grain size i

The suspended sediment load was computed from two separate flow-load curves based on USGS water quality data. The first flow-load curve applied from 1994 through March 2011. The second, supply-limited flood curve applied from April 2011 through November 2011. Gradations for the suspended sediment load were computed from USGS water quality samples.

The bedload portion of the sediment load was computed from a bedload rating curve for the Missouri River just upstream of the confluence of the Kansas River. This bedload rating curve was computed by using successive multi-beam bathymetric surveys (Abraham et al., 2011) with the time correction suggested in Shelley et al. (2013) and is provided in Figure 3.

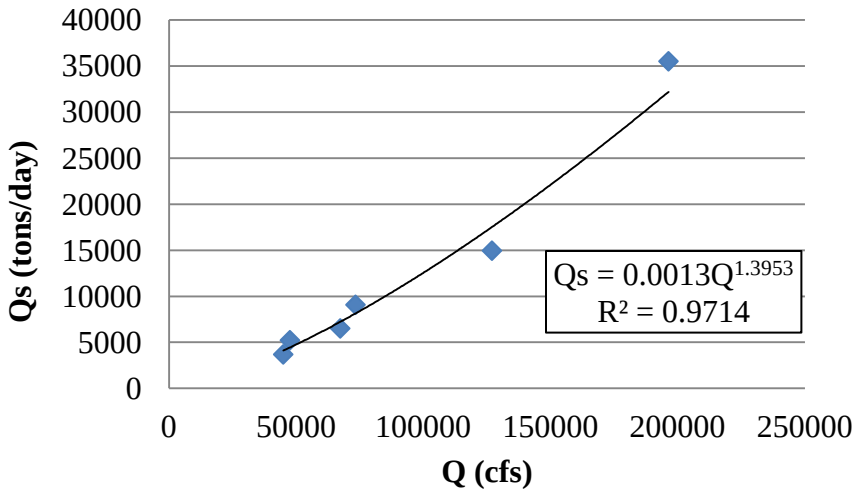

Figure 3 Missouri River Bedload Rating Curve at Kansas City (above Kansas River Confluence).

The gradation of the incoming total sediment load is a function of the relative contributions from bed load and suspended load, which varies by flow and shifts during the 2011 flood. From these, daily load series for each grain class were compiled in a DSS file using HEC-DSSVue 2.0 (USACE, 2009b) with the Period Cumulative (PER-CUM) data type, and a 'SEDIMENT' parameter (the required C: segment of the DSS path name) HEC-RAS 5.0 read the DSS file and matched the size specific load series with the corresponding grain classes.

Sediment rating curves at two major tributaries—the Platte River and the Kansas River—were included in the model as flow-load boundary conditions with the Rating Curve option, with loads and gradations estimated from USGS measurements.

DREDGING

HEC-RAS 4.1 includes algorithms to simulate navigation dredging. The Navigation dreding feature removes the material instantly, at a specified time, down to the specified template elevation. Dredging on the Missouri River is commercial dredging (sand and gravel mining), which differs from typical navigation dredging in several important respects. On the Missouri River, bed material is extracted and sold as aggregate for construction purposes. There is no target elevation, but rather a reported (or permitted) tonnage. On the Missouri River, commercial dredging takes are recorded as a daily location and tonnage. The navigation dredging features, with instantaneous, *a priori* dredge depths, in HEC-RAS 4.1 could not adequately reproduce this process.

HEC-RAS 5.0 includes new features better suited for modeling commercial dredging of river beds. First, a dredging start and end time can be specified so that dredging occurs gradually over time, not instantly. Second, the dredging can be specified as a target tonnage instead of a target elevation, allowing the cross section shape to respond to the mass removal. Third, the cross-section maintains the natural shape of the river bottom as material is removed, rather than the flat bottom channel the navigational dredging algorithms produce.

Dredging was included in the Missouri River degradation model as monthly tonnages at each cross-section with the start date the first day of the month and the end date the last day of the month. The model calibration used the standard "flat bottom" dredging algorithm, as the "natural bottom" routine was not yet available. The impact of dredging was restricted to the actual dredging tonnage, i.e. one ton of material extracted lowers the bed by a volume equivalent to one ton. Potential dredging effects due to bed disturbance and destruction of the armor layer were not explicitly modeled.

CALIBRATION AND VERIFICATION

The calibration/verification period runs from Aug 1, 1994 to Nov 30, 2011, with an intermediate calibration point Sep 30, 2009. The principal parameters which were varied to achieve calibration were the Manning 'n' values, the flow-based 'n' adjustment factors, the level of smoothing of the gradation data, and the sediment loading from the Kansas River. Channel geometry, moveable bed extents, incoming sediment load and gradation at the upstream model boundary, sediment transport function coefficients, and dredging were not used as calibration parameters.

EARLY HYDRAULIC CALIBRATION

A major high-flow event occurred within a year of the model start. Figure 4 compares model results to the water surface elevation at the USGS Missouri River gage at Kansas City. The computed water surface elevations are from the mobile-bed model run and therefore include slight bed changes over the course of the first year. However, as these changes are relatively small, Figure 4 is an indication of the ability of the model to reproduce channel hydraulics, more than the ability of the model to reproduce sediment fluxes.

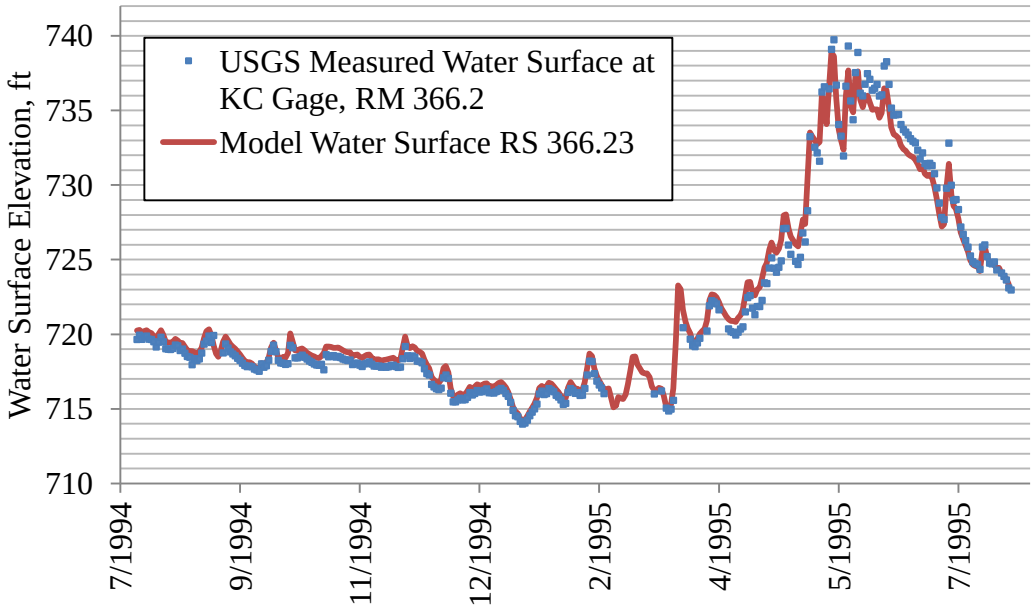

Figure 4 Water surface at Kansas City gage during first year of calibration period.

The average absolute difference between measured and modeled water surfaces is 0.67 ft. Agreement is better for steadily increasing and decreasing flows than rapidly fluctuating flows. In this particular event, input from the Kansas River and overbank storage issues were not reflected well in the model and causes rapid fluctuations near the peak. Notwithstanding this limitation, the model reproduces channel hydraulics reasonably well.

LONG-TERM HYDRAULIC CALIBRATION

Model water surface elevation agreement over the full calibration time period verified the temporal fidelity of bed change in the model. The model reproduced water surface elevations at the Kansas City gage with an average absolute error of 1.3 ft over the duration of the calibration period. For low flows less than 30 kcfs, the average absolute error is 1.0 ft.

VELOCITY CALIBRATION

Channel velocities were measured during and after the 2011 flood via ADCP. Figure 5 shows that the model channel velocities match measured velocities reasonably well for both a high flood discharge (153 to 225 kcfs) and a more moderate discharge (58 to 64 kcfs).

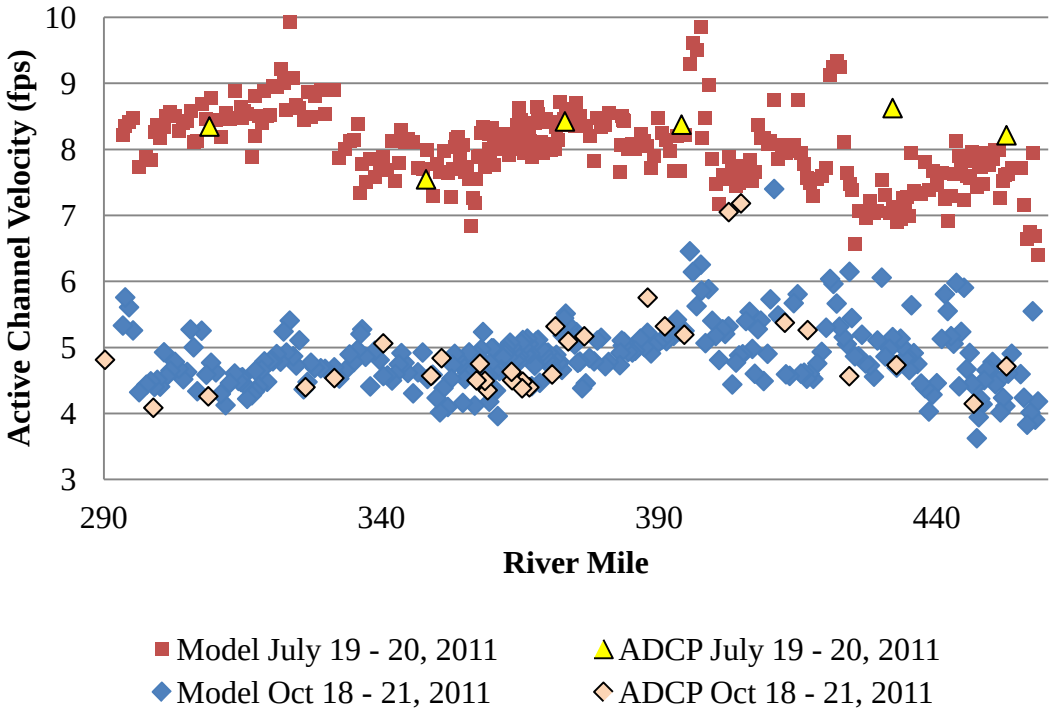

Figure 5 Velocity Comparisons.

SEDIMENT MASS CALIBRATION

The calibrated model simulates the magnitude and location of measured bed sediment change from 1994 to 2009 and 1994 to 2011, as indicated in Figure 6.

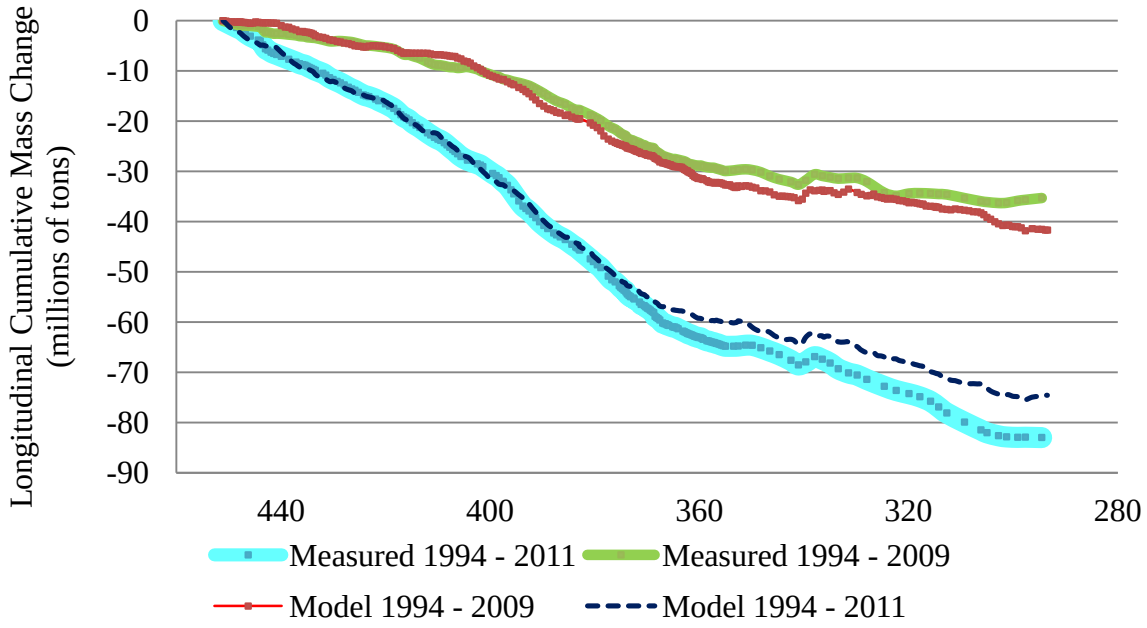

Figure 6 Mass Calibration.

The model outputs for water surface, mass change, and velocity over the calibration period approximate the prototype using realistic initial conditions and boundary conditions and appropriate model parameters.

CONCLUSION

This paper described the development of a one-dimensional HEC-RAS 5.0 mobile-bed model to simulate and predict degradation on the lower Missouri River. This model utilizes new sediment input and dredging features in HEC-RAS 5.0. Simulated water surface elevations, channel velocity, and sediment mass change, over the calibration period approximate the prototype using realistic initial conditions and boundary conditions and appropriate model parameters. This model demonstrates the utility of HEC-RAS 5.0 for bed degradation analysis in large, complex river systems with in-channel mining.

INTRODUCTION

Processes contributing to development of ephemeral gully channels are of great importance to landscapes worldwide, and particularly in dryland regions where soil loss and land degradation from gully erosion pose long-term, land-management problems. Whereas gully formation has been relatively well studied, much less is known of the processes that anneal gullies and impede their growth. This work investigates gully annealing by aeolian sediment, along the Colorado River downstream of Glen Canyon Dam in Glen, Marble, and Grand Canyons, Arizona, USA (Figure 1).

In this segment of the Colorado River, gully erosion potentially affects the stability and preservation of archaeological sites that are located within valley margins. Gully erosion occurs as a function of ephemeral, rainfall-induced overland flow associated with intense episodes of seasonal precipitation. Measurements of sediment transport and topographic change have demonstrated that fluvial sand in some locations is transported inland and upslope by aeolian processes to areas affected by gully erosion, and aeolian sediment activity can be locally effective at counteracting gully erosion (Draut, 2012; Collins and others, 2009, 2012; Sankey and Draut, 2014). The degree to which specific locations are affected by upslope wind redistribution of sand from active channel sandbars to higher elevation valley margins is termed "connectivity". Connectivity is controlled spatially throughout the river by (1) the presence of upwind sources of fluvial sand within the contemporary active river channel (e.g., sandbars), and (2) bio-physical barriers that include vegetation and topography that might impede aeolian sediment transport. The primary hypothesis of this work is that high degrees of connectivity lead to less gullying potential.

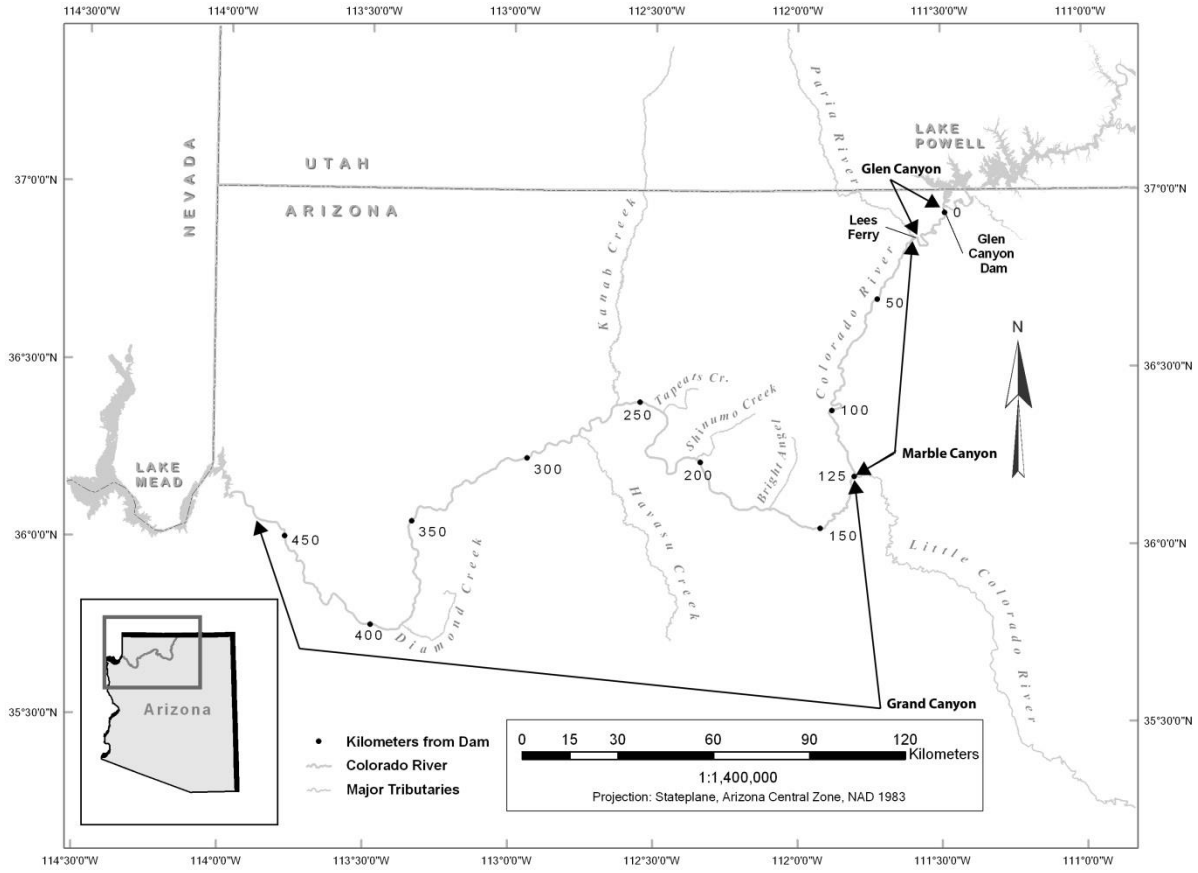

Figure 1 Map of the Colorado River downstream of Glen Canyon Dam, Arizona, USA.

METHODS

We have used a variety of remote sensing and field methods to map the distribution of fluvially-sourced aeolian sand within gullied valley margins above the active river channel (Draut, 2012; Collins and others, 2009, 2012; Sankey and Draut, 2014). We define the active channel as the area below the 1,270 m^3/s flood shoreline; 1,270 m^3/s is the approximate magnitude of recent controlled floods of the Colorado River from Glen Canyon Dam that have been conducted episodically since 1996. We have used remote sensing observations, including topographic modelling with high resolution automated digital photogrammetry and topographic change detection with lidar (light detection and ranging), to map and measure changes in gullies and fluvially-sourced aeolian surfaces (Collins and others, 2009, 2012; Sankey and Draut, 2014). Topographic change detection with repeat ground-based lidar surveys was conducted periodically from 2006 to 2010 at a total of 13 study sites (Collins and others, 2009, 2012).

In addition to high resolution change detection at sample locations, the spatial distribution of fluvially-sourced aeolian sand located above the active river channel has been mapped for six reaches of the river (Draut, 2012; Sankey and Draut, 2014). Mapping was completed in the field on high resolution imagery (22 cm-resolution). Fluvially-sourced sand units were identified as either active or inactive with respect to contemporary aeolian transport (Draut, 2012). Draut (2012) and Sankey and Draut (2014) showed that there is substantially less active sand area than inactive sand area throughout the river valley.

To investigate the effect of fluvially-sourced aeolian sand on gully development within these reaches, identification of potential gullies was conducted with high resolution digital elevation data (1-m grid cell resolution). Potential gullies were defined topographically as hillslope flowpaths with concave across-slope shape with potential to channel overland flow. Potential gullies were detected using a novel combination of overland-flow accumulation and topographic modelling procedures commonly available in GIS and remote sensing software. Methods for the identification of potential gullies are described in detail in Sankey and Draut (2014).

RESULTS

Sediment volume changes that were previously mapped with ground-based lidar and attributed to aeolian deposition (Collins and others, 2009, 2012) were summarized for three types of sites as a function of connectivity. The types were: 1) sites with recent Colorado River controlled flood sediment deposited upwind, and with a connected aeolian pathway from the active channel flood deposit to the site (where change detection was conducted); 2) sites with recent controlled flood sediment deposited upwind, but with reduced connectivity due to vegetation or topography that interrupted the aeolian pathway between the active channel flood deposit and the site; or 3) sites without a recent, upwind active channel controlled flood sediment deposit. Results are based on a small sample size, yet suggest that influx of fluvially-sourced aeolian sand is larger in valley margin landscape positions that have greater connectivity (Figure 2). Sediment volume changes were similar for type 1 and 2 sites, which was somewhat unexpected. A larger sample of sites could be studied in the future to either confirm this finding, or test whether changes in sediment volume vary as a function of transport barrier types (i.e, vegetation or topography) and characteristics (e.g. size, roughness, porosity).

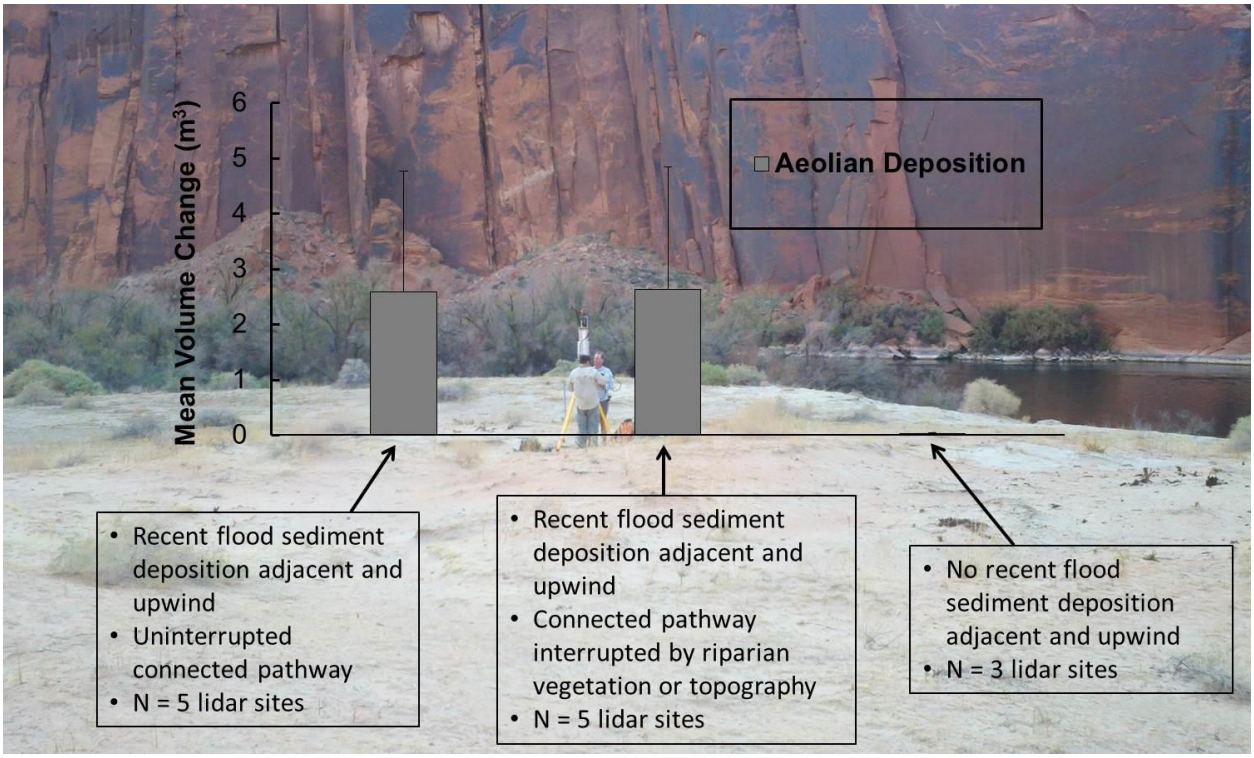

Figure 2 Volumetric surface change measured with ground-based lidar. Only volumetric changes attributed to aeolian deposition of fluvially-sourced sand are shown. Lidar study sites were located in valley margins above the contemporary active Colorado River channel and are prone to gully erosion. Individual site change data are from Collins and others (2009, 2012). Site change data are summarized by presence/absence of: 1) an upwind flood sediment source (sandbar); and 2) a topographic or vegetation barrier that might interrupt the connected pathway for aeolian transport of fluvially-sourced sediment to the higher elevation study site. Changes were determined at 1-3 year intervals for 13 sites between 2006 and 2010. Error bars show the standard error of the mean for n sites.

Figure 3 shows an example of the relative distribution of river-derived sediment above the active river channel for one reach of the river (70.8–98.2 km downstream of Glen Canyon Dam and within Grand Canyon National Park). In this reach, river-derived sediment that is active with respect to aeolian transport (showing evidence of contemporary aeolian sand transport) is located closer to the active river channel. This suggests that the degree to which valley margins are comprised of river-derived, active aeolian sand is influenced by connectivity, and specifically the length of the connected pathway to the active river channel and controlled flood sandbar deposits.

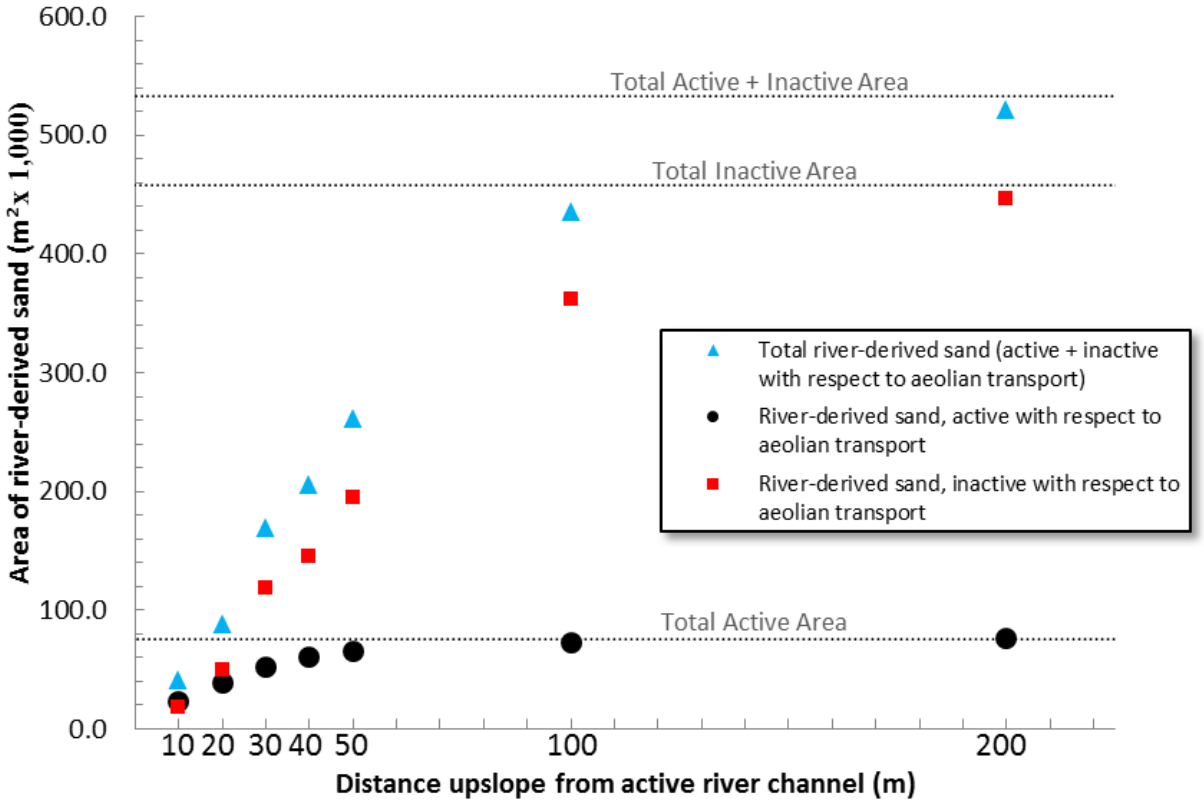

Figure 3 Distribution of river-derived sand that is active and/or inactive with respect to aeolian transport as a function of proximity to the contemporary active Colorado River channel. The active channel is defined as the area below the 1,270 m^3/s maximum controlled flood shoreline. Results are shown for a reach of the river (70.8–98.2 km downstream of Glen Canyon Dam) within Grand Canyon National Park.

The spatial intersection of mapped fluvially-sourced aeolian sand and potential gullies identified with digital topographic modelling indicate that gullies are less prevalent in areas where surficial sediment undergoes active aeolian transport (Figure 4). Potential gullies also have a greater tendency to terminate in fluvially-sourced sand that is active as opposed to inactive with respect to aeolian transport (Sankey and Draut, 2014). Although not common, examples exist in the records of historical imagery of gullies that underwent infilling by aeolian sediment in past decades and evidently were effectively annealed (Sankey and Draut, 2014).

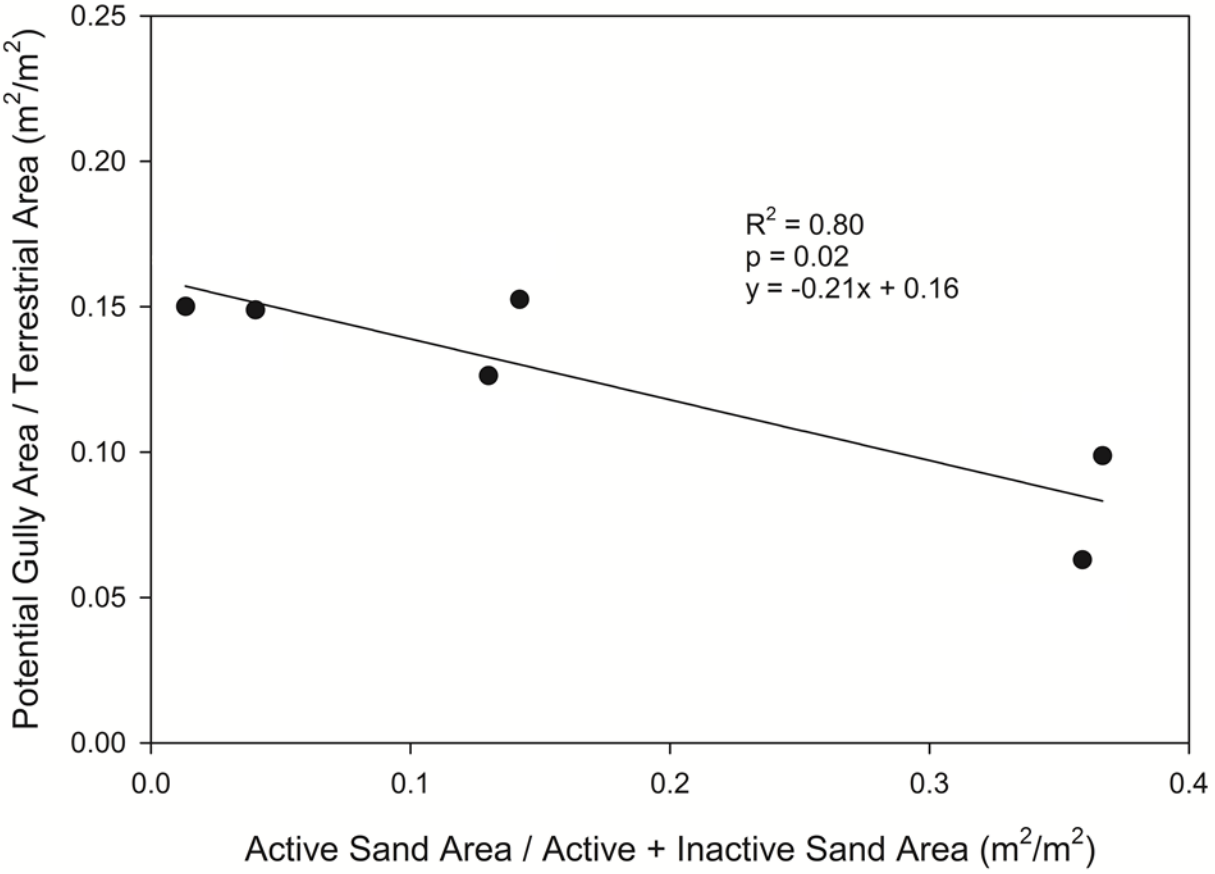

Figure 4 Relationship of area of potential gullies and active sand among six study reaches of the Colorado River in Glen, Marble, and Grand Canyons. Gullies are less prevalent in valley margins above the active river channel where river-derived sediment undergoes active aeolian transport. Figure is modified from Sankey and Draut (2014).

DISCUSSION and CONCLUSION

Connectivity is an important control on the distribution of fluvially-sourced sand in valley margins above the active channel of the Colorado River in Glen, Marble, and Grand Canyons. The distribution of fluvially-sourced sand can in turn influence the prevalence and extent of gullying in valley margins through annealing (e.g., infilling) mechanisms. The degree of connectivity between the active river channel and valley margins can therefore have an important influence on the potential for hillslope erosion in upland landscapes of the canyon-bound river. These investigations provide new evidence for an interaction of aeolian–hillslope–fluvial processes that can affect dryland regions substantially in ways not widely recognized. Continuation of this and related research will provide a basis for studies of natural and anthropogenic landscape change in the Colorado River and along similar river margins.

ACKNOWLEDGEMENTS

This study was supported by the U.S. Bureau of Reclamation through the Glen Canyon Dam Adaptive Management Program, with logistical and managerial support from the U.S. Geological Survey Grand Canyon Monitoring and Research Center. The authors thank the National Park Service and the Hualapai Tribe's Department of Cultural Resources for permission to conduct the field research.

VAN DEEMTER'S STEADY STATE ANALYSIS OF DRAINAGE IN AN INFINITELY DEEP HOMOGENEOUS SOIL PROFILE

M.J.M. Römkens (Ret.), USDA-ARS- Nat'l Sedimentation Lab, Oxford, Mississippi, matt.romkens@ars.usda.gov

INTRODUCTION

The rapid development of sophisticated numerical techniques aided by highly sophisticated digital computer technology has led to the usage of numerical schemes in preference to analytical approaches in seeking solutions to groundwater flow problems. While numerical schemes can address more conveniently saturated as well as unsaturated complex geometric flow regions, analytical approaches may offer more insight in the physics of the problem. This is particular true if one deals with two-dimensional geometrically simple saturated flow regimes. For this class of problems potential theory may offer elegant, but also mathematically difficult to obtain solutions. One of the earliest work of solving two-dimensional groundwater flow problem for steady state flow using potential theory was by Muskat and Wyckoff (1937) who solved problems of horizontal flow into wells or vertical flow under sheet piles in dams. Since that time, the subject matter has been of interest in steady state gravity flow problems involving seepage to groundwater tables or through earthen dams, into ditches, etc.

Interestingly, solution approaches using potential flow theory of the conformal type to solve drainage problems in agricultural land did never find much acceptance among agricultural engineers even though the conditions for which this approach could be used were very amenable to this technique when it concerned low lying bottomland areas in need of drainage. The exception is perhaps the work by van Deemter (1950), a mathematician who under the leadership of S. Hooghoudt addressed the need to account for radial flow resistances in fields with closely spaced drains as opposed to the case with widely spaced drains with a Dupuit-Forcheimer flow regime. His work (van Deemter, 1950) did not receive the attention it should have had. Van Deemter was far ahead in his time, but the mathematical complexity was not conducive for adoption by most practically oriented or applied drainage engineers. In this article, the author discusses in rudimentary manner van Deemter's work by bringing out highlights of his approach and to relate the relevance of this work in the context of erosion problem from upland areas. For details of his work, the author refers the reader to the dissertation itself or to a summary discussion of selected aspects of this work with a relevant derivation for a particular flow regime by Römkens (2013)

PRINCIPLES OF SOLUTION TECHNIQUE

The principle of the conformal solution technique is to describe the flow region in two representations: (1) the complex gravitational geometric field or the z-plane ($z = x + iy$), and (2) the potentials in the z-field or the ω-plane consisting of pressure $\varphi = \varphi(x,y)$ and stream potentials $\psi = \psi(x,y)$ or $\omega(x,y) = \varphi(x,y) + i\,\psi(x,y)$. Each point $z(x, y)$ in the flow field has a unique set of values for the potential function (φ) and the streaming potential (ψ). The objective is to determine the relationship $\omega = f(z)$. The common approach is to transform both the spatial geometric flow region or z-plane and the potential field or ω-plane of this flow region onto a common complex

field, say the t-plane in a 1:1 correspondence. Depending on the complexity of the flow field geometry and the potential field several successive transformation may be involved. The simplest case is for the flow field to have straight vertical or horizontal boundaries. Likewise for the flow potential field to consist of straight pressure and flow potential lines as boundaries of which the intersections are the vertices that are used in the transformations. The boundary conditions of the potential field may be open or closed and irregular posing challenges on finding the appropriate mathematical descriptions for the flow region. In practice, one may have to seek a simplification of the flow field geometry that closely approximates the real situation if this technique is to be successfully used. Also, the flow field may have sinks (drains or ditches) and sources (rainfall, infiltration points). Two special techniques, that often must be employed in the analysis are the Schwarz-Christoffel transformation that allows a polygonal surface to be projected on a half-plane and the Hodograph method which method describes the flow field in terms of a complex velocity field $W = - d\omega(z)/dz = u + iv$ and which is commonly used when dealing with an open nonlinear boundary such as a groundwater table receiving rain. In that case, the boundary is represented by a streamline where water may enter the flow region (rain) and the potential function $\Phi = (y + p/(\rho g)$ with $\varphi = K \cdot \Phi$ where p assumes the value p = 0 at the open boundary or air-water interface. It can be shown, using the Cauchy-Riemann equations in this Laplacian flow field that the complex velocity at points on this surface can be described by a circle:

$$W = -\frac{(K+N)}{2} \cdot \sin 2\alpha - i \cdot \frac{(K+N)}{2} \cdot \cos 2\alpha + i \cdot \frac{(K-N)}{2} \qquad (1)$$

where u and v are the component flow velocities in the x and y directions, respectively, α is defined by the relationship; $\cot g\alpha = v/\mu$. N is rainfall intensity and K is the soil hydraulic conductivity. More detailed descriptions of the methodology can be obtained from the source (van Deemter, 1950) or from a recent publication about this work by Römkens, (2013).

An example of how the conformal methodology approach was used for a simple case of rainfall on a bottomland incised by a drain or ditch with an impervious layer at a finite depth was given by Römkens (2009). His study concerned a homogeneous isotropic soil profile below the soil surface having a hydraulic conductivity value K and receiving a rainfall intensity N. In that study, seepage losses from a bottomland area with a border-zone of varying width were calculated. Van Deemter (1950) presented a generalized model for 6 combinations of drainage, deep drainage, seepage, evaporation and infiltration. Figure 1 summarizes schematically these combinations. In his analysis, he assumed that the soil profile or aquifer was infinitely deep, and therefore the streamlines were vertical at that depth. This condition appreciably simplified the conformal analysis. The flow adjoining flow regions stood in symmetry to the flow region under consideration and therefore the analysis became mathematically feasible. The flow region surface boundary was open and therefore water fluxes at this boundary consisted of either rainfall or evaporation. The sink/source P in this schematic was represented by a point which in the analysis was either a water supply pipe or a drain of finite size or a ditch. While the geometric region was similar for the different flow regimes, the type solutions obtained were of course flow regime-dependent.

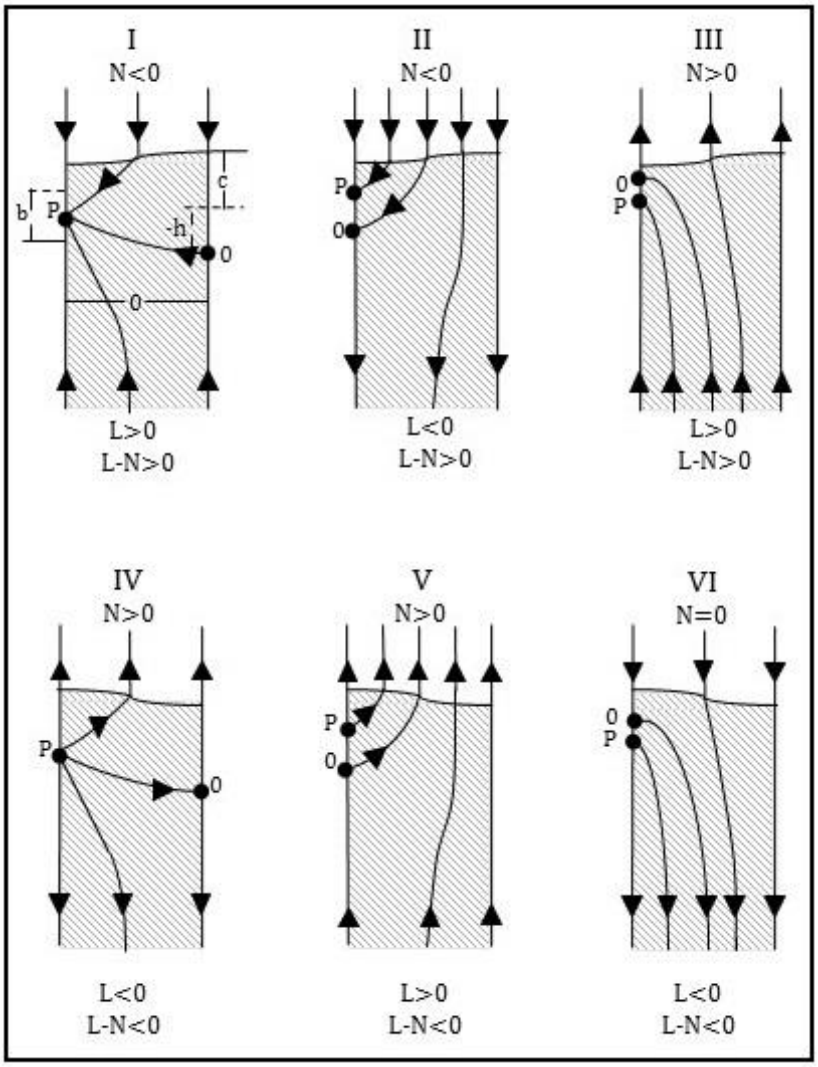

Figure 1 Groundwater flow regimes considered in the analysis by van Deemter: Drainage cases in I, II, III and infiltration cases IV, V, and VI. N = precipitation (rainfall) or evaporation expressed as an intensity and L = the deep drainage or seepage, also expressed as an intensity.

INFILTRATION AND DRAINAGE (CASE II)

The specific case considered in this article (Case II) concerns infiltration (N < 0)) with drainage and deep drainage (L < 0). In case I with seepage, the flow regime differs in that both rainfall and seepage contributes to drainage. The difference between these two flow regimes in otherwise the same geometric area is consequential when this technique is used to assess water quality issues. When different parts of the surface or of groundwater contribute different amounts of pollutant to the drains. A schematic of the flow region is shown in Figure 2.

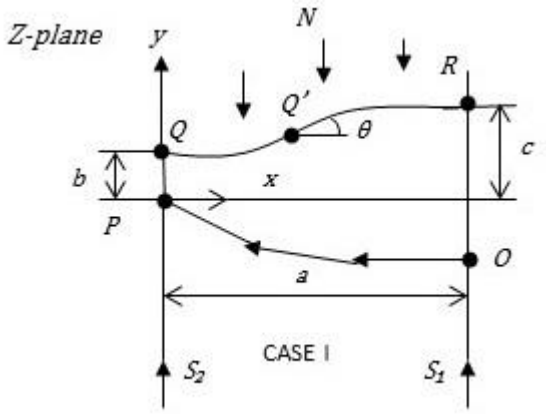

Figure 2 A schematic representation of the flow regime for infiltration, drainage, and deep drainage (Case II).

The boundary conditions for this flow region in terms of φ and ψ with the corresponding values of the vertices P, Q, R, S, in the z-plane are:

$$\begin{aligned} &\text{PQ (streamline):} && \psi = 0, \text{ with } z(P) = 0 \text{ and } z(Q) = i\cdot b \\ &\text{QR (phreatic surface)} && \varphi = K\cdot y \\ & && \psi = N\cdot x \\ &\text{RS (streamline):} && \psi = N\cdot a \text{ with } z(R) = a + i\cdot c \text{ and } z(S) = a - i\cdot\infty \\ &\text{SP (streamline):} && \psi = (N - L)\cdot a \text{ with } z(S) = -i\cdot\infty \text{ and } z(P) = 0 \end{aligned} \tag{2}$$

From these values, the boundary conditions in the Ω - plane defined by the relationship (3)

$$\Omega = \omega - i\cdot Nz = \varphi + Ny + i\cdot(\psi - N\cdot x) \tag{3}$$

can be determined. The flow region in the Ω-plane turns out to be, fortuitously, an infinitely long strip of finite depth (L-N)·a where the vertices are:

$$\begin{aligned} &\Omega(P) = -\infty \quad \text{and} \quad -\infty - i\cdot(L-N)\cdot a \\ &\Omega(S) = +\infty \quad \text{and} \quad +\infty - i\cdot(L-N)\cdot a \\ &\Omega(Q) = (K+N)\cdot b \\ &\Omega(R) = (K+N)\cdot c \end{aligned} \tag{4}$$

The product N·a represents the total amount of rainfall, while (N - L)·a represents the total amount of drainage in which rainfall was adjusted for seepage or deep drainage. For seepage (L > 0). Drainage constitutes the total amount of rainfall plus the amount of seepage, while for the case with deep drainage (L < 0) the amount of drainage equals the total amount of rainfall less the amount of deep drainage.

The spatial location of the open boundary is not defined but must be derived. An important parameter on this boundary is the point of inflection of the water table given by the angle θ. The flow velocity is defined by Eq. (1) and is -i·N at the vertices Q and R, which are the endpoints of the open boundary. At the vertices S the flow velocity is defined as −i·L, which is the seepage or deep drainage rate. From Eq. (1) the location of the center and the radius are determined on the hodograph W (see Fig. 3), which describes in effect the component velocities at all points of the open boundary including that at the inflection point Q'. At Q" the vertical velocity by virtue of Eq. (1) equals i·K.

In seeking the solution ω = f(z) for this flow regimes a common plane is sought onto which the geometric flow region and the potential field within this space are transformed so that a 1: 1 correspondence is obtained. The transformation equations can be obtained by mutual substitution. Figure 3 summarizes a series of conformal transformations of the flow field in the z-plane and ω-plane for Case II of van Deemter. From these transformations a number of parameter were identified to make a 1:1 correspondence possible. Those are:

$$\frac{\lambda^2 - 1}{2\lambda} = tg(\theta)$$

$$\frac{\mu^2 - 1}{2\mu} = (1 + \gamma) \cdot tg(\theta) = \frac{(K + L)}{(L - N)} \cdot tg(\theta) \tag{5}$$

$$\frac{\nu^2 - 1}{2\nu} = -\frac{K}{N} \cdot tg(\theta)$$

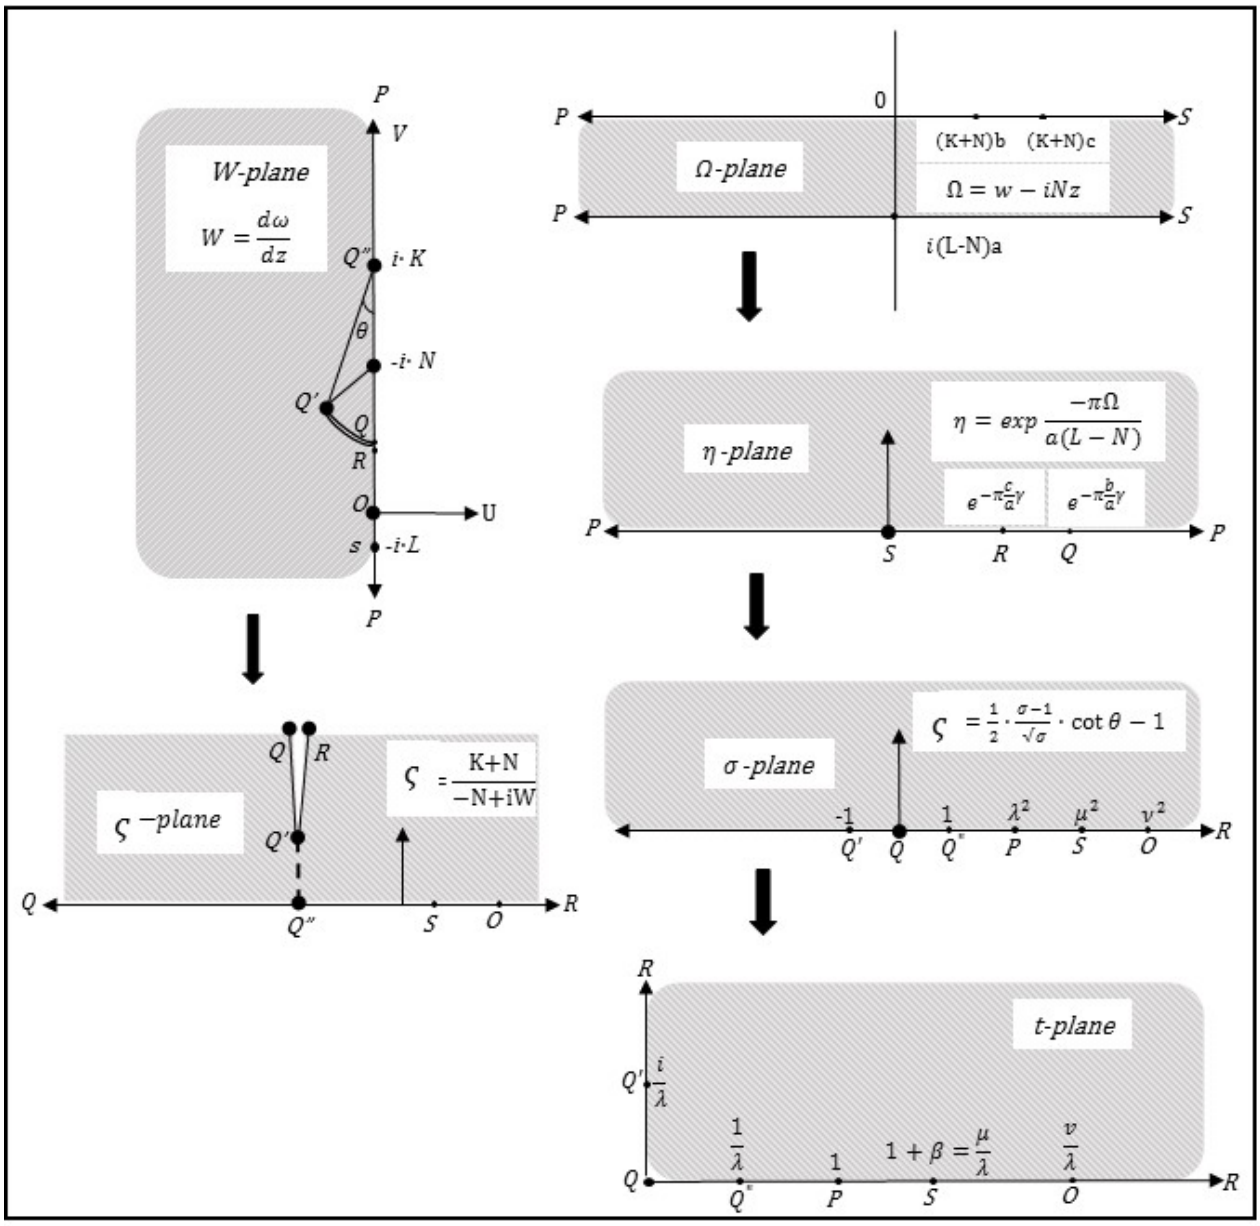

Figure 3 Conformal Transformations of the z-plane and W-plane onto the common plane t.

The fractional linear transformation between points on the upper half planes of η and σ yields the relationship:

$$\eta = \frac{(\sigma - \mu^2)}{(\sigma - \lambda^2)} \cdot \exp\left(-\pi\gamma\frac{c}{a}\right) \tag{6}$$

from which the identity:

$$(1+\beta)=\frac{\mu}{\lambda}=\exp\left(\pi\gamma\frac{c-b}{2a}\right)>1 \tag{7}$$

can be obtained with $\gamma = (K+N)/(L-N)$. Since the hodograph was presented in terms of the differential equation $d\omega/dz$, one must perform an integration to be able to obtain expressions for ω and z in terms of common independent variable. This is done by introducing the variable t so that $t = \frac{1}{\lambda}\sqrt{\sigma}$. The t-plane, shown in Figure 4, has as vertices: $t(R) = \infty$ and $i\cdot\infty$; $t(Q') = i/\lambda$; $t(Q) = 0$; $t(Q'') = 1/\lambda$; $t(P) = 1$; $t(S) = \mu|\lambda = 1+\beta$; $t(O) = \nu|\lambda$. It shows how the upper half of the σ-plane is projected on the first quadrant of the t-plane with the vertices located on the positive real and imaginary axes. By substituting in a systematic manner the t variable in a reverse order into the sequence of transformations one can now obtain expressions for z(t) and ω(t). These expressions are:

$$z=a+ic+i\frac{a}{\pi}\cdot\left[ln\frac{t-1-\beta}{t+1+\beta}+\frac{2}{\gamma}\cdot ln\frac{t+1}{t+1+\beta}\right] \tag{8}$$

$$\omega=K\cdot c+i\cdot Na+\frac{a}{\pi}\cdot\left[\begin{array}{c}(L-N)\cdot ln(t-1)-L\cdot ln(t-1-\beta)+N\cdot ln(t+1+\beta)+\\ (L-N)\cdot\frac{(K-N)}{(K+N)}\cdot ln\left(\frac{t+1}{t+1+\beta}\right)\end{array}\right] \tag{9}$$

with $\gamma = (K + N)/((L-N)$ and $1+ \beta = \mu/\lambda$. The veracity of these relationships can be verified upon substitution of selected t-values (for the vertices, see Figure 2). For instance from Eq. (8): $t = t(Q) = 0$ will yield $z = i\cdot b$; $t = t(S) = 1+\beta$ yields $z = -i\cdot\infty$ and $z=a -I\cdot\infty$; and $t(R) = \infty$ yields $z = a + i\cdot c$. Actually, the latter result was used as input to determine the integration constant. Similarly, from Eq. (9): $t = t(P) = 1$ one obtains $\varphi = -\infty$ and $\psi = i\cdot(N-L)\cdot a$; for $t = t(Q) = 0$ one obtains $\varphi = K\cdot b$ and $\psi = 0$; and for $t = t(R) = \infty$ one obtains $\varphi = K\cdot c$ and $\psi = N\cdot a$.

With the solutions of z and ω in terms of t it should now be possible, barring algebraic complexities, to calculate in principle at any point in the flow region the corresponding values of the potential function φ and stream function ψ. Of particular interest would be the groundwater table above the sink (P) and midway between sinks assuming mirror images of adjacent flow regions. Note that in calculating these values the t-parameter has a real value for points on the QR line segment in the t-plane of Figure 3.

From the spatial relationship, Eq. (7). The groundwater table can be determined by substituting in Eq. (7) $t = i\cdot s$ where s is a real number. Then the groundwater surface, which is the imaginary axis of the t-plane (Figure 3) is given by the relationships:

$$\frac{x}{a} = \frac{2}{\pi}\left[\frac{1+\gamma}{\gamma} \cdot arctg\,\frac{s}{(1+\beta)} - \frac{1}{\gamma} \cdot arctg \cdot s\right] \tag{10}$$

and

$$\frac{y}{a} = \frac{c}{a} + \frac{1}{\pi\gamma} \cdot ln\,\frac{(s^2+1)}{(s^2+(1+\beta)^2)} \tag{11}$$

The distance c midway point between two adjacent symmetrical flow regions and the point b directly above the drain, can be determined and are respectively:

$$\frac{\pi c}{a} = ln\left(1+\frac{2}{\beta}\right) + \frac{2}{\gamma} \cdot ln\left(1+\frac{\beta}{2}\right) \tag{12}$$

and

$$\frac{\pi b}{a} = ln\left(1+\frac{2}{\beta}\right) + \frac{2}{\gamma} \cdot ln\frac{\left(1+\frac{\beta}{2}\right)}{(1+\beta)} \tag{13}$$

The total flow rate into or out of the aquifer is determined by; (1) the pressure difference between the groundwater table level and the water level in the in the ditch or open water body to which the flow region is connected, (2) the size of the soil/surface water area through which the flow region drains or supplies water, and (3) the geometric configuration of the flow region. It is to be expected that the location of the groundwater table adjusts dependent on the amount of incoming (rain) or evaporation and to changes in the deep drainage or seepage rates. The effect of these changes are expressed in the parameter γ. In this treatise, the drain or supply line have a spherical perimeter. However, the flow regime in the aquiver is asymmetric and therefore the aquipotential functions away from a circular drain or supply line are not concentric. Adjustments must be made in selecting the locations of the sink or source to ensure a constant value for the aquipotential function around the drain circumference if an accurate value of water fluxes out (drainage) or into (infiltration) is to be obtained. In his work, van Deemter (1950) indicated that for small drains in relation to the flow region the aquipotential coincides with the drain water in the drain lines. On the other hand, Römkens (2009) shifted the location of the sink within the drain in an iterative manner such that the circumference was closely aligned with an aquipotential. At that point, the calculated flow rate and flow gradients at the perimeter are the correct ones. Having accurate values are important from both a hydrological standpoint of knowing how much water is discharged or must be supplied in a watershed, but also from an environmental standpoint of knowing the sources and amounts of pollutants in the flow region. In the van Deemter approach discussed here in which a drain with radius r_o, the aquipotential at the drain circumference is defined as:

$$\varphi_0 = K \cdot \left(\frac{P_0}{\delta g} - \mathrm{r}_0\right) \tag{14}$$

where p_o is the pressure at the drain and h_o is the equivalent water column height. The point on the drain perimeter below the center P is given in his analysis as $z_o = -i \cdot r_o$ in the z-plane and as $t_o = 1 + \delta$ in the t-plane, then δ can be determined using Eq. (8), which yields:

$$\frac{\pi r_0}{a} = ln\frac{\beta}{\beta-\delta} + \frac{(2+\gamma)}{\gamma}\cdot ln\frac{(2+\beta+\delta)}{(2+\beta)} - \frac{2}{\gamma}\cdot \ln\left(1+\frac{\delta}{a}\right) \tag{15}$$

Also, the aquipotential line at the bottom of the drain perimeter can be obtained from Eq. (7) yielding:

$$\varphi_0 = K\cdot c + \frac{a}{\pi}\cdot\left[(L-N)\cdot ln\,\delta - L\cdot ln(\beta-\delta) + N\cdot ln(2+\beta+\delta) + (L-N)\cdot\frac{(K-N)}{(K+N)}\cdot ln\frac{(2+\delta)}{(2+\beta+\delta)}\right] \tag{16}$$

From the above relationships, β and δ can be determined given known values for K, L, N, ho, and r_o.

Another point of interest is the location of vertice z(O), which is the confluence of the flow originating at the groundwater surface and the flow emanating at great depth of the aquifer. In that case, z(O) becomes t(O) = ν\λ in the t-plane. Then:

$$z(O) = a + i\cdot c + i\cdot\frac{a}{K}\cdot\left[ln\frac{\left(\frac{\nu}{\lambda}-1-\beta\right)}{\left(\frac{\nu}{\lambda}+1+\beta\right)} + \frac{2}{\gamma}\cdot ln\frac{\left(\frac{\nu}{\lambda}+1\right)}{\left(\frac{\nu}{\lambda}+1+\beta\right)}\right] \tag{17}$$

From Eq. (4) one can determine λ and ν for a known β and the value of h for z(O) = a + i·h.

INFILTRATION

The analyses for cases IV, V, and VI, representing sub-irrigation are very similar to those described for drainage in I, II, and III. In fact, the same formulae apply.

Drainage by incised ditches The analysis of drainage through cylindrical shaped drains was facilitated by the geometric simplicity. On the other hand, drainage of bottomland often takes place through incised ditches. Van Deemter addressed that problem as well and presented an analysis for two ditch geometries; (1) A rectangular incised ditch, kept water free but with a saturated bottom and aside wall that was also partially saturated (Figure 4), and (2) an incised ditch in which the side wall was impervious (Figure 5). In both cases the flow region was infinitely deep.

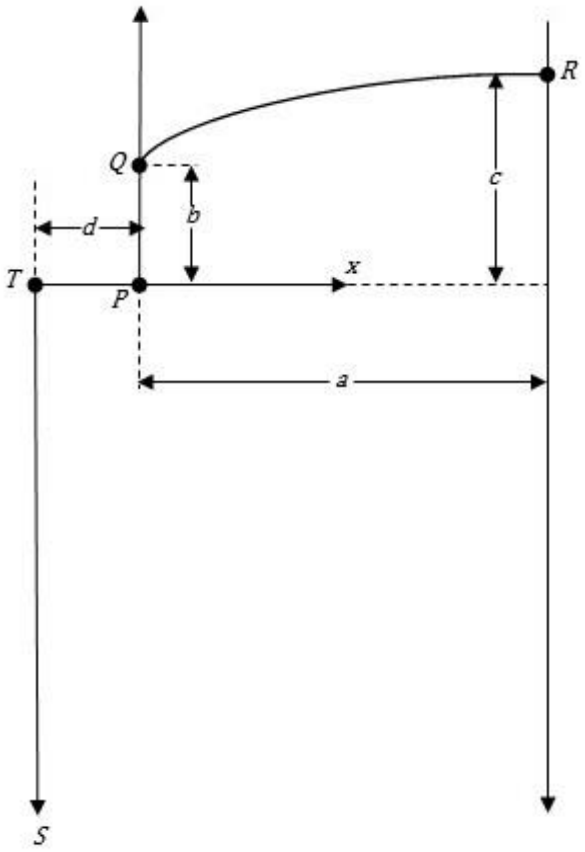

Figure 4

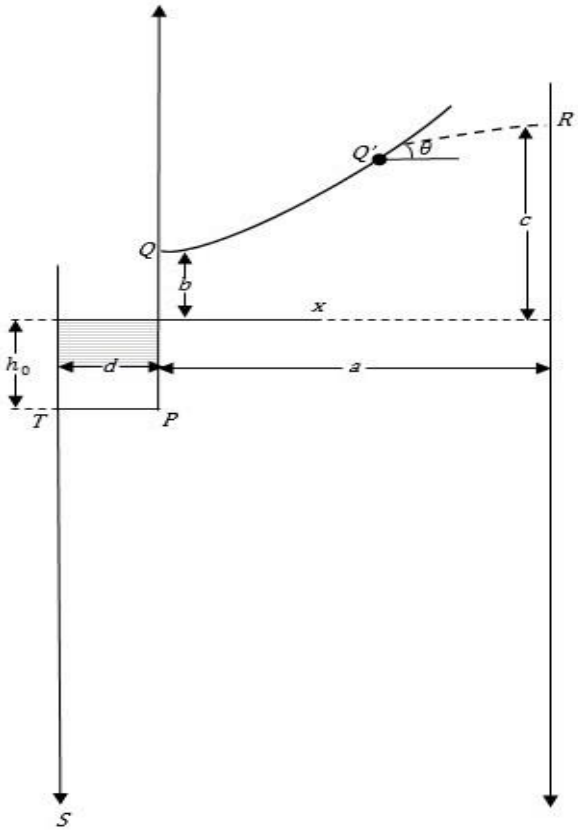

Figure 5

Again the solution approach was by conformal analysis and different mathematical expressions were obtained.

CONCLUDING REMARKS

The advanced analysis by van Deemter, done more than 65 years ago, represented a major breakthrough and achievement at that time. Yet, it never received the recognition it deserved. While the models and analysis described represented idealized situations void of geometric complexities and heterogeneity by layering and/or soil permeability variations., this technology as old as it is may be very useful in water management problems at the field and watershed scale of bottomland areas with drainage and irrigation needs.. From the erosion perspective, the analysis allows the calculation of seepage gradients at the soil profile-surface water interface and the determination of aequipotential surfaces in bank stability problems near ditches and channels. These calculations are the subject of further studies.

ORIGIN OF TILL RIDGES IN A NORTHEASTERN VERMONT VALLEY

John S. Moore, Retired National Geologist, Natural Resources Conservation Service (NRCS), United States Department of Agriculture (USDA)
Home: 7723 Modisto Lane, Springfield, VA 22153 (johnniednm@hotmail.com)

INTRODUCTION

Background: Since 2008 the author discovered several previously unreported till ridge sets in a northeastern Vermont (VT) valley. The question arose as to their mode of origin. To answer this question, the author selected one set for detailed field study, called Study Area 001 (figures 1 and 2). It is located along a northwest to southeast trending, a three-kilometer long segment of the Harvey-Symes valley (HSV) between Roy Mountain Wildlife Management Area and Lower Symes Pond near Ryegate, VT. The set contains no fewer than 90 ridges and mounds along both sides of the valley. Individual ridges are similar in composition of the boulder-size clasts, range in grain size distribution, and in shape, height, length, spacing (where clustered) and position on the landscape. Some ridges appear to have cross-valley counterparts. Study Areas 002 and 003 (figures 1 and 2) in Maine (ME) were control sites of known origin to contrast with conditions in Study Area 001 in VT.

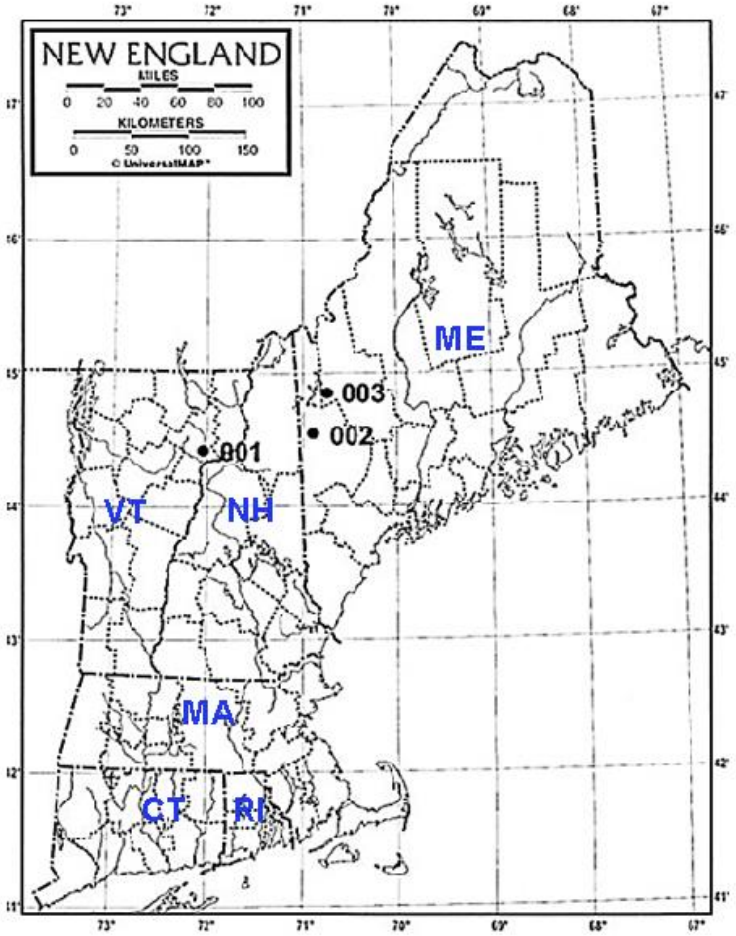

Figure 1 Regional map showing location of study areas (National Geographic Map of New England).

Purpose of Study: The purpose was to develop a classification system based on field criteria to determine the probable origin of the till ridge set in Study Area 001 and similar sets in this region. The classification would also

serve to improve reconstruction of late glacial history and post-glacial geomorphic events in northern New England, and may contribute to the understanding of global climate changes.

During fieldwork, the author considered two diametrically opposed hypotheses, erosion versus deposition. One hypothesis contends the ridges in a given set are interfluves formed by erosion, specifically, post-glacial dissection of a hillside till sheet by gullying and associated mass wasting processes. The other argues they are moraine ridges or ice-marginal deposits formed by periodic deposition of detritus released near the receding margin of the Laurentide Ice Sheet in New England. The author conducted two reconnaissance surveys in ME to serve as control sites because their origin is known to be erosional. Study Area 002 near Newry, ME (figures 1 and 2) is considered the largest known cluster of interfluvial ridges formed by post-glacial gullying of a till sheet in the region (Woodrow Thompson, Maine Geological Survey, personal communication, 2012). Study Area 003 is on the south flank of nearby Elephant Peak, ME (figures 1 and 2). This site offers a small analog of the Newry site that exemplifies active gullying and rilling on a well-exposed, unvegetated till sheet near a recently cut logging road. The study results provided field evidence to develop a classification to differentiate origin by either erosion or deposition. The classification addresses five physical parameters: swale morphology, swale soils, ridge morphology, drainage pattern and hydrology, and fate of eroded materials.

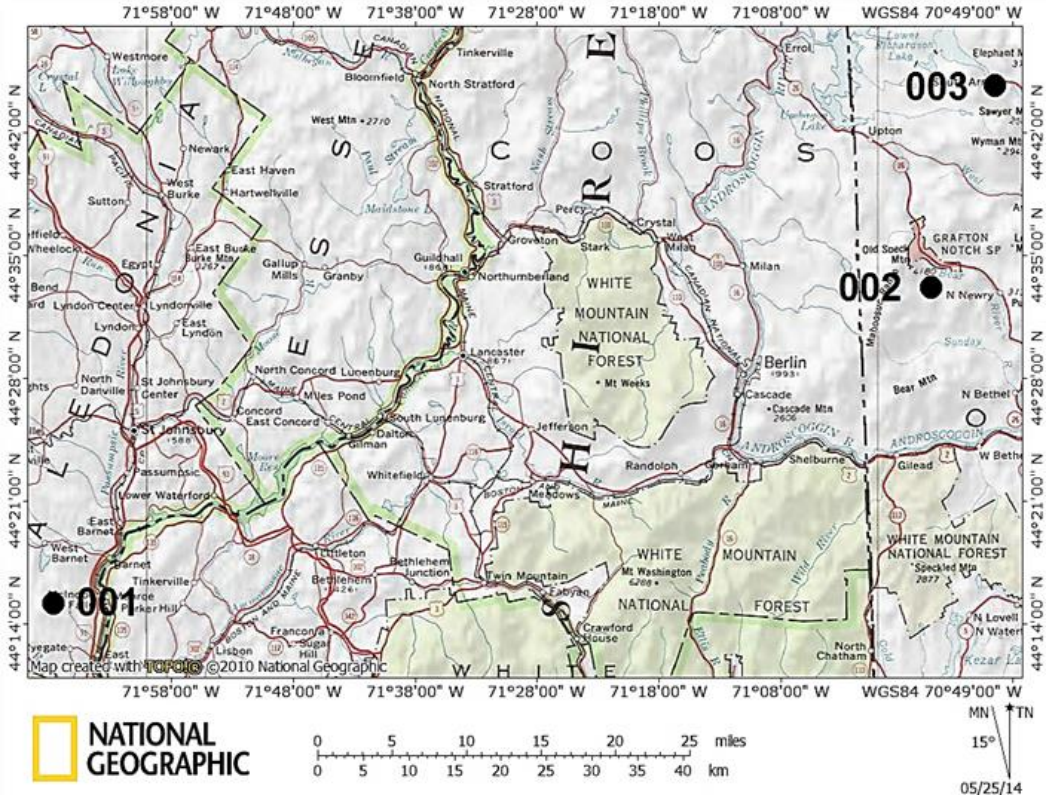

Figure 2 Shaded relief location map of Study Areas 001, 002, and 003, based on National Geographic Maps.

Definition of Moraine Ridge: Glacial geologists have not agreed upon a single definition or a classification scheme for moraine ridges. Moraine ridges that occur in sets have been variously termed ribbed moraine, washboard moraine, ridged moraine, corrugated ground moraine, recessional moraine, and other terms. For examples, refer to studies by Benn and Lukas (2006), Bennett and Glasser (2009), Hart and Boulton (1991), Hart and Rose (2001), Hättestrand and Kleman (1999), Koteff and Pessl (1981), Stewart, Bryant, and Sweat (1988), and Lundqvist (1969). Moore (1974) referred to them simply as recessional moraines. The fact remains, multivariate processes can construct a host of different landforms on various scales that manifest similar morphology and sedimentological characteristics. This paper applies the definition of moraine ridge used by Thompson (1999): *"A single-crested ridge of glacial sediment inferred to have been deposited at or near the ice margin and parallel to it"*. A swale is the low ground between adjacent ridges and is usually concave upwards in cross-section.

Definition of Interfluvial Till Ridge: This paper defines an interfluvial ridge or the broader, flat and uneroded area between adjacent gullies, as "*The high ground separating adjacent gullies flowing in the same direction and which were formed or are forming by fluvial and associated mass wasting processes that occur on the gully notch side slopes"* (Glossary of Geology, 1997). Interfluvial ridges tend to be oriented parallel with the fall line of the slope. Gully erosion on a till sheet produces consequent, ephemeral or intermittent streams that tend to form a dendritic drainage pattern.

Field Methods: Material and mass properties of soil and rock were described according standardized definitions of terms and field practices given in Moore (2001a, and 2001b) and ASTM D2488, "Standard practice for description and identification of soils (Visual-Manual Procedure)", also called the Unified Soil Classification System (USCS).

Base maps are seamlessly joined, 7.5-minute, US Geological Survey (USGS) topographic quadrangles available from the National Geographic's commercial software for computer-assisted drawings. The software also was used for track-recording and field navigation by a hand-held, Global Positioning System unit. Because some of the USGS maps use metric units and others use English units for contour elevations (six meters or 20 feet) and scales (kilometers and miles), both units are provided in the paper. Ridges that are less than six meters high are poorly discernible on these maps. Small ridges and isolated masses were not mapped. Due to innate ground irregularities, linear measurements were estimated by pacing and dead reckoning. The heights of features were measured by altimeters or by dead reckoning.

FINDINGS

Study Area 001: The till ridge set in Study Area 001 is a portion of a larger complex of hundreds of ridges and mounds that are mostly within the Roy Mountain Wildlife Management Area along the unnamed valley, herein referred to as Harvey-Symes Valley (HSV) between W. Barnet and Ryegate, Caledonia County, VT (figures 2 and 3). The black rectangle in figure 3 encloses the four-kilometer square study area which the HSV bisects longitudinally and follows the wet bottom. The northern margin of the study area is located at a valley bottom divide blocked by thick, hummocky till that effectively redirects perennial flow of Jewett Brook north to Harveys Lake. Streams south of the till divide flow into HSV to discharge into the Connecticut (CT) River at E. Ryegate, VT. The southern limit of Study Area 001 is near Lower Symes Pond.

Subsequent area surveys on nearby hills outside of Study Area 001 revealed small till ridges that partially wrap around upper sections of north facing hill slopes. These suggest nunatak formation and ice margin moraine deposition by retreating active ice. These ridges and numerous others in the vicinity are still under field study and are not shown on figure 3.

Numerous locally derived, angular to sub-rounded boulders up to 200 cubic meters in volume litter the surfaces of ridges and inter-ridge areas. Ridge lengths vary between several tens of meters and 200 meters. Average crest spacing on the both sides of HSV is approximately 60 meters. Ridge heights vary between three and 25 meters, but most are between four and six meters. Ridges tend to be straight and oriented between 60° (pointed down-valley) to perpendicular to the valley walls. The majority occur in declining fashion below the 318-meter (1040-foot) contour elevation. Frontal and distal side slopes of most ridges range between 25° and 35° and are nearly symmetrical in cross-section. Distal slopes are generally a few degrees steeper than frontal. Where angular, large boulders and cobbles are abundant in the till, slopes range between 35° and 45°. These ranges are consistent with angles of repose for unconsolidated, uncompacted, granular soils. Figures 5 and 6 illustrate a typical ridge in cross-section and in profile, respectively. Field assessment tests of unconfined compressive strength of numerous till boulders composed of foliated rock material ranged between 12.5 and 100 megapascals (MPa). Hammer blows perpendicular to schistosity gave higher values than parallel with it. Granite, gneiss, and quartzite boulders had values between 100 and 250 MPa. Angularity of edges and planar faces of large clasts were between sub-angular and sub-rounded, with sub-angular dominating. Large clasts showed no signs of weathering other than superficial iron oxide staining.

Grain-size gradation in till is variable from place to place and tends to be gap-graded. It consists of a coarse fraction ($\geq$ 3.0 inches) of cobbles through extremely large boulders that account for up to 80 % of till volume. The matrix varies between 10 and 25 % micaceous, fine sandy silt (ML), silty fine sand (SM), and non-plastic silt (ML). The clay fraction is low, ranging between 0 and 10 %. The gap accounts for less than 10 % of the till and consists of material between the coarse sand and coarse gravel range (approximately 10 to 40 millimeters).

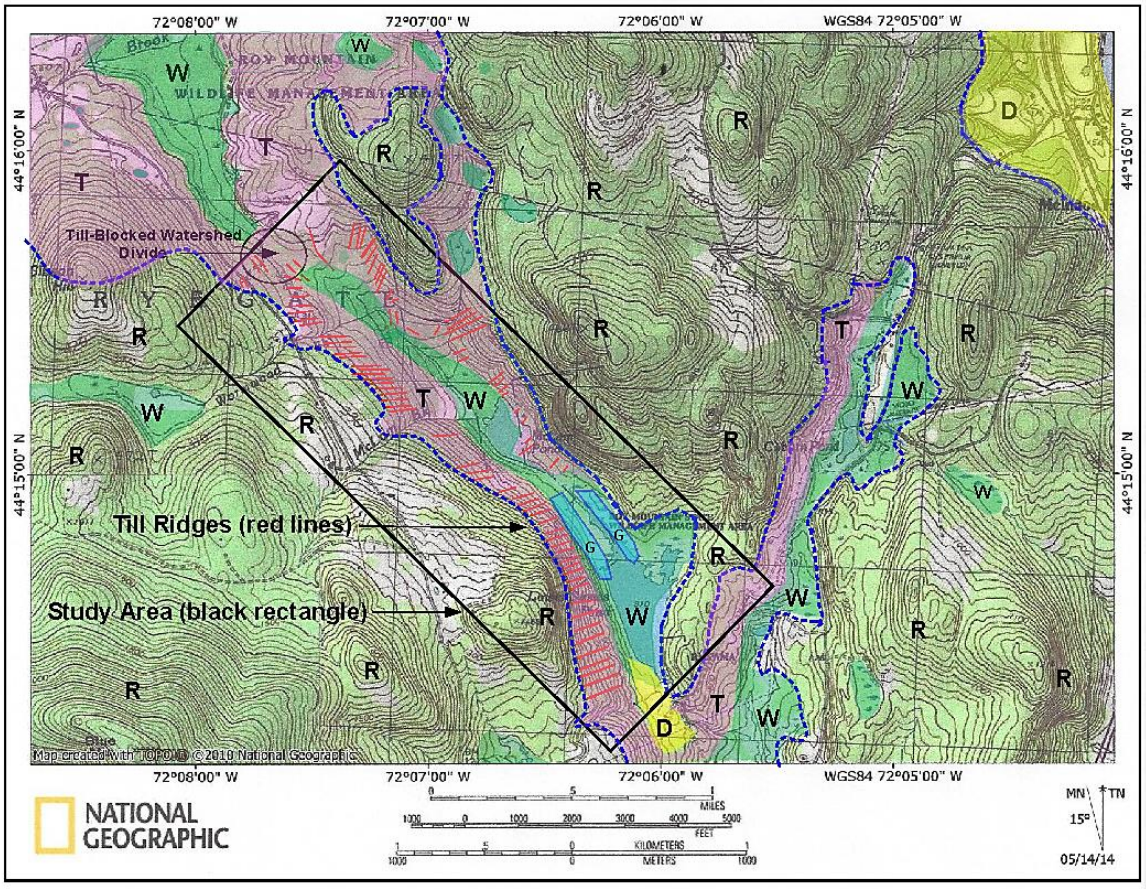

Figure 3 Generalized surficial geologic map of Study Area 001 drawn on integrated, National Geographic maps of USGS 7.5-minute topographic quadrangles. Contour interval is 20 feet (6 meters).

KEY TO SYMBOLS AND COLORS

R ***Dashed Blue Lines*****:** Inferred margins of areas of bedrock outcrop or thin till mantle above rock.

T ***Pink Overlay*****:** Areas of thick till, till ridges, and mounds. Red lines indicate till ridge crests within study area. Crest orientations are within +/- 10°. Ridges outside study area are not shown.

D ***Yellow Overlay*****:** Deltaic sediments in the sand- through cobble- size range, and undifferentiated lake sediments associated with proglacial Lake Hitchcock (not shown).

O ***Blue Overlay*****:** Small areas of glacial outwash (coarse gravels to large cobbles).

W ***Green Overlay*****:** Areas of natural ponds, wetlands, marshes, and wet floodplains. Those in valley bottoms were glacial meltwater channels. Those on higher ground were kettle holes or glacially scoured bedrock depressions that are now marshes or wetlands. Faded green is forested areas depicted on USGS base maps.

Figure 4 Explanation of symbols and colors used in figure 3.

The Natural Resources Conservation Service (NRCS), US Department of Agriculture (USDA), conducts county-wide soil surveys and classifies soils to a depth of 1.5 meters according to the texture-based, USDA Soil Classification System (Soil Survey Staff, 1999). The Caledonia County, VT soil survey (Gourley, 2007) indicates the USDA classification of soils on the ridges and in swale bottoms in Study Area 001 correlate well with the USCS. Cobbles and boulders are derived from local bedrock. Matrix fines are largely derived from local, foliated bedrock.

The material strength of foliated bedrock is inherently low and thus afforded little resistance to glacial erosion, abrasion, and percussion. Therefore, the rock readily disintegrated into non-plastic, fine particles.

In Study Area 001, swale drainage areas vary from a fraction of a hectare to approximately 10 hectares. There is no alluvium in the swale bottoms. They are perennially wet due to thin, poorly drained soils and organic-rich muck that cover dense till. Swales support denser and more water-tolerant ground vegetation than ridge sides and tops. Most swales have an ephemeral or intermittent stream channel that carries runoff from the nearby hills or from small, rock-fracture springs. Between rainfalls or during dry spells, intermittent stream channels are recharged by connate water seepage along the bases of till ridges. For example, after one flow event, a channel at the head of a swale was flowing one liter per minute. At its lower end, the stream was flowing five liters per minute. If clean, permeable alluvium were to occur in a swale bottom, stream discharge would decrease downstream due to infiltration into the alluvium. To check for Holocene alluvium, the author dug into 17 swales with a hand pick and never encountered fluvial sediment. In every case, bottom material consisted of a veneer of wet, organic-rich, silty muck overlying dense, slowly permeable till. Near surface water in swales is perched above and within poorly drained till and silty muck.

Figure 5 Cross-section of typical ridge viewed looking up axis. Ridge crest is crowned and varies between five and 10 meters in width. Height is three to five meters, and axis is approximately 150 meters long. Photo by author.

Figure 6 Profile view of ridge and swale near Lower Symes Pond. Photo by author.

Study Area 002: The site is on the southwest side of the Bear River valley, near Newry, ME (figures 1 and 2). It is the state's largest known interfluvial till ridge set. The set consists of at least 50 interfluvial ridges demarcated by adjacent gullies. The set is discernable on the topographic map (figure 7) and the aerial photo (figure 8).

The author traversed the entire site in July 2012 and made the following observations. The surface of the till sheet slopes between 10 and 30 % to the northeast. Gully incision depths vary between three and 25 meters. Because no bedrock is exposed in gullies, these depths provide an estimate for minimum till sheet thickness on this hillslope. All gullies in their upper reaches are V-notched. Large gullies widen downstream and present trapezoidal cross sections where small floodplains have developed. These floodplains have ephemeral or intermittent stream channels incised to a depth of 0.3 to 1.2 meters. During dry weather in July 2012, stream discharge in the lower reaches of large trunk gullies was no more than a few liters per minute. Discharges modestly increased downstream due to vadose water contribution from interfluves. Every gully channel has knickpoints in various places along its profile. During headcut advancement knickpoints migrate upstream or become erased by fluvial processes.

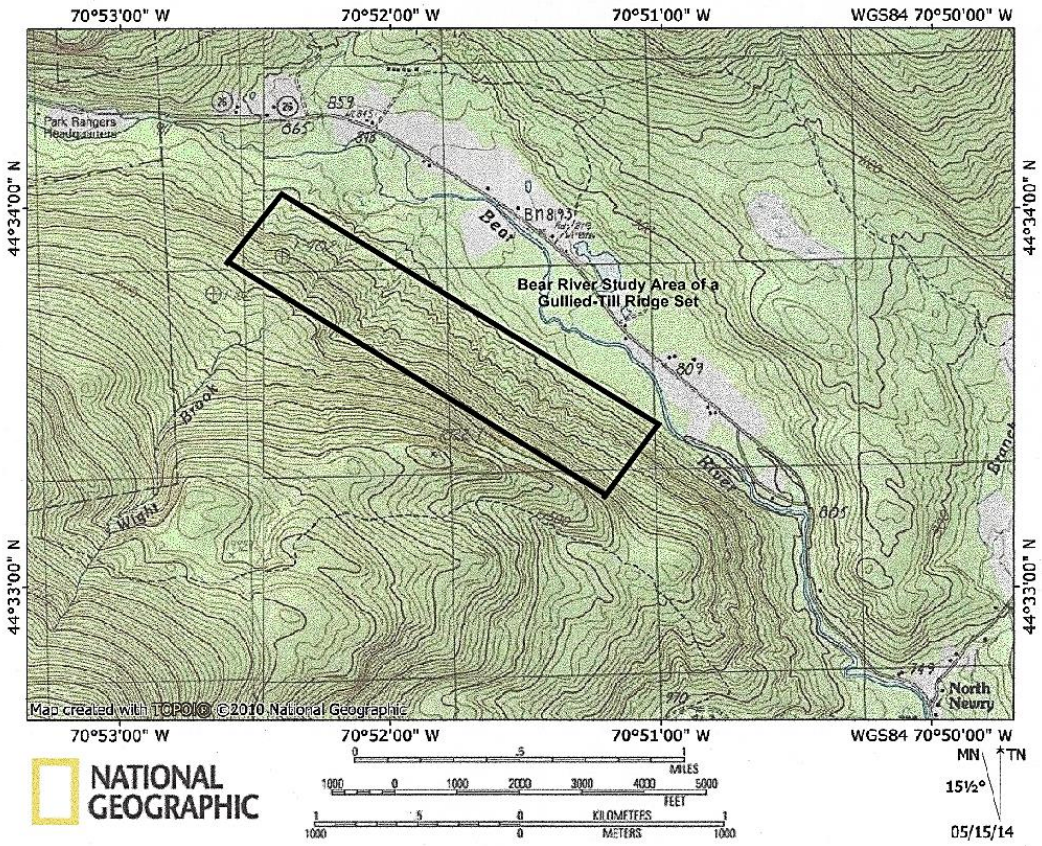

Figure 7 Topographic map of Study Area 002 near Bear River, Newry, ME. Contour interval is six meters.

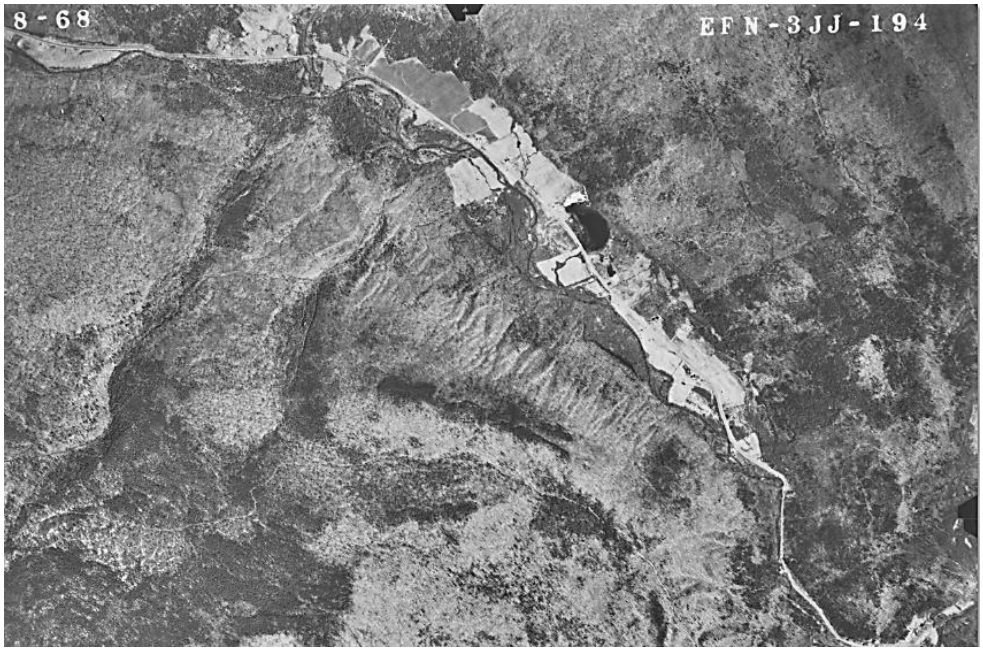

Figure 8 Vertical, aerial photo of figure 7, same scale. In center of photo, interfluvial ridges are well-exposed. Several trunk gullies branch into dendritic drainage patterns. Photo by USDA, Farm Services Agency.

Gully sidewalls are generally steep and irregular where mass wasting has occurred. Nevertheless, most reaches appeared stable with vegetated sidewalls, and the author could climb up or down them with little slippage. When slumps occur they form blockages that reroute the stream flows against the base of the walls. This intermittent process de-stabilizes the gully wall and induces additional mass wasting, which in turn, widens the gully. Individual boulders and cobbles can also perturb the flows with similar effect. All gully bottoms are covered by materials in the coarse gravel to boulder size range, with cobbles predominating.

The gullies are not regularly spaced (figure 8). Some adjacent gullies formed narrow interfluvial ridges. Flat, uneroded areas are well over 100 meters wide and reflect the original surface of the till sheet. Gully drainage areas vary between 5 and 50 hectares. The lengths of gullies in this cluster are similar because their upper ends, as well as the undissected portions of the till sheet, terminate against steep to vertical granite outcrops that trend NW-SE near hill 1822. Talus boulders at the base of the outcrop are not part of the till sheet. The boulders range between six and 20 cubic meters in volume.

The grain size distribution of the till is gap-graded. The matrix consists of non-plastic fines (ML and SM) through very fine sands (SW and SM) that collectively account for 20 to 30 % of the till volume. Clay content is minimal. Clasts larger than three inches (7.6 centimeters) account for 70 to 80 % of the volume. Large clasts vary between 0.020 and several cubic meters in size. The gradation gap occurs between the coarse sand through coarse gravel range. Basal ice comminution of local, foliated bedrock formations produce mostly fines. Crystalline rocks tend to yield clasts that reflect the spacing of discontinuities in the source rock mass. Size and shape of cobbles and boulders are usually functions of discontinuity patterns of the rock mass source area. Clast size may be further diminished by post-glacial weathering (mechanical disintegration or chemical dissolution), or by mechanical breakage and percussion during fluvial transport. Weathering may yield coarse sand through coarse gravel sizes provided the mineral constituents are similarly textured. In this area, most cobbles and boulders are sub-rounded, a characteristic that indicates reworking either by fluvial processes or by basal ice comminution near the end of the last glaciation.

Study Area 003: On Elephant Peak, ME, there is a small analog of the Bear River gully site. The site is a machine-cut slope adjacent to a new logging road ditch cut into till. Figure 9 shows the sharp break between the ditch side slope (30°) and the flatter (10°) slope above the ditch. The grain size distribution is similar to till in Study Area 002. The upper slope is analogous to unvegetated conditions that immediately follow ice recession when the till is well-exposed to rill and gully erosion (figure 9). Although spacing and depth of gullies and rills vary, they are roughly parallel to the slope. Headcut advance and dissection progress up through the flatter slope. Some gullies are branched. Slopes of undissected, interfluvial areas are essentially undisturbed, although rain has removed some fines to produce stone pedestals (figure 10).

Figure 9 A recently constructed logging road on Elephant Peak, ME. The side ditch that was excavated into a till sheet illustrates an unvegetated, sloping surface that is undergoing gully and rill erosion. Photo by author.

Figure 10 Close-up view showing how lag cobbles and boulders cause channel flows to impinge on the gully or rill side slopes. The side slopes become subject to mass wasting, and the channel widens, deepens, or changes direction. Photo by author.

DISCUSSION OF TILL RIDGE ORIGIN

Assessment of bedrock as it occurs regionally and locally is fundamental to reconstructing late glacial events in New England. Rock masses differ in composition, areal distribution, material and mass strength, and geologic structure. These factors collectively affect regional physiography, landscape form, and drainage patterns. During ice ages, near surface bedrock conditions can influence basal ice flow direction and determine the composition of glacial deposits.

An essential requirement for development of moraine and other ice-marginal deposits is a nearby, easily comminuted source of detritus. Study Area 001 follows a lineament formed by a mixed contact zone that measures 12 kilometers long by up to four kilometers wide in this region. The lineament trends through the long axis of Harveys Lake, the entire HSV, and lower Manchester Brook Valley (MBV). Its orientation aligns well with known flow directions of continental glaciers. The zone occurs along the margin of the Knox Mountain granite pluton that invaded foliated rocks of the Waits River and Gile Mountain formations. The mixed zone consist of unaltered xenoliths of foliated rock fragments embedded in granite, and a complex system of dikes and sills injected along cleavage and fractures of stratified units. The dike complex and inclusions in the granite indicate disruption and shattering near the border of the pluton (Hall, 1959; White and Billings, 1951; and Konig, 1961). During glacial advances, the buttresses afforded by Roy and Harvey Mountains and the steep, bedrock valley walls along HSV

steered basal ice south and southeast toward the Connecticut River valley. During recession, the outlet valley glacier in the HSV therefore had access to abundant, erodible rock material to form moraine.

An active glacier carries the bulk of ice-eroded debris within the lower few meters of its base. Koteff and Pessl (1981) stated that most till in New England was transported no more than 1.5 kilometers from its bedrock source. Throughout Study Area 001, ubiquitous, surface-exposed, large boulders express low to moderate edge and face rounding. These conditions, plus the composition of till components, including boulders and matrix alike, inarguably reflect local provenance. Koteff and Pessl (1981) considered end moraines as *prima face* evidence of stalled margins of active ice.

For the till ridge set in Study Area 001, the hypothesis of origin by Holocene erosion is not supported by field evidence. Severe summer storms that damaged VT in the past few years produced virtually no out-of-channel sediment in swales in Study Area 001. Furthermore, no alluvium occurs in swale bottoms that would have resulted from immediate, post-glacial erosion. Field evidence collectively indicates the predominant hydrogeology of swale bottoms is perched water above and within poorly drained till and organic-rich muck. Swales provide the primary outlet for connate water that slowly seeps from the toes of ridges. If swale bottoms contained permeable alluvial deposits, they would act as French drains where surface waters infiltrate into the alluvium, move downhill, and outlet into HSV River or Upper and Lower Symes Ponds. Stream discharges in swales would thus diminish downslope. The fact that the swales are perennially wet and mucky is clear evidence that the swale soils are slowly permeable.

Local topography indicates the HSV served as the primary flume for local glacial meltwater. The lower ends of ridges next to Upper and Lower Symes Ponds appear truncated along a common line parallel to a presumed hydraulic gradient during times of high meltwater discharge. The line of truncation is approximately three to five meters above current pond elevation. Meltwater also was likely responsible for breaching cross-valley moraines. Heyman and Hättestrand (2006) described these ridges as valley-side moraines. They defined them as "*sub-horizontal, relatively straight ridges situated on valley sides and formed at the margins of outlet glaciers during deglaciation of an ice sheet"*. They based this definition on morphology and topographic setting.

There are many significant factors that preclude the hypothesis that the ridges are interfluves formed by hydraulic erosion. (1) The drainage areas of all the swales are far too small to provide sufficient hydrodynamic energy to erode sediment larger than medium gravel. The enormous body of research on erosion and sedimentation unquestionably indicates that the hydrology of such small watersheds cannot enable the entrainment and transport of clasts greater than coarse gravel, even on bare surfaces (Yang and Huang, 2001). According to classic literature, the most erodible grain size range is 0.10 to 0.50 millimeter (modified Hjulstrom curve *in* Sundborg, 1956; and Shields Diagram *in* Vanoni, 1975). Thus, streams that flow through erodible materials quickly become turbid during the rising stage of a hydrograph. The fine fraction continues to move throughout the entire runoff event. At the end of a flow event suspended and bedload sediments drop out and become available for subsequent events. (2) The erodible size range accounts for only 20 % of the till volume. The remaining 80 % is therefore not erodible and would remain *in situ*. (3) The erosion hypothesis does not account for isolated ridges or ridges that are not parallel the fall line of the slope. (4) The volume of the space between all ridges in the set is conservatively estimated to be five million cubic meters. There is no evidence of any of this material down valley. The obvious site of deposition would be the MBV located just below the bedrock outlet of Lower Symes Pond. During the time of continental ice recession in this area, the MBV was an isolated arm of proglacial Lake Hitchcock. According to glacial rebound studies of the CT River valley by Koteff et al. (1993), Lake Hitchcock's surface elevation at this latitude was 246 meters (808 feet), the same elevation as today's Lower Symes Pond. Below the junction of HSV and MBV, the MBV is approximate one-half kilometer wide by four kilometers long above where Manchester Brook discharges into the CT River near E. Ryegate, VT. Except for trivial amounts of Holocene floodplain sediments, no fluvial, glaciofluvial, or lacustrine sediments occur in the MBV.

The field work in the three study areas provided sufficient evidence to develop a classification system (table 1) to identify the probable origin of till ridges as either depositional or erosional. The system uses five physical parameters: swale/gully morphology, swale/gully soils, ridge morphology, drainage pattern and hydrology, and fate of the eroded materials. No doubt other factors could serve as identifying parameters, but these five are adequate for field identification.

Table 1 Field classification criteria for determining origin of till ridge sets in VT.

PARAMETER	ORIGIN BY EROSION (Gullying and Mass Wasting)	ORIGIN BY DEPOSITION (Moraine/Ice-Marginal)
Swale/Gully Morphology	1. Cross-sections of gullies are steeply V-notched or trapezoidal. 2. Mass wasting occurs on steep gully sides and is initiated primarily by stream impingement at base of slope. 3. Gully bottom deposits consist of alluvium and reworked mass wasting debris. 4. Gullies always contain ephemeral or intermittent stream channels, some of which may have small flood-plains developed in alluvium. 5. Main stem gully may be branched with headcutting tributaries.	1. Swales may have small, ephemeral or intermittent stream channels till. 2. There is little to no fluvial sediment in swales. 3. In dry weather, intermittent streams are gaining due to connate water seepage from toes of adjacent ridges. 4. Cross-sections of swales are broad, and are concave upwards.
Swale/Gully Soils	1. Gully bottoms are covered by sorted alluvium as well as mass wasting debris released from sidewalls.	1. Alluvium is trivial to non-existent. 2. Swale bottom material is dense, slowly permeable till commonly covered with organic-rich, wet, silty muck.
Ridge Morphology	1. All interfluves and interfluvial areas are sub-parallel with ground slope. 2. Ridge tops and interfluvial surfaces reflect original slope of till sheet. 3. Margins along axis of interfluvial ridge tops are irregular due to headcutting tributaries of master gullies.	1. Orientation of ridges is not necessarily parallel to hill slope. 2. Ridges may occur in regularly spaced sets, or in-line clustered mounds. 3. Ridges may occur isolated from others. 4. Axes may be linear, curvilinear, or align with ridges on opposite side of valley. 5. Ridge sides rarely cut by gullies.
Drainage Area and Hydrology	1. Gullies expand by headcut advance-ment and tend to form consequent, dendritic drainage patterns over time. 2. As gully drainage area increases, the gully network produces greater discharges for similar runoff events. Greater discharges and flow depths directly increase hydraulic energy that can erode and transport larger particles. 3. Slumped boulders and detritus perturb stream flows and may initiate gully sidewall instability by changing meander patterns, developing micro-stream piracy, or forming new headcuts.	1. There is no headcutting at upper end of swales, thus swale drainage areas remain constant. 2. Drainage areas of swales are too small to provide adequate hydrodynamic energy to erode most constituents of till materials in swales. 3. Boulders in swale bottoms are *in-situ*, and may occur on top of or partially embedded in ground.
Fate of Eroded Materials	1. Gully-eroded sediments form alluvial fans at outlet of gully or discharge into the lower, major trunk stream. 2. High energy flows of major trunk valley stream may erode alluvial fans.	1. Fluvial erosion in swales or on ridges is minimal to non-existent. 2. There are no sediment deposits down-valley to account for the large volume of materials required for voiding by erosion between ridges.

CONCLUSIONS

The author conducted on-ground reconnaissance surveys of surficial deposits in Northeastern VT between 2008 and 2014 and encountered several till ridge sets along some valley slopes. The question arose as to the origin of these ridges. One 90-ridge set (Study Area 001) was evaluated to address two diametrically opposed hypotheses for ridge origin. One hypothesis contends the ridges in a given set are interfluves formed by erosion, specifically by Holocene gullying and associated mass wasting processes that dissect a hillside till sheet. The other hypothesis argues they are moraine ridges or ice-marginal deposits formed by periodic deposition of detritus released near the receding margin of the Laurentide ice sheet in New England. Two ridge sets in ME (Study Areas 002 and 003) were selected as control sites because they are clearly interfluvial ridges formed by erosion. Diagnostic field evidence gleaned from these two sites was contrasted with the VT set's physical characteristics.

The body of field evidence demonstrably supports the hypothesis that the VT till ridge set was formed as recessional moraines deposited by active, receding ice in the HSV during waning phases of the Laurentide ice sheet in this part New England. The following facts support this conclusion. (1) All swale drainage areas in Study Area 001 are far too small to generate streams with sufficient hydraulic energy to entrain and transport sediment larger than medium-sized gravel (approximately 10 to 40 millimeters). Given that up to 80 % of the local till consists of material greater than coarse gravel size, it is impossible for hydraulic erosion to create the inter-ridge voids. (2) There are no lag deposits or alluvial sediments in the swale bottoms to indicate that erosion processes have occurred. (3) If streams were competent to erode and transport all available grain sizes and in the volumes represented by inter-ridge voids, the question arises as to the fate of this material. The most logical sediment trap would have been the MBV just below the HSV, yet there is no appreciable sediment to be found. In fact, thorough field checking between the HSV and the CT River valley did not reveal any meaningful volumes of alluvial fan, stream alluvium, or lacustrine deposits (associated with proglacial Lake Hitchcock) to account for the material. (4) Cross sections of swales and ridges are gently rounded, concave and convex, respectively. These configurations are not consistent with small-scale valley development formed by stream erosion and concomitant mass wasting (Bloom, 1969). (5) In obvious contrast, cross-sections of gullies and interfluves in Study Areas 002 and 003 are more sharply defined than swales in Study Area 001. Gullies are V-notched where narrow, and trapezoidal in the downstream, wider reaches. Drainage patterns are sub-dendritic formed by consequent gullies that advanced by headcutting into a till sheet. (6) In Study Areas 002 and 003, the occurrence of gully bottom alluvium and evidence of mass wasting on gully sidewalls obviously indicate the interfluvial ridges formed by classic gully erosion.

Observations at the three study areas led to the development of a classification system to differentiate the two modes of till ridge origin. The classification uses five physical parameters: swale/gully morphology, swale/gully soils, ridge morphology, drainage pattern and hydrology, and fate of the eroded materials. Each parameter is identified by criteria to support each mode of origin. The field classification system will readily assist the field worker in determining the origin of till ridges by either erosional or depositional processes. When higher resolution imagery, such as Lidar, becomes more widely available, more glacial features undoubtedly will be discovered that cannot be discerned on USGS topographic quadrangle maps. Because the origin of newly discovered features should be ground-truthed, it is hoped the classification will serve to improve reconstruction of late glacial history and post-glacial geomorphic events in northeastern VT and in other similar regions.

ACKNOWLEDGMENTS

I thank David G. Johnson for his interest, time, and stimulating discussions, and for providing numerous constructive and thorough peer reviews of the manuscript. David accompanied me in the field on many occasions and offered a wealth of valuable ideas and useful critique throughout this study. I appreciate Jeffrey Noyes for his helpful discussions and ideas. I thank my wife Christine Moore for her critical editorial review of the manuscript. I thank Claudia Hoeft for providing substantive, editorial and technical review of the final manuscript.

ESTIMATING CONCENTRATIONS OF FINE-GRAINED AND TOTAL SUSPENDED SEDIMENT FROM CLOSE-RANGE REMOTE SENSING IMAGERY

Adam R. Mosbrucker, Kurt R. Spicer, Tami S. Christianson, and Mark A. Uhrich,
U.S. Geological Survey, Cascades Volcano Observatory, Vancouver, Wash., amosbrucker@usgs.gov

INTRODUCTION

Fluvial sediment, a vital surface water resource, is hazardous in excess. Suspended sediment, the most prevalent source of impairment of river systems, can adversely affect flood control, navigation, fisheries and aquatic ecosystems, recreation, and water supply (e.g., Rasmussen et al., 2009; Qu, 2014). Monitoring programs typically focus on suspended-sediment concentration (SSC) and discharge (SSQ). These time-series data are used to study changes to basin hydrology, geomorphology, and ecology caused by disturbances. The U.S. Geological Survey (USGS) has traditionally used physical sediment sample-based methods (Edwards and Glysson, 1999; Nolan et al., 2005; Gray et al., 2008) to compute SSC and SSQ from continuous streamflow data using a sediment transport-curve (e.g., Walling, 1977) or hydrologic interpretation (Porterfield, 1972). Accuracy of these data is typically constrained by the resources required to collect and analyze intermittent physical samples.

Quantifying SSC using continuous instream turbidity is rapidly becoming common practice among sediment monitoring programs. Estimations of SSC and SSQ are modeled from linear regression analysis of concurrent turbidity and physical samples. Sediment-surrogate technologies such as turbidity promise near real-time information, increased accuracy, and reduced cost compared to traditional physical sample-based methods (Walling, 1977; Uhrich and Bragg, 2003; Gray and Gartner, 2009; Rasmussen et al., 2009; Landers et al., 2012; Landers and Sturm, 2013; Uhrich et al., 2014). Statistical comparisons among SSQ computation methods show that turbidity-SSC regression models can have much less uncertainty than streamflow-based sediment transport-curves or hydrologic interpretation (Walling, 1977; Lewis, 1996; Glysson et al., 2001; Lee et al., 2008). However, computation of SSC and SSQ records from continuous instream turbidity data is not without challenges; some of these include environmental fouling, calibration, and data range among sensors. Of greatest interest to many programs is a hysteresis in the relationship between turbidity and SSC, attributed to temporal variation of particle size distribution (Landers and Sturm, 2013; Uhrich et al., 2014). This phenomenon causes increased uncertainty in regression-estimated values of SSC, due to changes in nephelometric reflectance off the varying grain sizes in suspension (Uhrich et al., 2014).

Here, we assess the feasibility and application of close-range remote sensing to quantify SSC and particle size distribution of a disturbed, and highly-turbid, river system. We use a consumer-grade digital camera to acquire imagery of the river surface and a depth-integrating sampler to collect concurrent suspended-sediment samples. We then develop two empirical linear regression models to relate image spectral information to concentrations of fine sediment (clay to silt) and total suspended sediment. Before presenting our regression model development, we briefly summarize each data-acquisition method.

RIVER REMOTE SENSING

Remote sensing is a rapidly growing subdiscipline in river science due to its ability to answer complex spatial and temporal questions; cost-effective data acquisition, processing and analysis; and the increasing adoption of geospatial technology by hydrologists (Marcus and Fonstad, 2010). River remote sensing has become a broad field. Active (e.g., lidar) and passive optical (e.g., photogrammetry) remote sensing provide precise topographic measurements to assess geomorphic characteristics and sediment transport of river environments. Spectral analyses of reflected electromagnetic (EM) radiation recorded by satellite-based optical sensors have been successfully used to estimate turbidity and SSC of large rivers over a broad range of time-scales and from low to medium concentrations (e.g., Curran and Novo, 1988; Mertes et al., 1993; Islam et al., 2001; Wang et al., 2009; Wang and Lu, 2010; Wang et al., 2010; Qu, 2014).

SATELLITE SENSORS

Satellite imagery provides retrospective and spatial information about a river system. Spectral analyses of satellite imagery are based on the measurement of reflected EM solar radiation. Material properties produce unique signatures, or curves, depending on reflection and absorption of different wavelengths (λ); sensors commonly record data in the

visible to short-wave-infrared spectra. Multispectral data are recorded as pixel unit values within a multilayer array, or raster image file. Each layer, or band, is sensitive to a unique wavelength range, commonly rendered as red, green, and blue (RGB), though imagery may contain dozens of bands.

In satellite remote sensing, pixel values, generally referred to as digital numbers (DNs), are calibrated into physically meaningful units of radiance (i.e., watts per unit area). Surface reflectance spectra, derived from atmospheric correction of radiance imagery, are then used to quantify features within an image. Maximum reflectance sensitivity of clear water is near the blue end of the spectrum (λ<500 nm), reflectance decreases as wavelength increases. Turbid water, with greater SSC, has increased sensitivity toward the red end of the spectrum (λ>600 nm), accounting for its brownish appearance.

The relationship between reflectance and SSC is affected by suspended material composition, water depth, SSC variation over depth, and view geometry (Qu, 2014). Empirically-developed models relating spectra to SSC in riverine and laboratory environments use linear, second-order polynomial, and logarithmic equations (Table 1). While most utilize the near-infrared (NIR) spectrum (λ>700 nm), of interest to our study is Islam et al. (2001) who used the blue spectrum of MODIS satellite imagery (Band 3, λ=459–479 nm) to estimate SSC in the Ganges and Brahmaputra Rivers (about 400–1,800 mg/L) (Table 1). Peak response of our consumer-grade sensor is 470 nm.

Table 1 Selected empirical models predicting river suspended-sediment concentration (SSC) from satellite imagery and laboratory measurements. The values of the surface reflectance of the water at the given wavelengths (r_i) are explanatory variables in these equations (*ith* band of a given sensor). Table modified from Qu (2014).

Sensor Platform	Wavelength λ (nm)	Spatial Resolution (m)	Location	Model	R^2	Samples (n)	Reference
MODIS satellite	841-876, 1230-1250	250-500	Yangtze River (China)	$SSC = -23.03 + 60.25(r_2 - r_5) - 23.03$	0.73	153	Wang et al., 2010
		250-500	Yangtze River (China)	$ln(SSC) = 4.117 + 0.262(r_2 - r_5)$	0.78	35	Wang and Lu, 2010
Landsat satellite	760-900	30	Yangtze River (China)	$ln(SSC) = -1.40060 + 3.18263 ln(r_4)$	0.88	24	Wang et al., 2009
MODIS satellite	459-479	500	Ganges and Brahmaputra Rivers (Bangladesh)	$SSC = -201 + 69.39 r_3$	0.98	10	Islam et al., 2001
Laboratory spectrometer	852	--	Lab, silt	$SSC = -23.367 + 116.869 r_{852} + 24.04 r^2_{852}$	0.99	10	Lodhi et al., 1997
	852	--	Lab, clay	$SSC = -23.367 + 116.869 r_{852} + 24.04 r^2_{852}$	0.96	10	Lodhi et al., 1997
	555, 754	--	Lab, clay (organic)	$SSC = -0.31 + 12.32(r_{555}/r_{754})$	0.92	7	Gin et al., 2003

CONSUMER-GRADE DIGITAL CAMERA SENSORS

We expand upon previous laboratory and satellite image analyses by evaluating the feasibility of using imagery acquired with a consumer-grade digital camera at a distance <10 m above a river surface to estimate SSC. Compared to satellite-based platforms, close-range remote sensing can measure smaller streams at similar wavelengths with as much as 1,000 times greater spatial resolution, and algorithms for spectral mixing and atmospheric correction are not needed (Mertes et al., 1993; Qu, 2014). The primary differences between industrial- and consumer-grade sensors are the characteristics of individual bands (Table 2). Whereas each band of satellite imagery is sensitive to radiation within a narrow and discrete bandwidth (e.g., 20–80 nm), consumer-grade sensors have a broadband response (e.g., 200–300 nm) with significant overlap among only three bands (Table 2).

Consumer-grade sensors are sensitive to wavelengths between 200 and 1,300 nm. However, manufacturers use ultraviolet (UV) and NIR interference filters to restrict recorded EM radiation to the visible spectrum (400–700 nm) in order to more precisely focus light rays onto a single plane (Figure 1). These filters, located in front of the sensor, can be removed to restore the full spectral range of the native sensor. Apparent brightness and color measurements are typically recorded in 8-bit integer (i.e., values 0–255) Joint Photographic Experts Group (JPEG) file format, which have a defined color space, or coordinate system (e.g., sRGB, Adobe RGB, ProPhoto RGB). File format type, bit depth, and color space determine the degree of signal processing, precision, and range of data.

Table 2 Spectral response characteristics for selected satellite and consumer-grade sensors (band λ in nm). Lighter grey area is native (unfiltered) response of a Nikon D800E sensor. Where known, peak response is given in white font. A Forest Technology Systems (FTS) DTS-12 turbidity sensor (emitted λ) is included for reference purposes.

Platform	Sensor	Band No.	Range (λ, nm)	Bandwidth (λ, nm)	UV Light 300	Visible Light 400 500 600	NIR Light 700 800 900 1000 1100 1200

[1]The Landsat TM sensor has three additional middle- to thermal-infrared bands (band 5–7, λ=1,550–12,500 nm). [2] The MODIS sensor has 31 additional bands (λ=450–14,385 nm). Abbreviations: ultraviolet (UV); near infrared (NIR).

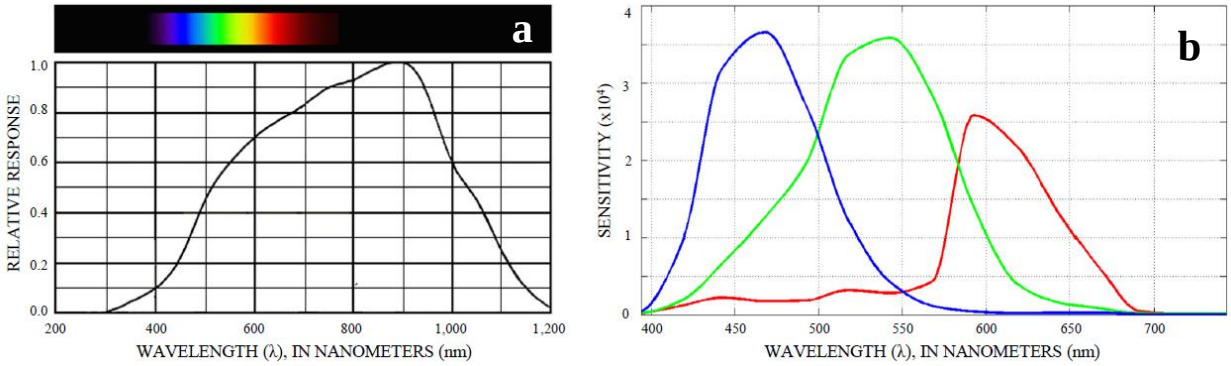

Figure 1 Spectral response curves of (a) native and (b) filtered sensor used in a Nikon D800E digital single-lens reflex (DSLR) camera. Response curves for sensors used in consumer-grade digital cameras from other manufacturers are similar. Figure modified from Profilocolore Sri (2013).

STUDY AREA

The May 18, 1980, eruption of Mount St. Helens consisted of a 2.5 km^3 debris avalanche followed by a blast density current, pyroclastic flows, lahars, and tephra falls (e.g., Lipman and Mullineaux, 1981). These disturbances severely altered the hydrogeomorphic regime of the upper North Fork Toutle River, whose 450 km^2 basin includes the north flank of the volcano. Our investigation was conducted at an existing USGS surface water discharge and suspended-sediment monitoring station, 13 river km downstream of the toe of the debris avalanche deposit (primary sediment source), and 2 river km below a sediment retention structure near Kid Valley, Washington (14240525). More than three decades after the eruption, the river continues to transport an average of 3 million tonnes (or megagrams, Mg) of suspended sediment per year; daily average SSC is 31–79,800 mg/L (water years 2007–2013). A significant portion of the annual SSQ is transported during infrequent high-streamflow events. Suspended particle sizes range from clay to sand; material is commonly 50–80% fines (i.e., <63 µm). Fines are well distributed in cross section and vertical profile. Bed material is dominantly sand. Annual mean water discharge at the station is 22.3 m^3/s (water years 1990–2013).

DATA COLLECTION AND ANALYSIS METHODS

To evaluate the feasibility of estimating suspended-sediment characteristics from close-range multispectral imagery, we developed a simple, reproducible, and effective methodology for image acquisition, sample collection, and analysis. Concurrent pairs of suspended-sediment samples and imagery were acquired during routine site visits between January and June, 2014. Data were collected over a range of hydrologic conditions and turbidity, with an emphasis on capturing high-flow events. In total, 716 photographs and 100 samples were acquired during this 6-month period. A calibration data pair consists of a series of normalized imagery and associated suspended-sediment samples.

SUSPENDED-SEDIMENT SAMPLES

Standard USGS field and laboratory methods were used for suspended-sediment sample collection and analyses (Guy, 1969; Edwards and Glysson, 1999). Suspended-sediment samples were collected using a D-74 depth-integrating sampler with a 0.48-cm-diameter brass nozzle (Edwards and Glysson, 1999; Davis et al., 2005) deployed from a bank-operated cableway. Primary samples used in the calibration dataset were collected at a single station within the camera's field of view. Secondary cross-section samples were collected using an equal discharge increment (EDI) method for future relation of results to cross-sectional mean concentrations. We collected full-depth and near-surface samples (i.e., 7 cm below the river surface), usually in two sets to assess variability (Topping et al., 2011).

Sediment analyses were performed at the USGS Cascades Volcano Observatory in Vancouver, Washington. SSC data were computed using the dry weight of all sediment from a sampled volume. Particle diameter was measured with a sieve and sedigraph. Primary samples (n=39) have wide variation in SSC (262–7339 mg/L) and particle size distribution (28–94% <63 µm; 10–33% <4 µm; 4–24% <2 µm). Root-mean-square error (RMSE) of lab results is about 4% (USGS, 2014), but sample data show a moderate to high degree of spatial and temporal variability. SSC for full-depth samples is typically <10% greater than near-surface samples and occasionally as much as 40% (due to sand in suspension near the streambed). Samples taken within a few minutes of each other in the same location have SSC values that differ by ≤25%. Particle size data show 9–30% less sand near the river surface.

CLOSE-RANGE MULTISPECTAL IMAGERY

CAMERA SYSTEM

One of the first tasks of our study was to select a camera system and develop a consistent procedure for data acquisition and analysis. We used the same camera system and configuration throughout the study. Camera sensor and lens (i.e., camera system) selection focused on optimizing spatial and spectral resolution, ability to calibrate white balance, automate exposure compensation, produce RAW image files (which have 64–256 times more brightness levels than a standard 8-bit JPEG files), select color space, and use a configuration file. Spatial resolution is a function of the sensor and the lens. Higher resolution sensors, commonly measured in megapixels (MP), combined with fixed focal length lenses (generally 35–85 mm) produce the greatest resolution; optical aberrations of lenses can have a significant impact on resolution.

Although data are widely available for spatial resolution and other image-quality parameters of consumer-grade digital camera systems, the spectral response of a specific sensor is difficult to obtain. DxO Labs, an imaging solution and standardization company, publishes image quality lab test results of digital image capture devices through their website (*http://dxomark.com*). DxOMark quantifies image quality using three resolution-normalized metrics: dynamic range, color sensitivity, and noise levels. For our purposes, we sought to maximize dynamic range and color sensitivity (or color bit-depth), while minimizing noise in an affordable off-the-shelf consumer-grade camera.

On the basis of these criteria, we chose a Nikon D800E digital single-lens reflex camera (DSLR) with a 70–300 mm focal length lens to provide flexibility. According to DxOMark lab results, this system has similar image quality to others costing as much as 10 times more. The camera uses a 864 mm^2 Sony IMX094AQP CMOS image sensor, which has 36.56 MP (4.8 µm each), a 14-bit non-linear analogue-to-digital converter (for 14.3 exposure values (EV) of dynamic range), 25.6 bits of color depth, and an ISO of 2979. The broadband sensor has a native spectral response range of 300–1250 nm, reduced to about 380–680 nm after passing through UV-NIR interference filters (Figure 1). The system allows JPEG files to be spectrally normalized through custom white balance calibration.

IMAGE ACQUISITION AND ANALYSIS

Immediately before, during, or after collecting suspended-sediment samples, we acquired multispectral imagery of the water surface at a camera station collocated at the sampling site. The camera was mounted to a handrail <5 m above the water surface at a 45° angle to maximize water surface penetration (Figure 2). The rail was marked to facilitate precise relocation of the mount. The same 70 mm focal length was used for all imagery; field of view was 28.8° horizontal and 19.5° vertical, imaging an ~8.9 m^2 frame, depending on river stage. This represents a nominal water surface sampling distance of 0.5 mm per pixel (i.e., medium- to course-sand) at the center of the field of view, which was set to the sample location, 1.5–2.1 m from the left bank (Figure 2).

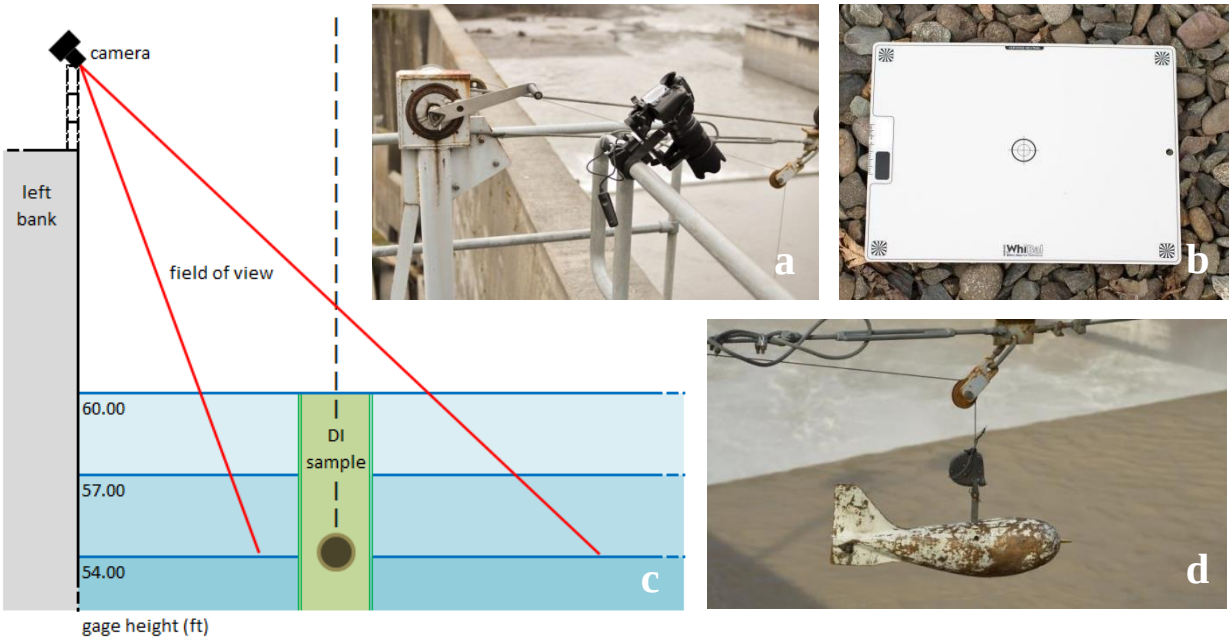

Figure 2 Field data collection panel showing (a) the camera system mounted on handrail near bank-operated cableway, (b) white balance calibration card, (c) relationship of camera field of view to suspended-sediment sample location, and (d) D-74 depth-integrated sampler deployed from the cableway. Views are downstream from left bank.

Initial methodology focused on maximizing the information capacity of each dataset, because we did not know what would prove to be most useful. Datasets consisted of three sequences of nine exposure-bracketed images (0.3–1.0 EV intervals) at a high frame rate (Figure 3). Each sequence used a different glass lens filter (clear, ultraviolet, polarized) to modify the water surface reflectance prior to sensor detection. To account for changing ambient lighting conditions, each sequence was normalized by a calibrated white balance target (Figure 2b). Camera settings optimized image quality at the expense of file size and shutter speed; a configuration file was used to ensure consistent in-camera processing settings. Consistent image acquisition proved challenging in some conditions, such as rapidly changing ambient light or presence of woody debris (drift) within the field of view. These were mitigated by acquiring additional bracketing sequences at wider EV intervals to prevent limited dynamic range from clipping the sensor output values. Sand boils on the river surface, which cause irregular dark patches, were common and could not be avoided.

A total of 15 datasets were collected during our initial investigation (Table 3). The limited scope of this study prevented comprehensive image analysis; we explored only a few spectral indices, file format conversions, and signal processing filters (e.g., low-pass). We sought to evaluate the use of a standard-precision file format (8-bit JPEG), medium-resolution color space (Adobe RGB), normal EV, and test the sensitivity among lens filters.

Each image file is comprised of three spectral bands within the visible spectrum; RGB (Red, 380–680 nm; Green, 380–680 nm; Blue, 380–620 nm). Due to the broadband response of the sensor, we focused our analysis on the peak of the response curve for each band (Red, 590 nm; Green, 540 nm; Blue, 470 nm). Descriptive statistic were computed

from uncalibrated, but spectrally normalized, DNs (pixel values) for each band as well as the average of all three bands; statistics included minimum, maximum, mean, standard deviation (1-sigma), and covariance.

Figure 3 Typical 10-frame dataset showing white balance reference card (WB) and -4 to +4 exposure value (EV) bracketing sequence. This example was acquired during diffuse (overcast) ambient lighting conditions.

CALIBRATION DATASET

A calibration dataset compiled image statistics and sample lab results. Imagery and suspended-sediment samples were paired by time of acquisition; time differences between images and physical samples were limited to ≤30 minutes for all pairs. Mean time difference for the dataset is 11 minutes. Samples were then grouped by near-surface, full-depth, and combined sample depths. All samples were analyzed for SSC and a subset for particle size distribution. We selected three representative size classes (<63 µm, <4 µm, and <2 µm) and computed mass concentrations from total SSC.

Table 3 Calibration dataset summary table. Sample total suspended-sediment concentration (SSC) is given as well as concentration of material finer than 63 µm (SSC_{fines}). Six SSC samples were excluded due to significantly different times (i.e., >30 minutes) between image acquisition and sample collection.

[1]Exposure value (EV) is the range of illuminance, as referenced to the camera exposure meter. For instance, a dataset with an exposure-bracketed sequence of -4 to +4 EV has a range of 8 EV. [2]Trend of turbidity is based on 15-minute unit values whereas sample collection took <5 minutes. [3]Turbidity is recorded using a Forest Technology Systems DTS-12 sensor in Formazin Nephelometric Units (FNU) (Anderson, 2005). Values exceeding the sensor maximum (1,850 FNU, denoted by an * in the table) are recorded from a Hach Solitax sensor in Formazin Backscatter Ratio Units (FBRU).

EMPIRICAL REGRESSION MODELS

Relationships between imagery, suspended-sediment concentration, and particle size were investigated using ordinary least squares regression. We used simple linear regression (SLR) to describe the covariability of these variables and evaluate the ability to predict suspended-sediment information from spectral measurements of a river surface. Statistical methods described in Helsel and Hirsch (2002) were used to develop and evaluate our models.

We began investigating the relationship between possible explanatory (x) and response (y) variables by generating a correlation matrix for our entire calibration dataset. From these results, we modeled the most highly correlated variables to evaluate the quality of fit and significance of the relationship. More specifically, we checked for non-linearity, heteroscedasticity (i.e., non-constant variability of residuals), and the coefficient of determination (R^2). Full-depth and near-surface samples were evaluated both individually and combined. From these exploratory data analyses, we found the explanatory variable B_{max} (maximum DN, or pixel value, of the blue band) using a clear lens filter to be most related to *SSC* and particle size response variables. Concentration of material smaller than sand (<63 µm, SSC_{fines}) was of greatest interest; other particle size classes were weakly correlated. We developed two SLR models: one for total *SSC* and another for SSC_{fines} response variables based on the B_{max} explanatory variable using combined full-depth and near-surface samples. Both models benefited from base-10 logarithmic transformation to achieve linearity, homoscedasticity, and normality of residuals (Helsel and Hirsch, 2002). Base-10 transformation, or equivalent power function regression, is common among turbidity-*SSC* regression and streamflow-*SSC* transport curves (e.g., Glysson, 1987; Curtis et al., 2006; Rasmussen et al., 2009; Uhrich et al., 2014).

CORRELATION OF IMAGERY TO SUSPENDED-SEDIMENT CONCENTRATION

Our final SLR model predicting *SSC* from B_{max} DN shows a statistically significant relationship between the two variables (t-statistic and p-value at 95% confidence interval; Figure 4 and Table 4). The model explains 90% of the variability in sampled SSC (R^2; Table 4). Probability plot correlation coefficient (PPCC, R^2=0.87) indicates that residuals have a homoscedastic pattern and near-normal distribution (Helsel and Hirsch, 2002; Rasmussen et al., 2009). The $\log_{10}$-transformed model is:

$$\log_{10}(SSC) = 12.707 - 4.225\log_{10}(B_{max}), \quad (1)$$

where

SSC is suspended-sediment concentration (mg/L), and
B_{max} is the maximum uncalibrated pixel value, in DN (8-bit, $0<x<255$).

The $\log_{10}$-transformated SLR model (equation 1) can be retransformed and corrected for associated bias, resulting in:

$$SSC = (5.0933 \times 10^{12})(B_{max}^{-4.225}) \times BCF, \quad (2)$$

where

BCF is a nonparametric bias correction factor.

It should be noted that Duan's smearing bias correction factor (*BCF*) (Duan, 1983) is a best estimate of the bias introduced by retransforming regression estimates to the original units (e.g., *SSC* in mg/L), computed using the average of residuals (e.g., Uhrich and Bragg, 2003; Rasmussen et al., 2009; Uhrich et al., 2014). The bias correction factor for equation 2 was determined to be 1.0461, yielding a final SLR model:

$$SSC = (5.3281 \times 10^{12})(B_{max}^{-4.225}). \quad (3)$$

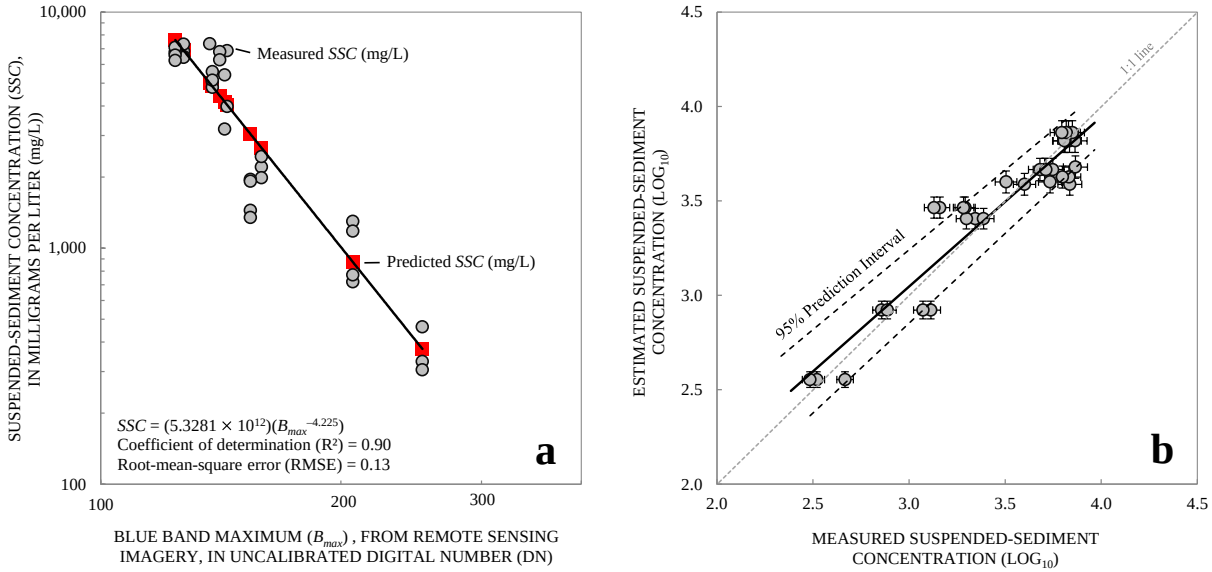

Figure 4 Results of simple linear regression (SLR) analysis using $\log_{10}$-transformed data for (a) spectra and suspended-sediment concentration (SSC) data, and (b) comparison of measured and estimated SSC in log space with 95% prediction interval and 5% error bars on measured concentration. Standard errors of intercept and slope are 0.560 and 0.256 respectively.

Table 4 Regression model summary with statistical diagnostics and analysis of variance (ANOVA). A multivariate regression model for the North Fork Toutle River station is shown for comparison purposes (Uhrich et al., 2014).

Response (y)	Explanatory (x)		Model	Obs. (n)	Conc. (mg/L)	R^2	RMSE	MSPE	Coefficient		
									SE	t-statistic	p-value
SSC	B_{max}		$\log_{10}(SSC) = 12.707 - 4.225\log_{10}(B_{max})$	33	305–7339	0.90	0.133	26.4–35.8	0.256	- 16.53	6.29E-17
SSC_{fines}	B_{max}		$\log_{10}(SSC_{fines}) = 14.484 - 5.111\log_{10}(B_{max})$	33	250–6438	0.90	0.163	31.3–45.6	0.314	- 16.29	9.43E-17
SSC			$\log_t(SSC) = -0.8054 + 0.1854\log_t T +$	653	30–10100	0.81	0.228				
	T	turbidity	$0.3545\log_t Tlag + 0.8952\log_t Q$						0.2882	0.64	0.52
	Q	discharge							0.2897	1.22	0.221
	$Tlag$	lag T value							0.04497	19.91	0.
	t	15-minute interval time									

Abbreviations: Coefficient of determination (R^2); model standard percentage error (MSPE); coefficient standard error (SE).

CORRELATION OF IMAGERY TO CONCENTRATION OF SUSPENDED OF FINES

The final SLR model predicting concentration of fine material in suspension (<63 µm) shows a statistically significant relationship that explains 90% of the concentration variability (R^2; Figure 5 and Table 4). Normality of residuals was significantly improved by logarithmic transformation (PPCC, R^2=0.90). The $\log_{10}$-transformed model is:

$$\log_{10}(SSC_{fines}) = 14.484 - 5.111\log_{10}(B_{max}), \quad (4)$$

where

SSC_{fines} is concentration of fine material (<63 µm) in suspension.

Retransformation of equation 4 with an associated *BCF* of 1.0675 yields a final SLR model in exponential form:

$$SSC_{fines} = (3.2540 \times 10^{14})(B_{max}^{-5.111}). \quad (5)$$

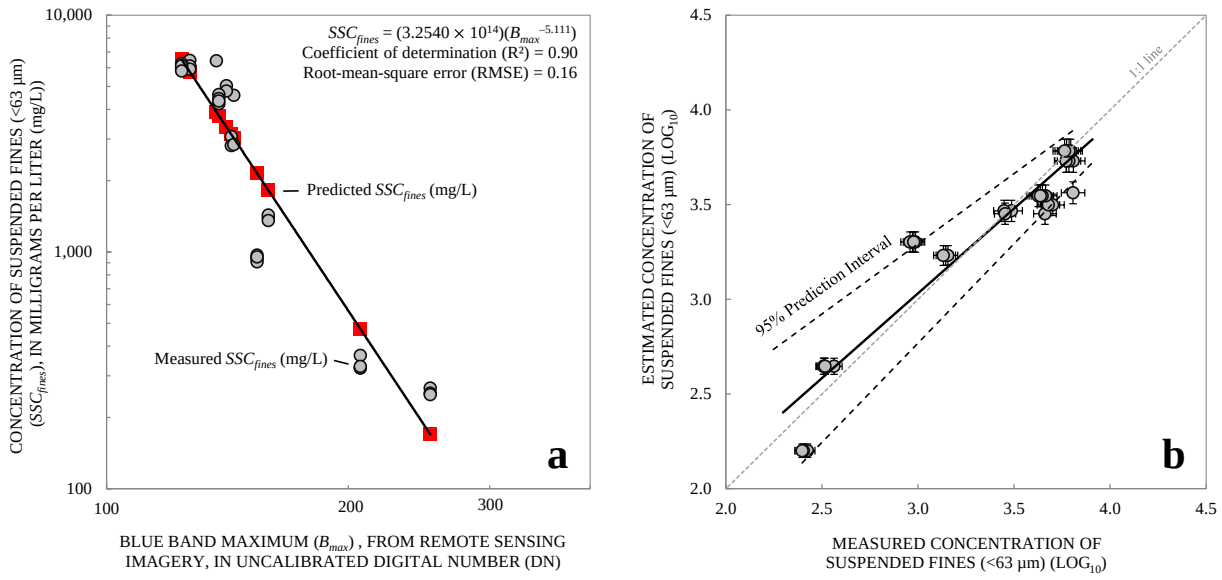

Figure 5 Results of simple linear regression (SLR) analysis using $\log_{10}$-transformed data for (a) spectra and concentration of suspended fines (SSC_{fines}) data, and (b) comparison of measured and estimated SSC_{fines} in log space with 95% prediction interval and 5% error bars on measured concentration. Standard errors of intercept and slope are 0.687 and 0.314 respectively.

DISCUSSION AND FUTURE STUDIES

Our results show that uncalibrated DNs (pixel values) extracted from RGB imagery of a river surface can be used as the explanatory variable in a SLR model to predict *SSC* (R^2=0.90). Modeled SSC values are -126% to 41% different than sampled SSC, with a mean error of -10%. The satellite-based spectral reflectance signature of turbid water is well established, with a positive correlation of the near-infrared (NIR) spectrum (λ>700 nm) to SSC. Because unmodified consumer-grade digital camera sensors are weakly sensitive to red and near-infrared wavelengths, we use the peak response of the UV-blue end of the spectrum (B_{max}, λ=470 nm), which yields a negative correlation (i.e., negative slope of regression line). Our finding makes logical sense; color saturation of a river's opaque brownish appearance increases as SSC in the river increases. In this situation, the response near the red spectra increases while the blue spectra decreases.

Expanding upon this result, we show that the same SLR explanatory variable (B_{max}) can be used to predict SSC_{fines} (R^2=0.90). This is not surprising, given that the response variables *SSC* and SSC_{fines} are strongly correlated (i.e., $SSC_{fines} \propto SSC$) for our data (fines average 3,204 mg/L or 72% of total suspended mass). Modeled SSC_{fines} error is -136% to 39% with a mean of -15%. Like the previous model, the regression line has a negative slope; opacity of water is largely a function of fines concentration. Given that the absorption of EM energy by water is the weakest in the blue spectra (i.e., greatest depth penetration), we expected B_{max} to be better correlated to SSC_{fines} than *SSC*. Our results show the SSC model is slightly better than the SSC_{fines} model.

Both models are less sensitive at concentrations above about 4,000 mg/L, despite the greatest error occurring below 2,000 mg/L. As the response of the blue spectra decreases, large changes to concentrations produce small changes to DN. Qu (2014) suggests that a weaker linear relation with increasing SSC is attributed to absorption by suspended sediments; the river surface appears darker and more opaque at greater concentrations. There may be several solutions to increase model effectiveness at greater concentrations. One possible solution is to use RAW to TIF conversions with greater DN range and precision (e.g., >8-bit JPEG). Another solution may be to acquire imagery in the near-infrared spectrum, accomplished with a NIR glass filter (e.g., interference <720 nm) or permanent removal of the UV-NIR interference filters in front of a DSLR sensor.

These results warrant continued investigation and refinement of our methods. Due to the nature of regression analysis, our empirical models are likely applicable only to waters with similar characteristics such as sediment composition.

Future work will investigate the applicability of our method to other river reaches and basins, as well as to additional camera systems. Deployment of a stationary time-lapse camera is a logical advancement to our initial feasibility study as this would provide time-series information and test the system in an operational environment. These methods may provide opportunities for rapid deployment of remote camera systems at sites not suitable for in situ equipment. If paired with concurrent turbidity data, automated processing of time-lapse imagery could feed a simple piecewise defined function, to select among turbidity-SSC regressions tuned to particle size classes. Such tuning could significantly increase the accuracy of record computation at sites known to experience hysteresis in the relationship between turbidity and SSC.

CONCLUSION

Our 6-month-long study evaluated the feasibility of estimating the concentration of fine sediment (clay to silt) and total suspended sediment using close-range remote sensing imagery of a river surface acquired with an off-the-shelf consumer-grade camera system. Two empirical simple linear regression models were developed from three-band imagery and concurrent physical sample pairs (n=33, 250–7339 mg/L). Results show statistically significant relationships (90% of variability explained) between the maximum pixel value (i.e., uncalibrated digital number) of the blue band (peak response at 470 nm) and suspended-sediment concentration response variables with mean errors of 10–15%.

Standard USGS sample-based methods of generating time-series records of suspended-sediment concentration and discharge can be time- and cost-prohibitive for some studies. Although near real-time application of turbidity-based regression models may overcome these restrictions, temporal variability in suspended particle size (fines in particular) can increase uncertainty due to hysteresis. The non-contact approach we present here can mitigate some of this uncertainty by providing near real-time estimates of fines in suspension. In addition, our method can directly estimate total suspended concentration without subjecting the sensor to environmental fouling, burial, or damage during high-streamflow events.

Integration of multiple geospatial tools is becoming commonplace in river science. Despite the limited scope of this study, our results make a significant contribution in the field of river remote sensing. This method provides a consistent and straightforward procedure to quantify suspended sediment in a river using a consumer-grade digital camera. Upon further investigation and refinement, imagery-based regression models could increase the accuracy of real-time estimates of concentration, which are vital to sediment-program cooperators dependent on these data.

Abstract The maintenance of alluvial sandbars is a longstanding management interest along the Colorado River in Grand Canyon. Resource managers are interested in both the long-term trend in sandbar condition and the short-term response to management actions, such as intentional controlled floods released from Glen Canyon Dam. Long-term monitoring is accomplished at a range of scales, by a combination of annual topographic survey at selected sites, daily collection of images from those sites using novel, autonomously operating, digital camera systems (hereafter referred to as 'remote cameras'), and quadrennial remote sensing of sandbars canyon-wide. In this paper, we present results from the remote camera images for daily changes in sandbar topography.

Figure 1 Typical setup of a remote camera system, at river mile (RM) 145.9, Grand Canyon. Visible is the waterproof box containing camera and electronics, and the 20W solar panel.

Beginning in the early 1990s, 35 mm film cameras were deployed at selected sites in the canyon to take photos daily at many of the long-term sandbar monitoring sites (Dexter et al., 1995). In 2008, higher-resolution digital cameras capable of taking multiple photos daily were installed at many of these sites, enabling rapid and low-cost analyses of sandbar response to geomorphic events. By 2014, all of the analog cameras had been replaced as well as additional cameras added

to the monitoring network for a total of 45 cameras. These camera systems are completely autonomous and can be left for months to years without maintenance. Each system (Figure 1) consists of a digital SLR camera controlled by a datalogger programmed with an intervalometer script that triggers the shutter release on the camera to take images at prescribed times. Solar panels are used for power, and the datalogger regulates and minimizes power usage by the camera such that batteries do not drain significantly, even in shaded locations. More details can be found in Bogle et al. (2012).

Controlled flood experiments have been periodically conducted to rebuild subaerial sandbars along the river, and the camera imagery is playing an increasing role in the evaluation of the floods' effects. Post-flood images are compared to pre-flood images taken at the same discharge, and qualitatively analyzed for change in sandbar size by visual inspection. Because of the unique geometry at each site, a particular sandbar may be more likely to change in either area or height (though not necessarily both), thus necessitating use of the general term "size." Each sandbar is manually classified as having undergone major negative size change (lost more than 15%, assigned a rating of "-2"), minor negative size change (-15% to -3%, "-1"), negligible size change (-2% to +2%, "0"), minor positive size change (+3% to +15%, 1"), or major positive size change (gained more than 15%, "2"). Examples are shown in figure 2. For a 2008 flood, 22 sites had three sets of topographic surveys corresponding with the photos. The surveys provided area and volume measurements for each site. To address the "size" conundrum described above, a composite change value was derived from these measurements. The visual analysis agreed with the composite topographic survey change values at 78% of the sites, and disagreed at 2%. Surveyed change was not visually recognized at 15% of the sites, and at 6%, surveys indicated that no change occurred where visual analysis indicated it had.

A 2012 flood was evaluated primarily by photo analysis, and a smaller subset of five surveyed sites was in 100% agreement with the outcomes. Of the 33 sites photographed, this flood produced positive change at 51%, negligible change at 39%, and negative change at 9%. Six months later, 28% of the sites were still larger, while 47% showed negligible change, and 24% were smaller. A 2013 flood, with 42 sites photographed, resulted in enlarged sandbars at 50% of the sites, negligible change at 38%, and negative change at 12%. Six months later, 27% were still enlarged, 50% had negligible change, and 17% were smaller. The two floods resulted in the same type of response at 61% of the sites, while 33% had a recognized change from one flood and negligible change from the other. Six percent showed responses of differing sign. These data show that, overall, the 2012 and 2013 floods were successful in building sandbars in the short term, but that long term results are only marginally improved. Resource managers can use these data (along with sediment budget data) to help design aspects of future controlled flood events, such as duration, peak flow, time of year, and up-ramp/down-ramp rates.

Figure 2 Photos of before and after the November 2012 controlled flood, at two monitoring sites on the Colorado River. The score on the lower right is the qualitative assessment of how much the sandbar changed in size - major negative size change (-2), minor negative size change (-1), negligible size change (0), minor positive size change (1), or major positive size change (2). Both sites in this example saw an increase in size, though to differing degrees.

While this method of photo analysis is based on qualitative assessment, it has been demonstrated to provide a rapid and fairly accurate metric for assessing the immediate downstream effects of controlled floods on bars. Results of controlled floods on sandbar maintenance were available to resource managers within two weeks of the flood events in 2012 and 2013. As well as their primary use in examining sandbar dynamics, these photo datasets can also been used for monitoring other aspects of the river corridor, including vegetation encroachment, spring discharge, endangered species habitat, archeological site protection, and recreational use patterns.

In order to provide a more accurate and quantitative assessment of how sandbar areas are changing with time, photos from the large (and ever-growing) archive of imagery are now being orthorectified using a network of surveyed ground control points at each site. An automated computer process extracts georeferenced shorelines from the orthorectified photos, and calculates an area value for the bar (Figure 3).

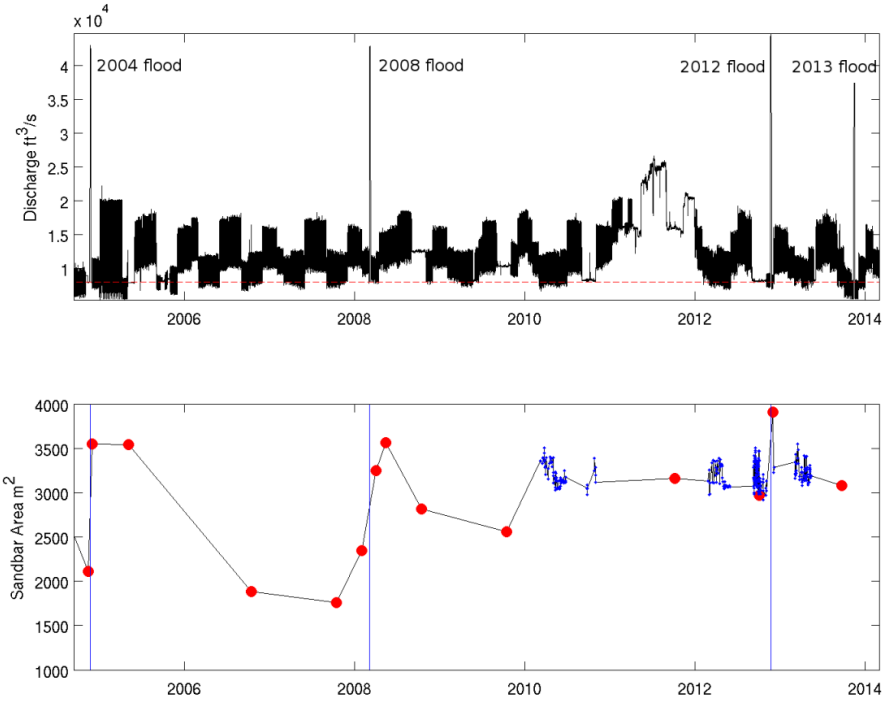

Figure 3 Top panel: the hydrograph at RM 30 in Upper Marble Canyon from summer 2004 to early 2014. The four controlled floods during this period are labelled. Bottom panel: the sandbar area at the RM 30.7 site, at a river discharge of 8000 ft^3/s, prior to the 2013 controlled flood. Red dots are from annual total station surveys. Blue dots are derived from remote camera images and show the short-term variability not captured by infrequent conventional monitoring.

Examining the changes in sandbar area for a given period can yield clues about the effects of different flow patterns on sandbar area and stability. The sandbar at river mile (RM) 30.7, for example, increased in area 33% as a result of the 2012 controlled flood (topographic surveys are in agreement). The next topographic survey, conducted 11 months later, shows the bar back to within 5% of its pre-flood size. Areas derived from the orthorectified photos, however, show that the bar had shrunk to this size within three months of the flood, and then maintained a mostly steady area for the following eight months (Figure 3). In the summer of 2011, for another example, flows were elevated (though not as high as during controlled floods) to equalize the amount of water in upstream and downstream reservoirs (Figure 3). Area calculations for the sandbar at RM 22.0 show the potential bar-building effects of these moderately elevated flows: this sandbar attained its largest area since the 2008 flood, including after the 2012 and 2013 floods.

A weakness of this method is the inability to recognize positive size change in sandbars that aggrade significantly while showing little change in area. To better derive a comprehensive calculation of size change, efforts are underway to extract 3D topographic data from image sets, thus potentially providing a means to estimate sandbar volumes. This process is facilitated by the dam-controlled diurnal stage fluctuations on this section of the Colorado River. Cameras are programmed to take hourly photos, and traces of the water's edge on the sandbar (hereafter

referred to as "shorelines") are extracted from rectified images using the same methods as above (Figure 4).

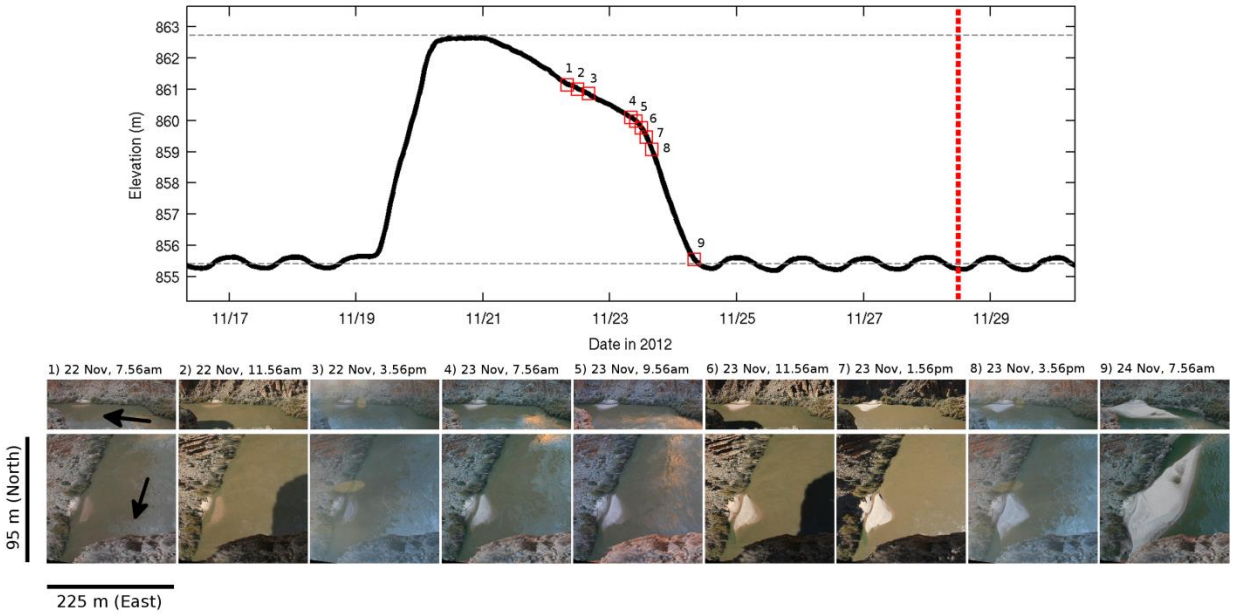

Figure 4 Top panel: the 2012 controlled flood hydrograph at RM 30. The dashed line shows the time when a conventional total station survey was carried out after the flood. The markers indicate the times an image was taken with the remote camera system at RM 30.7. Bottom panel: a time-series of those images, and orthorectified images, from which shoreline locations and elevations are extracted. The arrows in the first panels show the direction of river flow.

These shorelines essentially become contour lines if the stage at the time of the photo is known. A pressure transducer deployed at the site provides the river stage, and thus elevation of the shoreline at the time the photo was taken. Grouping several of these extracted shorelines over a diurnal stage fluctuation will constitute a contour map of the wetted portion of the bar. The process is schematized in Figure 5. The contour model made from the sequences of images in Figure 4 is shown overlain onto the rectified image, in Figure 6.

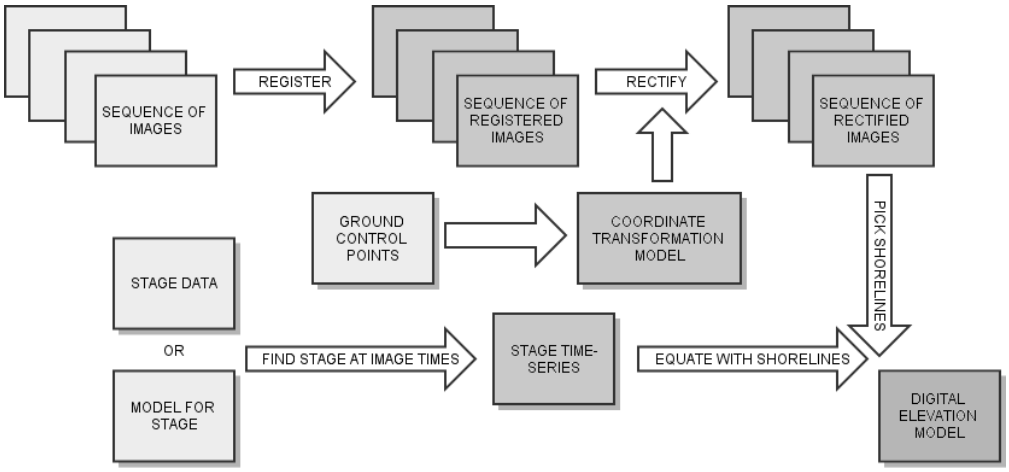

Figure 5 Schematic of the stages required to build a 3D digital elevation model (DEM) of a sandbar using a time-series of sandbar images which have been registered and rectified, and a known stage elevation or stage-discharge relation used to map shoreline elevations.

Figure 6 A colored DEM with contours of the RM 30.7 sandbar, overlain onto an orthorectified image of the bar after the 2012 controlled flood. This DEM was computed from the sequence of images taken during the flood shown in Figure 4, and associated stage elevations, following the methods summarized in Figure 4.

Change in pre- and post-event digital elevation models derived from the contour sets will allow estimates of volumetric changes to be made, and provide quantifiable topographic data that can be processed quickly and without the need to repeatedly send survey crews into the field. Such data provide valuable insight into sandbar changes during times between ongoing annual topographic surveys, especially for sandbars that don't change much in area, but may significantly aggrade - a characteristic that can be difficult to recognize with area calculations

and visual inspection methods. Knowing the sign of sandbar volume change can also be used to corroborate suspended-sediment transport data collected along the river by the USGS (Griffiths et al., 2012). During a flood event, for example, river reaches shown to have a negative sediment mass balance should also show sandbars that decreased in volume. While still in its developmental stages, this technique has the potential to provide high-resolution, low-cost topographic data to help resource managers better understand sandbar dynamics, in the short-term and the long-term, as a result of river management actions.

INTRODUCTION

Closure of Glen Canyon Dam in 1963 dramatically changed discharge and sediment supply to the downstream Colorado River in Marble and Grand Canyons. Magnitudes of seasonal flow variation have been suppressed, while daily fluctuations have increased because of hydropower generation. Lake Powell, the upstream reservoir, traps all sediment, leaving the Paria and Little Colorado Rivers as the main suppliers of fine sediment to the system below Glen Canyon Dam. The reduction in sediment supply, along with changes in discharge, have resulted in fine-sediment deficit (Topping et al., 2000), leading to a decrease in the size and number of alluvial sandbars (Schmidt and Graf, 1990; Schmidt et al., 2004). However, the understanding of these important spatial and temporal changes in sandbars located along the banks of the river have been limited to infrequent measurements mostly made by direct visitation and topographic surveying (Hazel et al., 2010).

Aerial photographs are the only data available from which it is possible to evaluate changes in alluvial deposits at a large number of sites and compare recent conditions with those that existed prior to the initiation of ground-based monitoring in the early 1990s. Previous studies have evaluated the effects of Glen Canyon Dam on sandbars by analysis of comprehensive maps of surficial geology that are based on seven sets of aerial imagery taken between 1935 and 1996 for selected reaches in the first 120 km downstream from Lees Ferry, Arizona (Figure 1). These studies showed that the area of exposed sand in eddy-deposition zones was less in the post-dam period than in the pre-dam period (Leschin and Schmidt, 1995; Schmidt et al., 1999b; Sondossi, 2001, Sondossi and Schmidt, 2001, Schmidt et al., 2004).

In this study, we extend these analyses to encompass a 74-year period by including maps of sand deposits visible in aerial imagery taken in 2002, 2005, and 2009 for the same reaches that were mapped in the earlier studies. Results are analyzed for two post-dam periods, based on the implementation of the first controlled flood in March 1996. The period from 1965 to March 1996 is the pre-controlled flood period and was dominated by flows that fluctuated up to the maximum capacity of the Glen Canyon Dam powerplant. Beginning in 1991, fluctuations were constrained such that maximum daily flows were typically less than 65 percent of powerplant capacity. Thus, the pre-controlled flood period also includes five years of restricted dam operations. This period also included unplanned spills from the reservoir in 1983, 1984, and 1986. We refer to the period from April 1996 to 2009 as the controlled-flood period. This period consisted entirely of restricted dam operations and included three controlled floods conducted as sandbar-building experiments. We show that the areal extent of exposed sand was greater in the images taken in the controlled-flood period than in the pre-controlled flood period. We also show that in the controlled-flood period, the area of exposed sand is negatively correlated with the elapsed time

since the most recent controlled flood.

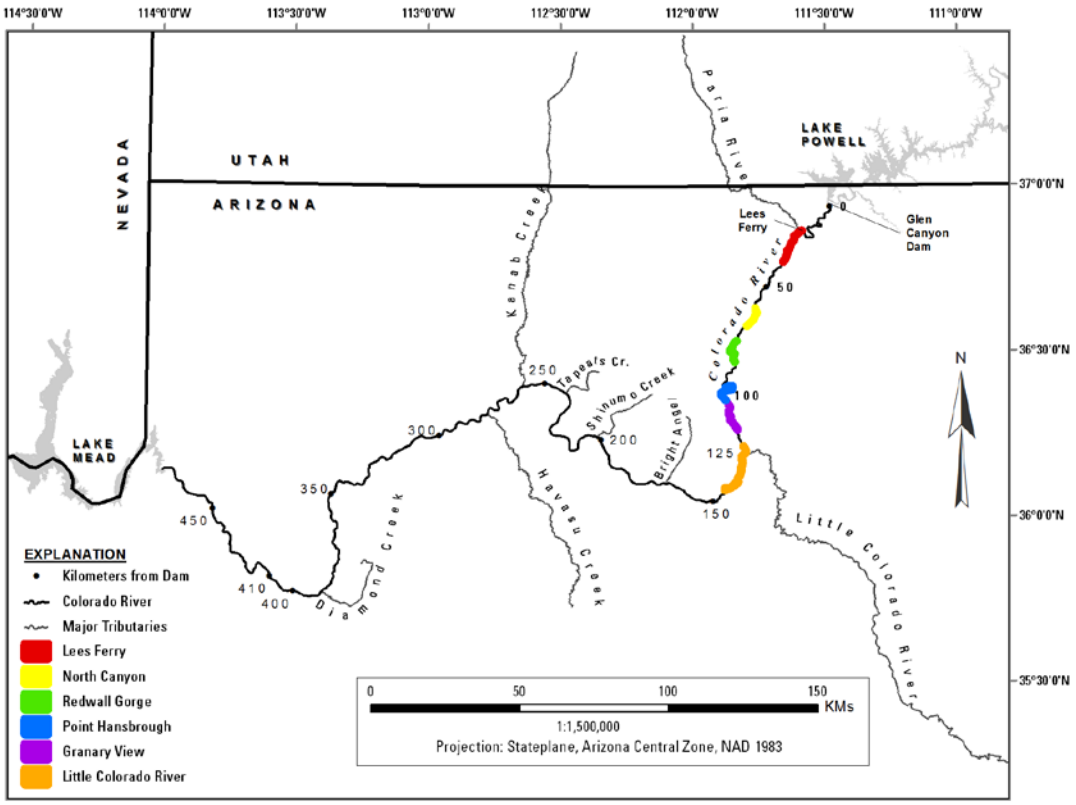

Figure 1 Location map of study area, showing Colorado River, major tributaries, and study reaches. The study reaches are informally named and range in length from 7.5 km to 20.3 km. The numbers show distance downstream from Glen Canyon Dam along the river centerline.

METHODS

We used high-resolution (25-centimeter pixel size) aerial imagery collected by fixed wing aircraft in May 2002, May 2005, and May 2009 to map the extent of exposed sand in each of the reaches examined by Schmidt et al. (2004). Each set of images was acquired during a steady dam release of approximately 227 m^3/s (8,000 ft^3/s), enabling a direct comparison of the area of deposits exposed above the water surface without introducing bias caused by difference in water surface elevation. Thus, we use the water surface elevation associated with 227 m^3/s as a reference elevation. The shoreline in each reach was determined by automated image classification of the water that was visually inspected for accuracy (Davis et al., 2012). We intersected the 227 m^3/s shoreline with the sand deposits mapped from the April 1996 images to create revised maps for the same sand deposits for 2002, 2005, and 2009 (Figure 2). Areas mapped as sand in 1996 and classified as water in the recent images were interpreted to have eroded. Conversely, areas that were below the water surface in 1996 and above the water surface in the recent images were interpreted to have aggraded. Eroded areas were subtracted from the 1996 maps and aggraded areas were added to produce the final maps of exposed sand deposits for 2002, 2005, and 2009.

We use the eddy-deposition zone (EDZ) accounting unit as defined by Schmidt et al. (2004) to track changes in sandbar area. The EDZ is the sum of all sand deposits that occur in an eddy that is downstream or immediately upstream from a channel constriction created by a debris fan (Figure 2). In this study, we report only on EDZs larger than 1000 m^2, consistent with the approach of Schmidt et al. (2004).

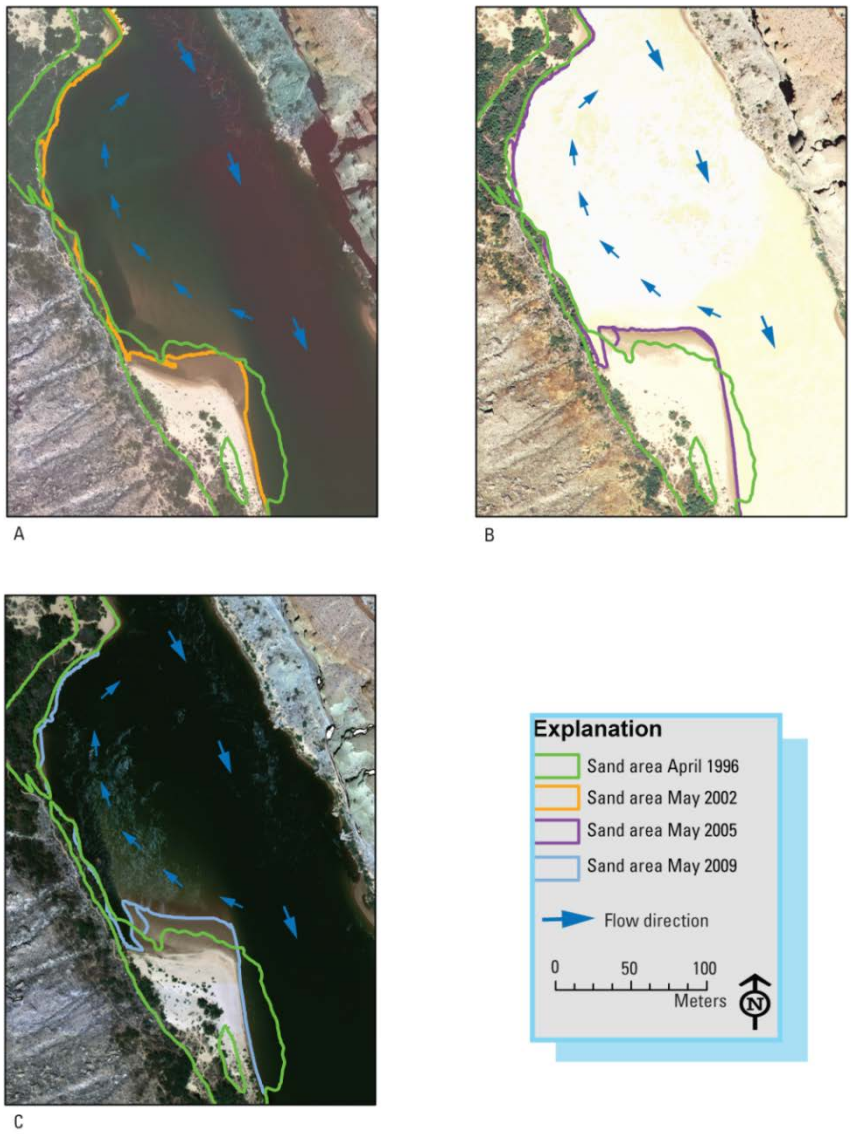

Figure 2 Aerial images at Saddle Canyon show comparisons of sand area mapped in April 1996 with sand area mapped in recent images. (A) Sand area in April 1996 and May 2002 on May 2002 image, (B) Sand area in April 1996 and May 2005 on May 2005 image, and (C) Sand area in April 1996 and May 2009 on May 2009 image. Blue arrows indicate flow direction. Debris fan constriction is in upper left area of images. Imagery from Grand Canyon Monitoring and Research Center archives.

Because the study reaches are of different lengths, ranging from 7.5 to 20.3 kilometers (km), we report the measurements of sand area as the total sand area within EDZs for each reach normalized by the reach length (m^2/km). Standard error was calculated for each reach by dividing the standard deviation of the area of exposed sand deposit per reach length by the square root of the number of sand deposits per reach length. Changes in exposed sand area greater than the standard error were considered significant. We also report on the eddy fill ratios, which are the ratio of exposed sand within each EDZ boundary to the area of the EDZ boundary. Thus, an eddy fill ratio of 1.0 would indicate the sandbar completely filled the eddy deposition zone. We compare eddy fill ratios from the 1935 images (the only set of pre-dam aerial photography that includes all reaches) with the average eddy fill ratio for the pre-controlled flood period and the average eddy fill ratio for the controlled flood period for each reach. We averaged the eddy fill ratio for each EDZ over the range of years of imagery common to all reaches, and then used the average value of the eddy fill ratios for all EDZs to determine the time period average. We chose these three time periods because they represent the pre-dam period of unregulated flows and two post-dam periods before and after controlled floods (Figure 3).

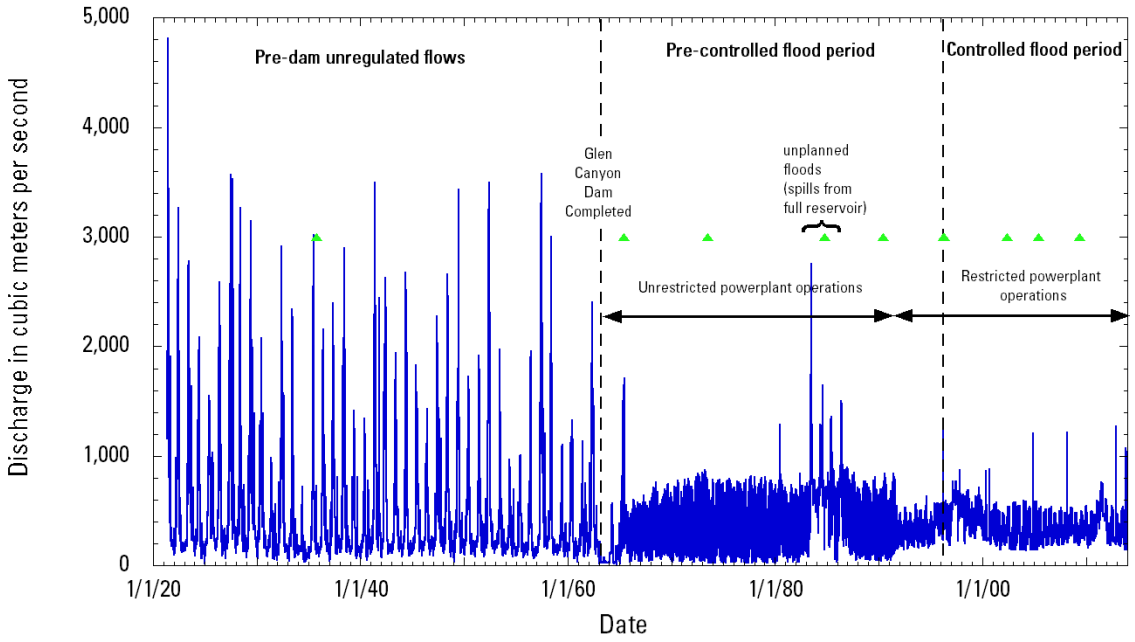

Figure 3 Discharge of the Colorado River at Lees Ferry, Arizona (USGS gage 09380000), 1922 to 2012. The pre-controlled flood period consists of unrestricted powerplant operations, restricted powerplant operations, and unplanned floods. The controlled-flood period consists of restricted powerplant operations and periodic controlled floods. Horizontal arrows show periods of unrestricted powerplant operations and restricted powerplant operations. Aerial imagery collection dates are marked with green triangles.

The first 26 years of the pre-controlled flood period consisted primarily of flows which fluctuated on a daily basis for hydroelectric power generation from daily low flows of about 140 m^3/s (5,000 ft^3/s) to daily high flows of about 850 m^3/s (30,000 ft^3/s). This period also included unplanned floods in 1983-86 that were spills from Lake Powell during years of large upper

Colorado River basin runoff. Beginning in 1991, the range of daily fluctuations was restricted such that daily low flows were about 200 m^3/s (7,000 ft^3/s) or higher and highs were 570 m^3/s (20,000 ft^3/s) or lower. The controlled-flood period consisted entirely of these restricted dam operations and included three dam releases above power-plant capacity (31,500 ft^3/s). Short-duration (less than 96 hour) controlled floods were released in April 1996, November 2004, and March 2008 to evaluate the use of dam releases for building sandbars (Webb et al., 1999; Melis, 2011; Schmidt and Grams, 2011).

We evaluated uncertainty by comparing the area of exposed sand we measured from the images to sand area measured by total station survey at 15 long-term monitoring sites for coincident dates in 2002, 2005, and 2009 (Hazel et al., 2010). To minimize the chance that deposits eroded or aggraded between comparisons, we only utilized total station surveys made within 2 weeks of aerial imagery collection. Analysis of the root-mean square error about the residuals indicates a 3,838 m^2 error between the sum of sand area from all 36 aerial photo measurements and the sum of total station measurements for all 15 sites, representing about 2 percent of the total sum of sand area (190,055 m^2) observed in all 15 EDZs as measured by total station (Figure 4). Error between the average of these 36 aerial photo measurements and the coincident total station surveys is 640 m^2, also about 2 percent of the average sand area (31,676 m^2) for the 15 sites.

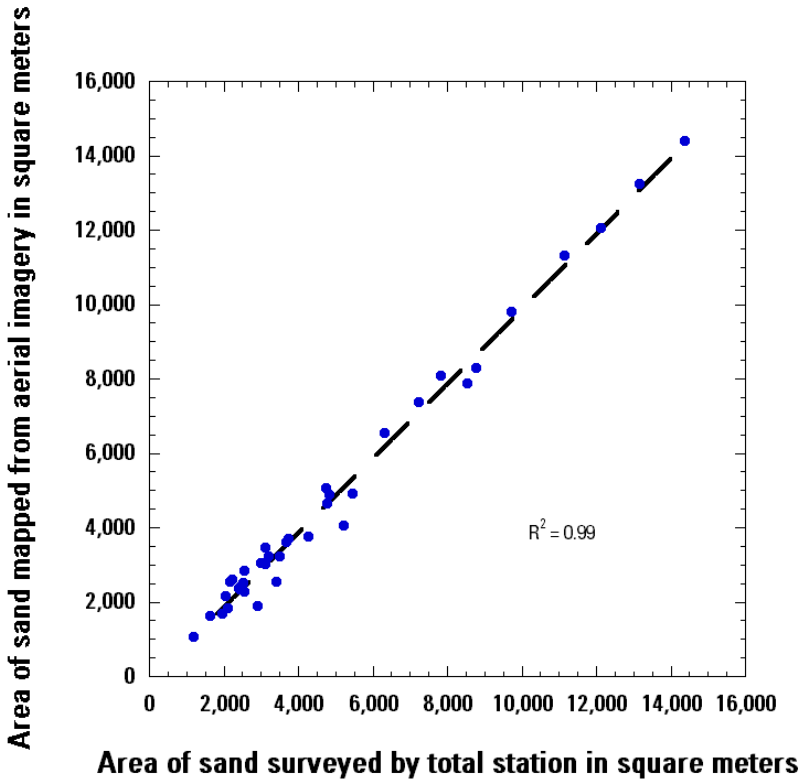

Figure 4 Comparison of change in sand area from aerial imagery to change in sand area measured by conventional total station survey of long-term monitoring sites. Line fit by least-squares regression shows a near perfect 1:1 correspondence between sand area surveyed by total station and sand area measured by analysis of aerial photographs.

RESULTS

In all reaches, sand area was less in 1965 than in 1935, supporting the conclusion previously reported by Schmidt et al. (2004). From 1965 to 1973, sand area decreased in all reaches (Figure 5). Between 1973 and 1984, sand area increased in all reaches. These increases are the result of deposition that occurred during the 1983 and 1984 reservoir spills (Schmidt and Graf, 1990). Sand area decreased from 1984 to 1990 in all reaches, except Granary View, which was not mapped from the 1990 images. From 1990 to March 1996, sand area increased in all reaches (except Granary View). During the 1996 controlled flood, bracketed by the March 1996 and April 1996 image collections, sand area increased in the Lees Ferry, North Canyon, Redwall Gorge, Point Hansbrough, and the Little Colorado River reaches, and decreased in the Granary View reach. These changes are consistent with the findings of Hazel et al. (1999) that many sandbars increased in elevation during the 1996 controlled flood without increasing in area. Sand area decreased from April 1996 to 2002 in the Lees Ferry, North Canyon, Redwall Gorge, and Little Colorado River reaches, and increased in the Point Hansbrough and Granary View reaches. From 2002 to 2005, sand area increased in all reaches. Between 2005 and 2009, sand area decreased in the Point Hansbrough and Little Colorado River reaches; no change occurred in the other reaches. In all comparison intervals described above, the reported changes are larger than the standard error of the population of all EDZs for each date and reach, respectively.

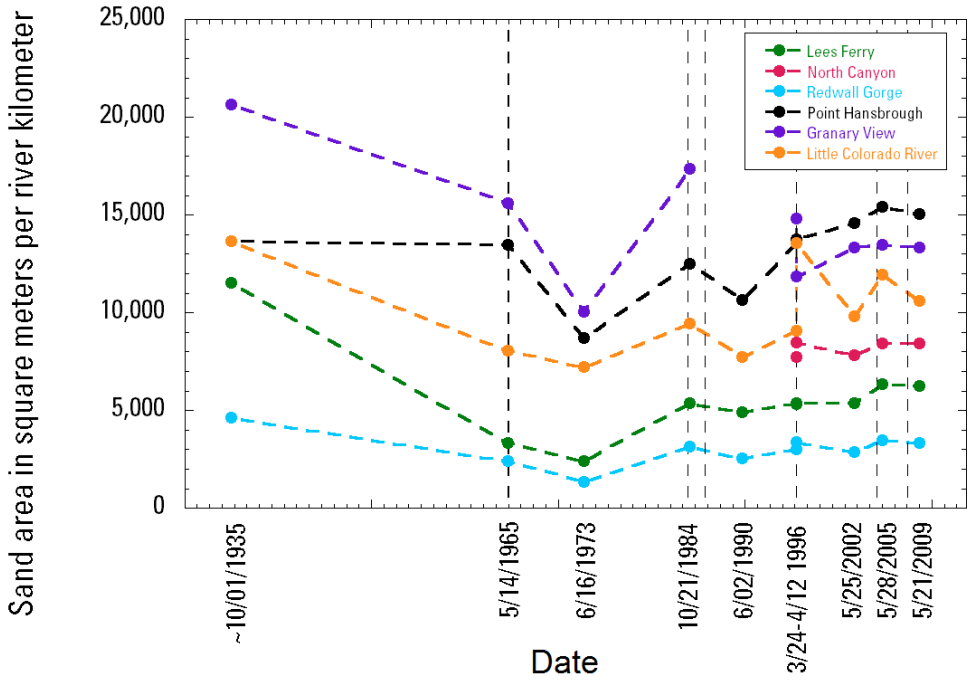

Figure 5 Total sand area within eddy deposition zones larger than 1000 m^2 per river kilometer (m^2/km) for all study reaches for 1935 through 2009, showing change between imagery collection dates. Vertical dashed lines indicate last flood event prior to imagery dates.

Median eddy fill ratios decreased from 1935 to the pre-controlled flood period, and then increased from the pre-controlled flood period to the controlled-flood period in three of five

reaches (Figure 6). Only in the Granary View reach did the median eddy fill ratio continue to decrease in the controlled-flood period. The Lees Ferry reach showed only a slight increase in eddy fill ratio value from the pre-controlled flood period to the controlled-flood period.

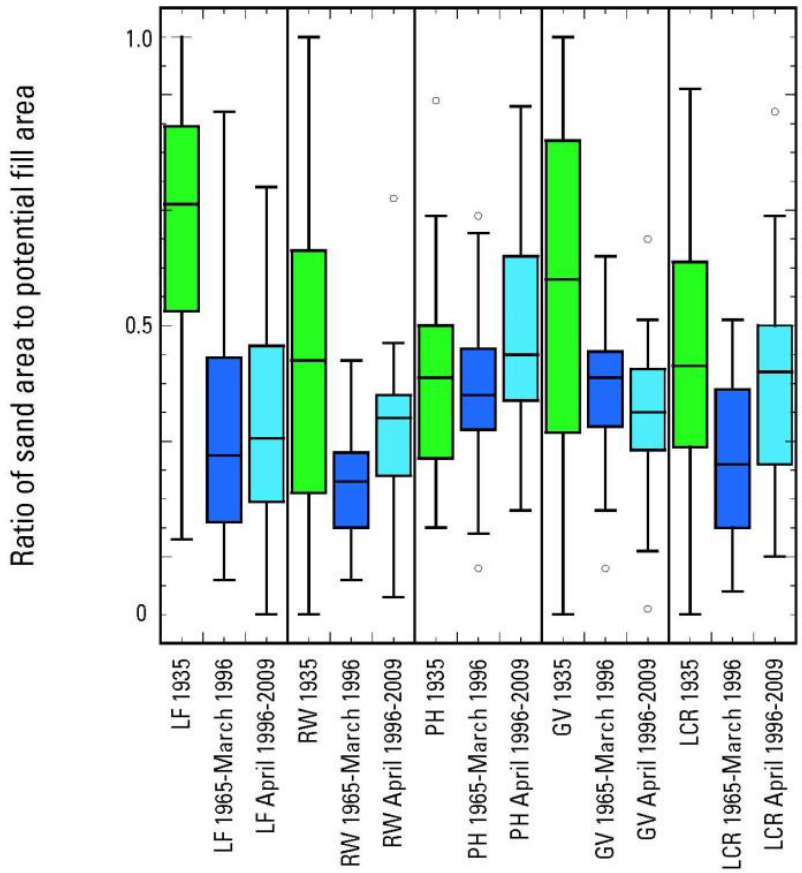

Figure 6 Box and whisker plots of the average eddy fill ratio (ratio of sand area to area of eddy deposition zone) for the pre-dam period, the pre-controlled flood period (1965 to March 1996), and the controlled-flood period (April 1996 to 2009). The median value is marked as the hingeline, the first and second quartiles are the boxes on either side of the median hingeline, the third and fourth quartiles are plotted as whiskers on either side of the boxes, and outliers are plotted as hollow circles.

We examined the effect of flow regime (Figure 3) on measured sandbar area by evaluating the relation between exposed sandbar area and elapsed time since the most recent flood event. Flood events were defined as releases of 1,161 m^3/s (41,000 ft^3/s) or more. The images from the pre-controlled flood period were collected between 1 week and almost 10 years following the previous flood. The images from the controlled-flood period were collected between 2 weeks and nearly 6 years following the most recent controlled flood. For the controlled-flood period, there is a strong correlation between measured sandbar area and elapsed time since the previous controlled flood (Figure 7). In this period, sandbar area was largest in April 1996, 0.5 months after the 1996 controlled flood; and sandbar area was smallest in 2002, 72 months after the 1996 controlled flood. The measurements of sandbar area in the pre-controlled flood period are not

strongly correlated with elapsed time since the most recent flood event.

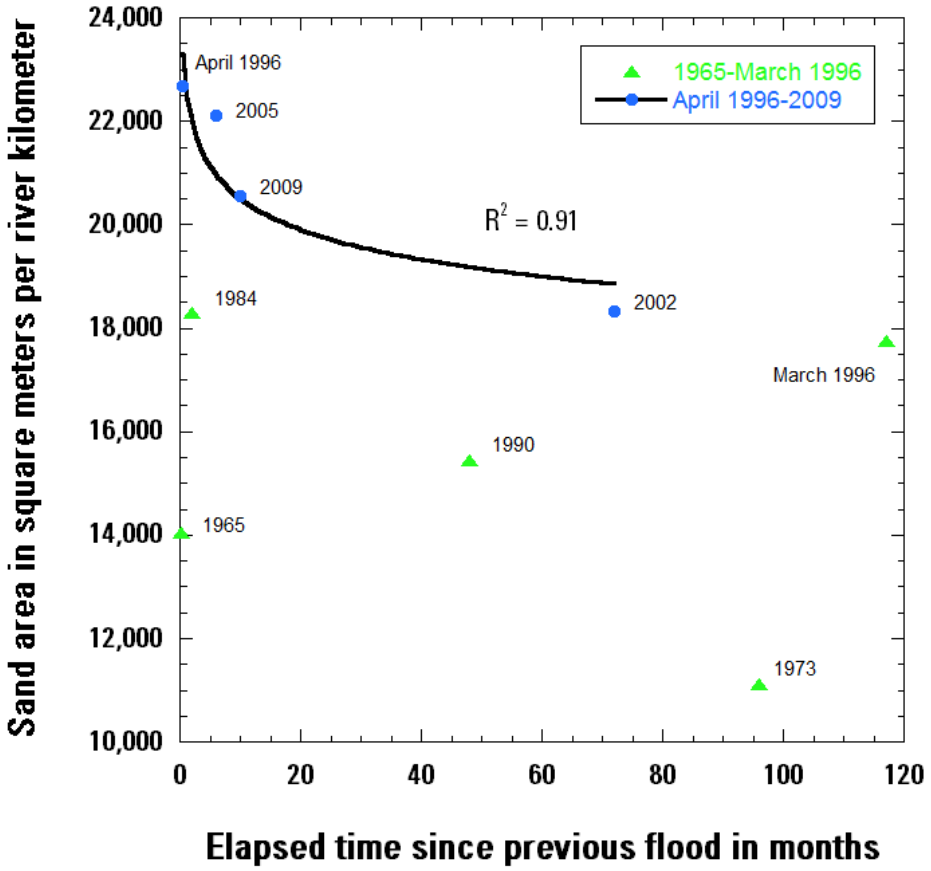

Figure 7 Post-dam reach area plotted against time elapsed since previous flood of 1,161 m^3/s (41,000 ft^3/s) in months. Power trendline fit to data from the controlled-flood period shows clear relationship with an R^2 value of 0.91, while no significant trend was observed in the data from the pre-controlled flood period.

DISCUSSION AND CONCLUSIONS

Previous analyses of aerial imagery concluded that the sandbar area in the post-dam photographs from the period before the first controlled flood was less than in the pre-dam era (Schmidt and Graf, 1990; Schmidt et al., 2004). Our analysis of more recent (2002 – 2009) post-dam imagery shows that sandbars in 2009 were still smaller than in the pre-dam period. There are, however, substantial differences in sandbar size between images collected in the periods with and without controlled floods. The relative proportion of EDZs occupied by exposed sand deposits was greater, on average, in the controlled-flood period than in the period preceding controlled floods. Only in the Granary View reach was the median sandbar size less in the images collected in the controlled-flood period than in the period preceding the first controlled flood, although some sandbars in this reach did increase in size. Importantly, the presence and absence of controlled floods are not the only differences between these two periods. The pre-controlled flood period consisted primarily of unrestricted fluctuating flows while the controlled-flood period consisted entirely of restricted fluctuating flows. Thus, the combination of controlled floods and restricted

powerplant operations is most likely responsible for the observed increases in sandbar size.

The strong correlation between sandbar area and elapsed time since the most recent controlled flood is consistent with previous studies of sandbar deposition and subsequent erosion of flood-formed bars (Hazel et al., 1999; Hazel et al., 2010; Grams et al., 2010). The negative correlation also illustrates that the mean among a set of images is sensitive to the timing of image collection. The image collection dates are neither a systematic nor a random sample. Thus, the average responses shown in Figure 6 only show the average among the image collection dates and are not necessarily representative for the time period. Because of this sensitivity to time of image acquisition and because all images were collected at different intervals relative to the most recent controlled flood, it is not possible to identify a trend in sandbar area with time between 2002 and 2009. The apparent trend between 2002 and 2009 shown in Figure 5 is most likely attributable to the shorter elapsed time between the 2008 controlled flood and the 2009 images.

Because the volume of sand above the reference discharge of 227 m^3/s is only a small fraction of the sand in storage (Hazel et al., 2006; Grams et al., 2015), changes in sandbar area determined from analysis of aerial images cannot be interpreted to reflect changes in total sand storage. Thus, although the images showed larger sandbars in the post-dam period with controlled floods than in the post-dam period before controlled floods, this does not mean that there was more sand in the system during this period.

This study involves only a subset of the reaches that comprise the entire length of the Colorado River in Marble and Grand Canyons, downstream from Glen Canyon Dam. These findings may not, therefore, be representative of the entire system. Ongoing work includes classification of the area of exposed sand for all of Marble and Grand Canyons using the same 2002 and 2009 images used in this analysis, and supplemented with images collected in 2013. This analysis will report on changes in sand area for approximately 1,400 EDZs between Glen Canyon Dam and Lake Mead, located 275 miles downstream.

ABSTRACT

The channel of the Middle Rio Grande (MRG) has been confined to a narrow corridor by riverside infrastructure and geology. It is actively evolving in most locations in response to reduced sediment loads and managed flow regimes due to reservoirs and diversions. In support of the Bureau of Reclamation's (Reclamation) responsibility for MRG Project river maintenance, river work identification and planning follows a systematic process involving: 1) monitoring and analysis: 2) need assessment; 3) work classification; 4) documentation of results (for 1-3); and 5) programmatic project and work planning.

This paper describes the methodology for step 2; determine the relative *Need* for river maintenance. The *Need* for river maintenance relies on both the *Value* of the maintenance and the *Likelihood* of the necessity for maintenance. In the described methodology, *Value* and *Likelihood* are rated by water resources professionals using technical factors associated with river conditions, public interests, and water delivery. Each factor has individual criteria which are updated as state-of-the-practice river hydraulic, geomorphic, and ecological monitoring and assessment improve. The final relative *Need* for river maintenance is the product of the *Value* and *Likelihood* ratings at each location. *Need*, *Value*, and *Likelihood* are terminology specific to this report and assessment methodology that describe the importance, benefit, and potential conditions for river maintenance work.

In applying the rating criteria to the MRG, the *Need* for river maintenance was calculated for 86 sites and 11 reaches for the value-based technical factors of Public Health and Safety and Water Delivery. Rating results from the application were consistent with professional and experiential judgment, and objectively reflected the significance of the sites and reaches for the technical factors. The next steps for *Need* for river maintenance are the development of ecologic and cultural resource ratings.

INTRODUCTION

The MRG Project purposes include performing channel maintenance, ensuring effective water delivery through the middle valley downstream to Elephant Butte Reservoir, reducing the risk of flooding, bankline erosion protection, as well as meeting international treaty water delivery obligations to the Republic of Mexico. These needs and services remain important in the present and are joined by newer considerations for habitat improvement to enhance the ecological function of the system within the Project's congressional authorization. Reclamation has responsibility for sound environmental stewardship with the National Environmental Policy Act of 1973, and the Endangered Species Act of 1973 for listed species and their critical habitats.

River maintenance can be divided into two general types for project development:

- Individual sites - These are projects designed to meet immediate and local river maintenance at specific locations.
- Reach-level strategies – The strategies are designed to holistically address large-scale, observed, geomorphic trends, on a proactive basis. Implementation of projects considers the entire reach is intended to work with the river's underlying governing processes along with enhancing river functions like providing habitat and water delivery.

The Middle Rio Grande River Maintenance Comprehensive Plan and Guide (Maintenance Plan and Guide) (Reclamation, 2012) discusses the MRGP Program, reaches, and strategies in more detail.

The MRG Project river maintenance work identification and planning follows a systematic process involving five main steps. They are:

1) Monitor, analyze, and document channel and floodplain conditions and changes – performed continuously.
2) Identify, evaluate, and rate sites and reaches to determine the relative *Need* for river maintenance – performed annually and as needed.
3) Assign a Maintenance Classification utilizing the following designations for each site or reach – performed annually and as needed. These classifications are patterned after the Review of Operations and Maintenance (Reclamation, 1991) process, recognizing that the river is not a facility but a system. Professional judgment and experience combined with information obtained during the *Need* for River Maintenance assessment are used to assign classes.
    - Class 1 – Maintenance is required in the short term (typically before the next high flow event or could be required immediately) because there is a high likelihood of substantial consequences if no action is taken. Work can be described as interim and unanticipated projects are commonly individual sites.
    - Class 2 – Maintenance can be planned in advance but the consequences of no action could be substantial in the near term (the next normal spring runoff or within the next few years). The class includes the majority of ongoing or normal river maintenance work at existing and new sites.
    - Class 3a – Maintenance can be planned in advance and the consequences of no action are less likely to be substantial in the near term (the next normal spring runoff or within the next few years). It is work that can be described as preventative maintenance and also includes habitat enhancement.
    - Class 3b – Maintenance can be planned and the consequences of no action are less likely to be substantial in the near term (the next normal spring runoff or within the next few years). Data collection and/or analysis are required to determine if preventative or normal maintenance (including habitat enhancement) is needed.
    - Class 4 – Maintenance is not anticipated to be needed in the near term (the next normal spring runoff or within the next few years) because change appears to be occurring at a slow rate. Work can be described as monitoring for potential changes that could accelerate the need for maintenance to the near term. This class also includes monitoring of completed projects.
    - Class 5 – Maintenance may be needed but is not within Reclamation's authority. Responsible parties will be notified if it appears that the consequences of no action could be substantial in the near term.
4) Document assessment results for each location in an individual Site or Reach Report and summarize Relative *Need* for River Maintenance results in a report.
5) Plan maintenance projects and work – annually and as needed. Information from Steps 1 through 4 above, plus programmatic considerations like resource management, policy, budgeting, and stakeholder collaboration are utilized for planning projects and scheduling. Scheduling may require adjustment given the uncertainties in predicting hydrology, geomorphic trends, modeling, etc. on an alluvial river.

This process follows Chapters 3-5 of the Best Practices in Dam and Levee Safety Risk Analysis (Reclamation and USACE, 2012) and the Maintenance Plan and Guide.

This report details the methodology developed for Step 2-Identify, Evaluate, and Rate the Need for river maintenance. *Need* is identified where conditions are causing or may lead to: impacts to public health and safety (e.g. flooding of homes and businesses); damage to riverside infrastructure (e.g. river erodes into a levee, heading, or canal); and reduced effectiveness of water deliveries (e.g. aggradation causes the loss of a competent channel).

The *Need* for River Maintenance relies on the combination of *Value* of the maintenance and the *Likelihood* of the necessity for maintenance. The technical factors of *Value* and *Likelihood* are rated by engineering, geomorphic, ecologic and cultural resources professionals. The technical factors are explained in more detail below. It should be noted that *Value*, *Likelihood*, and *Need* of river maintenance are not specific quantitative consequence, probability, or risk determinations resulting from conventional risk analysis approaches. The *Value*, *Likelihood*, and *Need* ratings are intended for comparative analysis amongst a group of sites or reaches. Step 2 is a screening tool for work identification and prioritization.

SITE AND REACH MAINTENANCE NEEDS

Site Identification:

Individual sites needing river maintenance are currently identified based on meeting any or all of the following general criteria (Reclamation, 2012; Maestas and Padilla, 2011; Smith, 2005):

- The continuation of current trends of channel migration or morphology will likely result in damage to riverside infrastructure within the near term
- Similar conditions have historically resulted in failures or near failures at flows less than the two-year flood
- Existing conditions could cause significant economic loss, danger to public health and safety, or loss of water

River conditions at sites that meet the above criteria are evaluated through ongoing monitoring, evaluation of historical trends, geomorphic analyses, and numerical modeling to help understand the middle Rio Grande system as referenced in Step 1. These same criteria also apply when determining the need for implementation of reach-based strategies. Additionally, habitat value and enhancement opportunities at a site or reach will be included as part of the identification of sites or reaches benefiting from river maintenance. (At the time of this report submission, work is in progress to develop the ecologic and cultural resource *Need* ratings). The benefit of habitat enhancement is primarily a function of the habitat needs of threatened and endangered species.

The evolving river morphology – as it responds to the variable drivers of change (e.g. hydrology and sediment loads) and the controls of change (e.g. bed and bank stability, base level control, floodplain connectivity, floodplain lateral confinement) – is the fundamental cause of river maintenance needs. The combination of Steps 1 and 2 reflects this linkage between the river's morphology and the need for maintenance. Evaluation of the *Need* for maintenance requires characterizing geomorphic processes and current conditions for each reach and site, then estimating the likely future conditions.

Maintenance Need (Likelihood and Value) Technical Factors:

Technical Factors and criteria associated with river conditions, public interests, and water delivery infrastructure are presented below. The technical factors are structured to allow for the site and reach criteria to be updated with advancements in river engineering and ecosystem understanding, and measurement and analysis techniques.

T

he criteria are only guidelines and experienced engineers should use professional judgment and the understanding of local conditions and fluvial processes during the ratings as well.

Likelihood-based Technical Factors

The *Likelihood* is a semi-quantitative estimate of the relative probability that conditions are causing or may lead to damage or impairment without future maintenance. When the damage or function impairment is imminent or has already occurred (e.g. levee failure or degraded habitat), the *Need* for river maintenance has been established so the *Likelihood* rating is simply the highest possible and thus the *Likelihood* Factors do not need to be rated.

1. Percent of Reach Length with Sites (Rating from 1 to 5)

This factor applies only to reach assessments and reflects how the evolving channel and floodplain fit within the lateral constraints of riverside infrastructure and geology. The number of identified maintenance sites is considered as well as the levee condition. Individual local sites are assumed to be ½ mile in length at a minimum; the total actual length for a reach scale project is also used when known. The total length of sites is divided by the reach length to get a normalized percentage of sites by reach.

- **Very low** – Sites occupy less than 5 percent of the reach length.
- **Low** – Sites occupy 5 - 15% percent of the reach length.
- **Moderate** – Sites occupy 15 – 25 percent of the reach length.
- **High** – Sites occupy 25 – 50 percent of the reach length. Downstream of San Acacia the levees rate as high or very high depending on condition.
- **Very high** – Sites occupy more than 50% percent of the reach length. Downstream of San Acacia the levees rate as high or very high depending on condition.

2. Bed and Slope Instability (Rating from 2 to 4)

A key criterion is the comparison of sediment transport capacity to sediment supply. The Maintenance Plan and Guide report provides information on the extent of imbalance as estimated by slope stability. Trends in bed material size, bed elevation and channel width are also important, but not all criteria need to be met for a rating. Local conditions may be used when known.

- **Low** – The reach slope is near the stable slope, bed material is stable, and bed elevation and widths are not changing
- **Moderate** – The reach slope is near the stable slope, local bed material and width changes are occurring, bed elevation may or may not be changing
- **High** – The reach slope is not near the stable slope, local bed material is not stable, and/or widths are narrowing and bed elevations are changing

3. Planform Instability (Rating from 1 to 5)

The main criteria are the current planform stage, the balance between sediment transport capacity and supply, and the degree of vegetation encroachment. Figure 1 shows the stages used below. More information can be found in Massong et al. (2010).

Planform changes are evaluated based upon likely conditions in the near term (< 5 years). Below are the descriptions of the classes:

- **Very low** – Planform is stage 1, A6, or M8 and sediment transport capacity is near supply, with no vegetation encroachment
- **Low** – Planform is stage 2, 3, or M5 and sediment transport capacity is near supply, with little or no vegetation encroachment
- **Moderate** – Planform is stage A4, M4, or M7 and sediment transport capacity is near supply, with little vegetation encroachment, or stage 3 with some vegetation encroachment
- **High** – Planform is stage A4, M4 or M5 and sediment transport capacity is not near supply, with vegetation encroachment present
- **Very high** - Planform is stage A5 or M6-M7 and sediment transport capacity is not near supply, with vegetation encroachment present

4. Bank Susceptibility to Erosion (Rating from 1 to 5)

The main criteria are the erosive susceptibility of the bank and the angle of attack. The erosive susceptibility of the bank includes the type of bank material, the type of river bed material, and the amount of vegetation. BSTEM (Simon et al., 2013) or meander evaluations may be used instead of the qualitative evaluation below. For reaches the same criteria are used and consider the majority of the reach length plus the sinuosity. Below are the descriptions of the classes for rating:

- **Very low** - mostly cohesive bank and/or dense root mass and/or gravel, very dense understory (have to crawl through), no incision, and a very low angle of attack (less than 20^o)
- **Low** - some cohesion and/or root mass, dense understory but can still walk, low level incision, low angle of attack (20^o to 30^o)
- **Moderate** - cohesionless banks (sand), sand bed with small amount of gravel, some understory, some open areas but can still drive, moderate level of incision, moderate angle of attack (30^o to 40^o), minor opposite bar and meander pattern
- **High** - cohesionless banks (sand), some gravel bed material, sparse vegetation (majority of area between bank and levee is open, minimal understory), high incision, high angle of attack (40^o to 60^o), opposite bar and meander pattern
- **Very High** - cohesionless banks (sand), very sparse vegetation (little to none), very highly incised, very high angle of attack (60^o to 90^o), strong opposite bar and/or meander pattern

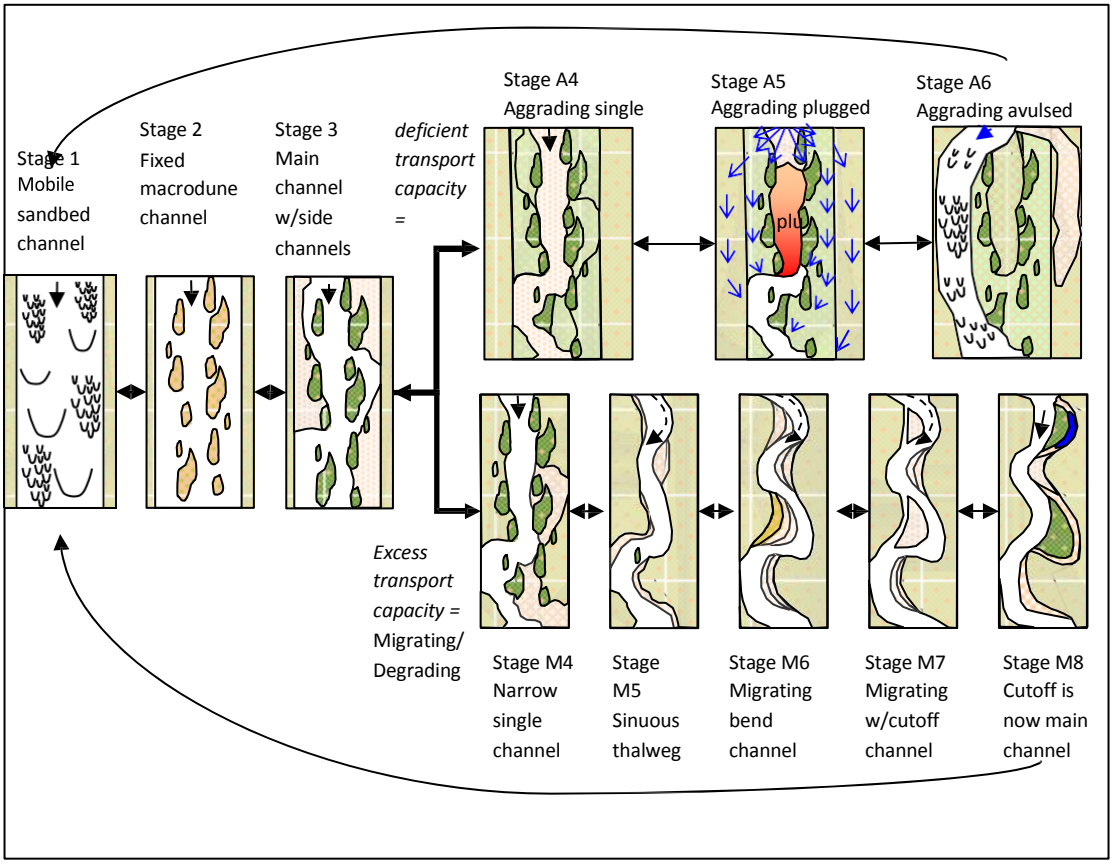

Figure 1 Planform cycles identified on the Rio Grande (Massong et al., 2010)

5. Proximity of infra-structure to river (e.g. levee toe or edge of facility) (Rating from 1 to 5)

The main criterion is the distance between the riverbank and the edge of the structure for river maintenance sites. For reach evaluations, the percent of the reach length where the meander belt width fits between the lateral constraints should be used as well as the percent of the area available between the constraints used by the meander belt width. The class descriptions are as follows:

- **Very Low -** greater than 200 feet. For reaches, the meander belt fits along 100 percent of the reach length and it uses less than 25 percent of the available area.
- **Low –** 150 to 200 feet. For reaches, the meander belt fits along a least 90 percent of the reach length and it uses less than 50 percent of the available area.
- **Moderate –** 100 to 150 feet. For reaches, the meander belt fits along less than 90 percent of the reach length and it uses less than 50 percent of the available area.
- **High -** 50 to l00 feet. For reaches, the meander belt fits along less than 90 percent of the reach length and it uses less than 75 percent of the available area.
- **Very High -** less than 50 feet. For reaches, the meander belt fits along less than 90 percent of the reach length and it uses more than 75 percent of the available area.

6. Past rate of lateral movement (Rating from 1 to 5)

The main criterion for this factor is the average rate of bank erosion and migration toward infrastructure. Typically, this average rate over several years will be based on aerial photography; unless the site is heavily monitored in which case it may be based on physical measurements. When known, the maximum rate of movement during one season should be considered. For reaches, professional judgment as to whether the average rate of movement for the reach as a whole is qualitatively very low to very high should be used to assign a rating class, but may be modified by consideration of the highest rate at a single location in that reach. Hydrology during the measurement period shouldalso be considered in the rating. For example, if flows have been low for several years and the rate of lateral

movement is low, it may be useful to look at rates of movement during periods of higher flows as well. Classes are:

- **Very Low** - channel is gradually moving toward the riverside facility, <5 ft/yr.
- **Low** - channel is slowly moving toward the riverside facility, 5 - 10 ft/yr.
- **Moderate** - channel is migrating at a moderate rate toward the riverside facility, 10 - 20 ft/yr.
- **High** - channel is migrating rapidly toward the riverside facility, 20 - 30 ft/yr.
- **Very High** - channel is migrating very rapidly toward the riverside facility, >30 ft/yr.

7. Channel and Floodplain Capacity Compared to MRGP Authorization (Rating from 2 to 4)

These criteria are used to evaluate the likelihood of flooding or other effects due to inadequate safe channel capacity. Capacity is reduced by sediment deposition that isn't mobilized by later flows. For example, this may be due to large grain sizes (e.g. coarse material supplied by arroyos), large sediment volume events (e.g. significant fires in the watershed), or vegetation encroachment with sediment trapping and stabilization. The time frame is the next few years. Middle Rio Grande Project authorization provides for Reclamation to maintain a channel capacity of not less than 5,000 cfs or the equivalent two-year return flow of the reach. Channel capacity is assessed through hydraulic modeling. When assessing floodplain and levee capacity with hydraulic modeling, an extra two to three feet of freeboard should be added in a perched system.

- **Low** - Capacity exceeds standards
- **Moderate** - Capacity meets standards
- **High** - Capacity is less than standards

8. Possibility of Channel Capacity Loss (Rating from 1 to 5)

Current trends are examined to determine expectations of a reduction, little change, or an increase in channel capacity. Hydraulic geometry trends should be used when available. The classes are:

- **Very Low** – channel capacity is increasing
- **Low** – channel capacity is generally constant, little or no channel narrowing
- **Moderate** – channel capacity is expected to slightly reduce every few years; with minimal levee raising, channel dredging, and minor channel narrowing and vegetation encroachment
- **High** – channel capacity is expected to reduce, continued levee raising or channel dredging are required, some channel narrowing and vegetation encroachment is occurring
- **Very High** – channel capacity is significantly reduced, levees need considerable raising or the channel needs considerable dredging year after year, significant channel narrowing and vegetation encroachment is occurring, plugs have occurred in past, bank heights are less than two to three feet.

9. Possibility of Levee or Embankment Failure (Rating from 1 to 5)

There are three main modes of levee failure: piping and internal erosion from flows against the levee, overtopping of the levee, and bank erosion into the levee. Only the first mode is assessed through this Factor.

- Water against Levee is of sufficient depth to cause failure through erosion or piping
  - **Very low** – no water against levee
  - **Low** - Engineered levee; water remains for few days; no sand boils; no longitudinal or lateral cracking; no sloughing; no extensive burrow holes; not an avulsion or plug prone area
  - **Moderate** - Engineered levee; water remains for several days; no sand boils; no longitudinal and lateral cracking; no sloughing; no extensive burrow holes; not an avulsion and plug prone area
  - **High** – Spoil levee; water remains for a few days; no sand boils; no longitudinal and lateral cracking; no sloughing; no extensive burrow holes; avulsion and plug prone area
  - **Very High** – Engineered or spoil levee; water remains for several days; sand boils, longitudinal and lateral cracking, sloughing, or extensive burrow holes present; avulsion and plug prone area
- Levee Overtopping – this is a failure mode, its condition is assessed through Factors related to channel capacity
- Bank erosion into levee – this is a failure mode, its condition is assessed through Factors related to bank erosion

10. Degree of Perching (Rating from 1 to 5)

The historical aggrading nature of, and the historic levees on, the Rio Grande have resulted in a channel bed that

may be perched above the local floodplain between the levees and may also be perched above the area outside the levees as shown in Figure 2. The average of the ratings from inside and outside the levee will apply in most cases. For reaches, the greatest percentage of cross sections in a reach determines the rating.

- **Very low** – Channel bed substantially below overbank elevation and/or outside of the levee system
- **Low** - Channel bed below overbank elevation and/or outside of the levee system
- **Moderate** - Channel bed near overbank elevation and/or outside of the levee system
- **High** - Channel bed higher than overbank elevation and/or outside of the levee system
- **Very High** – Channel bed substantially higher than overbank elevation and/or outside the levee system

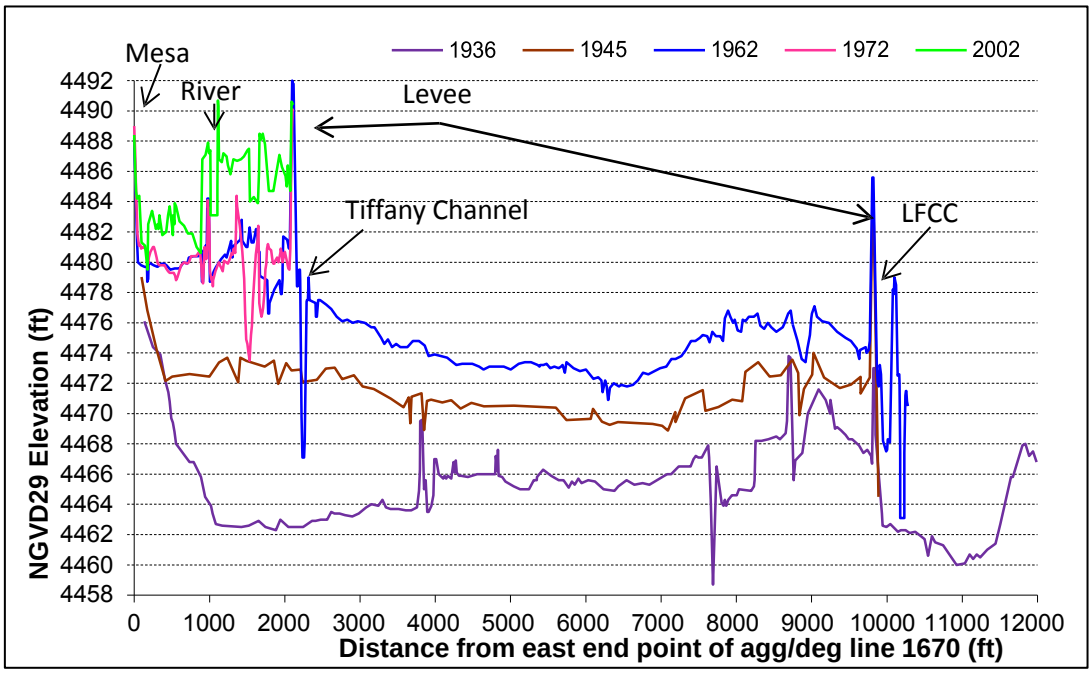

Figure 2 Agg/Deg Line 1670 where river is perched above floodplain and above valley

Value-based Technical Factors

Two factors (Public Health and Safety and Water Delivery) are used to estimate the *Value* or derived benefit of performing river maintenance at a site or reach from an authorized mission and public trust responsibility. *Value* of river maintenance from an ecological function and/or cultural resources viewpoint is not presented in this paper and is in development. Evaluation of the *Value* of performing river maintenance at a site or reach from an ecological function and/or cultural resources viewpoint could bring the number of *Value* factors to four. It is important to note the *Value* factors are rated linearly (i.e. 1-5) while the effects to the river system associated with any impacts (by the *Likelihood* factors) on these factors may be nonlinear.

1. Public Health and Safety (Rating from 1 to 5)

These criteria are used to evaluate the *Value* impact of no river maintenance and take into consideration the population concentration, the proximity of population to flooding (groundwater wells, septic systems, roads, homes, etc.) and the potential outcome of that flooding. Considerations include public infrastructure such as railroads, roads, and sewer lift stations. Rating descriptions were adapted from Smith (2005) and the Truckee Canal Issue Evaluation Report of Findings (2011):

- **Very low** –- Non-Populated Areas – No significant effects to the local population other than temporary minor flooding of roads or land
- **Low** – Sparsely Populated Areas – Minor property and environmental damage may occur. Damage is possible to sewer outfalls, recreation areas, rural roads, and bridges in low-lying areas. Direct loss of life is unlikely.

- **Moderate** – Moderately Populated Areas – Impacts could include moderate property and environmental damage. Damage to permanently occupied structures, recreation areas, local paved roads and bridges in low lying areas is possible. Terrain suggests direct loss of life is possible related primarily to difficulties in warning and evacuating recreationists/travelers and small population centers.
- **High** – Densely Populated Areas – Impacts could include extensive damage to permanently occupied structures, secondary roadways and bridges, and sewer lift stations. Terrain suggests direct loss of life is possible, related primarily to difficulties in warning and evacuating smaller population centers, or difficulties evacuating large population centers with significant warning time.
- **Very High** – Large Population affected – Impacts could include extensive damage to permanently occupied structures, primary roadways, bridges, and railroads, or regional effects such as contamination of Elephant Butte or Cochiti reservoirs. Terrain suggests direct loss of life could be high due to limited warning for large population centers and/or limited evacuation routes.

2. Water Delivery (Rating from 1 to 5)

These criteria are used to evaluate the *Value* impact on water delivery and riverside irrigation infrastructure of no maintenance. Consideration includes both impacts at specific sites (e.g. diversions) and downstream effects. Descriptive classes for infrastructure/function effects:

- **Very low –-** Little change to Water Delivery
- **Low** – Minor change to Water Delivery – impacts to drains for one to two miles,
- **Moderate** – Medium change to Water Delivery – impacts on secondary canals, irrigation/laterals (drains) for two to ten miles
- **High** – Major change to Water Delivery – impacts to main canals or multiple miles of damage to drains/canals (greater than ten miles),
- **Very high** – Regional change to Water Delivery – regional impacts on water delivery

CALCULATION OF SITE AND REACH NEED FOR MAINTENANCE

The steps to calculate the estimated Relative *Need* for River Maintenance are shown in Figure 3. As discussed earlier, the *Need* for River Maintenance is a function of the *Likelihood* of *Need* for River Maintenance and the *Value* of River Maintenance. The sources of change that lead to the *Likelihood* of *Need* for River Maintenance at a site or reach on the Middle Rio Grande can be grouped into three physical processes/ mechanisms: instability of channel bed, slope and planform; bank erosion leading to damage; and aggradation and/or island and bar growth leading to inadequate channel capacity. The 10 *Likelihood* Technical Factors (LTF) are therefore grouped into Potential for Channel Instability (LTF 1, 2, and 3), Potential for Bank Erosion (LTF 4, 5, and 6), and Potential for Loss of Channel Capacity(LTF 7, 8, 9, and 10), the geometric mean is calculated for each grouping. The Potentials for Channel Instability and Bank erosion are combined by calculating their geometric mean. The Potentials for Inadequate Channel Capacity and Channel Instability are also combined by calculating their geometric mean. These combinations provide both the Likelihood for Bank Erosion and Inadequate Channel Capacity Effects. Lastly, these Likelihoods are combined by taking their geometric mean to determine a composite Likelihood of Need for River Maintenance.

The *Value* Technical Factors (VTF) are then directly assessed through the criteria listed above. The Relative *Need* for River Maintenance of a reach or site is calculated by multiplying the *Likelihood* of *Need* for River Maintenance by each of the two presented *Values* (Public Health and Safety, Water Delivery) of River Maintenance. An overall *Need* for river maintenance is not calculated because each *Value* (Public Health and Safety and Water Delivery) can vary in importance due to programmatic considerations.

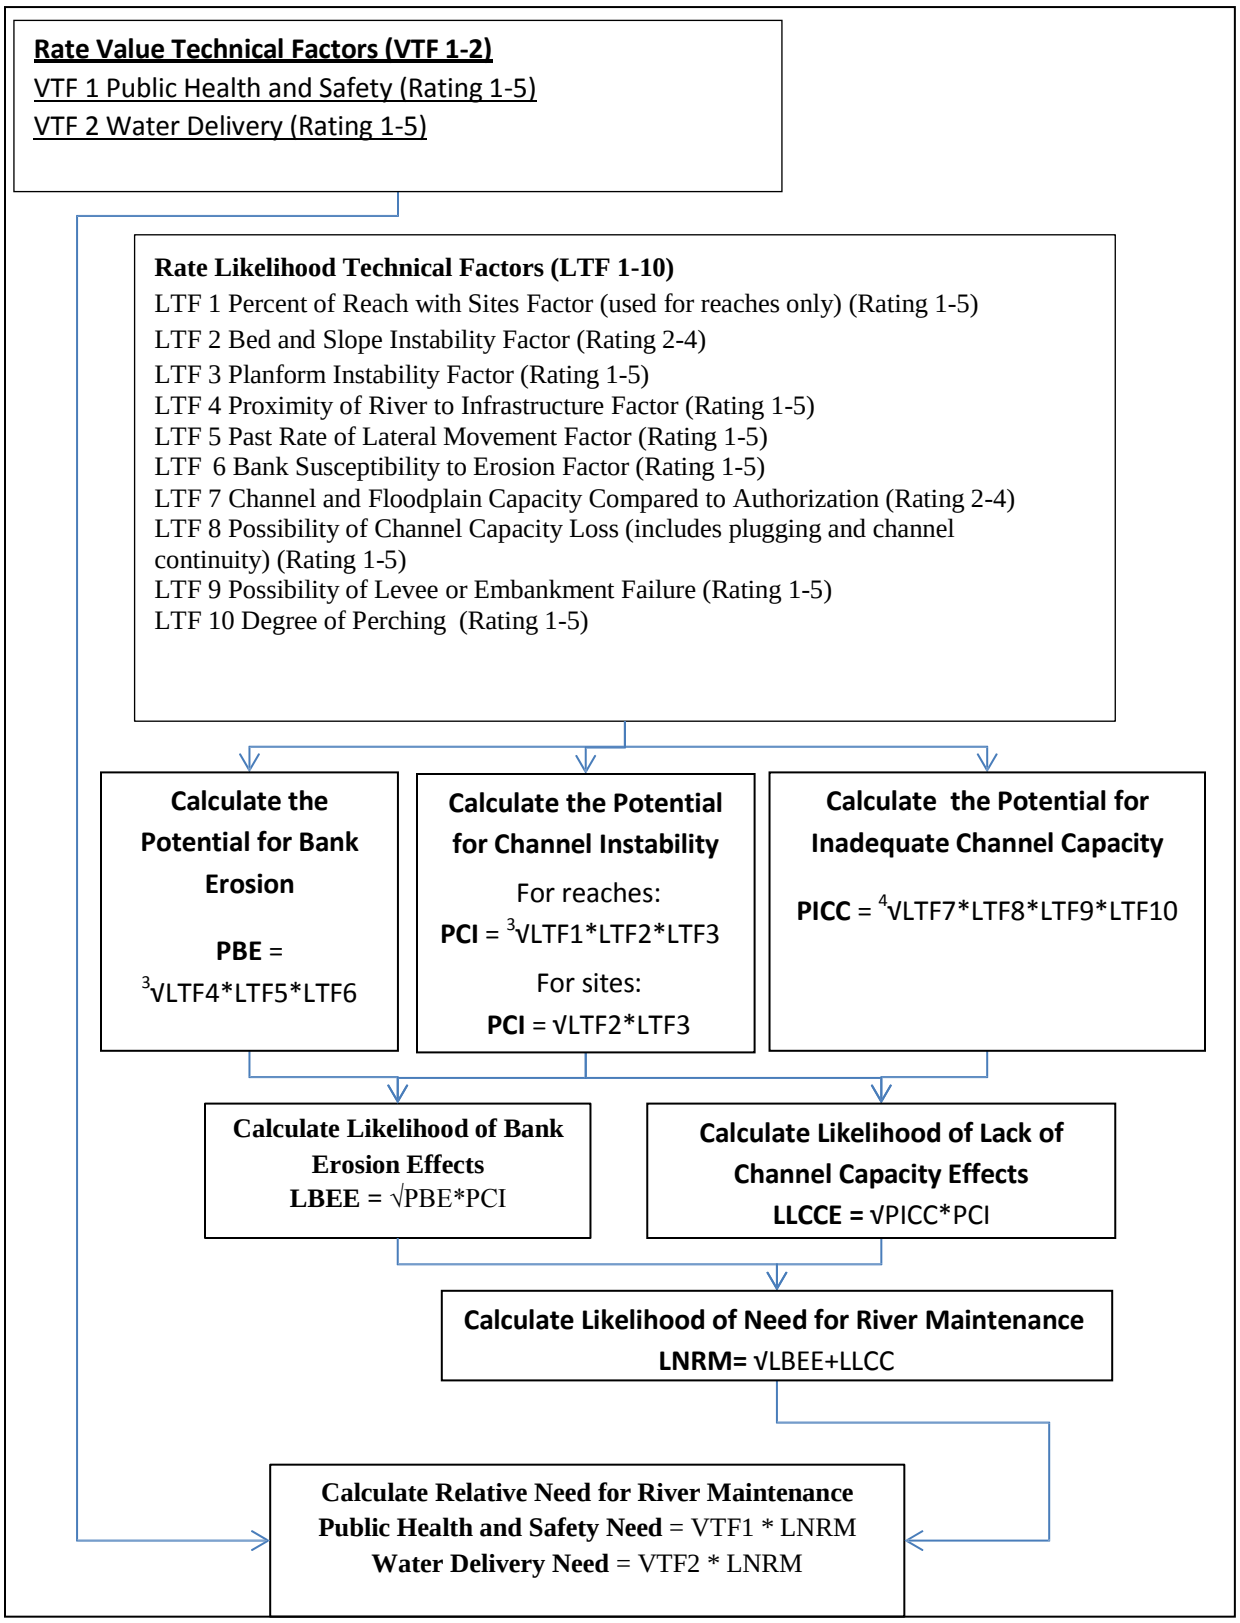

Figure 3 Flowchart of Relative Need for River Maintenance Determination

SITE AND REACH MAINTENANCE NEEDS RESULTS

Eighty six sites and eleven reaches were evaluated at current conditions. Final rating results for Likelihoods of Bank Erosion Effects, Channel Capacity Effects, Need for River Maintenance, and the Relative Needs for River Maintenance are presented in Reclamation (2014). Figures 4 and 5 below show the results of Need determination for the individual sites (only 17 shown, 86 rated total) and all eleven of the geomorphic reaches.

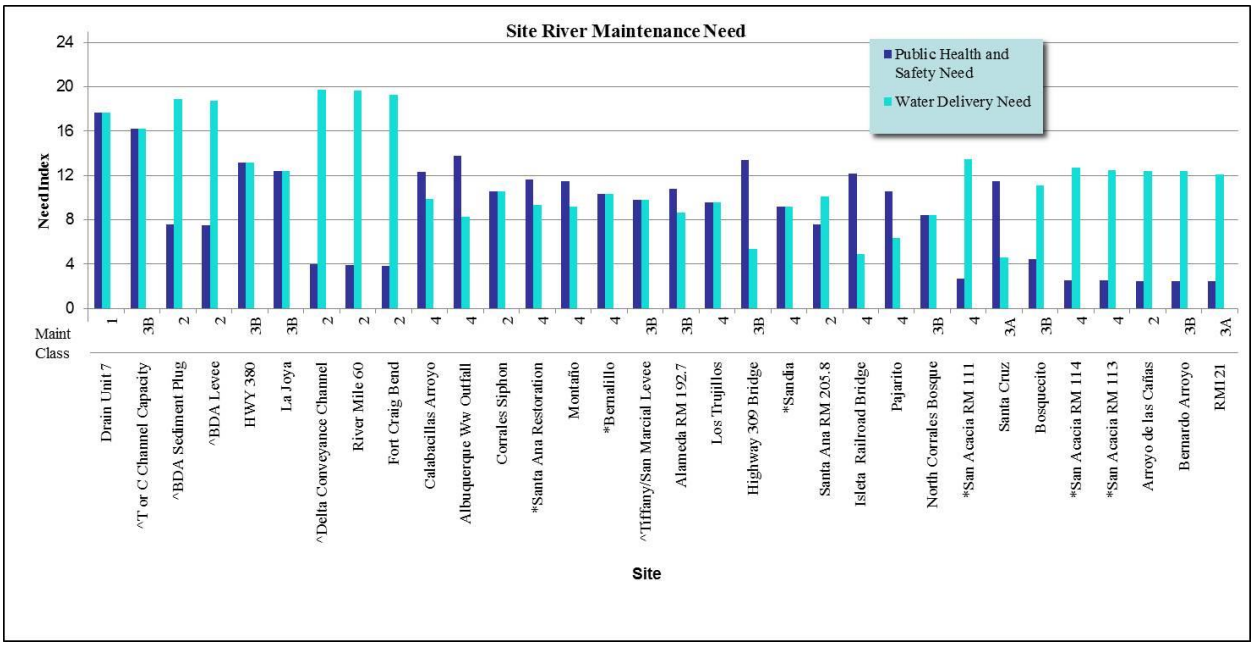

Figure 4 Site River Maintenance Need Results for Public Health and Safety; Water Delivery

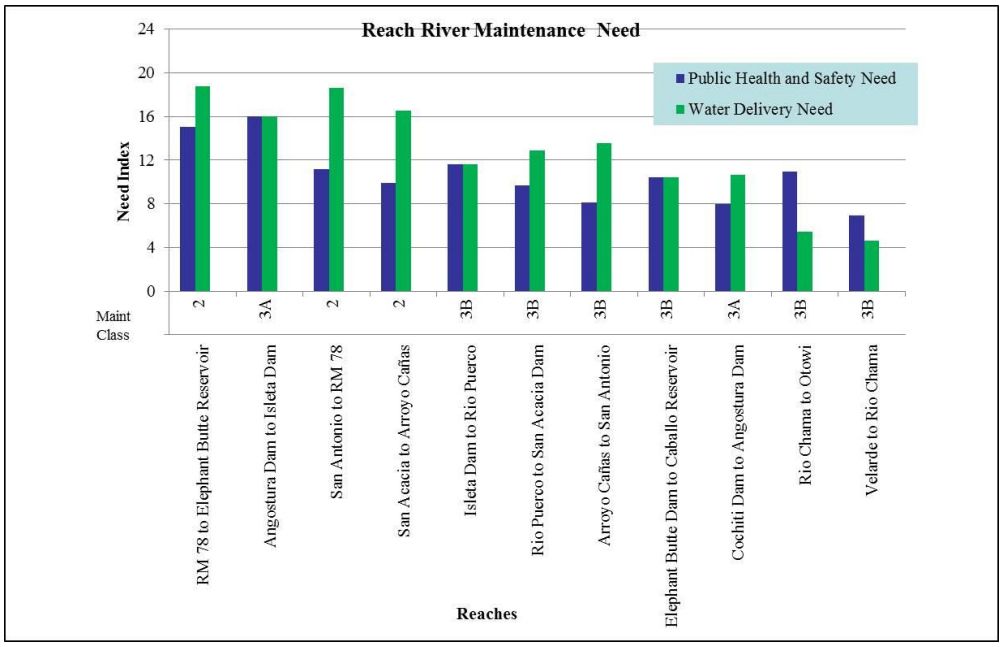

Figure 5 – Reach River Maintenance Need Results for Public Health and Safety; Water Delivery

These ratings provide semi-quantitative technical decision-making guidance for project planning. The assessment of the *Need* for river maintenance and assignment of a Maintenance Class occurred during a May 2014 workshop setting that best utilized the expertise of knowledgeable and experienced engineers, geomorphologists, biologists, and other professionals. The results of this workshop were documented for future reference related to maintenance need identification for the River Maintenance Program. Future updates to the ratings should be conducted and documented in similar workshops (with the best available tools/criteria for the Likelihood and Value Factors) as a part of the normal annual river review.

The Best Practices in Dam and Levee Safety Risk Analysis (2012) provides guidance on documenting or "making the case" for the Need for river maintenance. Chapters 3 and 4 are especially pertinent for further consideration. Other considerations in the final decisions on river maintenance work planning are the real-time circumstance and humanistic-based operational decisions that are made in regards to maintenance activities. Such considerations may include but are not limited to: area office priorities, scheduling, proximity to other sites, and if there is a potential for increased maintenance resulting from other non-Reclamation river projects. These considerations allow effective planning of river maintenance activities and may result in lower Class projects being undertaken concurrently with higher Class projects. The end result is anticipated to maximize the benefits from river maintenance. It is important to note that the Maintenance Class designations identified in Step 3 on page 2 of this report rely heavily on professional/experiential judgment and understanding the historic and real time dynamic river conditions.

The Maintenance Class Designations (1, 2, 3a, 3b, 4, and 5) indicate the recommended *Urgency* and corresponding level of response by the River Maintenance Program to the identified relative maintenance *Need*. There is not a simple correspondence of the factor ratings to Class Designations because the criteria do not directly evaluate the *Urgency*. *Urgency* for river maintenance reflects the apparent response time before further impacts occur to the identified *Values*. The *Urgency* is strongly dependent on professional judgment and experiential considerations derived from observing and monitoring the river system. Urgency can further be analyzed by defining the hydrologic loadings/triggers that drive river response to create a *Need*. These loadings include single events and also long term river flow trends involving frequency, magnitude, and duration. The *Likelihood*, *Value*, and *Need* ratings help inform the Maintenance Class designation. Since Technical Factors and criteria to rate the Ecological Function *Value* of river maintenance are not available at this time, it should be noted that the Maintenance Classes may be adjusted or a separate class structure for habitat restoration added after development of those Technical Factors and criteria.

Overall, this tool helps to systematically evaluate all sites and reaches with consistent Factors for *Likelihood* and *Value* to arrive at a relative *Need* determination for the two *Values* of Public Health and Safety and Water Delivery. This methodology is intended to be a rapid assessment tool to be applied at least annually in response to the dynamic river and hydrologic conditions on the Middle Rio Grande. It should be noted that even though the Potential for Channel Instability, the Potential for Inadequate Channel Capacity, and the Potential for Bank Erosion along with the Values of Public Health and Safety and Water Delivery are rated for the sites and reaches, not all potential effects to the river system are explicitly accounted for. This is due to the non-linear relationships in the rating Factors for predicting channel response and associated impacts; their scale (localized and reach level effects); their spatial variability (varying geomorphic conditions in each reach); and the temporal nature of effects occurring from a progression of physical processes due to specific hydrologic events or long term trends.

MORPHOLOGICAL IMPACT OF A REHABILITATION PROJECT: SRH-2D MODELING ASSESSMENT

Yong G. Lai, Technical Service Center, U.S. Bureau of Reclamation, Denver, Colorado, ylai@urbr.gov; David Gaeuman and David J. Bandrowski, Trinity River Restoration Program, U.S. Bureau of Reclamation, Weaverville, California, dgaeuman@usbr.gov, dbandrowski@usbr.gov

Abstract. Geofluvial modeling is carried out using a coupled morpho-dynamic and bank erosion model referred to as SRH-2D. This model is used to predict the geomorphic impact of the Upper Junction City (UJC) rehabilitation project located on the Trinity River in Northern California. This geofluvial model was developed for the study and consists of two components: (1) a 2D mobile-bed model (SRH-2D) for vertical stream bed changes and hydraulic forces acting on bank toes; and (2) a bank retreat model for lateral bank erosions. The geofluvial model is first calibrated between a "pre-erosion" baseline condition from April 2009 and a measured "post- erosion" condition from August 2011. The model was found to be capable of predicting vertical bed changes and lateral bank erosion. The calibrated model is then applied to assess the potential future impacts of the river rehabilitation project on channel morphology under two scenarios: a 2011 "post-erosion" condition and a 2012 "design construction" condition. A comparison of the two provides necessary data with which to evaluate the potential design impact of the UJC project over a hypothetical evolution scenario.

INTRODUCTION

Stream bank erosion is a natural geomorphic process occurring in all alluvial channels. It is an important mechanism by which a channel adjusts its size, shape, and slope to convey the supply of both water and sediment. In recent years, both one-dimensional (1D) and two-dimensional (2D) numerical models have been used to predict channel responses, but most either ignore bank failure mechanisms or implement only simple ad hoc methods. Not accounting for stream bank failures in mobile-bed simulations may result in biased or erroneous predictions of degradation, aggradation, equilibrium channel geometry, and sediment loadings.

Most river restoration and rehabilitation projects are carried out without performing a quantitative geofluvial assessment. Physical analyses are usually restricted to hydraulic simulations only, due to the limited amount of practical and reliable geofluvial models available. A number of mobile-bed sediment transport models are available, such as HEC-RAS, SRH-1D, CONCEPTS, CCHE2D, and SRH-2D. They are versatile and offer extensive capabilities and choices in modeling the vertical changes in stream bed elevations. However, most of them do not take lateral bank erosion into consideration, except for CONCEPTS and SRH-2D, and cannot be used to predict lateral stream changes.

Recently, SRH-2D has been extended to include a bank erosion module, which is the motivation behind the present study. In this study, we investigate how the geofluvial SRH-2D model performs when tested against a field case at the Upper Junction City (UJC) rehabilitation project on the Trinity River in Northern California. Further, we demonstrate how a 2D geofluvial model like SRH-2D may be used to assess the impact of a proposed river rehabilitation project design on local channel morphology.

NUMERICAL MODEL AND MODELING DETAILS

SRH-2D Model Description SRH-2D is a 2D, depth-averaged, hydraulic and sediment transport model for river systems under development at the Bureau of Reclamation. The hydraulic flow model, documented by Lai (2008; 2010), has been widely utilized by internal and external users. The sediment transport module is used to predict vertical stream-bed changes and has been described by Lai and Greimann (2008; 2010) and Lai et al. (2011). The sediment module tracks multi-size, non-equilibrium sediment transport of suspended, mixed, or bed load for both cohesive and non-cohesive materials. The effects of gravity and secondary flows are accounted for by displacing the direction of the sediment transport vector from that of the local depth-averaged flow vector.

Recently, SRH-2D has been expanded for geofluvial modeling by developing and incorporating a number of bank modules (Lai et al., 2012; Lai and Wu, 2013; Lai et al., 2015). The simultaneous vertical and lateral modeling capability, i.e., geofluvial modeling, has been reviewed and summarized by Lai (2014). With the latest SRH-2D model, main channel fluvial processes may be solved with the regular 2D depth-averaged mobile-bed module, while the lateral bank erosion processes are solved with bank modules. In this study, the latest geofluival SRH-2D model is used.

Modeling Steps and Scenarios SRH-2D modeling, in general, includes the following steps: (1) selection of the solution domain; (2) mesh generation and definition of boundary conditions; (3) assigning topography, flow roughness and bed sediment gradations; (4) model calibration; and (5) model applications. The first three steps are discussed herein; the remaining two steps are reported later.

Two sets of modeling scenarios are carried out at the UJC project reach. The first set of model runs is for model calibration and validation using the 2009 "Pre-erosion" baseline condition (named "*Pre_E*"). The *Pre_E* runs use the 2009 terrain as the initial bathymetry and the 2009- 2011 three-year hydrograph is simulated. The predicted 2011 topography is compared to the measured 2011 terrain data. The second set of runs applies the calibrated model for assessing the impact of design construction on stream morphology. Two scenarios are simulated: the 2011 "post-erosion" condition (named "*Post_E*") and the 2012 "Proposed Design" condition (named "*Design*"). The *Post_E* runs utilize the 2011 terrain as the initial bathymetry while the *Design* runs adopt the design condition topography of the UJC river rehabilitation project as the initial bathymetry. The morphological changes under *Post_E* and *Design* conditions are simulated with the same three-year hydrograph as the *Pre_E* condition. Since the topography of the proposed design condition was close to the 2011 terrain, and all model parameters are the same, a comparison of the *Pre_E* and *Design* modeling results provides the necessary data to assess the impact of the proposed design condition on future channel morphology. Note that only a three-year hydrograph is used so prediction of the form of the long-term equilibrium channel has not been attempted. Also note, the actual "As-built" or "constructed" topography was not evaluated for this study.

Solution Domain, Mesh and Initial Terrain The solution domain and one of the meshes developed for the present study are shown in Figure 1a. The solution domain is about 4,000 feet in channel length and averages 700 feet in width. The meshes are generated using Surface-water Modeling System (SMS) software. Two meshes are generated corresponding to the calibration and application modeling runs. The same mesh is used with *Post_E* and *Design* scenarios so that the differences of the model results are due mainly to the *modifications* introduced by the design condition. Meshes consist of mixed quadrilaterals and triangles with a total of 18,414 and 19,119 cells, respectively, for the *Pre_E* and *Post_E/Design* scenarios. There are three initial terrains for all modeling runs: the 2009 pre-erosion (*Pre_E*); the 2011 post-erosion (*Post_E*); and the proposed 2012 design condition (*Design*) scenarios. A 3D perspective view of the initial terrain for the *Design* scenario is shown in Figure 1b.

Flow Resistance and Bed Gradation The flow resistance and initial bed/subsurface sediment gradation are the two major inputs to the model. The flow resistance is computed with the Manning's roughness equation. In this study, the Manning's coefficient (*n*) is based on estimation from previous studies on the Trinity River. The solution domain is divided into three zones (Figure 2) and *n* for each zone is assigned as: 0.035 for the main channel and the bare floodplain, and 0.085 for the vegetation zone. The bed and subsurface sediments in the main channel are based on field survey data and divided into two layers. The surface layer has a thickness of 0.65 ft and the subsurface layer has an infinite thickness. The gradations of the two layers are similar, with a medium diameter about 29 mm (Figure 3a). The bare floodplain is assumed to be uniform with a sediment gradation as the subsurface layer of the main channel. Only deposition is allowed in the vegetation, so no bed gradation is needed.

(a) Sediment Gradation (a) Daily Discharge Hydrograph

Figure 3 Bed and subsurface sediment gradation in the main channel and daily flow discharges from April 29, 2009 to September 3, 2011 at the Upper Junction City site

Boundary Conditions and Other Model Inputs Time-accurate unsteady simulations are carried out using the daily mean flow hydrograph from April 29, 2009 to September 3, 2011 (USGS gaging station 11526250), which includes three spring runoff events (Figure 3b). This hydrograph is used as the upstream flow boundary condition for all model runs. Sediment load is needed as another upstream boundary condition. Sediment rating curves developed by the Trinity River Restoration Program, based on the 2006-2007 sediment data at the Douglas City site of the Trinity River, are used. Water surface elevation (stage) is needed as the downstream boundary condition. A stage-discharge rating curve is developed using HEC-RAS modeling results for a much larger reach and is used as the boundary condition.

A total of nine sediment size classes are used to represent bed materials ranging from 0.25 to 181 mm in size. The Trinity sediment transport capacity equation developed by Gaeuman et al. (2009) is used as the equilibrium rate. The Trinity capacity equation is a modified version of the equation developed by Wilcock and Crowe (2003). For a sediment size class *k*, it may be expressed as:

$$\frac{q_{t,k}^{*} g(s-1)}{(\tau_b / \rho_w)^{1.5}} = p_{ak} G(\phi_k); \qquad \phi_k = \frac{\theta_k}{\theta_r}\left(\frac{d_k}{d_{50}}\right)^{\alpha_k} \tag{1}$$

where $q_{t,k}^{*}$ is the volumetric sediment transport rate per unit width, p_{ak} is the volumetric fraction of sediment size class *k* on the bed surface, $s = \rho_S / \rho_w$, ρ_w and ρ_S are the water and sediment density, respectively, *g* is the gravitational acceleration, τ_b is the bed shear stress, $\theta_k = \tau_b / [\rho_w g(s-1)d_k]$ is the Shield's parameter of sediment size class *k*; θ_r is the reference Shield's parameter, d_k is the diameter of sediment size class *k*, and d_{50} is the median diameter of the sediment mixture in bed. The function in the transport equation is expressed as:

$$G(\phi) = \begin{cases} 14.0(1 - 0.894/\phi^{0.5})^{4.5} & \phi \geq 1.35 \\ 0.002\phi^{7.5} & \phi < 1.35 \end{cases} \quad (2)$$

Two parameters must be defined to apply the above equation: θ_r and α_k. The parameter θ_r is a reference value above which sediment is mobilized and α_k is the exposure or hiding factor to account for reduction in critical shear stress for larger particles and increase in critical shear stress for smaller particles The standard Trinity equation used the following values:

$$\theta_r = 0.021 + 0.0155\exp(-20F_s) \quad (3a)$$

$$\alpha_k = 1 - \frac{0.7}{1 + \exp(1.9 - d_k / 3d_{50})} \quad (3b)$$

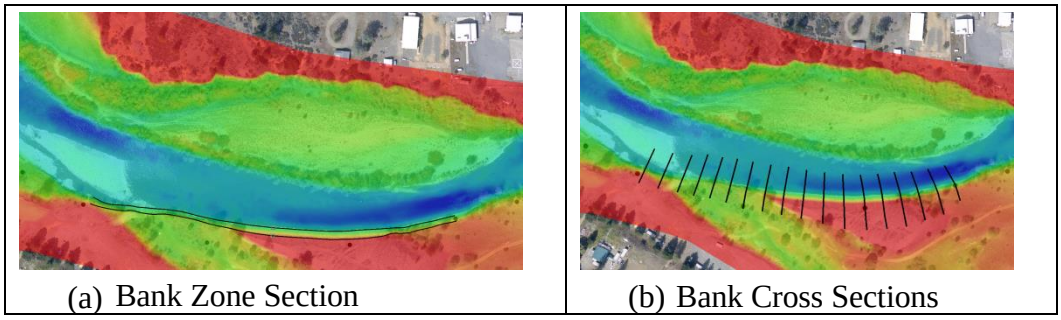
where F_s is the fraction of sand on the bed surface (the cutoff diameter of the "sand" may range from 1 to 4 mm). In this study, a constant reference value $\theta_r = 0.035$ was used. As a comparison, the Wilcock-Crowe (2003) equation used the following default values:

$$\theta_r = 0.021 + 0.015\exp(-20F_s) \quad (4a)$$

$$\alpha_k = 1 - \frac{0.67}{1 + \exp(1.5 - d_k / d_{50})} \quad (4b)$$

Other model inputs included the following. The time step is five seconds, mainly for numerical stability control. The active layer thickness is 0.15 ft, about five times d_{50} and 1.5 times d_{90}. The bedload adaptation length is based on the work of Lai (2013) derived from Seminara et al. (2002); other runs used a constant adaptation length of 80 meters.

Bank Module Inputs Additional input parameters are related to the bank properties for a coupled morpho-dynamic and bank erosion modeling. A section of the river left bank is selected for bank retreat modeling (Figure 4a) with sixteen bank cross sections simulated over six-hour time steps (Figure 4b). Field data collected by Cardno ENTRIX (2012) showed that the selected bank section consisted of essentially uniform and non-cohesive materials. A linear retreat bank module for non-cohesive materials, therefore, is used for the model, and the key input parameters are the critical shear stress and erodibility of each bank. In this study, both the critical stress and erodibility were estimated by Cardno ENTRIX (2012), and no attempt is made to improve the model prediction of bank retreat by changing either parameter.



(a) Bank Zone Section (b) Bank Cross Sections

Figure 4 The bank zone section (left) and bank cross sections (right) selected for bank retreat modeling under the *Pre_E* scenario (black lines on the left figure show the bank toe and top)

RESULTS OF CALIBRATION STUDY

Model runs, with and without bank erosion modeling, are made under the *Pre_E* condition for model calibration and validation. The predicted net erosion and deposition depth during the 2009-2011 time period is shown in Figure 5 and is compared with the measured data (left three figures). The survey data suggested that three pools, marked as "Pool 1," "Pool 2" and "Pool 3," were subject to deposition while a section of the left bank, marked as "Bank Erosion," experienced significant bank erosion. The zoom-in views of the same plots are displayed on the three right figures. In addition, the predicted bed elevation changes at the deepest points of Pool 1 and Pool 2 are plotted in Figure 6.

The results show that erosion on the left bank cannot be predicted without using the bank module, but is predicted reasonably well when the bank module is used. The model predicts that the eroded bank sediments are deposited in the stream near the bank and are not transported very far downstream. More than 50% of the eroded bank sediments are large gravels and small cobbles that are difficult to entrain once deposited in the stream. Therefore, the impact of the eroded bank sediments on the downstream half of the reach is relatively small. Upstream of the bank erosion zone, the with- and without- bank model runs produce similar results. Therefore, the without-bank run may also be used to assess the model capability to predict the riffle-pool

processes at this site.

Two major discrepancies are identified between the model predictions and measured sediment. First, the model predicts much more deposition than the measured data in three pools. Second, the riffle erosion downstream of Pool 2 is not predicted by the model. The predicted bed elevation changes at the deepest points of the first two pools are plotted in Figure 6. A total of five and eight feet of deposition are predicted in Pool 1 and 2, respectively; the corresponding measured depositions are approximately 2.2 and 3.2 feet. The over-prediction of the pool filling process is a consistent problem with any depth-averaged numerical models because such models do not take the horizontal vortices into consideration (Logan et al., 2010). 3D models may have the potential to improve the predictions; but this is yet to be proven. Other factors might contribute to the over-prediction of the pool filling process. High uncertainty in the initial bed gradation specification of the riffle areas is one of them. Over-prediction of erosion at riffles might lead to increased deposition in the downstream pool. The sediment transport capacity equation may also be the cause of the poor predictions, as most existing equations are based on reach-averaged or depth-averaged variables.

Model results show that riffle erosion downstream of Pool 2 is predicted after the 2009 and 2010 runoff seasons; the area, however, changes to depositional after the 2011 runoff. The reason for the failure of the numerical model to predict the riffle erosion in the area is unclear. Possible causes include potential inaccuracy in the initial bathymetry and/or bed gradations, neglecting the impact of bank vegetation, or overestimating of the upstream sediment supply at high discharges. We speculate that the most likely cause is the mature vegetation along the nearby right bank which was inundated only during high discharges in 2011 but not represented by the model.

Downstream of the bank erosion zone, model results are less accurate because of uncertainty in the accuracy of the stage-discharge rating curved used to define the downstream boundary condition.

ASSESSMENT OF PROJECT IMPACT

Description of Project Impact Assessment Runs The calibrated model is next applied to assess the impact of the rehabilitation project on stream morphology at the UJC site. It is expected that the pool-filling processes would not be well predicted but processes such as bank erosion; the side channel filling with coarser sediments; and vertical stream bed change downstream of the

pools would be predicted reasonably well. Two scenarios are simulated: the 2011 post-erosion condition (*Post_E*) and the 2012 design (*Design*) condition. The two use the same model inputs except for the initial terrain. Therefore, the differences of results between the two are due to the modification for the design topography at the UJC rehabilitation project.

Summary Findings The predicted net erosion and deposition during 2009 through 2011 for the two scenarios are compared in Figure 7, and Figure 8b shows a zoomed-in view of the *Design* run. The differences of the predicted net erosion and deposition between the two runs are plotted in Figure 9b. Positive depth in Figure 9b means that the bed elevation of the *Design* scenario is lower than that of the *Post_E* scenario. The following conclusions may be drawn based on the model results (for location terminology, refer to Figure 8a):

- Deposition was predicted in both the left and right side channels, as seen in Figure 7b. The model results after 2009 and 2010 runoffs are further plotted in Figure 9a. A comparison of the predicted deposition in the two side channels between Figure 9and Figure 7b shows that the predicted deposition occurred mainly during the 2011 runoff event. The peak discharge is 6,040 cfs and 7,520 cfs, respectively, in 2009 and 2010; while the peak is 12,900 cfs in 2011. Therefore, the predicted side channel deposition is mainly due to flows higher than 12,000 cfs.
- The only side channel deposition that might be of concern for the project is the entrance zone of the downstream right side channel. Increased deposition is expected with flows higher than 12,000 cfs.
- The predicted side channel deposition may not be a concern for other locations in the two side channels. With regard to the upstream left side channel, the entrance to the side channel is predicted to erode (Figure 8b) if the initial bed materials in the entrance are the same as the main channel (d_{50}=29 mm). However, much coarser sediments were used in this area when the project was built in 2012. Slight deposition is predicted downstream of the entrance zone in the left side channel (including the pool). However, only fine sediments, less than 10 mm, are deposited. For the downstream right side channel, deposition is limited to the entrance and three side channel pools. Again, only fine sediment deposition is predicted, and they are not considered to be of concern.
- A major potential impact of the design condition (*Design*), based on the model results, is that the main channel downstream of the designed island could experience deposition in some areas and erosion in others (see Figure 9b). However, the left bank zone is not predicted to experience higher rate of lateral erosion than the 2011 post-erosion condition due to the design condition (compare results in Figure 7). On the contrary, the *Design* is predicted to lead to slightly less bank erosion. Less deposition in the stream near the bank erosion zone is probably due to less bank erosion predicted with the *Design* scenario. Note that the model does not consider other bank sections.
- The model predicts some deposition in the channel to the left of the designed island and erosion in the channel to the right. In view that the 2011 *Post_E* scenario is predicted to be erosional in the same area, erosion in the right spilt channel may not be a concern. The deposition on the left split channel might be an important risk to consider since the deposited sediment sizes are not small. The model predicts that sediment deposited in the left split channel will have a d_{50} of around 15 to 17 mm.

CONCLUDING REMARKS

A coupled morpho-dynamic and bank erosion model is carried out for the Upper Junction City (UJC) rehabilitation project on the Trinity River. The objectives of the study are twofold. First, the study is to test SRH-2D geofluvial modeling capabilities and verify whether the bank erosion module can correctly simulate observed bank erosion in study area. Second, after model calibration, SRH-2D is applied to assess the impact of the UJC rehabilitation project on channel morphology.

Calibration and validation modeling runs are carried out by comparing the 2011 measured terrain data with predicted topography obtained by simulating changes to the 2009 pre-erosion baseline (PB) condition caused by 2009 through 2011 hydrology. The necessary bank erosion model inputs, mainly the critical shear stress and erodibility, are estimated from the field measurements. The geofluvial SRH-2D model is shown to be capable of predicting bank erosion and bed level changes. The model can predict pool-filling processes only qualitatively.

The SRH-2D is also applied to assess the impact of the rehabilitation project on channel morphology. Due to potential uncertainties of numerical models, only a relative comparison can be made between the two scenarios. Relative comparisons are often more accurate than the absolute prediction with channel morphology changes. The model results have led to a number of important conclusions with regard to the impacts of the design on stream morphology.

BATTLE CREEK: LESSONS LEARNED FROM TINKERING AT A CONFLUENCE

Steven E. Yochum, Hydrologist, US Forest Service, National Stream & Aquatic Ecology Center, Fort Collins, CO, steveneyochum@fs.fed.us

prepared for the 10th Federal Interagency Sedimentation Conference
April 19-23, 2015, Peppermill Hotel, Reno, Nevada, USA

Abstract

In the Autumn of 2008 a stream restoration project was constructed in Battle Creek just above the confluence with the Little Snake River, on the border between Colorado and Wyoming. Relevant structures were cross vanes and stream barbs, with the objectives apparently being bank stabilization and habitat enhancement for game fish. After construction, floods occurred in 2009, 2010, and 2011, including a 100-year flood in the Little Snake. With this flooding, a substantial volume of sediment was deposited in the vicinity of the Battle Creek cross vanes, forcing a channel avulsion and rapid bank erosion along multiple reaches. A review was performed to determine the likely causes of this problem. Based on a site assessment, an evaluation of historic aerial imagery, and a hydraulic model, it was concluded that the installed structures did not cause the sediment deposition and resulting bank erosion. Decreased sediment transport capacity due to backwater effects imposed by the Little Snake flooding was most likely the cause of the deposition, with the problem compounded by riparian grazing reducing the quality of the vegetative condition. Structural measures should not have been installed on Battle Creek in the vicinity of the confluence due to periodic aggradation induced by Little Snake River flooding. While these structures likely did not worsen the aggradation problem, they also provided little benefit since bank destabilization is primarily the result of backwater-induced sediment deposition and insufficient vegetative cover. Instead, riparian fencing and grazing management should have been the focus, to encourage robust riparian vegetation growth that can resist destabilization induced by the periodic sediment deposition. This project illustrates an example where livestock management should have been the core approach used in riparian restoration, rather than an engineered approach; more detailed analysis and planning by a stream-focused group of specialists was needed early in this project.

INTRODUCTION

Of particular need in the stream restoration community is enhanced understanding of where structural bank stabilization measures are needed versus where livestock grazing management alone is instead adequate to address instability issues. To help inform a discussion of this issue, this case study of a bank stabilization project constructed in 2008 on Battle Creek, in Northwest Colorado, was developed. This reach of Battle Creek is immediately upstream of its confluence with the Little Snake River. Key project features were two cross vanes constructed in Battle Creek; one stream barb constructed in Battle Creek; and one additional cross vane constructed on the Little Snake downstream of the confluence. Riparian grazing management was not included as a part of this project. Following construction, floods occurred in 2009, 2010 and 2011, including a 100-year flood in the Little Snake. With this flooding, a substantial amount of sediment was deposited on and just upstream of the upper cross vane installed on Battle Creek, which forced a stream channel avulsion and rapid bank erosion. An additional bar was deposited downstream of this location, on the west bank between the two cross canes, with a second

rapidly-eroding bank on the opposite bank. An investigation was performed to develop an understanding of how this problem could have been avoided. This paper provides an overview of the condition of this stream reach, as well as a historical and analytical assessment of dominant fluvial geomorphological processes that led to the resulting undesired state. From this postmortem assessment, conclusions are drawn to reduce the chances that such a result will be repeated in similar future situations.

ASSESSMENT METHODS

The stream condition was assessed and a forensic analysis was performed using a combination of methods, including a visual assessment of current geomorphic and hydraulic condition, identification and elevation measurements of high flow indicators, a flow frequency analysis, historic aerial photo interpretation, a greenline vegetation assessment, topographic surveying, and hydraulic modeling.

The flow frequency analysis for the Little Snake was performed using a logPearson analysis of streamgage records. For Battle Creek, a regional regression approach was implemented (Capesius and Stephens, 2009), through the Streamstats web application. Historic aerial photos were downloaded from the U.S. Geological Survey's Earth Explorer (http://earthexplorer.usgs.gov) and orthorectified in ArcGIS. The Greenline vegetation assessment was performed using the methods presented in Burton et al. (2011). Topographic surveying was performed using Trimble survey-grade GPS, with an Online Positioning User Service (OPUS) solution used to establish the benchmark.

The hydraulic analysis was performed using 1-dimensional gradually-varied flow modeling, using HEC-RAS. To assess the impacts of backwater effects on sediment transport, stream power and shear stress were computed within the reach of interest in Battle Creek. The sediment transport rate is directly proportional to stream power and shear stress, with reductions in these variables reflecting decreased sediment transport capacity and the potential for sediment deposition. This deposition causes channel aggradation and bank instability. Stream power is computed as $\Omega = \gamma Q S_f$, where Q is the discharge, γ is the specific weight of water, and S_f is the friction slope. Average boundary shear stress is computed as $\tau = \gamma R S_f$, where τ is the shear stress and R is the hydraulic radius. Backwater effects cause a reduction in energy slope, which reduces stream power and shear stress. This in turn reduces the sediment transport rate, causing deposition and aggradation. Channel flow resistance, as Manning's n, was estimated using photographic guidance (Barnes, 1967; Aldridge and Garrett, 1973) as well as through the use of a quantitative approach (Jarrett, 1984).

STREAM CONDITION

On-the-ground conditions were documented in April and June of 2012. With a drainage area of 302 mi^2 at the Battle Creek confluence, the Little Snake River is a snowmelt-dominated stream that drains portions of Northern Colorado and Southern Wyoming. Average annual precipitation varies from 19 to 55 inches (from PRISM; Daly et al., 2008). Battle Creek, at its confluence with the Little Snake, has a drainage area of 83.3 mi^2 and average annual precipitation that also varies from 19 to 55 inches. Both streams carry a substantial quantity of sediment load, with frequent bars within the channels (Figure 1 and 2). Both the Little Snake and Battle Creek have a mature

cottonwood gallery. Battle Creek enters the Little Snake with an atypical upstream orientation. Substantial sediment deposition is evident in Battle Creek just above the confluence (Figure 2). Combined with the impacts of grazing practices on riparian vegetation, this deposition resulted in rapid bank erosion rates that are problematic for the landowner.

In the Autumn of 2008 a project was constructed in Battle Creek and the Little Snake River, in vicinity of the confluence. The objectives of this project were unclear in the project documentation, but apparently the principle objectives were streambank protection and fish habitat enhancement. The project consisted of a series of cross vanes, J-hook vanes and other barbs, and minor channel realignments. Key features relevant to Battle Creek are: two cross vanes constructed in Battle Creek and one stream barb constructed in Battle Creek, armoring the channel with a continued upstream confluence orientation; one cross vane constructed on the Little Snake downstream of the confluence (Figure 2), and a few willow clump transplants along Battle Creek. During the next three years, out-of-bank flow occurred each year.

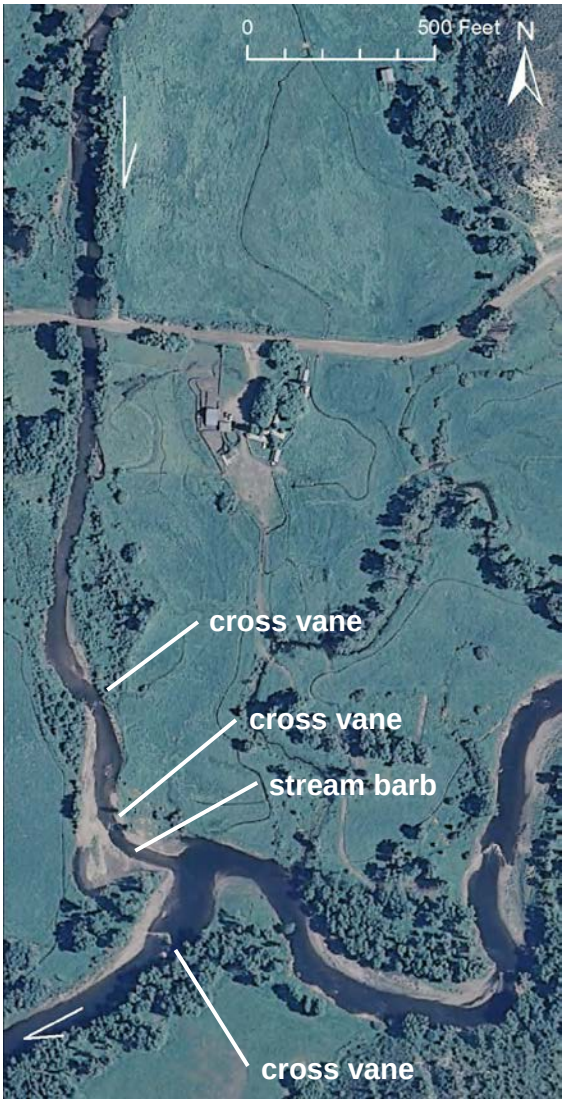

Figure 1: Battle Creek at the Little Snake River confluence (7/23/2009).

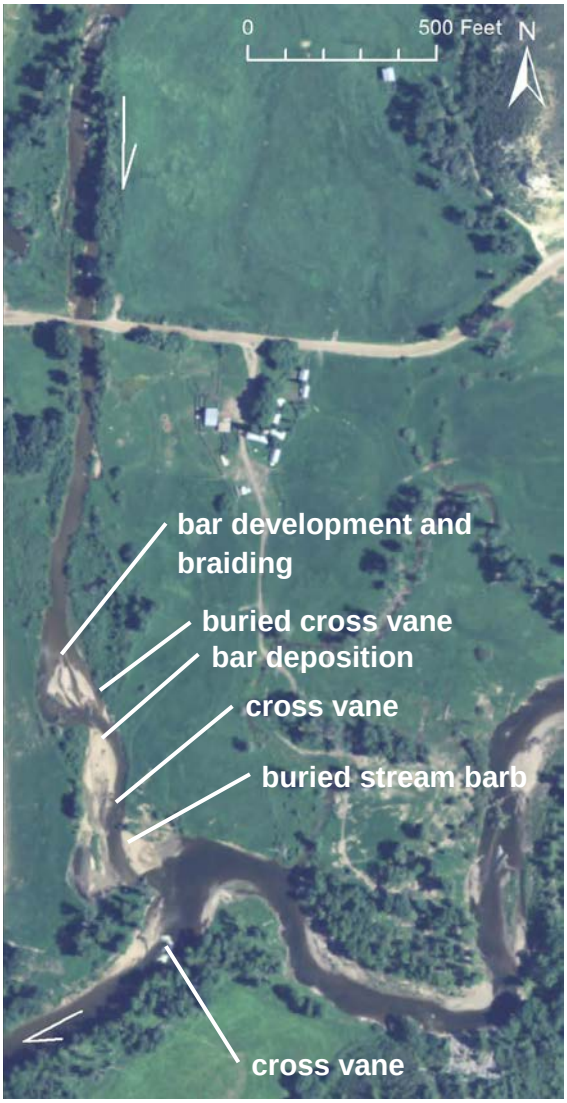

Figure 2: Battle Creek at the Little Snake River confluence (7/23/2011).

A substantial amount of sediment was deposited on and just upstream of the upper cross vane installed on Battle Creek (Figures 2 and 3). This local aggradation extends for a length of about 200 feet. This deposition forced an avulsion of the stream channel to the west of its previous location (Figure 1). The channel has a braided form within this short extent, with the preferential flow channel currently on the west edge of this depositional bar. A meander bend and point bar is forming to the east of this channel. In the vicinity of this depositional bar, both sides of the channel have willows along much of the banks, but coverage is patchy with grazing apparent on both banks, negatively impacting willow- and sedge-induced bank stability. The streambank on the west side of the depositional bar, adjacent to the principal flow channel, is actively eroding (Figure 4). A few of the patchy willows that were once present along this bank were laying in the channel. The fenceline and aerial imagery indicate rapid bank erosion rates.

An additional bar has been deposited downstream of this location, on the west bank between the two cross canes (Figures 2 and 5). Opposite this point bar, a second rapidly-eroding bank is present (Figures 5) as the stream attempts to increase its meander planform. A cross vane that appears to be functioning properly is located just downstream of this eroding bank. No willows are present on this bank. The aerial imagery (Figures 1 and 2) indicate that this bank is not eroding as quickly as the upstream bank. Heavy grazing was apparent along this bank, along with indications of additional feeding in this pasture.

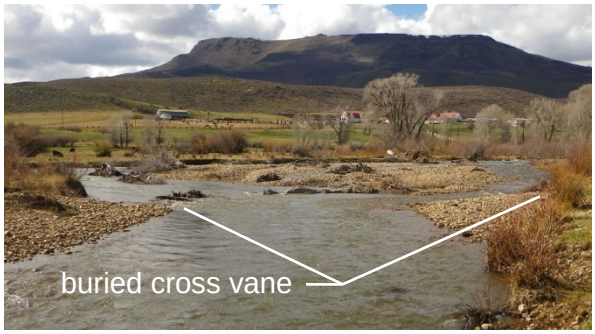

Figure 3: Upper cross vane, with sediment deposition and braiding just upstream.

Figure 4: Rapidly-eroding streambank adjacent to depositional bar.

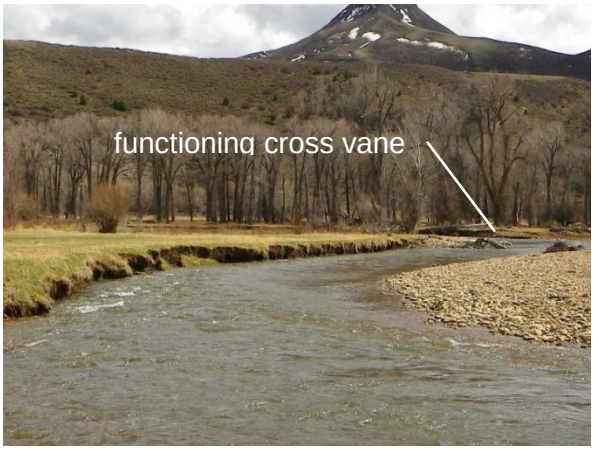

Figure 5: Rapidly-eroding streambank, opposite of an additional depositional bar.

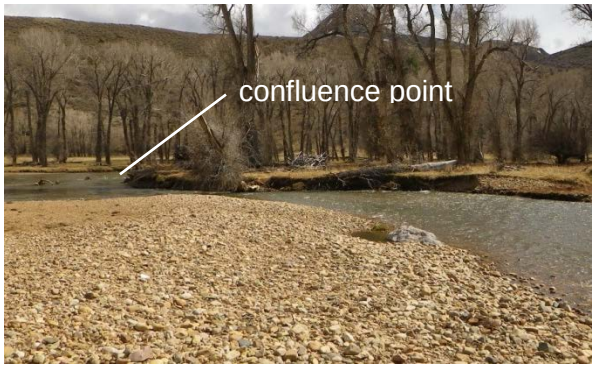

Figure 6: Confluence bar, with variable bed material size.

The third and final depositional bar is at the confluence (Figures 2 and 6), with the bar extending from north to south across the constructed channel location. This bar consists of multiple sediment sizes, with coarse material deposited on fines. A portion of a stream barb can be seen protruding from the bar (Figure 6). The growth of this bar mirrors the erosion of 20 to 30 feet of the confluence point between 2009 and 2011. Alongside this erosion the pool in the Little Snake just upstream of the confluence has been reported to have filled substantially. Additionally, flood debris is present on the fenceline on the west side of Battle Creek, showing the approximate high flow elevation for the Little Snake in 2011.

RESULTS AND DISCUSSION

Flood-Frequency Analysis

On the Little Snake, a streamgage (USGS 09253000, Little Snake near Slater, CO) is located approximately 5 miles upstream of the confluence, measuring discharge from 253 mi^2 (compared to 302 mi^2 at the confluence). With 65 years of record, the results of the log-Pearson flow-frequency analysis are provided (Table 1). A 1.5-year event, which is likely similar in magnitude to the bankfull discharge, is about 1700 cfs. Peak flow typically occurs from mid-May through early June. In 2011, peak flow of 4890 cfs occurred on June 6th. This was a ~100-year flood. In 2010, peak flow of 3230 cfs occurred on 5/29/2010, which is between a 5- and 10-year flood. In 2009, peak flow of 2710 cfs occurred on 6/3/2009, which is between a 2- and 5-year flood.

Flow frequency results for Battle Creek, from Streamstats, are provided (Table 1). With prediction errors ranging from 74 percent (100-year) to 110 percent (2-year) and application of the StreamStats equations to the Little Snake streamgage indicating accurate estimates of frequent events and substantially underestimated infrequent events, confidence in these estimates is moderate throughout the return interval range. Extrapolated from these estimates, a 1.5-year event is about 600 cfs. Rick Dornfeld, of River Fixer LLC, estimated bankfull flow to be about 500 cfs (Dornfeld, 2008). A streamgage was operated on Battle Creek (USGS 09253400, Battle Creek near Encampment, WY) approximately 15 miles upstream of the confluence. It measured discharge from only 13 mi^2 of the total 83.3 mi^2 catchment. This gage was operated from 1956 to 1963 and 1985 to 1988. While not relevant for computing flow frequency at this site, these data do indicate that peak flow timing occurs from mid May through early June, similar to the Little Snake. Local SNOTEL snowpack monitoring sites (Battle Mountain, 317; Sandstone RS, 732) indicate that Battle Creek peaked a bit later than average in 2011 and a bit earlier than average in 2010.

Table 1: Flow-frequency estimates for Battle Creek and the Little Snake River.

Return Interval (years)	Battle Creek (cfs)	Little Snake River (cfs)	Peak Flow Years in Range
1.25	----	1490	
2	660	2200	
5	1030	3090	
10	1260	3610	1943, 1952, 1957, 1958, 1997, 2008, 2010
25	1610	4210	1974, 1995, 1996
50	1850	4610	1983 (~25-year flood)
100	2140	4980	1984, 2011

Historic Aerial Photography

An important component of an assessment is an understanding of the historical range of variability; understanding the range of variability of past conditions can provide insight on what future conditions can be expected. Aerial imagery from 1953 to 2004 is illustrated (Figure 7 to 10). Throughout this 58 year record Battle Creek and the Little Snake have fairly consistent morphology but some interesting cycles and shifts in form are observable.

Over this period, the aerial images indicate cyclic sediment deposition and vegetative colonization along the last 1000 feet of Battle Creek upstream of the confluence. In 1953 (Figure 7), an upper depositional bar is apparent in Battle Creek (orange oval). This bar is in a similar location as the bar deposed in 2010 and 2011. A couple of small unvegetated bars are also visible in the lowest portion of Battle Creek (red circle). By 1968 (Figure 8) the upper depositional bar (orange oval) has become well vegetated though an avulsion across the bar is visible. Flow appears to be split at this point in time. The lower depositional bar has enlarged a bit, with a short series of exaggerated meanders at the confluence. Between 1968 and 1980 (Figure 9) the (streamwise) left channel has filled in the formerly unvegetated upper bar (orange oval) and Battle Creek flows in a single, relatively strait channel through this upper reach. This portion of the floodplain appears to be well vegetated. The increasing meandering form indicated in 1953 and 1957 straitened in 1968 and maintained this form in 1980. The lower depositional bar (red circle) has again increased in size and maintained little vegetative growth, with a growing point

Figure 7: Aerial image (8/23/1953).

Figure 9: Aerial image (7/28/1980).

Figure 8: Aerial image (9/1/1968).

Figure 10: Aerial image (8/4/2004).

bar and increasing meander extent along the well-vegetated confluence point (green oval). In 2004 (Figure 10), the upper reach in Battle Creek is again increasing its meander form while the meander at the lower reach (red circle) is becoming tortuous, as Battle Creek attempts to flank the dense stand of vegetation at the confluence point. Side bars are apparent in the upper reach. Following the flood events of 2010 and 2011, the 2011 image (Figure 2) shows Battle Creek above the confluence to be once again increasing its meander form and depositing substantial quantities of sediment in similar locations as those indicated in 1953 (upper depositional bar) and 1968 and 1980 (lower depositional bar). Some of the vegetated confluence point has eroded, despite the armoring provided by the dense vegetation. The cyclical sediment deposition, vegetative colonization, and erosion is likely due to decreased velocities, shear stress and stream power from backwater effects induced by the Little Snake, with the location varying due to relative peak flow timing, flood magnitude, and flood duration. This bar material is subsequently colonized by vegetation, with a slightly sinuous form repeatedly initiating and straightening.

Vegetation Assessment

A green line assessment (Winward, 2000) of the last ~1000 feet of Battle Creek, at the confluence with the Little Snake River, was completed on June 19, 2012. Plant communities were identified and quantified in three separate, 343 feet transects (two on the east bank, one on the west bank). Approximately 20% of the footage surveyed on the east side of Battle Creek consisted almost entirely of introduced cool season grasses, as part of a pasture. Upstream of this area, seedlings and young saplings of narrow leaf cottonwood, coyote willow, and other woody species, and herbaceous wetland plants (Carex spp. primarily), were encountered much more frequently. The west bank of Battle Creek included a large expanse of cobble and sand, and willow seedlings or sprouts, along with introduced cool season grasses. Some narrow leaf cottonwood sprouts/saplings and a few other mature woody species (shrubs) were also present in this area.

Percent composition of each community type was determined for the reach, and each community was assigned a stability class and index. A stability index of the reach was calculated. Overall, the stability of this reach is rated as moderate to poor. The plant communities were also assigned a successional rating, and a percent late seral type was calculated based on the capability group value of this stream type. Approximately 11 percent of the identified plant communities are classified as late seral, and the successional status of the reach was determined to be very early seral to early seral.

A woody species regeneration assessment was also completed by evaluating numbers of seedlings, sprouts, mature, decadent, and dead woody species in each of the two transects on the east bank of Battle Creek, just upstream of the confluence with the Little Snake. Numerous seedlings and young saplings (123 or 75% of total number of individuals) of narrow leaf cottonwood and coyote willow were found, primarily upstream of the pasture area. Several moderately to severely grazed individuals of these species were also found. A few dead individuals were noted. Approximately 41% of all individuals were browsed, which is considered moderate grazing pressure. The woody plant community of the area upstream of the pasture is healthy in that numerous seedlings and saplings were found, but grazing pressure, if continued, could slow recovery. Few woody plants were found adjacent to the pasture area.

The cottonwood gallery along the Little Snake at the confluence with Battle Creek was not quantified, but observed. It appears to consist of numerous seedlings, sprouts, and young trees, several large mature trees, and a few dead trees. This community appears healthy.

Hydraulic Modeling

For this assessment, a relatively-simple model was created for Battle Creek from the bridge to the confluence for ~bankfull flow, as well as the 10-year and 100-year flows. Eighteen cross sections were implemented. The downstream boundary condition was assumed to be the peak water surface elevation in the Little Snake, as indicated by flood debris. This elevation was 6694.5 feet. The estimated Manning's *n* values for this reach are provided (Table 2).

Table 2: Battle Creek channel Manning's *n* estimates. Implemented *n* = 0.040.

	Manning's *n*
Barnes 1967	0.045
Aldridge and Garrett 1973	0.040
Jarrett 1984	0.025
Average:	0.037

Modeled stream power and shear stress for the ~bankfull, 10-year, and 100-year flows in Battle Creek are illustrated (Figure 11 through 13). In all tested cases, stream power and shear stress decrease substantially at the point where deposition in the stream channel occurred in 2010 and 2011. Since sediment transport capacity is directly proportional to stream power, the modeling results indicate that the sediment deposition (and subsequent bank instability) is the result of backwater effects from the Little Snake reducing flow velocity and sediment transport capacity.

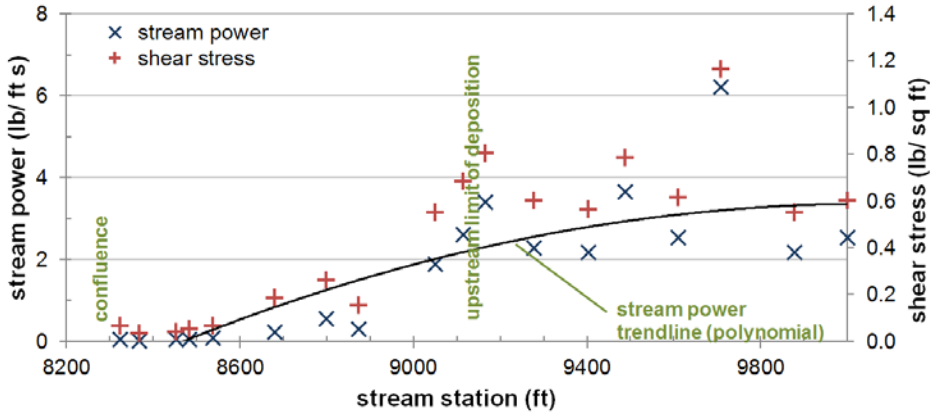

Figure 11: Modeled stream power and shear stress, ~bankfull flow in Battle Creek.

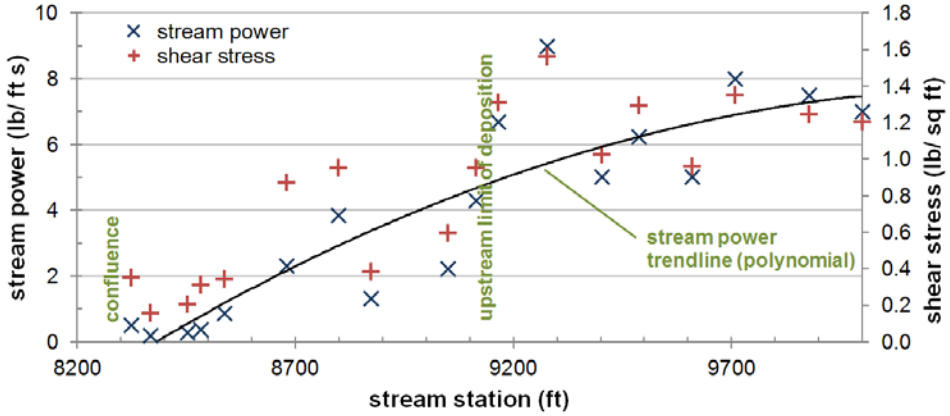

Figure 12: Modeled stream power and shear stress, 10-year flow in Battle Creek.

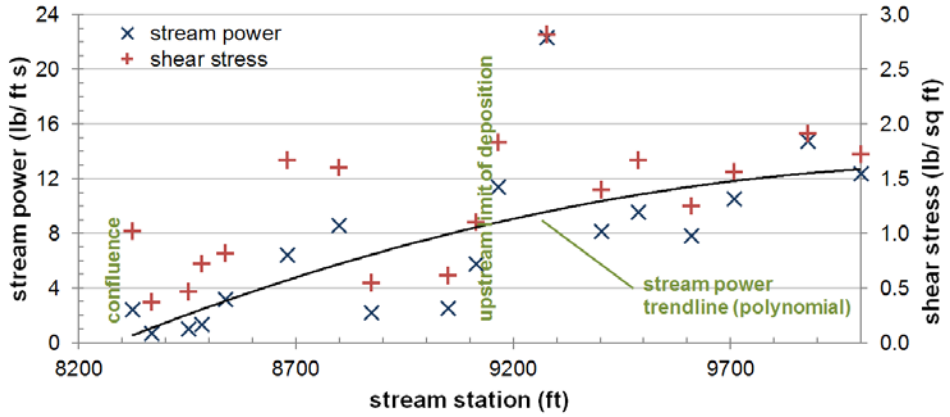

Figure 13: Modeled stream power and shear stress, 100-year flow in Battle Creek.

Interpretation of Dominant Mechanisms

Observations of current conditions, a historic aerial photography interpretation, and hydraulic modeling indicate that the Battle Creek aggradation problem and resulting bank instability that occurred since the structural stabilization measures were installed in 2008 are likely the result of backwater effects from high flow on the Little Snake River. Specifically, during high flow increased water surface elevations in the Little Snake result in increased flow depths and decreased velocities, shear stress, and stream power for the portion of Battle Creek immediately above the confluence. In turn, this results in reduced sediment conveyance capability and bedload deposition throughout the reach of concern. This deposition then encourages channel bank erosion, as new flow paths form through the deposited material. Bank erosion is facilitated by grazing practices that have discouraged robust and diverse vegetative growth along portions of the reach. The upstream-oriented confluence and Little Snake cross vane both cause increased water surface elevations at the confluence, worsening the problem.

Structural measures should not have been installed on Battle Creek in the vicinity of the confluence. While these structures likely did not worsen the aggradation problem, they also provided little benefit since bank destabilization is primarily the result of backwater-induced sediment deposition and insufficient vegetative cover. Instead, riparian fencing and grazing management should have been the focus of the Battle Creek portion of this project, to encourage robust vegetation growth that can resist destabilization induced by the periodic sedimentation. Additionally, a much more substantial revegetation component should have been included in the project.

Review of historic aerial imagery and development of hydraulic modeling prior to the project implementation would have indicated the problematic nature of stream work on Battle Creek just above the confluence. Review of the recent aerial imagery would have also shown that the channel had been recently relocated. This work should have been performed by qualified staff during the planning phase of the project. The lack of such planning resulted in the needless use of limited restoration funding, highlighting the importance of proper planning by staff with the expertise to understand fluvial processes and riparian vegetation.

CONCLUSIONS

A postmortem was performed on a failed streambank stabilization project, to assess the most likely causes. Using the results of a site assessment, a greenline vegetation assessment, an evaluation of historic aerial imagery, and hydraulic modeling, it was found that the installed project did not address the cause of the bank instabilities. These structural features on lower Battle Creek should not have been installed, due to periodic aggradation induced by backwater effects from the Little Snake during flood flow. Instead, riparian fencing and grazing management, combined with a revegetation component, should have been the focus of the project within this reach. Proper project planning by qualified staff could have identified the most appropriate strategy for addressing the landowners resource concerns prior to project implementation; this project illustrates the need for specialists to be available for the proper implementation of stream projects, to reduce the inefficient use of government funds.

ACKNOWLEDGEMENTS

David Levinson is appreciated for reviewing this manuscript. Theresa McGovern and Lori Jazwick performed the greenline assessment of vegetative condition; their efforts and Theresa's included summary was a valuable addition to this report. Field assistance was provided by Adam Dossett, Joe Messina, Clay Thompson, Megan Vasquez, and Justin Robbins. Their assistance was appreciated. Chris Gauthier, Vance Fulton, and Robert Molacek also contributed onsite insights to the stream condition. Additionally, coordination by Mark Shirley and Lori Jazwick was helpful.

Abstract: Global and climate changes, in addition to local land use changes, are altering hydrology that affects runoff and sedimentation. The U.S. Army Corps of Engineers (USACE) wishes to evaluate the effects of these changes to its project performance and reservoir storage capacity by updating reservoir sedimentation information (RSI, including sedimentation surveys, sediment load measurements, and other investigations related to sedimentation) to account for global and climate change. The goals of the current study are to assess the state of existing RSI, review and update existing methods and policies to support updated RSI, develop a strategy to update RSI, make broad estimations of the associated costs to update RSI, and prioritize needs for RSI updates.

Current RSI status was reviewed for five USACE districts using a list of specific RSI needs identified by the team of experienced engineers. Available RSI data were investigated and cataloged through interviews, site visits and conference calls with the selected districts. Costs were estimated to update RSI for the five districts and then extrapolated to the entire U.S. Army Corps of Engineers yields portfolio. This estimated amount would fill current data gaps, but does not include funding for ongoing RSI updates, which should also be considered. This amount also does not include any funds directed specifically at addressing impacts of global climate change on reservoir sedimentation, an issue which has not been considered in a significant way to date.

Additionally, a strategy was developed to update RSI that reflects new and changing conditions that impact the ability of RSI to meet intended objectives.

INTRODUCTION

Global and climate changes are altering hydrology that manifests as changes in the form (snow vs. rain), intensity (peak, seasonal, average), and duration of precipitation. In addition, ground state (frozen, saturated, unsaturated), evapotranspiration, and other factors have a significant effect on runoff. These changes may lead to and/or exacerbate modification of land use and land cover – including changing agricultural practices – that are major contributors to sedimentation in U.S. Army Corps of Engineers (USACE) reservoirs. The monitoring of sedimentation in USACE reservoirs is a vital part of a sustainable management plan for these projects. It is

essential that USACE establish baseline information on reservoir sediment levels and remaining storage capacity, and determine how future global and climate changes will impact sedimentation.

In 1981, USACE published Engineer Regulation (ER) 1110-2-4001, *Notes on Sedimentation Activities*. This regulation provides policy and guidance for the preparation of an annual report on sedimentation activities, including sedimentation surveys, sediment load measurements, and other investigations related to sedimentation. In 1989, USACE published Engineer Manual (EM) 1110-2-4000, *Sedimentation Investigations of Rivers and Reservoirs*, which provides details on the annual sediment report and also describes the Sediment Studies Work Plan (SSWP). The changes that have occurred over the intervening 30 years since the publication of ER 1110-2-4001 – especially changes in land use and land cover driving runoff and erosion – make it imperative that USACE update its understanding of the current state of reservoir sedimentation to support sustainable water management. Prioritizing reservoir sedimentation information (RSI) data gaps, and filling those gaps, is essential in developing a sustainable path forward while continually evaluating and adapting to future sedimentation impacts at all USACE reservoirs. Development of a RSI update and collection strategy will be vital to minimizing reservoir vulnerability to sedimentation impacts.

REVIEW AND ANALYSIS OF RSI

RSI Data Types: RSI study team members reviewed the current status of RSI within the five districts and analyzed the types of RSI, storage methods and organization. A team brainstorming session identified the types of RSI describing past or current conditions in district reservoirs. During this brainstorming session, the group identified a list of RSI datasets, shown in Table 1. The first four items on the list are considered the most important RSI items to fill district RSI data gaps and have the highest priority when funding requests are made. The other items have different levels of importance that depend on the authorized purposes of the district reservoirs, sedimentation issues, and overall RSI needs.

The RSI list was used as a guide during site visits and phone interviews with the districts. The following sections describe the RSI data collection methods and current RSI status by district.

RSI Data Collection Methods: During the initial review process, team members discussed RSI needs and a few districts provided a summary of their RSI status. The information was used to create RSI spreadsheet templates to be filled-in by district managers or staff participating in the study. The goal of the spreadsheets was to help account for and catalogue the RSI data for each district (including documenting the existence of sedimentation surveys, sediment load measurements, etc.) as well as present the information from various districts in a standard format. Apart from the data collection spreadsheets, interviews were conducted with five districts. During these interviews, the list of specific RSI needs (see Table 1) was used as a guide to help collect and characterize the state of the RSI.

Table 1 District Specific RSI Needs

Most important	1.	Topographic and/or Hydrographic Sedimentation Surveys – how collected, when, datum
	2.	Area-capacity analysis, changes with time
	3.	Aerial imagery/photography
	4.	Sediment samples/characteristics – cores vs. surface samples
	5.	Studies that include climate change
	6.	Sediment chemistry/quality
	7.	Project information (pools, authorized purposes, water control)
	8.	Anecdotal evidence/observations
	9.	Measured sediment load, inflow
	10.	Sediment rating curves
	11.	Gage/sediment gage locations, information
	12.	Sediment management activities (e.g., dredging, flushing, sluicing, etc.)
	13.	Past sediment studies
	14.	Sediment models
	15.	Volume depletion at different pools
	16.	Original design information
	17.	Funding over time, sources (especially alternative sources)
	18.	Sediment Studies Work Plan (SSWP)
	19.	Environmental factors driving data collection
	20.	Operational impacts, e.g., stage-frequency shifts, reallocation of pools/storage
	21.	Water surface profiles

RSI Spreadsheet Templates: Two types of spreadsheets were prepared for each district: (1) a Project Summary Form and (2) a set of individual project forms. The number of individual project forms matched the number of reservoir projects within a particular district (e.g., if a district has 35 reservoirs, then the set of forms contained 35 sheets). The following sections present a brief summary of the RSI spreadsheet templates.

Project Summary Form. The project summary form is designed to be a brief synopsis of all district projects. Table 2 describes some of the data fields included in the form while Figure 1 shows an example of the form (truncated).

A space is included at the bottom of each sheet to list any annual sedimentation reports, such as Notes on Sedimentation Activities, Sediment Studies Work Plan – SSWP, etc.

Table 2 Summary of RSI Spreadsheet Project Summary Form Fields

Data Type Field	Field Information
Authorized Project Purpose(s):	▪ Project authorized and/or operational purposes
Sediment Survey:	▪ Date of the latest and previous sediment surveys ▪ Survey method
Reservoir Pool and Spillway Information:	▪ Original reservoir storage ▪ Reservoir storage calculated from the most recent survey ▪ Volume lost between the original and most recent surveys ▪ Percentage loss between the original and most recent surveys
Permanent/Dead Storage:	▪ Permanent or dead storage volume (if applicable)
Sediment Allowance:	▪ Reservoir sediment allowance in years - number of years until reservoir is expected to be full of sediment and no longer operational

Figure 1 Project Summary Form Spreadsheet Example (truncated)

Individual Project Forms. Individual project forms were created for each project within a district and the files were named for that project. The forms are meant to include a more detailed summary of the RSI data for the project, including the data collection year, methods, and format in which the data are stored. There are two tabs within each individual project spreadsheet: (1) Project Information and (2) Data Types. Each of these sheets is described below.

(1) Project Information: The Project Information sheet includes a brief summary of the project. An example of the data sheet form is shown in Table 3. At the bottom of the form is space to list any data gaps, sources of funding, and an estimate of funding required to fill the gaps.

Table 3 Project Information Spreadsheet Example

Project Name:	Coldbrook							
Location of Reservoir/Dam								
Latitude:	43° 27' 14" N (Google Earth)							
Longitude:	103° 29' 21" W							
City, State, County:	Hot Springs, South Dakota, Fall River County							
Basin:	Missouri River/Cold Brook							
District:	Omaha – NWO							
Division:	Northwestern – NWD							
Dam Description								
Date of Dam Closure:	1953							
Type of Dam:	Rolled Earthfill							
Dam Length:	925 ft							
Top of Dam Elevation:	3675.0 ft (NGVD29)							
Drainage Area:	70.5 sq. miles							
Reservoir Surface Area:	(1972) 279 acres at elevation 3667.2 ft (NGVD29)							
Spillway Length:	200 ft							
Reservoir Pool Elevation	Main reservoir pools and maximum elevations (NGVD29)							
Flood Surcharge:	3667.2 ft							
Flood Control:	3651.4 ft							
Multipurpose:	3585.0 ft							
Spillway Pool:	Not applicable							
Storage Capacity	Storage capacity per latest survey (based on 1972 survey)							
Flood Surcharge:	10,898 acre-ft							
Flood Control:	7,250 acre-ft							
Multipurpose:	520 acre-ft							
Spillway Pool:	Not applicable							
Sediment Gage(s):	No sediment gages							
Authorized Project Purpose:	Flood Control	Navigation	Water Supply	Water Quality Control	Recreation	Hydropower	Flow Augmentation	Fish & Wildlife
	X				x			x
List data gaps: (1) There are no sediment data of any type or water surface profile data for this project. (2) Area & capacity tables for early survey years cannot be located. Tables for these years need to be recalculated. (3) Elevation data are presented in vertical datum NGVD 29. This data should be converted to NAVD 88 per USACE standards.								
Describe sources of funding, and provide an estimate of additional funding required to fill in the data gaps: Funding sources include O&M Base Line, O&M Non-Routine, and O&M End-Of-Year Reprogrammed Funds.								
Additional information (e.g. sediment management activities):								

(2) Data Types: The Data Types sheet includes a more detailed description of the RSI data for each project. The Year of Data Collection is included with a time sequenced history of sediment surveys and other RSI data. In addition to identifying the year of data collection and method, the type of format the data are stored in is also included, such as DSS, PDF, Excel, paper, etc. Data

fields included in the Data Types sheet are Topography & Survey, Aerial Imagery/Photography, Sediment Measurement and Sediment Chemistry/Quality. At the bottom of the each Data Types form is a list of relevant sediment reports and any related sediment models. An example spreadsheet is shown in Table 4.

DATA GAP SUMMARY

A review of the current status of District RSI was completed for five of the six districts participating in this study. The purpose of this phase of the study was to investigate and catalog the available RSI data through interviews, site visits and conference calls with the selected districts. A summary of findings by RSI category is provided in this section.

Summary by RSI Category. In general, the districts indicated that there has not been funding to support critical RSI needs or even to maintain a routine sediment survey schedule. None of the Districts interviewed have ever prepared a SSWP as outlined in EM 1110-2-4000 (1989). The original purpose of preparing a SSWP was to document and identify potential sediment problems, including reservoir sedimentation. These work plans were meant to be used at the district level to include cost estimates to complete routine sediment surveys or any other sediment study. Although SSWPs have not been prepared by the five districts interviewed, most prepare an annual report of sedimentation activities that is sent to the respective USACE division office. In general, these reports identify sediment activities for the year, and describe RSI needs for the upcoming year. The reports typically include associated costs for the critical RSI needs, or the estimates are included in the Operations and Maintenance Work Request in which RSI updates are prioritized by need for the upcoming year.

Sediment Surveys: Overall, districts have not had the funding to update topographic or bathymetric surveys (or both) on a regularly scheduled basis to estimate sedimentation rates as suggested in EM 1110-2-4000. However, over the last few years, the Omaha District has received funds from multiple business lines to update all the mainstem project surveys and about half of the tributary projects. The Baltimore District receives funding for sediment surveys from federal and local sponsors. All their permanent pool reservoirs were resurveyed in 1996-2000. The surveys included both bathymetric and topographic surveys. Since this time, five of the wet dams were resurveyed by boat between 2010 and 2012. The Los Angeles District has only been able to survey about half of the reservoirs over the last 10 years. The District has all dry dams, except for one wet dam. Survey methods for the past 10-12 years have primarily been photogrammetry and LiDAR for the dry dams, and single-beam hydrographic surveys for the wet dams. A few of the dams in the District have not been surveyed in more than 40 years.

Hydrographic single-beam surveys are used for the Fort Worth and Huntington Districts. For Fort Worth, there are nine reservoirs requiring new surveys. Some of these are not meeting the terms of their water supply contracts to be resurveyed every 15 years. The Huntington District has been able to fund several sediment surveys over the last few years, but there are still 13 reservoirs that have not been resurveyed within the past 10 years, and require updates.

ADDITIONAL DATA						
Water Surface Profiles		E	E	E		E
Datum		NGVD29	NGVD29	NGVD29		NGVD29

Datum: In general, most of the Districts use the 1929 vertical datum to store data. However, the Los Angeles District indicated that there have been some datum issues. Original surveys may have been done using MSL, NGVD29, NAVD88, or some local datum. The elevations used in the District's area-capacity tables have been converted to NGVD29 datum in order for all dams to have consistent vertical datums.

Sediment Studies and Models: In general, sediment studies have not been conducted, unless project based. There have been no studies related to climate change apart from a Garrison Dam study that included some climate change data. Also, districts indicated that models have not been used for sediment management activities or to dictate management decisions.

Area-capacity Analysis: In general, area-capacity or elevation-capacity curves are updated once a survey has been completed, unless funding is unavailable. Curve data since the 1990s are stored in electronic format for all districts. The Fort Worth and Los Angeles Districts use DSS to store the data, while the other districts use Excel. Most districts also store the data in water control manuals, sedimentation survey reports and/or binders set-up for each project. Historic area-capacity data or pre-1990s data are mostly in paper format – apart for the Los Angeles District where all storage data has been transferred to DSS. Several districts also indicated that much of the original area-capacity data or historic data have been lost or misplaced. For example, most area-capacity and survey information for the Baltimore District prior to 1993 was lost after an office move. The Omaha District has historic area-capacity data still in microfiche or paper format.

Water Surface Profiles (WSP): Data for WSP have only been collected at the Omaha and Huntington Districts. The Omaha District collects most WSP data in-house, but occasionally uses WSP data collected by the U.S. Geological Survey (USGS) or an outside contractor. The Huntington District collected WSP data as part of original reservoir design, but have not been updated since that time.

Sediment Sampling: Sediment cores and bed material samples are no longer collected in-house by any of the districts. The only districts that once collected sediment data on a routine basis were Omaha and Fort Worth. Omaha stopped collecting in-house suspended sediment samples and density measurements in the 1980s. Suspended sediment data for the District are now collected by the USGS at six sediment gages. The District collects bed material under contract when funding permits. Fort Worth collected sediment data until the early 1990s. The other districts have collected little or no sediment data.

Sediment Management Activities: Sediment management activities are generally reflected in O&M records for project maintenance. Shoaling and dredging operations have occurred at some of the Omaha District projects. Operations management requests money through "non-routine funding," then issues a request for proposal before contracting out the work. Fort Worth indicated that dredging is done only to keep intakes open for water supply – not for regaining storage capacity. Studies showed that removing sediment was ineffective based upon the cost to dredge versus the amount of storage gained. Erosion at banks is an issue with some of the Fort Worth reservoirs. Although the eroded areas provide more storage in the flood pools, volume is lost in the conservation pools. The only other district surveyed where dredging has been used is in Baltimore, at Hammond Lake for boat access. The Baltimore District indicated that other management activities included raising the normal water level about 5 feet due to sediment issues at Almond Lake. There has been some discussion that the water surface elevation may need to be raised again. Los Angeles District reservoir gates are checked and cleaned annually. There are also some gravel removal activities that take place, but this is not a routine activity. The District also indicated that there are some sediment issues with seasonal flooding.

Huntington District indicated there are no current or past dredging activities. Dillon Lake, however, has lost most of its conservation pool to sediment, but this only affects recreation – not flood control. Another sediment issue occurs at Beach City Lake (completed 1936) where the reservoir is full of sediment.

RSI Data Gaps and Funding Sources: Overall, the districts identified routine execution of sediment surveys to be the main RSI need. Other needs are sediment gages and funding to support topographic studies to supplement bathymetric surveys. Most districts identified O&M as the main source of funding. The Baltimore and Fort Worth Districts indicated that there has also been some project-based sponsorship from state or local sources. An overall cost of approximately $7.5 million was estimated to fill high priority data gaps.

Scaling of Findings. One of the goals of the current study is to scale these findings to the whole of USACE and make estimations of the data gaps. This is a challenging task, as those USACE commands with major reservoir responsibilities have a wide array of geographic, climatic, operational, and political differences. Nevertheless, the five districts from which detailed RSI information was gathered form the basis for our projections.

The inventory of USACE dams shows 704 structures at 556 projects. Out of the 556 dam projects, it appears that about 409 are for traditional impoundment rather than navigation or other purposes (about 75% of inventory). The five districts providing detailed RSI data have 119 dams collectively, and therefore represent about 30% of the total.

There are some items specific to certain districts that need to be considered when trying to extrapolate findings USACE-wide. For example, Omaha District has some of the largest dams, located on one of the largest rivers in the country (Missouri River). Los Angeles District has mostly dry dams. Fort Worth District is concerned with losses in the conservation pool due to water supply obligations.

Based on the study results to date and WEST Consultants past work with multiple other USACE districts, our judgment is that the five surveyed districts are probably above average with regards to collection and management of RSI.

Taking the above into account, and applying it to the $7.5 million needed to close the RSI gap for the five districts and their 119 dams, our estimate is that $25 million would be needed to fill current RSI data gaps USACE-wide. This estimated amount would fill current gaps but does not include funding for ongoing RSI updates, which should be part of the conversation. This amount also does not include any funds directed specifically at addressing impacts of global climate change on reservoir sedimentation, an issue which has apparently not been considered in a significant way to date.

RSI UPDATE STRATEGY

Working together the project team developed a strategy to prioritize and update RSI that reflects new and changing conditions that impact the ability of RSI to meet intended objectives. The strategy includes a characterization of classes of projects that may require similar level of effort

to update, characterization of changes on a regional or national basis that may apply to groups of projects, development of methods and processes to assist in updates, and required new policy and guidance updates (mainly USACE Engineer Regulations [ER] and Engineer Manuals [EM]).

The update strategy is built around a three-tier decision tree that builds from (a) baseline data, (b) data needs for purpose, geography, and size; and (c) possible future data needs based on climate change.

a. The review of the current status of RSI was used to support the update strategy. RSI common to all reservoirs was identified as the baseline data required for each project.

b. Commonalities in collected data associated with the project purposes were identified. Datasets were then classified in a manner to support the specific project purposes. Geography, reservoir size, and environmental issues and constraints were also considered when identifying data to collect.

c. Because a goal of the overall project is to consider reservoir response to climate change, data that may be needed in the future but is not currently collected was also addressed. This may not be a specific data set but the type of data necessary.

The update strategy identifies data collection methods, resolution, and frequency that need to be considered for the update of the USACE Sedimentation EM (1110-2-4000) and writing a new ER that will address collecting reservoir data.

Individual Project Data Needs. In addition to a baseline data set, each project may require additional RSI data specific to the project purpose(s), geographic location, reservoir size, etc. The project purpose impacts both the type of RSI collected and frequency of data collection while the other considerations have more of an effect on frequency and methods of data collection. For example, 3 of the 15 projects within the Baltimore District have an authorized project purpose of water supply. The District indicated that these projects have been made the highest priority for data updates in order to monitor the amount of storage loss due to sediment deposition and the resulting storage available for water supply. Specific data collection needs may be based project authorizations such as Navigation, Flood Risk Management, Ecosystem/Water Quality/Fish & Wildlife, Hydropower, Recreation, and Water Supply/Irrigation and were identified as part of the study. A decision tree was developed to cover the range of project uses with RSI data needs defined based on those uses. All USACE projects have an authorized purpose of flood risk management. Therefore, the minimum baseline RSI should include two topographic/bathymetric surveys and area-capacity computations to determine the total volume occupied by sediment, sedimentation patterns, and the shift in the stage-area and stage-storage curves. Ideally, the first survey will have occurred before filling of the reservoir, and the second at a point in time that will allow estimation of deposition rates, identification of spatial and temporal deposition patterns, and recognition of potential sedimentation issues. Guidance on reservoir sedimentation investigations is given in EM 1110-2-4000 (USACE, 1989).

Workplan and Sediment Management Strategies. The project team recognized that RSI feeds into development of a sediment work plan, including management strategy, as shown in Figure 2.

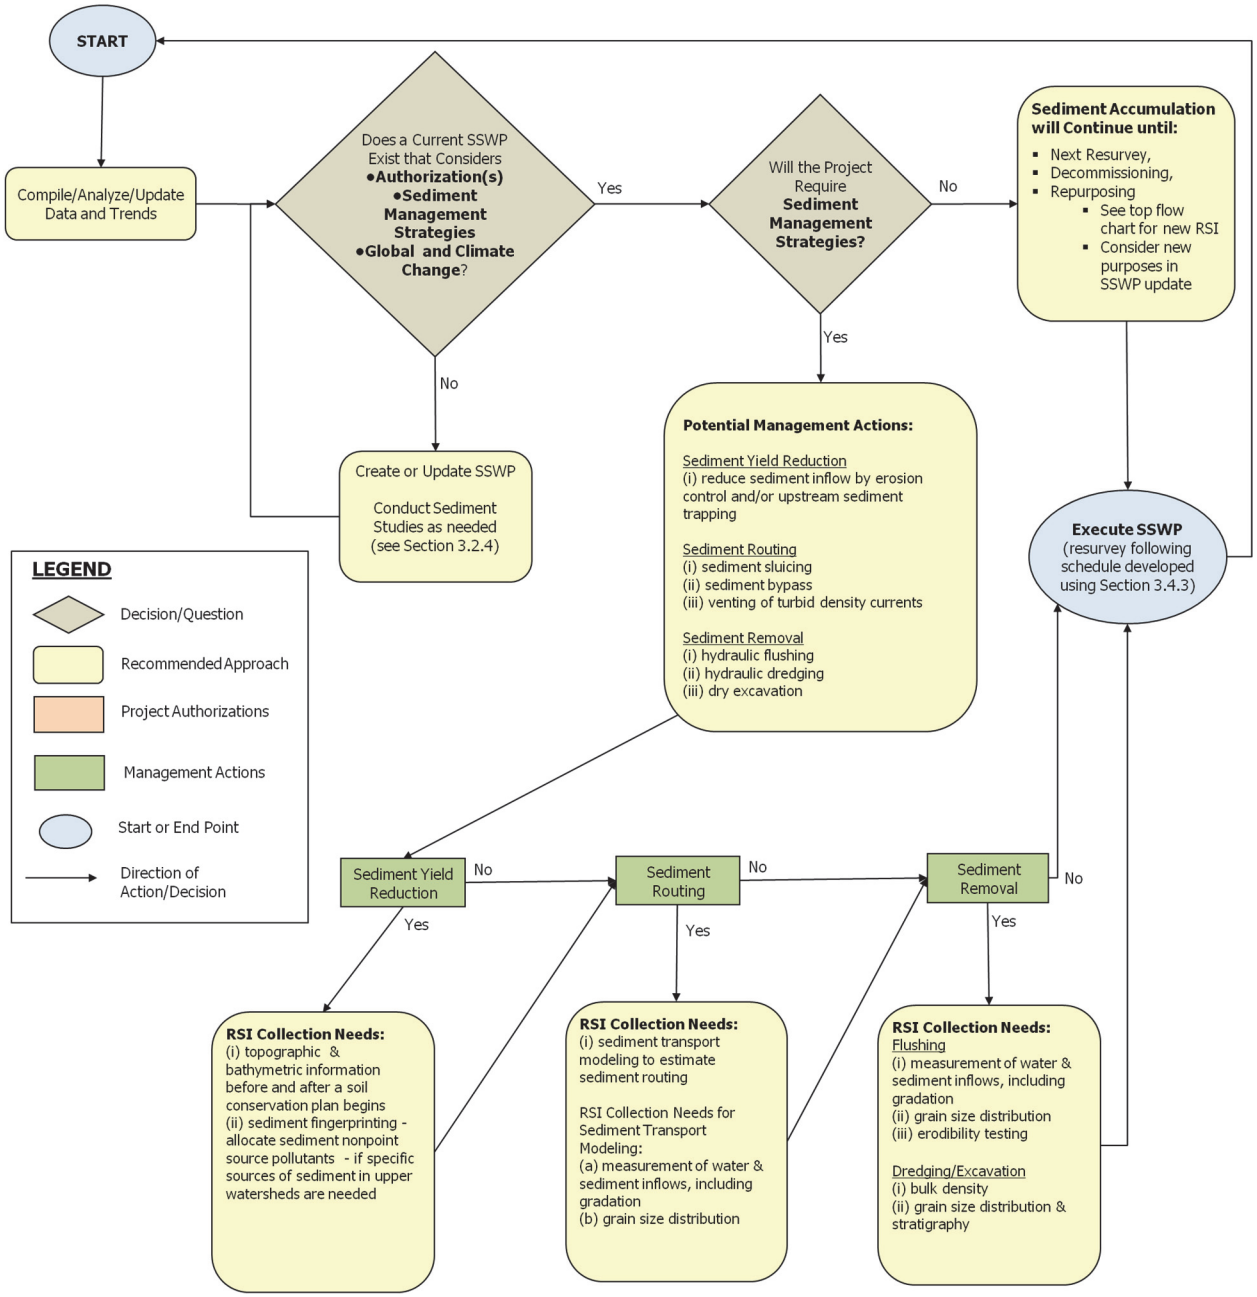

Figure 2 Workplan and Strategy Development

Sediment Studies Work Plan. EM 1110-2-4000 describes the purpose of the SSWP. Potential sediment problems and opportunities should be identified in a project SSWP. Any problems identified in the document become the basis for developing and organizing a sediment investigation. The SSWP should consider project authorizations, sediment management strategies, and global and climate changes; if not, the SSWP should be updated and any needed

sediment studies should be conducted. Reservoir sustainability should also be addressed within the SSWP. Sustainability planning should be conducted in accordance with ER 1110-2-8153 (USACE, 1995) using a staged approach. Sustainability planning may involve consideration of sediment management activities (and the RSI necessary to carry these out) or, if no feasible sustainable actions are identified, planning for reoperation or decommissioning.

Sediment Management Strategies. Different strategies for management of reservoir sedimentation are abundant in the literature. Selection of the best management strategy or action is not always straightforward, even in the present. However, given the physical characteristics of a reservoir or system and projected future conditions (e.g. future with hydrology and sediment inputs identical to the past, or future with the same affected by climate change, etc.) it may be possible to identify one or more potential future management strategies.

Sediment management methods may be broadly separated into three categories:

1. Sediment Yield Reduction – reduce sediment inflow to the reservoir
2. Sediment Routing – pass sediment around or through the reservoir
3. Sediment Removal – remove deposited sediment via hydraulic or mechanical means

Further subcategories are defined based on timing, location, and details of individual measures.

If none of the above actions are feasible or will not result in a sustainable reservoir, other management options should be considered, such as reservoir reoperation, repurposing, dam removal, or returning the dam to a run-of-river system. Most USACE dams are used for multiple purposes. As the different reservoir zones begin to fill, management practices in the future may change to account for the lost storage. For example, managers of a multipurpose reservoir with little conservation pool left may be able to increase the capacity by decreasing the capacity of another, higher, zone, or by raising the dam. Another example is a reservoir commissioned for purposes of water supply and flood risk management may be reauthorized for ecosystem management, changing from a multi-purpose to single-use reservoir. A reservoir that is reauthorized to serve a different purpose will also have new RSI needs. If a reservoir no longer serves a useful purpose, removal should be considered to restore the river to its natural pre-dam condition to the extent possible. In cases where the dam is not removed, managers may let a reservoir fill, which would eventually allow more sediment to pass over the spillway and lead to increased sediment loading to downstream reaches, including any downstream reservoirs.

CLIMATE CHANGE: NATURAL VARIABILITY IS A BIG DEAL TOO!

David C. Curtis, Ph.D., Vice President, WEST Consultants, Inc., Folsom, CA, dcurtis@westconsultants.com, Om Prakash, Ph.D., PE, Project Manager, WEST Consultants, Inc., Folsom, CA, oprakash@westconsultants.com

Abstract: Climate changes. That's what climate does. It is a natural and dynamic process. The National Weather Service (NWS) recognizes on-going climate change by publishing new figures for average climate every ten years. Climate averages for precipitation, temperature, and other weather parameters are computed on a 30-year basis but only updated once per decade.
With all of the discussion about anthropogenic (i.e. man-made) climate change, it is easy to overlook just how variable our natural climate can be in the relatively short-term. Our climate can and does vary by significant amounts within one human lifetime and well within the design lifetime of our water infrastructure. Sometimes this fact gets lost in the noise of the climate change debate. Part of the reason is the relatively short records of our key meteorologic and hydrologic parameters.

Here's an example. Sacramento, CA, has one of the longest rainfall records in the western US. Annual rainfall totals are available from 1850 to present. Over the 164 year record from 1850-2014, the average annual rainfall was 18.34 inches. However, the 30-year moving average rainfall varies from 20.42 inches in 1896 down to 14.51 inches in 1937 and up again to 20.47 inches by 2007. That's 30-40% swing of 30-year average rainfall in a single lifetime. (Human lifetime, not geologic time!) Most of our short records completely miss that signal. Recent streamflow reconstructions of Sacramento River flows using tree ring data show this signal repeatedly over the past 1100 years. That such significant changes can occur relatively fast has major implications for water resources infrastructure design. That such significant changes can occur relatively fast has major implications for water resources infrastructure design.

This presents explores and presents findings regarding rapid variation of "climate averages" in northern California and Oregon using long-term rainfall records. It also emphasizes the importance selecting climate models that replicate this multi-decadal signal when analyzing impacts of climate change. These results suggest that not only is stationarity dead, it likely wasn't really alive in the first place. We simply assumed it was.

INTRODUCTION

Climate changes. That's what climate does. It is a natural and dynamic process. The National Weather Service (NWS) recognizes on-going climate change by publishing new figures for average climate every ten years. Climate averages for precipitation, temperature, and other weather parameters are computed on a 30-year basis but only updated once per decade.

With all of the discussion about anthropogenic (i.e. man-made) climate change, it is easy to overlook just how variable our natural climate can be in the relatively short-term. Our climate can and does vary by significant amounts within one human lifetime and well within the design lifetime of our water infrastructure. Sometimes this fact gets lost in the noise of the climate change debate. Part of the reason is the relatively short records of our key meteorologic and hydrologic parameters.

This paper explores findings regarding rapid variation of "climate averages" in northern California using long-term rainfall records and insights from paleoclimatological proxies. It also emphasizes the importance selecting climate models that replicate this multi-decadal signal when analyzing impacts of climate change. These results suggest that not only is stationarity dead, it likely wasn't really alive in the first place. We simply assumed it was

RECENT OBSERVATIONS

In the western US, most precipitation and stream gages were installed in the latter half of the 20th Century. As such, 50-80 year records are considered long. Only a handful of gages date back to the 1800s. Sacramento, CA, has one of the longest rainfall records in the western US. Annual rainfall totals are available from 1850 to present. Figure 1 shows the highly variable annual Sacramento rainfall from 1850. The average annual rainfall for the past 164 years is a little more than 18 inches. The rainfall trend over the entire period of record, shown in Figure 2, indicates just a very slight downward trend.

The linear rainfall trend shown in Figure 2 suggests that, overall, rainfall amounts in Sacramento have been stable over the past century and a half. However, that is not the whole story.

The US National Weather Service reports climate averages on a 30-year basis. These averages are updated once per decade. In addition to being a standard reporting interval for climate averages, the 30-year time frame is similar to the time horizons used in common planning studies for civil infrastructure.

A much more dynamic picture emerges by shifting the trend analysis for the full Sacramento record to a shorter trend on the same scale as planning studies. As Figure 3 suggests, the 30-year moving average rainfall ranges from a peak of more than 20 inches annually in the 1890s to a minimum of less than 15 inches before recovering to more than 20 inches again by the 1990s. Overall, that's a 30-40% swing of 30-year average rainfall in a single lifetime. (Human lifetime, not geologic time!) Most rainfall records completely miss that signal. What these rainfall records do capture is a precipitation regime with a strong upward trend over the last 60-70 years of the 20th Century.

The California Department of Water Resources (DWR) monitors precipitation at 8 locations in a 15,700 square mile area in the northern Sierra Nevada Mountains (Roos, 2009). DWR has maintained the Northern Sierra 8 Station Index since 1921. Figure 4 presents a scatterplot of Sacramento's annual precipitation versus the Northern Sierra 8 Station Index during the overlapping period of record, 1921-2013. Sacramento's annual rainfall and the Northern Sierra 8 Station Index are highly correlated. Using the linear trend line shown on Figure 4, Sacramento's annual precipitation explains about 77% of the variance in the 92 year record on 8 Station Index values.

Such strong correspondence between the annual rainfall in Sacramento and conditions in the Northern Sierra since 1921 suggests that the Sacramento annual rainfall is a reasonable indicator of conditions throughout the Northern Sierra. Given this strong correspondence, it is likely that the Northern Sierra was relatively wet during the last half of the 19th century and became increasingly dry during the first half of the 20th century before rebounding to a relatively wet condition over the last 70 years.

LOOKING FURTHER BACK

Tree ring data are also useful indicators of past climate, when direct observations of rainfall or streamflow are unavailable. The California Department of Water Resources (DWR) recently commissioned a research project to reconstruct hydroclimates for the Klamath, San Joaquin, and Sacramento River basins from tree ring data. (Meko et al, 2014) The project reconstructed unimpaired streamflows in the Sacramento River basin for 1100 years, 900-2010 A.D. (See Figure 5)

The 30-year trailing average annual streamflow volume is plotted on Figure 5 as the heavy black line. Throughout the 1100 year record, Sacramento streamflow drifted back and forth from wet regimes to dry and back to wet again. The 30-year trailing average of reconstructed Sacramento River annual volumes over the last half of the 19th Century and through the 20th Century follows a pattern that is very similar to the 30-year trailing average of Sacramento's annual precipitation. This result is not unexpected as one would expect streamflow volumes to follow persistent precipitation patterns.

Looking again at the long-term trends in streamflow volumes (30-year trailing averages in Figure 5), repeated wet/dry cycles appear throughout 1100 year reconstructed record. The 30-year trailing average annual streamflow volume maxima is often 25-50% greater than preceding minima. Repeatedly the transition from a hydroclimate maximum to a hydroclimate minimum occurs relatively quickly; on the order of 3-4 decades.

Evidence that a warming atmosphere is already impacting the region comes from Salzar et al. (2009). Salzar examined tree ring widths from three locations in western North America near the tree line. Growth behavior at the tree line may be a sensitive indicator of a changing atmosphere. More hospitable conditions (i.e. warmer) may promote growth. Less hospitable or colder conditions may inhibit growth. Figure 6, using data from Salzar, shows recent growth rates unseen for more than 3,500 years. The authors suggest that dramatic environmental changes, most likely linked to increased temperature, promoted accelerated tree ring growth.

LOOKING AHEAD

Recent observations of precipitation in California and examination of paleo proxies for precipitation show that natural variability is an important feature of California's climate; a feature present long before the industrial age. Furthermore, Hawkins and Sutton (2011) suggest that natural variability will be the dominant source of total precipitation uncertainty over the next 10-30 years. Since this time frame is in line with time horizons of many water resources planning efforts, understanding and accounting for natural variability is imperative.

Changes in temperature and precipitation patterns have interrelated impacts on water resources. While natural variability will likely dominate California's precipitation uncertainty for the next several decades, it's clear that anthropogenicly driven temperature impacts such changing the rain/snow mix during winter months and earlier snowmelt may already be strongly present and can't be ignored.

Recognizing that there is a strong signal of natural variability emphasizes the importance selecting climate models that replicate this multi-decadal feature when analyzing impacts of future climate change. California's natural climate variability can either amplify or mitigate decadal scale anthropogenic climate change impacts.

Looking ahead, California water managers face a two-fold challenge. First, natural variability is a critical component to understand. Secondly, anthropogenic changes add an additional layer to California's climate complexity. Planning for California's water future must recognize and address a robustly dynamic climate now impacted by human activities of the post industrial age; impacts that we are just beginning to understand.

ICE JAM PROCESSES AS INFLUENCED BY CLIMATIC VARIABILITY AND HYDROPOWER OPERATIONS: LOUP RIVER

Roger Kay, P.E., Hydraulic Engineer, U.S. Army Corps of Engineers, Omaha, NE, Roger.L.Kay@usace.army.mil

Abstract: The Loup River is the largest tributary of the Platte River and drains approximately 15,200 square miles in the State of Nebraska. Like many rivers in the region, the basin is subject to flow regime changes due to reservoirs and diversions for irrigation and hydropower. The Loup Power District operates one such hydropower plant, with flows diverted from the Loup River near Fullerton, NE, through a 35-mile canal with return flows to the Platte River downstream of the Loup River confluence. Approximately 69-percent of the annual Loup River flow is diverted for hydropower purposes in an average year.

Operational experience dictates canal flows cease when the river carries any quantity of floating ice during cold periods, to allow the canal to form a smooth ice cover and prevent entrainment of ice floes which would reduce the canal's conveyance capacity. During such periods, all flow is allowed to pass downstream through the natural river channel, carrying large quantities of ice. This operational constraint has led to the perception among local residents that these operations lead to an increased flood risk due to ice jam formation. During a recent relicensing process, FERC asked the Loup Power District to demonstrate what impact their operations may have on downstream interests, including ice processes.

Loup Power District asked the U.S. Army Corps of Engineers, Omaha District, to evaluate the impact of project hydropower (Project) operations on ice jam flooding due to any changes in hydrology, sediment transport and channel morphology on the Loup and lower Platte Rivers related to the operation of the hydropower plant. The methodology utilized included a review of flood histories, a statistical overview of climatic data, and hydraulic modeling of the study area. The statistical overview of climatic data included evaluation of temperature, snowfall, snow depth and precipitation for multiple weather stations within the study area covering a period in excess of 110 years. The climatic data was evaluated for accumulated freezing degree days (AFDD) to assess initiation of ice processes, formation of intact ice cover, thickness and quantity of ice prior to breakup and any correlation to history of ice jam flooding. Temporal trends and variability in AFDD were also assessed, as well as any correlation between snowfall depths and rainfall with occurrence of ice jams. Results of the flood history and statistical analyses of climatic data were utilized to assist in appropriate parameters for one-dimensional (1-D) hydraulic modeling of ice jam formation during freezeup and breakup periods. Two-dimensional (2-D) hydraulic modeling utilizing DynaRICE validated many of the results of the 1-D hydraulic modeling.

Results of the analyses and hydraulic modeling indicate that hydropower operations have not significantly changed the ice regime of the Loup River, nor contributed to an increased risk of

damaging ice jam flooding. The results also indicate that subtle trends in climatic variability and floodplain development may lead to an increased flood risk due to ice jams over time.

INTRODUCTION

Goals and Objectives: The goal of the study of ice jam flooding on the Loup River was to evaluate the impact of Project operations on ice jam flooding on the Loup and Platte Rivers between Fullerton, Nebraska, and North Bend, Nebraska. The study also was to develop an ice jam and/or breakup predictive model (limited to examination of Project effects), as well as identify operational or structural measures to mitigate or minimize Project effects on ice jam formation and subsequent flooding, if it was demonstrated that operation of the Project materially impacts ice jam formation on the Loup and Platte Rivers (Kay, et al, 2011).

Study Area: The study area includes the Loup River from Fullerton (approximately 7 miles upstream of the Loup Power Canal Headworks) to the confluence with the Platte River (the Loup River bypass reach), the Platte River from just upstream of the confluence of the Loup and Platte rivers to North Bend, and the Loup Power Canal from the Headworks to the Tailrace Canal confluence with the Platte River below the Loup-Platte confluence (Figure 1).

Figure 1 Study Area near Columbus, NE.

Methodology: Several methods were employed to determine if the operation of the Loup Power Canal contributes materially to the formation of ice jams along the study reach. These methods included a review of flood history, a statistical overview of meteorological data, and hydraulic modeling of the study area.

DATA COLLECTED

Flood History: A review of all available records was conducted to determine when significant flood events occurred along the study reach. The flood history was heavily influenced by Nance County Journal articles, which were some of the only records of floods before the 1930's.

Significant Floods in Lower Loup Basin: Significant floods were defined as those that resulted in loss of life and/or significant property damage. Significant floods were noted as occurring in March of either 1848 or 1849, March 1881, May 1904, February 1905, February 1907, March 1910, June 1923, April 1935, March 1936, February 1941, June 1947, February 1948, March 1960, August 1966, March 1969, February 1971 and March 1993. The 1904, 1923, 1935, 1947,

and 1966 floods were not ice-affected however. The 1960 event is not documented as being ice-affected on the Loup River, but was a significant ice-affected flood on the Platte and Elkhorn Rivers in Nebraska. For purposes of this paper, the March 1960 event is not considered an ice jam event on the Loup River.

Other Ice Related Floods: Other ice-affected floods were those that were noted as either causing low-land flooding in various records or as noted in USGS records as stage readings influenced by backwater caused by ice. There were 17 separate ice-affected flood events noted in records. USGS gaging station at Genoa indicated 32 years where the peak stage was due to backwater caused by ice; however, records prior to 1962 did not indicate the cause of backwater-influenced peak stages, so there may be as many as 10 additional years where the peak stage was influenced by ice. It was noted, however, that not all ice-affected peak stages resulted in flood stage being exceeded (Kay, et al, 2011).

Flow and Ice Thickness Measurements: The USGS maintains a network of stage-discharge gages throughout the Loup River basin. Data from two stations, listed in Table 1 below, were compiled for flow data.

Table 1 USGS Gaging Stations with Flow Data, Loup River.

Station ID	Station Name	Period of Record
06792500	Loup River Power Canal near Genoa, Nebr.	December 1936 – Present
06793000	Loup River near Genoa, Nebr.	August 1928 – June 1932, October 1943 – Present[1]

[1] Monthly Data Only, October 1953 – April 1955

Thirty sets of ice thickness measurements covering 60 years at four stations (North Loup River at St. Paul, NE; Middle Loup River at St. Paul, NE; Loup River at Genoa, NE; and Loup River at Columbus, NE) were provided by the USGS. Most ice thickness measurements were from years with below average air temperatures.

Meteorological Data: Applicable meteorological information near the study area was used, with data gathered from NOAA's National Climatic Data Center (NCDC). Temperature, snowfall, snow depth and precipitation data were collected for five stations listed in Table 2. Columbus and Genoa were selected as the primary stations for data computations, as both stations are at similar latitudes, and both have the same number of complete water year observations. Although within the study basin, St. Paul was a secondary station as its latitude is south of Columbus and Genoa, and the station has a shorter period of record. Madison and David City records were used primarily to synthesize missing daily temperature data at the two primary and one secondary station through use of multiple regression techniques.

Table 2 Climate Data Stations.

Climate Station	Period of Record
Columbus 3NE, NE	1894 – 2010
Genoa 2W, NE	1893 – 2010
St. Paul 4N, NE	1900 – 2009
Madison, NE	1895 – 1994
David City, NE	1897 – 2010

Bathymetric Data: Bathymetric surveys were collected between bank lines at 110 georeferenced cross-sections located from just downstream of the Loup Power Canal Headworks to just upstream of the Union Pacific Railroad (UPRR) bridge west of Columbus. These cross-sections were then overlain on a digital elevation model (DEM) and extended in ArcGIS to include potential overbank flow areas. HEC-GeoRAS was used to cut new cross-sections based on the extended cross-section alignments, and the surveyed cross-sections were then merged into the newly cut cross-sections and saved to a new geometry in HEC-RAS. The HEC-RAS geometry with the combined surveyed and extended cross-sections were then merged with an existing georeferenced hydraulic model geometry extending from approximately one mile downstream of the Platte-Loup confluence to upstream of the UPRR bridge west of Columbus to create a geometry extending from the Platte River at the Loup Canal Tailrace upstream to the Loup River at the Loup Power Canal Headworks Diversion. The bathymetric data, in conjunction with the DEM was also used to create a two-dimensional grid for modeling ice transport and jamming processes near the Loup Power Canal Headworks and near Columbus.

ANALYSIS

Statistical Analysis of Climatic Data: Freezing degree days (FDD) are a measure of daily average air temperature departure from freezing (32°F/0°C), with temperatures below freezing resulting in a positive FDD value and temperatures above freezing resulting in a negative FDD value. FDD can be cumulatively summed through the winter season, providing accumulated freezing degree days (AFDD), which can be used as a measure of a winter's severity. Statistical analysis of AFDD, coupled with physical measurements of ice, snow and rain, were performed to determine if the frequency and/or severity of ice jam formation has changed since commencement of Project operations.

Statistical Analysis of AFDD: The Project must cease diversions through the canal when moving ice is present on the Loup River, so the AFDD required to initiate ice production (and hence movement) in the Loup River were computed based on dates when Project flows, as recorded by USGS at Station 06792500, dropped to near zero. The AFDD required to form a stable ice cover on the Loup River (hence cessation of ice movement and resumption of Project operations) was also determined and was based on dates when Project flows returned to near normal. The annual peak AFDD value ($AFDD_{max}$), changes in AFDD during the months of January, February and post-February (referred to as $AFDD_{month}$), the change in AFDD in the 21 days preceding $AFDD_{max}$ ($AFDD_{-21}$), and the change in AFDD in the 7 days following $AFDD_{max}$ (MDD_{+7}, or melting degree days), as well as relationship between $AFDD_{max}$ and increases in Loup River discharge following $AFDD_{max}$ were all compiled as well.

Temporal Trends in AFDD: Trend analyses were performed to determine if AFDD data has changed over time, looking at annual $AFDD_{max}$ values, annual $AFDD_{month}$ values, cyclical changes in $AFDD_{max}$ over periods of 5, 10 and 30 years, annual $AFDD_{-21}$ values, annual MDD_{+7} values, and the change and variability in the Julian date of $AFDD_{max}$ (JD_{max}, where JD=1, or JD_1, is October 1 of each Water Year).

Ice Thickness Computations: Measured ice thicknesses and AFDD data from the nearest climate station were used to back-compute the coefficient for the modified Stefan equation.

Estimate Ice Thickness for Historic Ice Jams: Ice thickness values for each year just prior to breakup were estimated based on the $AFDD_{max}$ for each year, as well as a range in modified Stefan equation coefficients as determined from the statistical review of actual ice measurements.

Relationship Between Snow Cover and/or Rain and Ice Jams: Snow depth (measured on-ground depth) and snow accumulation (accumulated seasonal snowfall depth) data at Genoa and Columbus were compiled, and temporal relationships between snow cover and temperatures were analyzed, as well as any relationships between snow accumulations and $AFDD_{-21}$ and MDD_{+7} (limited to years with documented ice jams).

HEC-RAS Modeling: The HEC-RAS model was calibrated to the most recent rating curve at the Genoa gage for open water flows up to 3,000 cfs to determine the channel n-value. Higher flows were then used to calibrate overbank n-values to the Genoa gage rating curve. Flows for with- and without project hydrology were provided from the Loup Power study report (Loup River Public Power District, 2012).

Ice Formation and Freezeup Jam Formation: Flows representing the 10-, 25-, 50-, 75-, and 90% by duration flows for the months of November, December, and January (typical months for an ice cover to form) were modeled in conjunction with an ice cover. The ice n-value and thickness varied with channel velocity based on previous observations by the author and experience. Multiple iterations were needed to evaluate velocities and adjust ice n-values and thicknesses to achieve a stable ice cover consistent with velocity results.

The ice cover geometry was then adjusted to allow jamming at all cross-sections with the 10% exceedance flow to identify the most likely locations for freezeup jams to form based on available channel flow area, ice thickness, profile increase and constrictions and bends in the river. Nine potential jam locations were identified in this manner. Areas that consistently had velocities too high to allow stable ice cover formation were identified as well.

Ice Breakup and Breakup Jam formation: In order to model breakup ice jams accurately, an estimate of the volume of ice in the river prior to breakup must be known. Two single layer ice thicknesses were modeled, based on results of AFDD computations with the modified Stefan equation for average AFDD and 1-standard deviation above average AFDD at breakup to determine the initial volume of ice available at initiation of breakup. Ice jams were allowed to form at the previously identified 9 locations, with 4 locations adjusted either upstream or downstream to allow for more realistic ice jam shape and size. The upstream extent of each ice

jam was determined based on the volumes of ice previously computed and reduced by 50% to allow for broken ice pieces that are pushed into overbanks and ice that melts during transport into the jam location. Flows modeled for breakup jams were the 0.5-, 0.2-, 0.1-, 0.05-, and 0.02% ACE event assuming both current operations and no canal diversions allowed.

DynaRICE Modeling: Modeling the transport of ice floes is beyond the capabilities of a one-dimensional model such as HEC-RAS. Therefore, the two-dimensional DynaRICE ice-hydraulic numerical model was used to simulate ice transport in the Loup River, as well as ice jam initiation. The primary purpose of the DynaRICE modeling was to determine if there were any differences in ice formation and ice jamming processes with and without diversions into the Loup Power Canal. The model was calibrated against UGSG data and highwater marks from the 1993 flood near Columbus.

Two flow conditions representing 3,400 and 2,000 cfs (flows exceeded 25% and 50% of the time during freezeup conditions) were modeled for freezeup conditions near the headworks; lower flows were not modeled as the bathymetry was too coarse to accurately model shallower flows. Two historic breakup ice jams, 1969 and 1993, were simulated at Columbus as well.

RESULTS OF ANALYSES

Some of the more significant results are summarized in the following section. A more complete record of results may be found in Kay, et al (2011).

Frequency and Severity of Flooding: The record indicates 12 significant ice jam related floods and 6 open water floods along the Loup River between Genoa and Columbus between 1848 and 2010. However, records prior to the late 1800's are inconsistent, and it is possible that there are undocumented flood events during this period. Table 3 below compares the number of floods during the known period of record, including pre-Project and post-Project operations.

Table 3 Occurrence of Documented Significant Floods Before and After 1937.

Period of Record	Number of Documented:		Annual Probability of:	
	Ice Jam Floods	*Open Water Floods*	*Ice Jam Floods*	*Open Water Floods*
1848 – 1936 (88 years)	7	3	0.0795	0.0341
1893 – 1936 (43 years)	5	3	0.1163	0.0698
1937 – 2010 (73 years)	5	3	0.0685	0.0411

As can be seen, the annual probability of ice jam related flooding appears to be higher in the years preceding Project operations. The decrease in probability of ice jams cannot be credited towards Project operations, but it does discount the idea that Project operations have increased the frequency of significant ice jams. It is notable that in every year that a significant Loup River ice jam has occurred since Project operations commenced, one or more significant ice jams occurred on other Nebraska streams of similar characteristics, such as the Platte and Elkhorn Rivers. This tends to support the occurrence of ice jams as regular natural process, given the right set of ice and meteorological conditions preceding the ice jam event, irrespective of Project operations.

The occurrence of ice jams relative to meteorological conditions was also examined. Although an $AFDD_{max}$ of 1000 has about a 20% annual chance of occurrence (see Figure 2), 70% of the documented ice jams since 1905 occurred in years with $AFDD_{max}$ exceeding 1000. However, the flood of 1907, which caused four fatalities in Columbus, occurred in a year with near average $AFDD_{max}$. An $AFDD_{max}$ exceeding 1000 does not constitute a certainty of having an ice jam; less than one-third of years with $AFDD_{max}$ exceeding 1000 experienced a significant ice jam. It is noted that $AFDD_{max}$ is consistently greater at Columbus than the other stations. Since ice growth and thickness is directly correlated to FDD, it is possible that ice thickness is greatest at Columbus, which may lead to a greater risk of breakup ice jam formation at Columbus, as greater force would be required to lift, break up and transport a thicker intact ice cover.

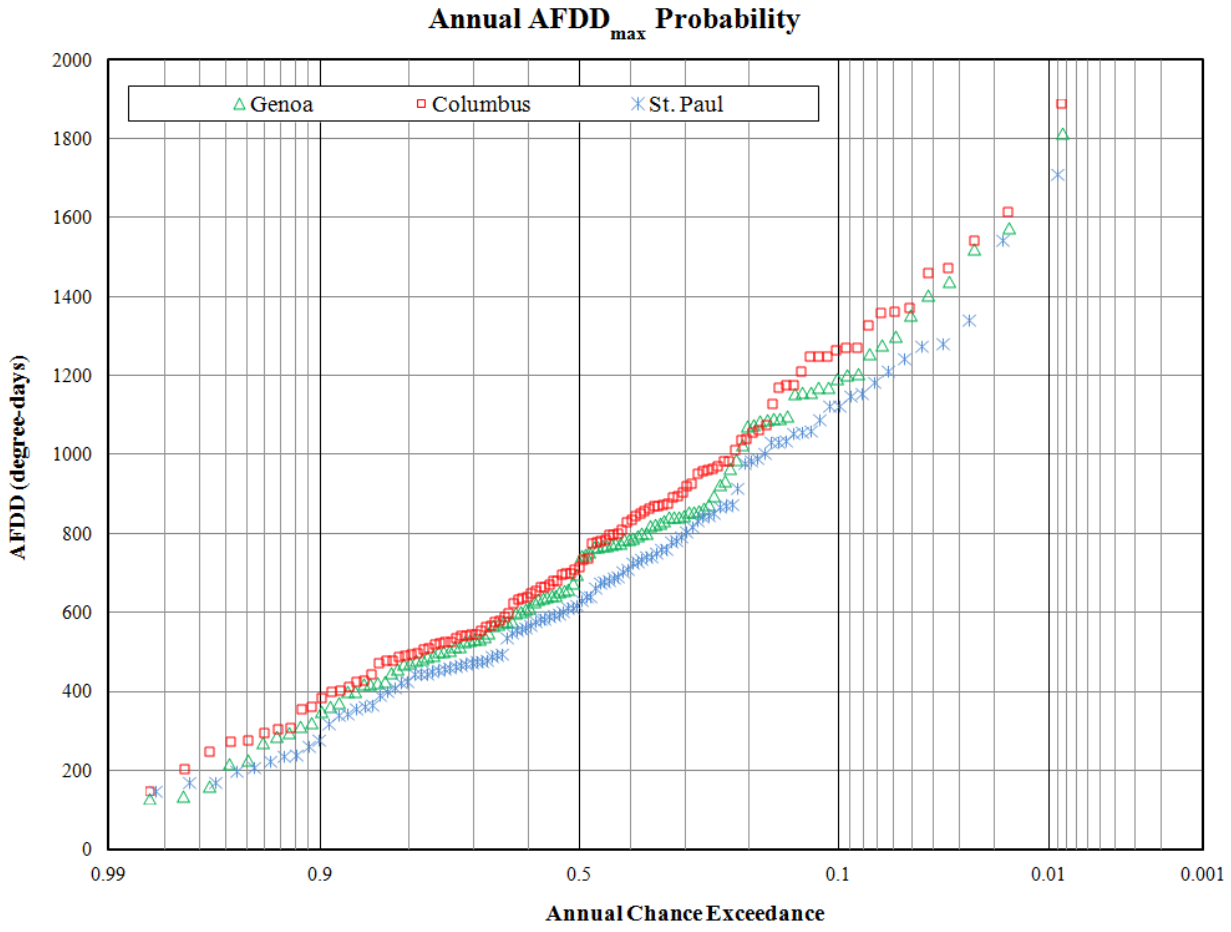

Figure 2 Annual $AFDD_{max}$ Probability at Genoa, Columbus and St. Paul.

The $AFDD_{-21}$ values may be an indicator of ice jam occurrence. Kay (2007) notes that more MDD are needed to initiate ice cover breakup on the Platte River in years with higher $AFDD_{-21}$ values. This is presumably due to greater ice growth (and hence less ice deterioration) immediately preceding ice breakup, leading to an ice cover with greater strength and therefore higher probability of resulting in jam formation. Sixty percent of the documented significant ice jams occurred in years with above average $AFDD_{-21}$. When the occurrence of $AFDD_{max}$ is

coupled with above average $AFDD_{-21}$, only 2 years, 1918 and 1893, had no documented significant flood; all other years with this combination of $AFDD_{max}$ and $AFDD_{-21}$ had significant ice jam flooding.

Likewise, higher values of MDD_{+7} may also indicate a greater likelihood of ice jam formation. White and Kay (1996) discuss that thawing degree days may be indicative of the rapidity of snowmelt but was weakly correlated with stage (i.e., severity of flooding) on the Platte River in Nebraska. Kay (2007) notes that MDD_{+7} is correlated with the increase in discharge in the 2 days preceding the peak discharge associated with an ice breakup event on the Platte River at North Bend, Nebraska. For the Loup River, 70% of the documented significant ice jams occurred in years with above average MDD_{+7}. A combination of $AFDD_{max}$ exceeding 1000 and above average MDD_{+7} results in a 50% chance of significant ice jam formation.

A review of precipitation data indicates that years with a high snow accumulation generally correlate with high discharges on the Loup River, although there was no correlation between snow accumulation and discharge with the occurrence of ice jams. However, it was noted that 80% of ice jams occurred in years with above average snowfall, and 60% of the significant ice jams occurred with snowfall in the 20^{th} percentile or higher. Only 1 significant ice jam formed in a year with a below average $AFDD_{max}$, and that was due to a rainfall event occurring on top of an existing snowpack, which indicates that rainfall may increase the probability of ice jam formation.

Although no factors point to Project operations contributing to ice jam severity, floodplain development may be a significant contributor to the severity of ice jam flooding along the lower Loup River. Floodplain development at Columbus that may impact stages include a levee along the left bank of the Loup River, highway and railroad embankments crossing the right overbank, as well as a residential development in the right overbank surrounded by a ring levee. Notable backwater under ice-affected conditions in the vicinity of the residential development and Highway 81 road crossing were noted by USACE (1994), as well as a reduction in floodplain conveyance due to these right overbank developments (USACE, 1996).

Temporal Climatic Trends: Trend analyses were performed on $AFDD_{max}$, $AFDD_{-21}$, MDD_{+7} and $AFDD_{month}$ at each of the three climate sites. It is noted that the value in any particular year is random, as a year with low $AFDD_{max}$ may be followed by a year with high $AFDD_{max}$. None of the data shows an obvious trend when looking at the entire record, as each data set exhibits a very low correlation coefficient due to the year-to-year variability. The trends over the period of record for the various parameters noted above are shown in Table 4.

Table 4 Annual Rate of Change of Key Climate Data Related to Ice Jam Formation.

Parameter	Annual Change in Value over Period of Record at:		
	Columbus	*Genoa*	*St. Paul*
$AFDD_{max}$	-0.34	-1.21	-0.24
$AFDD_{-21}$	-0.69	-0.32	-0.30
MDD_{+7}	+0.01	-0.04	-0.10
$AFDD_{Jan}$	+0.21	-0.13	-0.01
$AFDD_{Feb}$	-0.86	-1.15	-0.81
$AFDD_{Mar}$	+0.06	+0.07	+0.27

The general trend in data points to slight warming with time, although the magnitude of this increase varies with parameter and location. Two of the strongest trends are in $AFDD_{-21}$ and $AFDD_{Feb}$; both of these are significant in regards to ice breakup, as ice breakup tends to occur in late February or early March, so both $AFDD_{-21}$ and $AFDD_{Feb}$ would be indicative of ice growth just prior to breakup. The warming trend shown for both $AFDD_{-21}$ and $AFDD_{Feb}$ would indicate that breakup ice jams in the future may be less severe on average, as the ice would tend to be slightly thinner and weaker with less AFDD prior to $AFDD_{max}$ occurring. It may also indicate, however, that the ice cover will break up more readily, leading to more frequent ice jams. This may also indicate that the average ice breakup date may occur earlier on average; however, this may be offset by the slight cooling shown for $AFDD_{Mar}$ and MDD_{+7}. $AFDD_{max}$ also shows a downward trend at all three sites, which would also tend to indicate that ice jams may become slightly less severe in the future, as ice thickness would be slightly reduced, on average.

$AFDD_{max}$ does not just exhibit a downward trend, as a review of 5-, 10-, and 30-year averages of $AFDD_{max}$ indicate a cyclical nature with $AFDD_{max}$ trending up and down on a 25-35 year cycle. The Figure 3 below shows the 5-, 10- and 30-Year $AFDD_{max}$ averages at Columbus over the period of record. Similar trends were noted at both Genoa and St. Paul, although the cyclical nature of the data is not as pronounced at St. Paul. It is likely that the cyclical nature of the data will continue into the future, which would indicate that the next 10 years should likely be a period of higher $AFDD_{max}$.

A comparison of the 30-year average in $AFDD_{max}$ with the occurrence of significant ice jams can be seen in Table 5. It appears from this data that the occurrence of significant ice jams is decreasing in frequency. This data also indicates that ice jams are twice as likely to occur, on average, during periods of higher $AFDD_{max}$ than periods of lower $AFDD_{max}$. This is likely due to the high $AFDD_{max}$ periods having about a 30% probability of $AFDD_{max}$ greater than 1000, while the low $AFDD_{max}$ periods have about a 10% probability of $AFDD_{max}$ greater than 1000. This would indicate that ice jams should occur about three times more frequently during periods of high $AFDD_{max}$ as opposed to low $AFDD_{max}$, if $AFDD_{max}$ greater than 1000 was the sole indicator of ice jam formation. Since the record seems to indicate that periods of high $AFDD_{max}$ are only twice as likely to have ice jams than periods of low $AFDD_{max}$, it is apparent that there are factors other than high AFDD that determine the likelihood of an ice jam occurring.

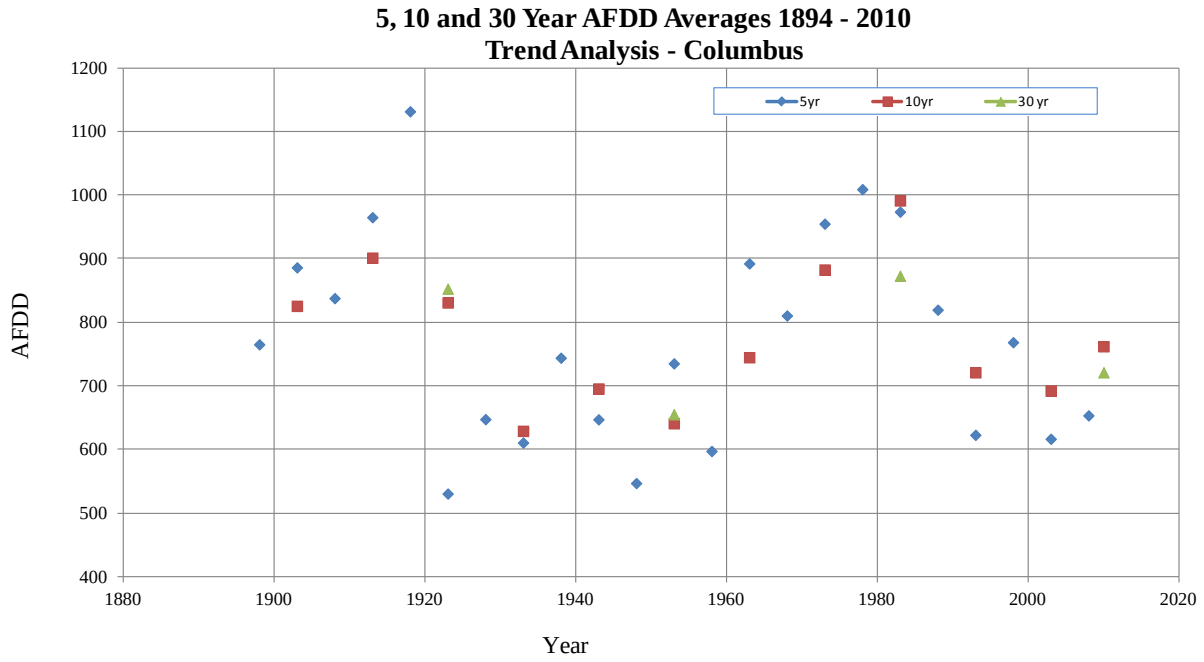

Figure 3 Average $AFDD_{max}$ Over Various Periods of Time.

Table 5 30-Year Average $AFDD_{max}$ and Ice Jam Occurrence.

	Genoa	Columbus	St. Paul	Number of Significant Ice Jams
1894 – 1923	822	853	-	4
1924 – 1953	656	655	614	3
1954 – 1983	831	872	809	2
1984 - 2010	636	721	600	1

A final trend analyzed was the Julian Date of $AFDD_{max}$ (JD_{max}), assuming JD_1 corresponded with the start of the water year on October 1, JD_2 with October 2, etc. Generally, the date of $AFDD_{max}$ is a good precursor to determining when the river ice will breakup, although in some years, most noticeably 1993, the breakup occurred prior to $AFDD_{max}$ being achieved. A review of JD_{max} over the period of record indicates that JD_{max} is occurring between 0.8 to 1.4 days earlier per decade, depending on location. This is consistent with the trends shown in Table 4 as well, as warmer temperatures will on average lead to $AFDD_{max}$ being reached at an earlier date. When the JD_{max} and $AFDD_{max}$ are averaged by decade, both show the same general cyclical trends noted in Figure 3 and shown in Table 6. However, the standard deviation of JD_{max} shows a marked increase during the past 20 years, while standard deviation of $AFDD_{max}$ does not. The reason for this significant increase in variability in JD_{max} is not readily apparent. However, it may be indicative of a more variable weather pattern with more sustained warming periods, generally occurring earlier, which would be consistent with the inter-decadal change in JD_{max} occurring earlier, as well as the decreases in $AFDD_{-21}$ and $AFDD_{Feb}$ noted earlier in this paper.

Hydraulic Modeling: Results of the HEC-RAS modeling indicate 9 locations where freezeup jams are most likely to occur between Columbus and the Loup Power Canal Headworks. These results also show that stages are higher in the Loup River when all flows are passed down the Loup River; however, this is due strictly to the higher flows, rather than any change in ice regime. Perhaps somewhat surprisingly, there was no difference between no-diversion and diversion flows in producing stretches of river where velocities are too great to sustain a stable ice cover (except via upstream progression of a downstream ice cover increasing dynamically from upstream ice transport). This indicates that regardless of Project operation, there are certain reaches of the river that can, under the right circumstances, produce significant volumes of frazil ice, which would materially impact the potential for ice jams to occur, as the volume of the ice cover can greatly increase.

The HEC-RAS modeling also indicates 8 locations where breakup jams are most likely to form, all of which correlate with historic accounts of various ice jams of varying severity. There was one historic location, however, that the HEC-RAS model did not predict as forming an ice jam, which was just downstream of the Highway 81 bridge at Columbus, where the 1969 and 1993 ice jams formed. This may be due to a lack of detailed channel bathymetry in this location, rather than an issue with the HEC-RAS ice routine.

The DynaRICE modeling showed a freezeup jam occurring in the bend just downstream of the Genoa gage, with a thin ice cover progressing upstream towards the Canal Headworks with Loup River flows of 2000 cfs or greater, which correlated very closely with ice jam locations predicted in the HEC-RAS modeling for similar discharges. Although HEC-RAS cannot presently simulate the dynamic growth of an ice cover or ice jam, the DynaRICE modeling appears to validate the location of ice jam formation selected by the HEC-RAS modeling. The results of both modeling efforts seem to indicate slightly greater volumes of ice produced in the Loup River between the Canal Headworks and Columbus, although this slight increase in volume does not appear to contribute to a significant stage increase during ice cover formation, nor does it contribute significantly to the volume of ice available at breakup to form an ice jam.

CONCLUSIONS

A review of flood history shows that the occurrence of significant ice jam flooding has not increased since the Loup Power Canal commenced operations. A lack of historical data precludes a similar comparison of minor ice-affected flooding; however, a thorough review of climatological data and use of hydraulic models does not show a difference in the occurrence of minor ice-affected flooding due to operation of the Loup Power Canal. Other factors, such as climatic variability and floodplain developments may lead to an increased flood risk during an ice jam; however, as these factors are often subtle over time, they may be overlooked as a cause of increased flood risk. It is the opinion of the author that the Loup Power Canal has not significantly changed the ice regime of the Loup River between the Headworks and its confluence with the Platte, nor has it increased the risk of significant ice jam flooding.

CLIMATE CHANGE, WATER SUPPLY, AND RAINFALL-RUNOFF RELATIONSHIPS FOR SMALL INTERMITTENT STREAMS IN SOUTHERN CALIFORNIA

Peter M. Wohlgemuth, Hydrologist, USDA Forest Service, Pacific Southwest Research Station, Riverside, California pwohlgemuth@fs.fed.us

Abstract: Changing climates and altered hydrologic regimes have made future southern California water supplies uncertain. Coupled with the enormous expense and potential unreliability of large water conveyance projects, these uncertainties have led to a renewed interest in developing local water sources. Southern California is an area where water resources are scarce yet critical to support both agriculture and burgeoning population centers. The San Dimas Experimental Forest (SDEF), located in the San Gabriel Mountains about 45 km northeast of Los Angeles, experiences a Mediterranean climate with cool wet winters and hot dry summers. Multiple small watersheds 15 to 40 ha in size have been monitored for precipitation and runoff since the mid-1930s in the Bell Canyon study area. Vegetation type strongly controls water yield, presumably reflecting the rooting depth and the water demand of the different vegetation classes. Generally, higher rainfall years produce more runoff than drier years, as expected. However, runoff is also influenced by inter-annular antecedent conditions and the distribution of precipitation throughout the rainy season. An understanding of the rainfall-runoff relationships in these small intermittent streams may help guide the prospects of developing a local water source in southern California.

INTRODUCTION

If the model projections are correct, climate change will profoundly affect global weather patterns. Although there is considerable variability among the many models, the general consensus is that temperatures will increase and precipitation will decrease in most continental areas (Cayan et al., 2008). This will alter the local hydrologic cycle (the disposition of rain and snow, evaporation, transpiration, the timing of snowmelt, water storage) that will in turn affect water supplies. In southern California, the Mediterranean pattern of wet winters and dry summers is projected to continue. However, some models predict that the area could experience periods of up to 30 years where annual rainfall is more than 10 percent below historical levels (Cayan et al., 2008), and the annual precipitation could decrease by 20 to 40 percent by the year 2100 (EPA, 2013).

Water is already a scarce commodity in southern California. Most of the water for agriculture, industry, and domestic use must travel hundreds of kilometers from northern California and the Colorado River in large conveyance projects. However, these engineered water systems are currently at capacity and may be unreliable in the future, as they face issues of aging infrastructure and legal restraints for environmental concerns (Meisen and Phares, 2011). Meanwhile, demand for water is expected to remain high.

Prior to the advent of the large engineering projects that supply water to southern California, local sources had to suffice. However, interest in local supplies declined once the conveyance projects were completed and satisfied most of the regional demand (Freeman, 2008). The disturbing prospects of most climate change scenarios coupled with the potential problems and

expense of large conveyance projects have made future water supplies for southern California uncertain. These uncertainties have led to a renewed interest in developing local water sources. Nearly 40 percent of the current demand for water in southern California is still produced from local aquifers (Freeman, 2008). Moreover, developing local supplies through storm water management, using reclaimed wastewater, and groundwater management is seen as the best new source of water for future southern California needs (Nelson, 2012).

One possible source of water not currently being exploited is the intermittent streamflow from the hundreds of canyons in the mountains that ring the coastal plains and valleys of southern California. While some of this water recharges the groundwater reservoir, both naturally and by being directed into spreading grounds, much of the stormflow is quickly routed by flood control structures to the ocean. Perhaps some of this water could instead be harvested for local water supply.

The USDA Forest Service has been monitoring rainfall and stream discharge in the canyons of the San Gabriel Mountains since the 1930s. This paper explores the lessons learned from these extensive rainfall-runoff relationships that could perhaps help guide the prospects of using intermittent streams from mountainous canyons as a potential local water supply. The objectives of this study are as follows: 1) to synthesize long-term rainfall and runoff records from the San Dimas Experimental Forest; and 2) to determine the influence of rainfall distribution, antecedent conditions, and vegetation type on runoff quantity.

STUDY AREA

The San Dimas Experimental Forest (SDEF) is a nearly 7000 ha research preserve administered by the USDA Forest Service, Pacific Southwest Research Station, and has been the site of extensive hydrologic monitoring for over 80 years (Dunn et al., 1988). The SDEF was originally established in 1933 to document and quantify the hydrologic cycle in semiarid uplands with intermittent headwater streams. With its headquarters at Tanbark Flat (34^o 12' N latitude, 117^o 46' W longitude), the SDEF is located in the San Gabriel Mountains, about 45 km northeast of Los Angeles, California (Figure 1).

Elevations in the Bell Canyon study area range from 750 to 1050 m and topography consists of a highly dissected mountain block with steep hillside slopes and steep channel gradients. Bedrock geology is dominated by Precambrian metamorphics and Mesozoic granitics that produce shallow, azonal, coarse-textured soils (Dunn et al., 1988). The region experiences a Mediterranean-type climate, characterized by hot, dry summers and cool, moist winters. Temperatures range from -8^o C to 40^o C. Mean annual precipitation, falling almost exclusively as rain, is 715 mm in the SDEF (80-year record), but rain during individual years can range from 252 to 1848 mm.

Native vegetation in Bell Canyon consists primarily of mixed chaparral. Plant cover on south-facing slopes ranges from dense stands of chamise (*Adenostoma fasciculatum*) and ceanothus (*Ceanothus* spp.) to more open stands of chamise and black sage (*Salvia mellifera*). North-facing hillsides are dominated by scrub oak (*Quercus berberidifolia*) and ceanothus, with occasional

hardwood trees – live oak (*Quercus agrifolia*) and California laurel (*Umbellularia californica*) – occurring on moister shaded slopes and along the riparian corridors (Wohlgemuth, 2006).

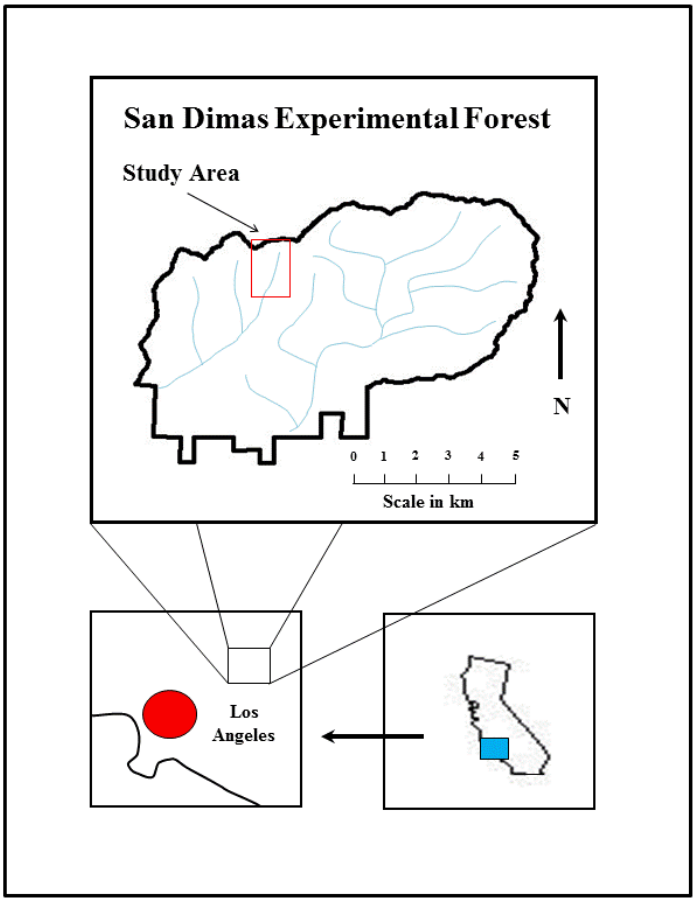

Figure 1 Location map of the San Dimas Experimental Forest.

One of the management treatments following a wildfire in 1960 involved type-converting the native chaparral vegetation in some watersheds to a mixture of perennial grasses. It was thought that type-conversion would aid in future fire control and would enhance water yield by replacing deep-rooted shrubs with shallow-rooted grasses (Rice et al., 1965). These perennials included a variety of wheatgrass species (*Agropyron* spp.), Harding grass (*Phalaris tuberosa* var. *stenoptera*), big bluegrass (*Poa ampla*), smilo grass (*Piptatherum miliaceum*), and blando brome (*Bromus hordaceous*) (Corbett and Green, 1965). Since 1960, many of the seeded grass species have disappeared from the sites and substantial amounts of buckwheat (*Eriogonum fasciculatum*) and black sage have established on the type-converted watersheds.

METHODS

Four small watersheds were selected for study in Bell Canyon (Figures 1 and 2): two in type-converted grass vegetation – Bell1 (32 ha) and Bell2 (41 ha) – and two in native chaparral –

Bell3 (25 ha) and Bell4 (15 ha). Two raingages monitored precipitation inputs across the study watersheds, one at the headwaters and one at the outlets (Figure 2). Although rainfall was very similar between these two gages, total annual rain was computed as the area-weighted average of the two stations. In addition to annual totals, rainfall is also characterized by the amount received during the highest three-month period, or quarter, describing the timing of major rain events throughout the year. Rain was assumed to be spatially uniform across the landscape and was computed as cubic meters based on watershed area.

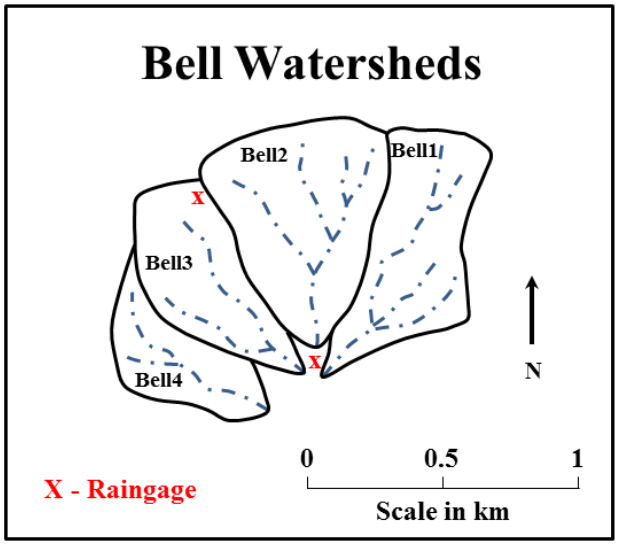

Figure 2 Bell study watersheds.

Prior to 1969, stream discharge for all watersheds was measured in small 90° v-notch weirs for low flows (<50 l s^{-1}) and 0.91 m (3-foot) flumes for higher flows. Following the 1969 floods that destroyed most of the low-flow gaging equipment, all streamflow was monitored in large 120° v-notch weirs in Bell1, Bell2, and Bell3. However, a reconstructed 90° v-notch weir and flume arrangement continued to measure flow in Bell4. Stage height for each instrument was measured in a stilling well by a float-operated recorder to produce a paper chart. In the office, stage heights were manually read from the stream charts at 6 hour intervals and at inflection points during storm events. Discharge was computed from stage height using rating curves developed for each instrument and summed over the time intervals to get an annual water yield in cubic meters. Partial-year records resulting from equipment failure or missing charts were not used in any subsequent analyses.

RESULTS AND DISCUSSION

Rainfall and stream runoff values for each of the Bell study watersheds from hydrologic years (October to September) 1960 to 2000 are arrayed in Table 1. While continuous precipitation records are available from the two raingages over the period of study, stream discharge measurement was sporadic. A wildfire in 1960 and subsequent debris-laden flows prevented continuous stream gaging for three years following the fire. A large flood destroyed the low-flow gaging equipment in all watersheds in 1969. Stream charts are missing for Bell4 from the

Table 1 Rainfall and stream runoff values for the Bell watersheds for hydrologic years 1960 to 2000. First quarter – Oct. to Dec. Second quarter – Jan. to Mar. Third quarter – Apr. to June. Fourth quarter – July to Sep. TC – type converted grass vegetation. NC – native chaparral vegetation. Runoff Ratio = Annual Streamflow/Annual Rainfall. (.) – full-year records not available because of equipment failure or missing stream charts.

1960s and from Bell1 from the 1970s. Miscellaneous missing charts and equipment failures (pen problems, clock stoppages, and float problems) have created additional data gaps for all watersheds throughout the study period. Thus, only half the runoff years were available for analysis.

Average annual rainfall over the study period was 750 mm, slightly more than the mean for the 80-year record on the SDEF. For subsequent comparisons, annual rainfall was divided into three categories: high (> 150 percent of average or 1130 mm; n=8); low (< 50 percent of average or 380 mm; n=7); and normal (between 380 mm and 1130 mm; n=26).

Because of the disparity in watershed size, stream runoff was normalized by area for meaningful comparisons (Table 1). Additionally, the runoff ratio (Ratzlaff, 1994), or the percentage of rainfall that leaves the watershed as streamflow, was calculated. A runoff ratio is a commonly used metric in hydrologic studies to describe basic watershed behavior. For this study, runoff ratios ranged from 1 percent to 75 percent for all watersheds and all years, with an average of 14 percent. These values correspond well with other published runoff ratios for southern California watersheds (Burke et al., 2013; Kinoshita and Hogue, 2015).

There was a distinct difference in stream discharge associated with vegetation type. Both the normalized runoff and the runoff ratio were similar within the vegetation classes of type-converted grass (Bell1 and Bell2) and native chaparral (Bell3 and Bell4). However, considerably more water flowed from the grass watersheds than the chaparral (Table 1; Figure 3). This general trend confirms earlier studies at the SDEF and from similar areas in California and Arizona (Hill and Rice, 1963; Hibbert, 1971; Rich and Gottfried, 1976; Pitt et al., 1978) and supports the rationale for replacing deep-rooted shrub species with shallow-rooted grass to increase water yield (Rice et al., 1965). Higher water yield from grass-dominated watersheds suggests that extensive type conversion of southern California shrubland to grasses could substantially increase local water supplies. However, apart from the wholesale ecosystem changes and effects on native fauna, previous studies have shown that there are serious environmental consequences of type conversion, including increased erosion in the form of soil slips and slope failures (Rice et al., 1969) and degraded water quality (Riggan et al., 1985).

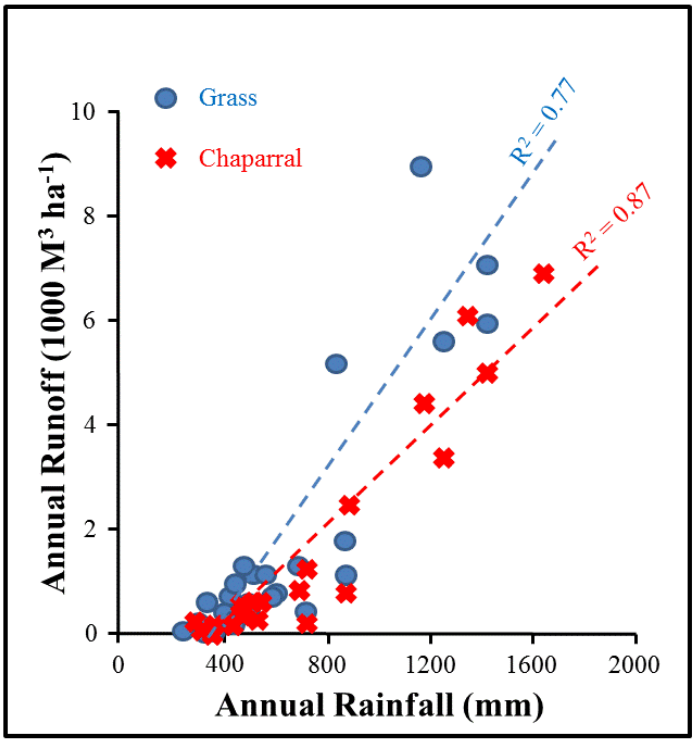

Figure 3 Runoff as a function of rainfall by vegetation type in the Bell Watersheds.

There is a good correlation between stream runoff and precipitation for both vegetation types (Figure 3). However, for the intermittent streams in Bell Canyon, heavy and protracted rainfall can produce streamflow throughout the entire year. In this case, rain from one year could continue to generate surface flow into the following year. This poses a problem with the runoff ratio (Table 1) in that flow is also affected by inter-annular antecedent conditions. So in Bell Canyon, when a high rainfall year is followed by a normal or even a low rainfall year, more runoff is produced in that following year than would otherwise be expected (in Table 1, compare 1968 with 1975 or 1976; compare 1981 or 1999 with 1987 or 1990). In contrast, a high rainfall year is always associated with high runoff, no matter what the prior conditions (1978 or 1995). Therefore, there is a lag in stream discharge from a previous high rainfall year that can enhance flow in the subsequent year.

Another factor that may affect streamflow is the distribution of rain storms throughout the year. Except under the high rainfall lag condition mentioned above, intermittent streams require early season storms to saturate the soil mantle before flow is generated by later storm events. Rainfall amounts for the highest three-month period for each year in Bell Canyon are shown in Table 1. Of the 41 hydrologic years of record, the greatest rain was received 28 times in the second quarter (Jan. to Mar.), 12 times in the first quarter (Oct. to Dec.), and once in the third quarter (Apr. to June). For low rainfall years, low runoff was produced no matter when the rain fell. Similarly, for high rainfall years, the distribution of rain was not a factor in generating the high flows. However, for more average rainfall conditions, those years that had wet second quarters generally produced higher amounts of runoff compared to those years with wet first quarters (in

Table 1, compare 1974, 1976, 1982, and 1991 with 1971, 1975, 1985, 1988, and 1989). Therefore, in normal rainfall years, the timing of storms can affect the amount of streamflow.

SUMMARY

The prospects of reduced rainfall resulting from global climate change and the potential unreliability of large conveyance projects have made future water supplies in southern California uncertain, prompting a renewed interest in developing local sources. One potential source is the intermittent streamflow from the canyons of the local mountains. Long-term research from the San Dimas Experimental Forest in the San Gabriel Mountains shows that stream runoff is strongly correlated with rainfall amounts and that this flow is mildly enhanced when major storms occur later in the rainy season. Streamflow is also greater than expected the year following heavy rains, as a lag component of the high rainfall carries over to the subsequent year. More water is produced from catchments that have been type-converted to grasses than from native chaparral shrublands, presumably reflecting the rooting depth and water demand of the different vegetation classes. While it is tempting to recommend future type-conversion to increase water yield, this must be balanced by the wholesale ecosystem changes and the negative environmental consequences associated with this method of vegetation change.

JUSTIFYING INFLOW DESIGN FLOOD FOR DAM HYDROLOGIC SAFETY: HOLISTIC COMPARISON OF METHODS

S. Samuel Lin, Civil Engineer, FERC, Washington, D.C., Shyangchin.Lin@FERC.gov

Abstract: The approach of selecting adequate inflow design floods (IDFs) is critical to verifying the existing or implementing designing acceptable hydrologic safety for dams. The purpose of this paper is to present state-of-the-methods for selecting an IDF in a technically defensible fashion by way of: (1) Clarifying the hypothetical dam failure scenarios between both hazard-classification based preliminary IDF determination and the more refined potential failure modes (PFMs) based IDF determination; (2) Discerning the iterative process needed for an optimal IDF determined from the refined incremental consequence approach (ICA); and (3) Recognizing the merits of the refined risk-informed decision making (RIDM) approach as a more advanced method and its challenges as well. Two example application cases are provided to illustrate and compare the IDF selection processes of those methods which are addressed in this paper.

Note: The opinions and views offered here are those of the author, and are not necessarily those of the Federal Energy Regulatory Commission, individual Commissioners, or other members of the Commission's staff.

BACKGROUND INFORMATION

Federal and State agencies bring commitment to public safety. The Federal Emergency Management Agency (FEMA) published the P-94 guidance document entitled, "Selecting and Accommodating Inflow Design Floods for Dams" in August 2013. It provides updated guidance for the analysis, evaluation, and assessment of the hydrologic safety for new and existing dams. Its release was intended to provide a flexible framework within which both federal and state agencies can develop and update guidelines according to their varied goals and resources. To be consistent and stable over time, the basic philosophy and principles are described, but not all procedures provided, in order to adequately manage the hydrologic safety risk to dams by passing a required minimum magnitude flood flow for the sake of public safety.

The methodologies of both deterministic and probabilistic approaches, shown in Fig. 1 Methodologies of IDF Selection: Deterministic vs. Probabilistic Methodology, are correctly being used to facilitate dam safety risk management for evaluating hydrologic safety of dams. The deterministic approach includes the prescriptive approach based solely on a dam's hazard potential class, and the ICA is based on the incremental upstream/downstream inundation situations. The more advanced probabilistic approach is a quantitative risk oriented RIDM process to meet a defined tolerable risk level.

To illustrate the merits and shortcomings of the deterministic and probabilistic approaches as described, two case studies are presented as examples (for reference only) to demonstrate an optimal hydrologic safety protection for a dam. Non-structural solutions to IDF issues such as considering the effectiveness of Emergency Action Plan (EAP) execution on dam failure consequences, removing dam, land acquisition, structure abandonment, etc. are not discussed in this paper.

IDF BASED HYDROLOGIC SAFETY STRATEGY

Prescriptive method, ICA method and RIDM approach are available techniques to develop a quantified hydrologic safety strategy for dams to accommodate the wide variety of situations, available resources, and conditions. The IDF analysis starts from hypothetical dam failure assumptions under various flood loading conditions for dam failure potential consequence magnitude estimations. The PFMs of a dam system including dam and appurtenant structures can be identified through a PFM analysis (PFMA) exercise. In practice, the dam breach assumptions are evaluated to use the most conservative parameters resulting in a worst downstream inundation scenario for the relatively simpler prescriptive approach but more realistic, physically based PFMs parameters are used for the refined ICA and RIDM approaches. Thus, the prescriptive method's assumed parameters are often greater than the ICA/RIDM methods'. The subsequent consequence (life and property losses, environmental damage, etc.) are estimated basically based on dam failure-induced flood flow inundation levels at the downstream impact areas.

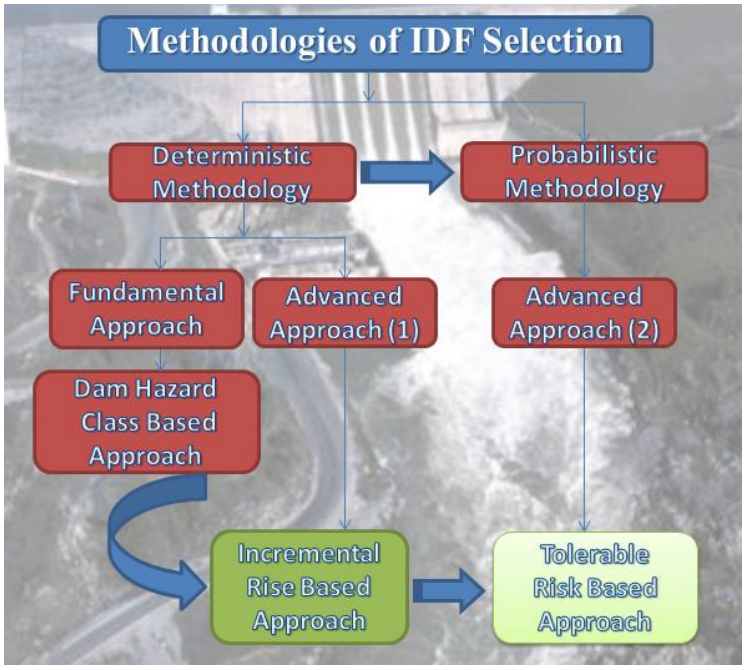

Fig. 1 Methodologies of Inflow Design Flood Selection: Deterministic vs. Probabilistic Methodology

In general, a PFM is defined as a process (i.e., dynamic mechanism) in which the dam could reasonably and logically be expected to fail under a certain adversarial condition equal to or greater than its failure threshold. The most common hydrologic PFMs include overtopping erosion of embankments/abutments, erosion and back-cutting of earthen channel spillways,

cavitation of chute channels, internal erosion (seepage and piping), dam overturning/sliding, and overstressing of the structural components of the dam, all of which may be caused by high reservoir levels due to extreme hydrological events. To attempt to avoid these PFMs, spillways are designed to safely pass the justified IDF based on the analysis results of any of the above mentioned alternative approaches.

Guiding Definitions of IDF: An IDF can technically be defined in three ways. The first is by the dam hazard class based prescriptive IDF. The second is the flood flow above which the incremental increase in downstream inundation water surface elevation due to failure of a dam is no longer considered to present an unacceptable additional downstream threat. The first and second definitions are based on deterministic approach results. The third is probability based and the IDF is the flood flow above which the consequence risk due to failure of a dam does not exceed a given level of "tolerable risk". For instance, some agencies using two tolerable risk indices to justify the IDF selection such as averaged annual failure probability (AFP) of a dam and a resulting averaged annual life loss (ALL).

Inundation Loss Rating Factors: For an IDF study, it is required to perform and provide a precise assessment of the downstream adverse impact potentials as the consequences of upstream dam failure caused by various hydrologic loading conditions. In assessing the consequences, the likelihood of loss of human life and property damage must be evaluated using dam failure analysis results and sound engineering judgment. Two rating factors commonly used to determine such likelihood are inundation depth and associated flow velocity. The references of theoretical and experimental data for building vulnerability (from Karvonen et al., 2000) and on humans and monoliths (after Lind/Hartford, 2000) can be used as a judgment basis for harmful rating factors.

Vital Importance of Implementation of the IDF Requirement: The IDF is utilized as the flood hydrograph entering a reservoir that is used as a basis to design and/or modify a specific dam and its appurtenant works; particularly for such as sizing the spillway and outlet works, and for determining the maximum flood overtopping prevention height of a dam, freeboard, and flood storage requirements. Thus, appropriate selection of the IDF is the first step in evaluating or designing a specific dam to address hydrologic PFMs and reduce risks to the public to an acceptable degree of hydrologic safety. As a result, seeking such an IDF for a dam is important to balance the risks due to its potential hydrologic failure with resulting downstream consequences and the benefits derived from the dam.

SUITABLE HYPOTHETICAL DAM FAILURES FOR HAZARD CLASSIFICATION AND REFINED IDF APPROACHES

The prescriptive approach is the method for a planned or existing dam to be evaluated for a prescribed standard, based on the hazard potential classification of the dam. This method's IDF criteria are intended to be conservative through a more conservative hypothetical dam failure scenario. It is a relatively simpler approach than other two refined approaches. But it is not

intended to assure that there is an economical marginal benefit from designing for such a conservative IDF. For some cases, specifically, this approach's IDF may be just a preliminary value and could be further reduced by the PFMs based refined ICA or RIDM approaches as shown in Fig. 2 Methodologies of IDF Selection: Preliminary Study vs. Refined Study. The basic cause is due to different dam failure assumptions as addressed below.

Failure assumptions for Hazard Classification Based Preliminary IDF Determination: The hazard potential classification of the dam is performed with the philosophical idea that is all about a dam's hypothetical worst failure case scenario. Namely, the existing dam conditions are not considered. A dam must be assumed to fail by any magnitude flood event for the purpose of evaluating its associated worst hazard potential. Thus, a hypothetical dam failure is estimated using worst dam breach parameters which are not necessarily based on the dam's PFMs. Table 1 Recommended Prescriptive Approach IDF Requirements for Dams under Flood Loadings illustrates the IDF requirements using the prescriptive approach.

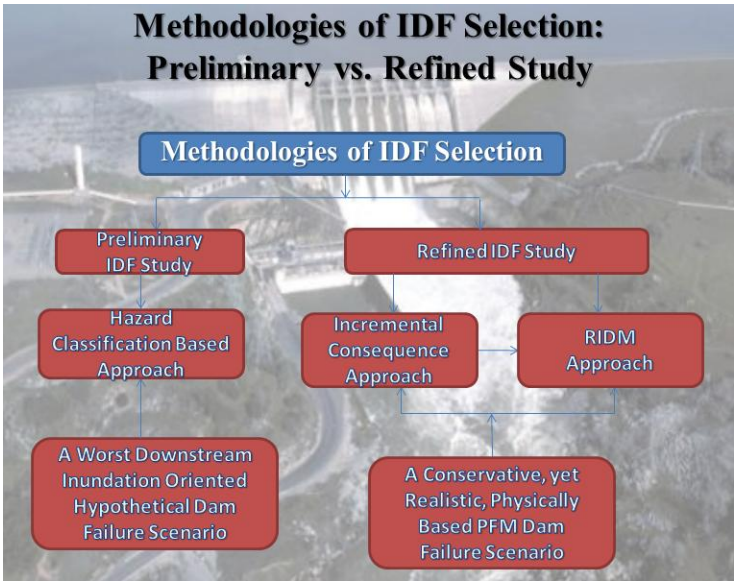

Fig. 2 Methodologies of Inflow Design Flood Selection: Preliminary Study vs. Refined Study

Table 1 Recommended Prescriptive Approach Inflow Design Flood Requirements for Dams under Flood Loadings

Hazard Potential Classification	Definition of Hazard Potential Classification	Inflow Design Flood (IDF)
High	Probable loss of life due to dam failure or misoperation (economic loss, environmental damage, or disruption of lifeline facilities may also be probable, but are not necessary for this classification)	PMF
Significant	No probable loss of human life but can cause economic loss, environmental damage, or disruption of lifeline facilities due to dam failure or misoperation	0.1% Annual Chance Exceedance Flood (1,000-year Flood)

Low	No probable loss of human life and low economic and/or environmental losses due to dam failure or misoperation	1% Annual Chance Exceedance Flood (i.e. 100-year flood) or a Smaller Flood Justified by Rationale

Failure assumptions for PFMs Based Refined IDF Determination: The philosophical idea and engineering concepts for refined IDF approaches are a direct contrast to dam hazard classification based IDF approach. The philosophical idea is about a dam's realistic capability to safely pass a required flood event given the existing dam conditions. Whether or not a dam is assumed to fail depends upon its PFMs under extreme hydrologic loading conditions. The engineering concept is that a hypothetical dam failure should be estimated using reasonably conservative, realistic, physically based dam breach parameters related to the dam conditions.

A Hybrid Case of Hazard Classification and PFM Based Failures: In dam hazard classification studies, only the most severe dam failure scenario is assumed. However, the most likely mode of dam failure for the selection of IDF is not always the most severe. For example, the concrete portion of a composite dam system (e.g., composed of concrete and embankment dams) is assumed to fail to produce the largest uncontrolled flow downstream to classify the dam's hazard potential. On the contrary, for a refined IDF analysis, the PFM of the embankment portion should be considered since it is most likely to fail during a critical overtopping event.

ICA METHOD'S ITERATIVE PROCESS TO OPTIMIZE IDF

Conceptual Scheme: As indicated above, the IDF selection using ICA is the flood above which there is a negligible increase in downstream inundation depth, flow velocity, and/or consequences due to failure of the dam when compared to the same flood without dam failure. Figure 3 Schematic Illustration of ICA for the selection of IDF presents a schematic of such a comparison. This process is continued until the flood of greatest magnitude that causes incremental consequences is identified.

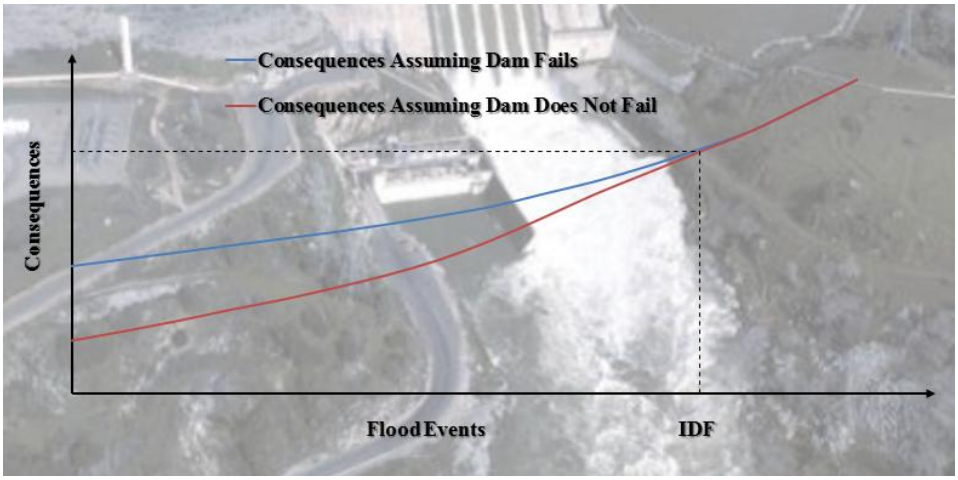

Figure 3. Schematic Illustration of Incremental Consequence Approach for the selection of IDF

Good Engineering Practices (GEPs): The GEPs consist of proven and accepted engineering methods, procedures, and practices that provide appropriate, cost-effective, and well-documented

solutions to meet user-requirements and compliance with applicable regulations. In GEPs, an appropriate measure needs to be studied to modify a dam to increase its conveyance capacity to safely pass the derived initial IDF value. For some cases, moreover, it must go through an iterative process as shown in Fig. 4 Incremental Consequence Approach: A Complete Iterative Process to Further Refine the Initial IDF's flow chart. The resulting IDF can be further refined by taking into account the hypothetically added spillway capacity. Thus, a comprehensive measure to modify a dam to increase its conveyance capacity to safely pass an adequate IDF must go through such an iterative process. The Case 1 example provided later illustrates the process of repeating the analysis until convergence to attain a minimum acceptable IDF.

Potential New Adverse Impacts: In the iterative process for the IDF selection and implementation, several hydraulically advantageous measures may be utilized to improve the spillway capacity to meet requirements while some disadvantages described below could also exist which should be identified and avoided by performing a supplemental PFMA (SPFMA) exercise:

- Raising the crest of dam: It can increase the downstream consequences should the dam fail by creating a larger dam breach flood wave or it may increase upstream inundation consequence during extreme flood events.
- Widening the spillway, or lowering the crest of the spillway and installing crest gates: It may actually increase the risk to the downstream public by increasing the spillway flows during hydrologic events that occur more often.
- The above measures could also introduce new PFMs, thus increasing dam failure risk.

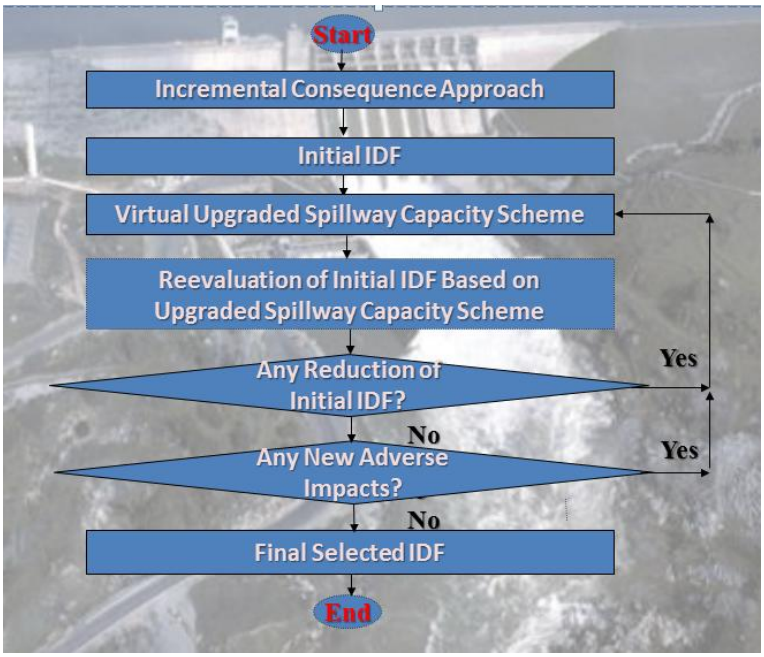

Fig. 4 Incremental Consequence Approach: A Complete Iterative Process to Further Refine the Initial Inflow Design Flood

PROBABILISTIC APPROACH TO SELECTING IDF

Risky Society toward a New Modernity: We live in a contemporary "high risk society" in which risk is everywhere. We may estimate either the cost-effectiveness between the well-being and risk or the risks to compare with tolerable risk levels by means of probabilistic risk assessment (PRA). The pursuit of absolute safety or zero risk is impractical, and self-deception. A risk assessment is not the sole basis for a decision, but rather it provides a systematic way of understanding a dam's PFMs, quantitative probabilities of loadings and structural failures, and the potential consequences and associated uncertainties. Current complementary use of the probabilistic method of RIDM approach to the deterministic method can be significantly expanded by state-of-art risk-based analysis for more realistic dam hazard potential assessment. Such a RIDM process provides a defensible basis for making decisions and helps to identify the greatest risks and prioritize efforts to minimize to a tolerable risk level or even eliminate them if it is possible.

Risk-informed Process: The RIDM approach in a risk-based system synthesizes the ICA with risk estimation through using information and reports available for the dam under study, historical performance of comparable dams, and experience based engineering judgment, etc. Specifically, RIDM is a decision making process to decide on a course of action for dam safety improvement. Qualitative and quantitative information about dam safety risks are considered along with other project-specific information. Risk-informed hydrologic hazard analysis includes a site-specific evaluation of the probabilities of a full range of extreme hydrological events and performance of the dam during those events, and evaluates in more detail the social, economic, and environmental consequences of failure. In short, RIDM is a tool for evaluating hydrologic events in a risk-based context and the level of effort is proportion to safety issues.

Quantitative Risk Indexes: Risk can be expressed in terms of life-safety and economic consequences on an annualized basis. The units of measure for dam safety risk are such as loss-of-life per year for life-safety, and costs (dollars) per year for property damages and economic losses. For instance, the RIDM process can include specifically assessing individual incremental life safety risk using probability of loss of life, societal incremental life safety risk expressed as a probability distribution of potential life loss (See F-N Chart of Fig. 5 A commonly recognized standard for life loss tolerable risk), and societal incremental life safety risk expressed as an averaged ALL. As an example, some agencies use two major tolerable risk indices to justify the IDF selection including averaged AFP of a dam (e.g., AFP $\leq 1.0 \times 10^{-4}$/year), and a resulting ALL (e.g., ALL $\leq 1.0 \times 10^{-4}$ lives/year). As examples, some merits of RIDM approach compared to the ICA method are illustrated in Table 2 Examples of Advantages of RIDM Approach over ICA Method from a practical perspective on how this approach works more realistically for an advanced IDF study.

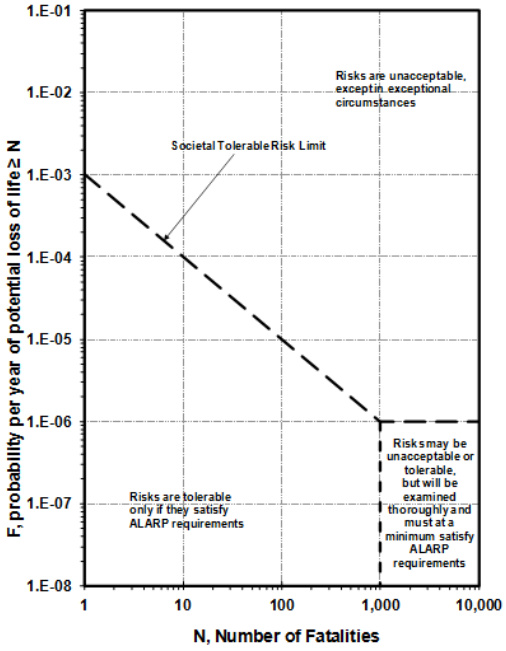

Fig. 5 A commonly recognized standard for life loss tolerable risk ("ALARP": As Low As Reasonably Practical" - the residual risks can be cost effectively reduced further)

Table 2.1 One Example of Advantages of RIDM Approach over Incremental Consequence Approach Method

ITEM	RIDM APPROACH	ICA METHOD
Dam Failure Mechanism Rationalization		
Consideration and evaluation of dam PFMs on critical uncertain sequential factors	More realistically sequential occurrence probabilities estimated as needed based on a flood event tree risk model in which loading, response and consequence of dam failure are represented by levels of branching	Subjective, conservative overall assumptions usually made on one single PFM without specifically describing the failure mode's sequential physical process
Measurement of a PFM parameter's variation	The variation considered by an uncertainty analysis (i.e., risk analysis)	A deterministic way used through sensitivity analyses
Judgment on likelihoods of PFMs occurrence	Numerical engineering judgment by quantified risk analysis based on reasonable representation of probabilities of "System Response Probability (SRP)"	Best engineering judgment on likelihoods of PFM categories I/II (most or considered but not most significant PFMs) but lacking consistency without clear criteria
Assumption on dam overtopping failure depth (i.e. the "threshold inflow flood" depth) based on factors of duration, down-stream slope protection, flow velocity, etc.	Assuming several most likely overflow depths with varied probabilities to fail the dam matching various flood magnitudes of the rising limb of a flood hydrograph regardless its frequency magnitude	Assuming a single flood frequency based conservative overtopping flow depth, some even overly conservatively assuming at a reservoir peak level

Dam breach size	Varied cases of multiple assumed sizes with individual probabilities while actual size remains uncertain	A method simplified as one single size causing a worst inundation scenario through a sensitivity analysis which may be overly conservative
Uncertainties on structural component functions	Gate reliability, spillway debris plugging, etc. driven by probabilities based on historical records	Dam structural component functions usually assumed as designed without flexibility

Table 2.2 Three Examples of Advantages of RIDM Approach over Incremental Consequence Approach Method

ITEM	RIDM APPROACH	ICA METHOD
Consequence Estimation		
Consequence model of life and property loss estimates in terms of downstream structures	Life and property loss estimates associated with each end node of the probability based event trees	Life and property loss estimates as a lump sum figure
Life loss estimation	Uniform ALL risk basis	One life loss considered equivalent to significant life loss consequence
Justification of IDF		
Risk reduction decision making basis for a selected IDF	Quantitative risk reduction measurements allowing uncertainties judgment and flexibility of IDF by ALARP principle	No overtopping allowed for IDF
Final justified solution	Tolerable risk levels of such as APF/ALL to be satisfied	Analysis result of insignificant inundation incremental rise
Sensitivity analyses for structural and non-structural measures to reduce dam failure hazard potential	Exploring the effects of modifying dam structure and adjusting the evacuation effectiveness	Exploring the effects of adjusting parameters of dam structure breach rather than including evacuation effectiveness
Solutions for Achieving Required IDF		
Justification solutions to an inadequate spillway system	Both structural/non-structural measures such as improving evacuation effectiveness	Structural measures only as a common approach
Risk reduction assessment for acceptable life and property safety risks	Using ALARP principle to evaluate the strength (i.e., adequacy and degree) of justification of risk reduction options (e.g., USBR uses increasing justification to reduce the APF)	Only the required IDF based spillway capacity upgrading as the solution

CASE STUDIES ON SELECTING IDF

Case I study on Incremental Consequence Approach: The ICA initial IDF could be reduced by taking into account the hypothetically added spillway capacity through an iterative process.

Refer to the paper by D. Steines, etc. (2003), which discusses the case of Otter Rapids Dam (Fig. 6 Otter Rapids Dam Built in 1908). The dam was classified as a high hazard potential impounding structure so the prescriptive approach resulting IDF was the PMF of 35,600 cfs. The

reason for a selected relatively smaller IDF than an initial one is that the iterative process of ICA was used to reevaluate the IDF. The IDF is influenced by routing extreme flood events through a hypothetical upgraded total spillway capacity, and vice versa the determined new spillway design is dependent on the reexamined IDF.

In this specific case by adding spillway capacity, through lowering the crest, the reservoir storage would be reduced and the discharge increased for a given flood magnitude. The reduced storage would result in lower reservoir elevations. The increased discharge would result in higher downstream river stages. The differential head between the reservoir and the tailwater would be reduced significantly. Therefore, the incremental rise in the downstream flood elevation due to a dam failure would be reduced. As summarized in Table 3 Example of a Selected IDF through an Iterative Refined Process, the adopted converged IDF is reduced 50% or 13.2% from 35,600 cfs or 20,500 cfs to 17,800 cfs, respectively. Lowering the spillway in this case would not increase the risk to the public by more frequent flooding events.

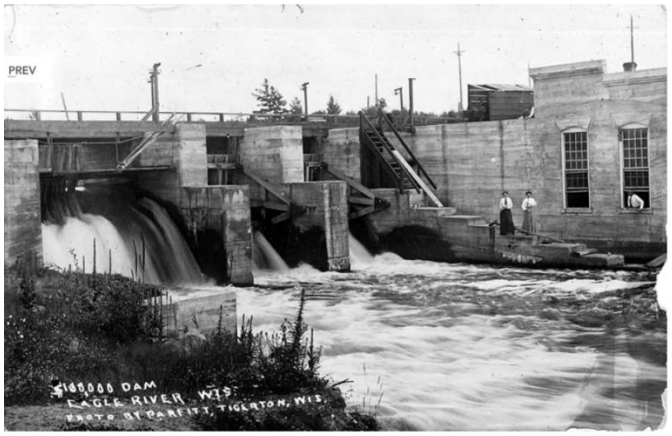

Figure 6. Otter Rapids Dam Built in 1908

Table 3. Example of a Selected Inflow Design Flood through an Iterative Refined Process

Hazard Classification Based Preliminary IDF (i.e. PMF) (cfs)	ICA's Refined Initial IDF (cfs)	Selected Converged IDF (cfs)	Reduction (%) by Selected Converged IDF	
			Preliminary IDF	Refined Initial IDF
35,600	20, 500	17,800	50.0	13.2

Case II study on RIDM Approach: The PFM based probabilistic consequence driven risk assessment is applied as a tool for the selection of IDF.

Refer to the paper by J. Hedien (2013), which discusses the case of two concrete core-wall earth embankments on the same river (Fig. 7 Upstream and Downstream Tandem Dams A & B Located on a Same River) which have insufficient spillway capacities to pass the preliminary IDFs of PMFs without overtopping and failing the dams. By applying the ICA, a key result in

Table 4 shows the comparison of determined IDFs between based on hypothetical dam failures occurring at dam crest overtopping depths of 10 feet (i.e. at the reservoir peak level) and two feet (best judgment). Another key result shows the comparison of selected IDFs between the ICA and the RIDM method.

The RIDM approach assesses both the probability of the flood loading and the probability of the resulting adverse response to evaluate AFP of each dam. The estimated total risk is the summation of risk from the identified PFMs. Based on the noted acceptable tolerance risk standards in the table, the IDFs of 60,000 cfs and 65,000 cfs were selected for the upstream and downstream dams, respectively. A 99% evacuation effectiveness was assumed (i.e. 1% not evacuated). Reductions from the prescriptive method's to the ICA's and RIDM approach's IDFs are 53% and 71%, respectively as shown in Table 4 IDF Study Results by ICA and RIDM Process for Two Tandem Dams.

Figure 7. Upstream and Downstream Tandem Dams A & B Located on a Same River

Table 4. Inflow Design Flood Study Results by Incremental Consequence Approach and RIDM Process for Two Tandem Dams (IDF unit: 10^3 cfs)

Tandem Dams	**Preliminary IDF by Prescriptive Method: Governing PMF (Cool Season)**	**ICA Refined IDF: Assumed Overtopping Failure Depths**		**RIDM Approach Refined IDF to Meet Tolerable Risk Levels***	**Final Adopted IDFs**	***For this example, the accepted **Tolerable Risk Levels** set by an agency and a foreign country committee : AFP ≤ 1.0 x 10^{-4}/year (BOR) & ALL ≤ 1.0 x 10^{-4} lives/year (ANCOLD)
		10 feet at Peak Reservoir level	Two Feet			
U/S Dam A	223	129	70	60	60	
D/S Dam B	230	230	135	53	65	

ADVANTAGES AND CHALLENGES OF IDF SELECTION METHODS

The FEMA P-94 guidance document (2013) should be utilized for the appropriateness and applicability of hydrologic safety design criteria for dams. The basic philosophy and principles are described in sufficient detail to promote a compatible approach among state and federal agencies in the design and evaluation of dams from the standpoint of hydrologic safety. Considering many engineering analyses are based on limited information, estimation results may not be fixed but inherently will have a margin of uncertainty and are subject to change as new information is obtained. Whichever IDF selection approach is applied needs to include a periodic review of information such as dam conditions, present and reasonably anticipated future upstream and/or downstream developments for hydrologic characteristics/regime and potential hazard changes, etc. to ensure the validity of the conducted IDF analysis results.

Either a deterministic or probabilistic approach can be used to effectively select the IDF to accommodate a wide variety of situations, available resources, and conditions which might be encountered in practice for a specific dam. For the purpose of comparison, three IDF selection approaches' advantages and challenges are summarized below:

Prescriptive Method: The conventional prescriptive approach is well understood in the dam safety community as a simple and efficient approach intended to be conservative to allow for effectiveness of resource utilization while providing reasonable assurance of the public safety.

Advantages: The intent of this method is to provide straightforward definitions that can be applied uniformly by all federal and state dam safety agencies and can be readily understood and easily accepted by the public for its conservative result. When other two methods described below are costly, risky and challenging to analyze and tackle challenges in a manner outside the normal convention, the prescriptive IDF criteria are recommended.

Challenges: Dam failure assumptions are not based on physical conditions but a worst downstream inundation scenario. As a result, it may be cost prohibitive to design for an overly conservative IDF. The required IDFs in Table 1 are not suitable for the sunny-day failure governed hazard classification cases so that adequate IDFs should be separately studied.

ICA Method: An incremental procedure can provide a framework for evaluating the benefits of mitigating hazards presented by hydrologic deficiencies by routing a wide range of extreme flood magnitudes through the dam. When warranted, engineers can perform additional investigations using advanced analytical tools and methods to more precisely evaluate incremental consequences.

Advantages: This information can be used to select an IDF that reduces risk to the public without spending limited resources on conservative designs that result in marginal reduction of flood risk.

Challenges: A comprehensive iterative process is not usually performed. In addition, the uncertainty associated with the analysis is not quantified, so the resulting IDF is usually more conservative than further realistically based RIDM result.

RIDM Process Method: The risk driven resulting IDF is often determined using a sliding scale between a lower threshold flood event and the maximum theoretical event.

Advantages: Applying this method is an unconventional approach to assess how safe a dam is and is also able to compare with other public safety risks in an understandable, consistent fashion. The uncertainty associated with the analysis is specifically reflected as a probability based consideration and analysis of information rather than conservative unquantified assumptions. Thus, the RIDM selected IDF is often smaller than the other two methods. The computed risks for various hydrologic loading conditions are compared against tolerable risk guidelines. The objective is to reduce risks below a tolerable risk limit. Better data would enable to reduce subjectivity significantly in risk analysis and decision-making. The consequence risk may be more reliably estimated considering the potential inundated structure has been evacuated before the failure of a dam by assuming a certain evacuation effectiveness.

Challenges: Although the present trend appears to be in such a direction of practice, major challenges of RIDM approach include below:
(1) Technical Challenges: Many agencies have to overcome the deterministic mindset and may not have the resources or training necessary to conduct or review such a comprehensive probable flood hazard analysis (PFHA); opposite to data based statistical objective probability, quantitative risk is largely subjective and almost entirely a matter of judgment by limited experts; reliable data on dams, dam components, and operations are generally not available to meet specific needs of risk assessments for individual dams or even components of dam systems;
(2) Difficult to Administer: The considerable variety in risk-based analysis criteria will complicate any precise comparisons between criteria used by different agencies. It will also result in a variation or imbalance of risk tolerances with regards to dam safety throughout the country. Thus, widely acceptable, defensible guidelines for consistent methods and uniform risk tolerance need to be established. Moreover, because risk may change with time, reevaluating risk on a periodic basis is needed; and
(3) Resources Consuming: The staff, cost and time resources required are much more than the other two IDF study methods.

CONCLUSIONS AND SUGGESTIONS

- Each of three IDF selection methods has its individual concepts, principles, merits and disadvantages. However, if the IDF value resulting from the ICA method may have a potential to be significantly reduced from the prescriptive method, then an iterative process needs to be completed, or a full range of risks based RIDM method can be used, in order to ensure an optimal IDF value.
- Each agency has a unique authority, mission, and management practice. The FEMA P-94 guidance points to individual agency processes for agency specific guidance on the definition of IDF based on incremental consequences and how to use risks to inform decisions. However, the consistency and uniformity of guidance between them is needed in the long run for a same standard of dam safety risk management across the nation.
- RIDM based on qualitative and quantitative risk assessments is the process of using information about risk to assist in decision-making with regards to a wide variety of dam safety activities. This would include decisions regarding a variety of actions such as: IDF selection; frequency of inspection; need for increased instrumentation; need for additional technical studies; assessment of how uncertainties affect the level of risk; sufficiency of evidence to support the need for remedial action; selection of a remedial action to address an

identified deficiency; prioritization of projects or actions; the sequence in which remedial actions are taken at a given dam or group of dams, etc.

- Risk is all about uncertainties, so all sources of uncertainty should be considered. Risk assessment should be unbiased and risk reduction should make economic sense or life loss reduction ALARP. The application of RIDM is a technical challenge but also an opportunity to deliberate more realistic conditions for obtaining a more refined IDF value. A requirement for acceptance of the estimated IDF should include provisions for the dam owner to engage an independent peer review or review board consisting of experts in this area of study to oversee the study and approve the analyses and final results.
- There are certain principles that are held in common for consistency and correctness about the urgency of completing required dam safety actions which should be commensurate with the level of risk for varied safety aspects such as adequate interim risk reductions before upgrading existing spillways to accommodate required IDFs. However, what the defined level is needs collaborative efforts between agencies. (Available references: the USACE – DSAC (Dam Safety Action Classification) and USBR – DSPR (Dam Safety Priority Rating)).
- Hazard potential classification is based on consequences of dam failure irrespective the cause of failure. The FEMA P-94 document's Table 2, "IDF Requirements for Dams Using a Prescriptive Approach" and its foot notes indicate required and recommended minimum IDFs. The notes can clarify that this table is based on flood scenarios, not sunny-day failures. Or the table title can be clarified as "under Flood Loadings" like Table 1 in this paper.
- Some agencies use the term "spillway design flood" (SDF) as IDF. In application, both terminologies can mean differently for some cases. For instance, if the derived IDF for an existing or planned dam is smaller or greater than the flood used for the design of spillway capacity, then the used design flood should be appropriately called SDF rather than IDF.
- Climate change concerns are addressed in the P-94 document. Experts argue that engineers can improve climate change resiliency incrementally by making small changes with minimal additional investment to the projects they are already planning or constructing. In addition, because the effects of climate change won't be the same in all areas and funding for infrastructure projects is limited, it would be advisable to determine the areas of highest risk to critical infrastructure when deciding how to allocate adaptation and mitigation spending.

ACKNOWLEDGEMENTS

My heartfelt gratitude is extended to both FERC's Division of Dam Safety and Inspections management, particularly Director, William Allerton for the opportunity to be a Steering Committee member to provide inputs/comments for the FEMA P-94 document and those for their helpful suggestions on this paper. Furthermore, I appreciate the primary contributors and other committee members for their dedicated work and perspectives and insights and other experts' additional contributions that make the P-94 document substantially benefit the users.

Abstract

For hydrologic design purposes, the Natural Resources Conservation Service (NRCS) has historically used rainfall distributions derived from rainfall-frequency data. The rainfall distribution represents the cumulative rainfall from the beginning to the end of the design storm. The rainfall distribution is non-dimensional, and begins at a value of zero and ends at a value of 1.0. The Type I, Type IA, Type II, and Type III rainfall distributions are in general use throughout the United States. NRCS hydrologic models including Engineering Field Handbook Chapter 2 EFH-2, USDA (2014), WinTR-55 Small Watershed Hydrology, USDA (2010) and WinTR-20 Project Formulation Hydrology, USDA (2010) make use of these rainfall distributions.

The Type I, Type II, and Type III rainfall distributions were developed from rainfall-frequency data contained in the United States (US) Department of Commerce publications US Weather Bureau Technical Paper 40 (1961) and National Weather Service (NWS) Hydro-35 (1977). USDA NRCS Technical Paper 149 (1973) describes the way in which the Type I and Type II distributions were developed and shows plots of rainfall versus duration at several locations. These legacy rainfall distributions are being replaced with rainfall distributions developed from data contained in the NWS National Oceanic and Atmospheric Administration (NOAA) Atlas 14. Volumes 1 (2006) through 9 (2013) have been released and cover 37 states, Puerto Rico, US Virgin Islands, and selected Pacific Islands.

The standard design rainfall distributions are based on nesting the high intensity short durations within the longer lower intensity durations. For example, the maximum rainfall in 5 minutes is assumed to be within the maximum 10-minute rainfall, which is within the maximum 15-minute rainfall. This process is continued until the 24-hour duration is reached. The non-dimensional aspect of the rainfall distribution is that the durations from 5 minutes through 12 hours are represented as a ratio of that duration rainfall to the 24-hour rainfall.

Maps of these rainfall ratios were developed using Geographic Information System (GIS) technology. The goal was to identify regions of similar rainfall distribution. A map of a multi-state area with a group of regional rainfall distributions was developed along with 24-hour rainfall tables for use in hydrologic models.

Site-specific rainfall distributions based on NOAA Atlas 14 rainfall-duration-frequency data for a location may be developed. This approach preserves the intensities within a rainfall distribution with minimum error. A computer program was written to use NOAA Atlas 14 partial duration rainfall-frequency data at a specific site to develop a set of rainfall distributions for WinTR-20. A unique rainfall distribution may be developed for each return period from 1 year (100% chance) through 500 years (0.2% chance). When developing these rainfall distributions, rainfall at durations of 5, 10, 15, and 30 minutes and 2, 3, 6, and 12 hours are smoothed in order to make sure

the rainfall distribution and resulting runoff hydrographs are smooth. The 60 minute and 24 hour values are not changed in the smoothing process.

INTRODUCTION

The four components of the NRCS hydrologic model are 1) runoff curve number, 2) time of concentration, 3) dimensionless unit hydrograph, and 4) rainfall magnitude and distribution. Each of these has been the subject of many technical papers by authors within the government and private sectors. As research and new data have become available, analysis techniques for these components have been improved individually. The authors' opinion is that if each of these components is analyzed according to the best available data and research, collectively they will produce the most accurate estimate of hydrologic response from a watershed. This concept is important because so many applications of the NRCS hydrologic model are for ungaged watersheds. In the case of gaged watersheds, the input data for each model component may be calibrated. This paper describes significant updates to both the rainfall magnitude and distribution as proposed for use in the NRCS hydrologic models (Engineering Field Handbook Chapter 2 (EFH-2), WinTR-55, and WinTR-20). Before the publication of NOAA Atlas 14 Volumes 1 through 9, NRCS used rainfall data from Weather Bureau Technical Paper 40 and NOAA Atlas 2 (in western states) for evaluation and design of engineering projects. The rainfall data and design rainfall distributions based on these data were used for so many years by NRCS and engineers in the general public that their use been considered standard operating procedures. The publication of NOAA Atlas 14 has caused serious consideration as to how to move forward in this age of highly advanced computers, GIS data, and software. Implementing such changes has taken significant time and work with respect to both developing technical procedures, and informing and training engineers within the government and private sectors.

Traditional principles and new technology and data have been combined to produce the rainfall data and rainfall distributions to replace the legacy rainfall data and rainfall distributions used for so many years.

This paper describes the treatment of NOAA Atlas 14 data after it is acquired for a given project site. The two major concepts explained are data smoothing and development of the design rainfall distribution. These methods are described in USDA-NRCS NEH Part 630 Chapter 4 Storm Rainfall Depth and Distribution (2014 draft).

DATA SMOOTHING

Since precipitation durations were analyzed independently in NOAA Atlas 14, there are cases when the precipitation intensity between successive durations does not uniformly decrease as duration increases. In developing a design rainfall distribution, this factor is of critical importance.

Several mathematical techniques were investigated to develop a procedure which is computationally efficient, accurate, practical, stable, and robust. The relationship of rainfall intensity (inches/hour) and duration is smoothed since the generated hydrograph is primarily dependent on the relationship of precipitation intensity with duration.

The relationship of intensity and duration is based on a factor called incremental intensity. Incremental intensity is defined as the difference in precipitation divided by the difference in duration. The incremental intensity for the 5-minute duration is equal to the 5-minute precipitation divided by 1/12 in inches per hour. The incremental intensity for the 10-minute duration is the 10-minute precipitation minus the 5-minute precipitation divided by 1/12 (the difference between 5 and 10 minutes in units of hours). Incremental intensity is calculated and smoothed for each return period independently. Plotting this relationship on a log-log scale, it may be a straight line, have slight curvature, or have several dips or waves. An example of plot of original data is shown in figure 1.

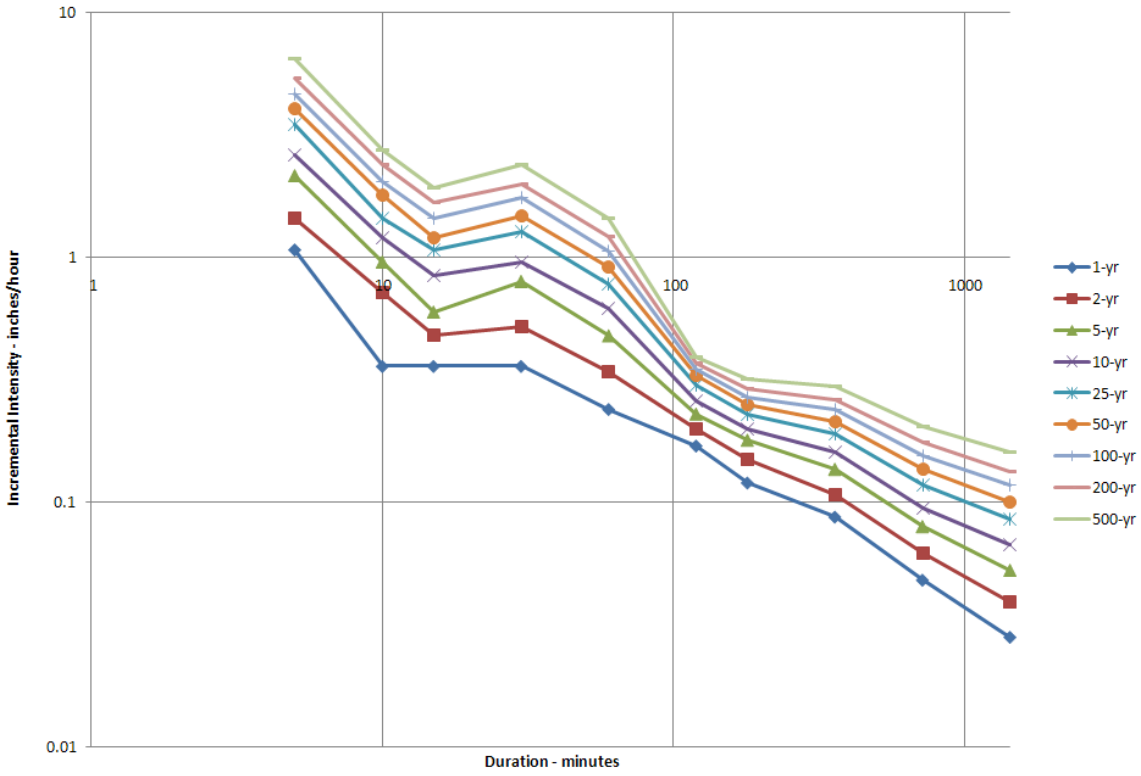

Figure 1 Incremental Intensity plot for original data for Sun City California, not smooth between 10 minutes and 6 hours.

The smoothing procedure keeps the 60-minute and 24-hour precipitation unchanged from the original NOAA Atlas 14 partial duration values. The 5-, 10-, 15-, 30-minute, and the 2-, 3-, 6-, and 12-hour values are open to adjustment. The smoothing procedure computes a straight line on the log-log plot which extends from 5-minute to 60-minute durations. The line is placed such that the squared difference between the smoothed 5-, 10-, 15-, and 30-minute incremental intensity values and the original values is minimized and the 60-minute precipitation is equal to the original value. A second straight-line segment is computed on the log-log plot that extends from the 60-minute value to the 24-hour value. This line is placed such that the incremental intensity for 60-minute duration is the same as calculated for the first line segment and the 60-minute and 24-hour precipitation values are unchanged. Calculating the adjusted values of precipitation involves a trial and error optimization procedure. An example of data smoothing is shown in figure 2.

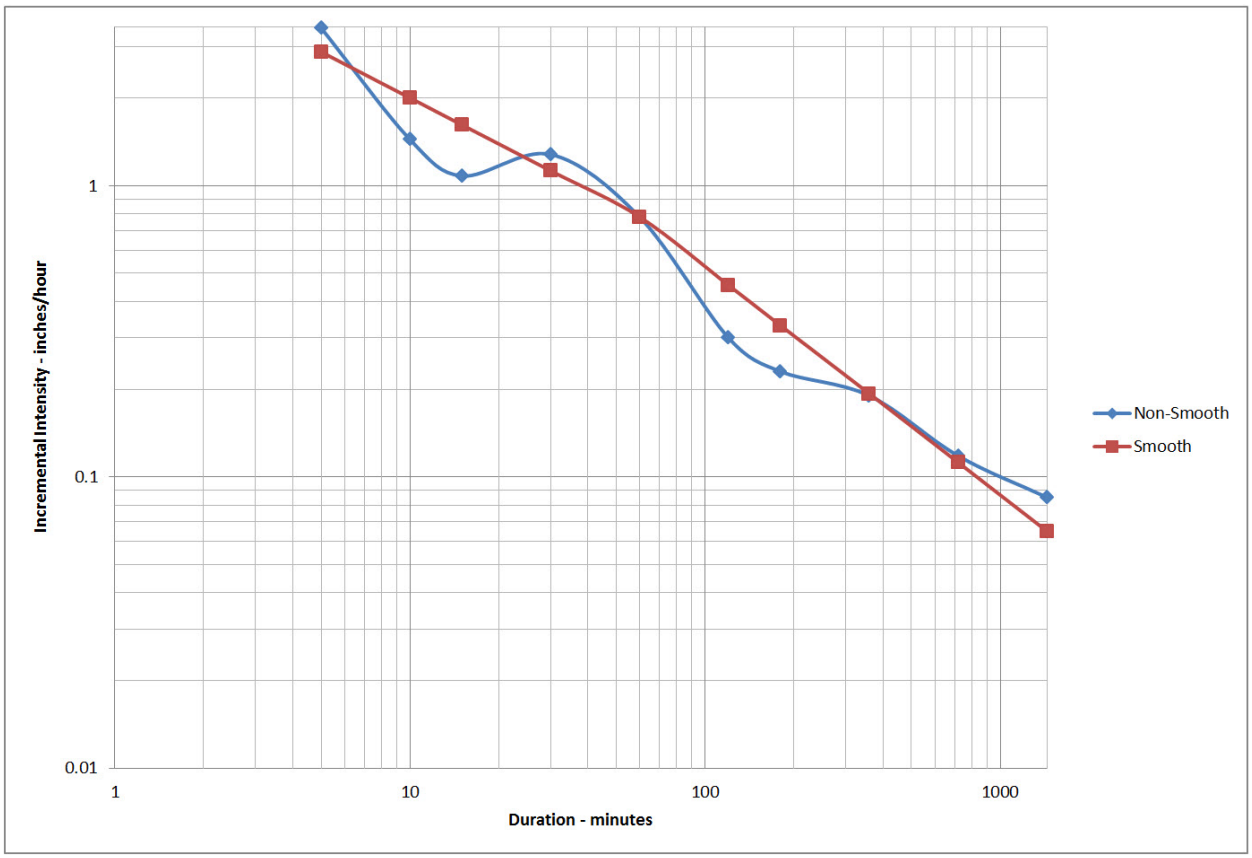

Figure 2 Plot of 25-year (4% chance) smoothed and non-smoothed incremental intensity at Sun City, California.

TEMPORAL DISTRIBUTION

A procedure has been developed that will derive rainfall distributions to cover the wide range of climatic conditions from tropical to arctic that occur in the US (Merkel, 2006).

The method used to construct the 24-hour rainfall distribution insures that the maximum rainfall of any duration less than 24 hours is included in the distribution. One of the principles of hydrology is that the peak discharge for a watershed is determined primarily by rain falling in a duration that equals the time of concentration (see USDA NEH Part 630 Chapter 15, 2010). The 24-hour rainfall distribution has the maximum 5-minute rainfall occurring at 12 hours. The maximum 10-minute rainfall is centered around 12 hours, and includes the maximum 5-minute rainfall, and so on. In this way, a single rainfall distribution for 24 hours may be used for any watershed with time of concentration less than 24 hours.

Input to the method consists of a set of rainfall values at durations of 5, 10, 15, 30 and 60 minutes and 2, 3, 6, 12, and 24 hours. These data may be original or smoothed. Naturally, the smoothness of the rainfall distribution depends on the smoothness of the relationship of duration and incremental intensity as shown in figure 2. The plot of the smooth rainfall distribution based on data in figure 2 is shown in figure 3.

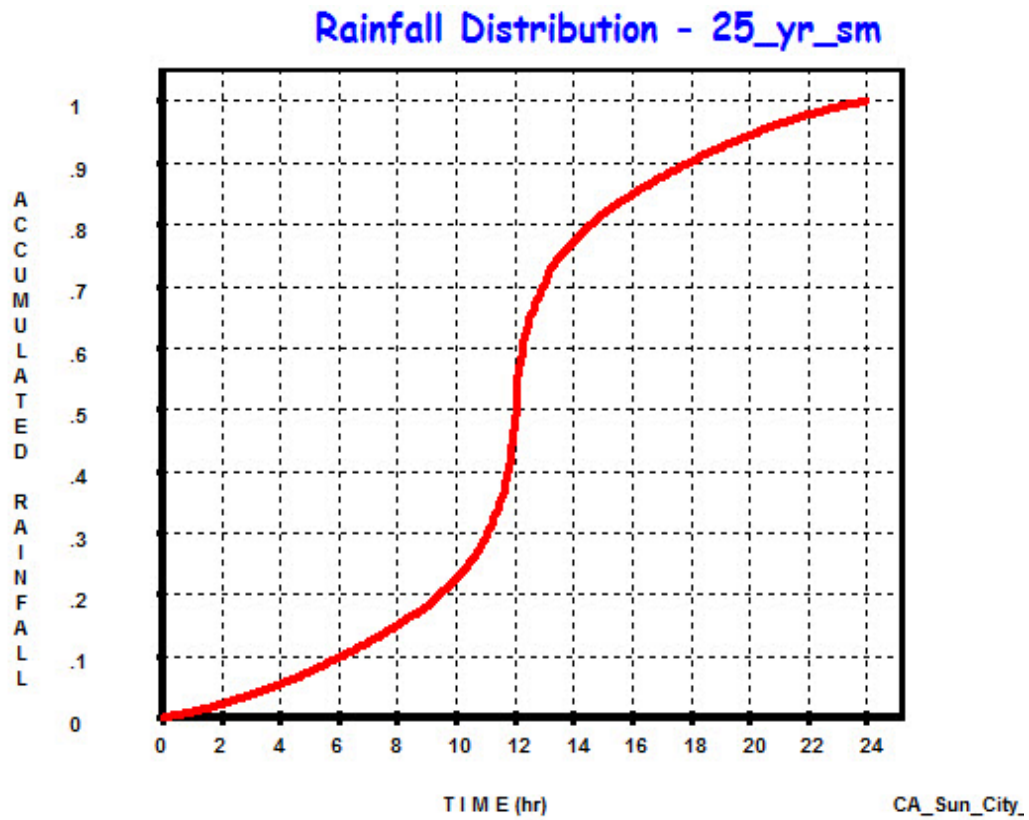

Figure 3 25-year (4% chance), 24-hour rainfall distribution for Sun City, California based on smooth data.

REGIONAL RAINFALL DISTRIBUTIONS

Figure 4 shows where to apply the regional rainfall distributions developed for the Ohio Valley and neighboring states and designated as A, B, C, and D.

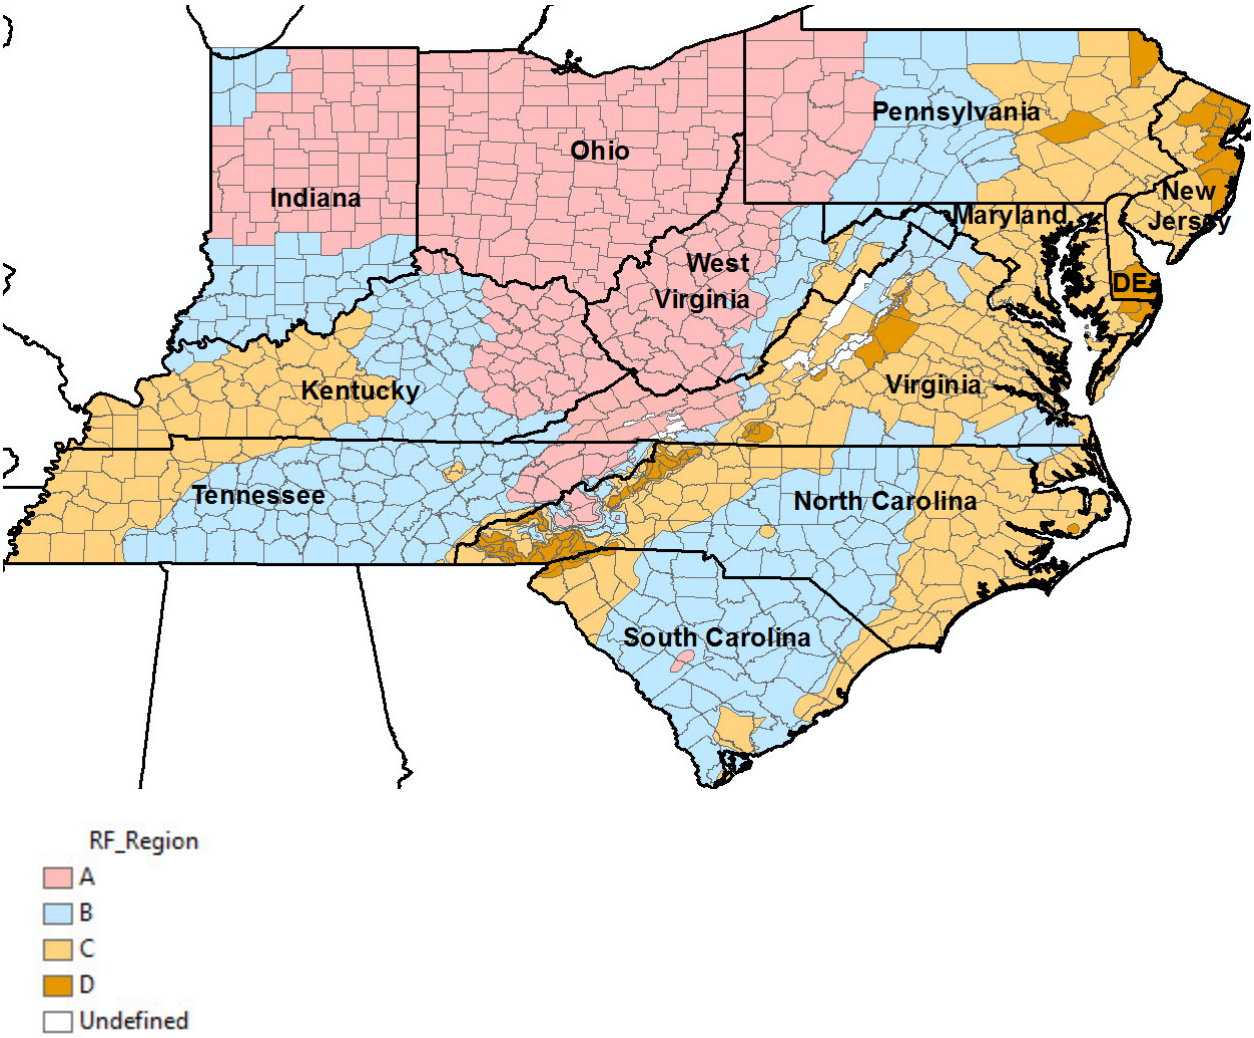

Figure 4 Regional rainfall distributions for the Ohio Valley and neighboring states.

Regional rainfall distributions were also developed from NOAA Atlas 14 data for California, Nevada, and 17 midwestern and southeastern states. Documentation and maps for these are available from the NRCS West National Technical Support Center at http://go.usa.gov/rXYw and clicking on "Technical Information".

The boundaries of the rainfall distribution regions are based on the ratio of the 25-year (4% chance), 60-minute rainfall to the 25-year (4% chance), 24-hour rainfall. Areas with a ratio greater than 0.48 are assigned rainfall distribution A. This is the most intense rainfall distribution. Areas with a ratio between 0.43 and 0.48 are assigned rainfall distribution B. Areas with a ratio between 0.38 and 0.43 are assigned rainfall distribution C. Areas with a ratio less than 0.38 are assigned rainfall distribution D. This is the least intense rainfall distribution. Once the boundaries were determined, the average ratio for each duration was determined based on the 25-year (4% chance) return period. These included the ratios of the 5, 10, 15, 30, and 60 minute to 24-hour ratio; and the 2, 3, 6, and 12 hour to 24-hour ratio. These average ratios were used to develop the 24-hour rainfall distribution for each of the four regions as shown in figure 5.

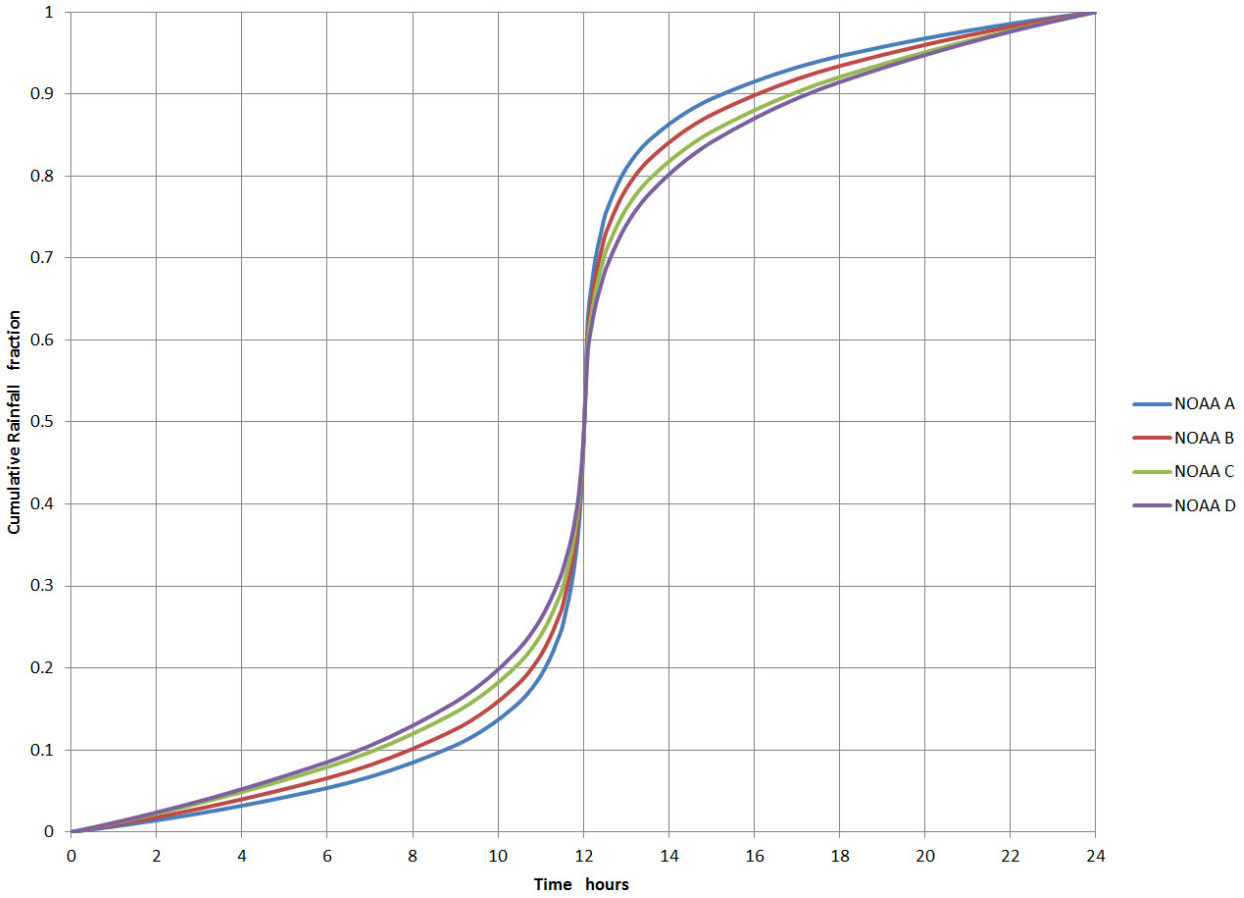

Figure 5 Plot of A, B, C, and D 24-hour rainfall distributions for the Ohio Valley and neighboring states.

These tables are available at a 0.1-hour time interval in the WinTR-20 User Documentation and WinTR-20 software.

SUMMARY

NRCS is replacing the use of its legacy rainfall distributions (Type I, Type IA, Type II, and Type III) with rainfall distributions based on NOAA Atlas 14 precipitation-frequency data. Regional rainfall distributions are being developed for use in the Engineering Field Handbook Chapter 2 computer program (EFH-2), Small Watershed Hydrology computer program (WinTR-55), and Project Formulation Hydrology computer program (WinTR-20). Site-specific rainfall distributions may also be developed using the WinTR-20 computer program.

These rainfall distributions are based on the 5-minute through 24-hour rainfall depths for a specific return period. Unique rainfall distributions may be developed for the 1-year (100% chance) through 500-year (0.2% chance) storms. Before the rainfall distribution is developed, the user has the opportunity to smooth the 5-minute through 24-hour rainfalls.

By developing new rainfall distributions using NOAA Atlas 14 data, the rainfall distributions will reflect the rainfall depth versus duration data at the project location more accurately. This will lead to more accurate estimates of peak discharges and hydrographs for design of projects.

AN INNOVATIVE APPROACH TO EVALUATE DOWNSTREAM FLOOD IMPACT FROM MODIFIED DAM OPERATIONS CONSIDERING EFFECTS OF STORM PATTERN AND TIMING

Henry Hu, Sr. Project Manager, WEST Consultants, Inc., Bellevue, WA, hhu@westconsultants.com; James Hathorn, Chief, Water Management Section, Mobile District, U.S. Army Corps of Engineers, Mobile, AL, james.e.hathorn.jr@usace.army.mil; Beth Faber, Hydraulic Engineer, Hydrologic Engineering Center , U.S. Army Corps of Engineers, Davis, CA, beth.a.faber@usace.army.mil

West Point Dam is one of the critical elements in the Apalachicola-Chattahoochee-Flint (ACF) Rivers system. It officially operates for flood control to reduce flood damages along the reach of the Chattahoochee River between West Point Dam and Columbus. The U.S. Army Corps of Engineers evaluated two flood operation alternatives at West Point Dam, an Early Refill condition and a Fall Stepped-down condition. Because the flood operation guide curve determines available flood storages, which affects the peak and volume of reservoir releases during flood operations, any modification to the guide curve may have some direct impacts on flood conditions downstream. For the Chattahoochee River between West Point and Columbus, the flood damage site is at Columbus. A flood operation alternative is acceptable only if it does not significantly increase the flood frequency curves at Columbus. This paper presents an innovative approach used to evaluate the flood impacts of modified flood operations at West point Dam on the flood conditions at Columbus.

The flow in the Chattahoochee River at Columbus is regulated. The magnitude of flood discharge at Columbus is primarily influenced by the magnitude of storms, which have two distinct types. One is general cyclonic storms typically occurring in winter and spring months. The other is intense tropical storms typically occurring between the summer and fall seasons. As a result, large flood events do show seasonal distributions and variations in hydrograph shapes. At the same time, due to flow regulation, it is also affected by flood operations at West Point Dam and the upstream dams, which typically vary month to month. Therefore, the combined regulated flood frequency relationship at Columbus is a function of two variables, storm and month. For each month, a regulated flood frequency relationship was developed by applying a series of hypothetical flow hydrographs with different shapes and different exceedance probabilities to a reservoir model and by associating the resulting regulated peak flows at Columbus with the exceedance probabilities of the input hypothetical hydrographs. The monthly regulated flood frequency curves was then combined to produce a combined regulated flood frequency curve at Columbus using the total probability theorem. Combined regulated flood frequency curves at Columbus were developed for the baseline and proposed conditions, and were used to evaluate potential impacts from the modified dam operations.

UNCERTAINTY ANALYSIS USING MONTE CARLO TECHNIQUES IN THE HYDROLOGIC MODELING SYSTEM (HEC-HMS)

William Scharffenberg, HEC-HMS Lead Developer, U.S. Army Corps of Engineers Institute for Water Resources, Hydrologic Engineering Center, Davis, CA, William.A.Scharffenberg@usace.army.mil; Angela Duren, Hydraulic Engineer, U.S. Army Corps of Engineers, Portland District, Portland, OR 97204; Matthew Fleming, U.S. Army Corps of Engineers Institute for Water Resources, Hydrologic Engineering Center, Davis, CA, Matthew.J.Fleming@usace.army.mil

INTRODUCTION

Traditional hydrologic simulation has focused on developing algorithms to represent each of the components of the hydrologic cycle. A great deal of effort has been dedicated to developing physically appropriate process representations and parameter estimation techniques. The Hydrologic Modeling System (HEC-HMS) is one modeling framework that takes this approach with components for precipitation, snowmelt, transpiration, infiltration, runoff, and channel flow among others. An automatic parameter estimation tool is also available.

The modern hydrologic simulation approach is often limited by knowledge uncertainty and natural variability. Knowledge uncertainty describes both our inability to fully understand hydrologic processes and the situation where we lack the observational data necessary to parameterize models. Natural variability describes inherent unpredictability in boundary conditions such as climate or initial conditions like soil moisture. Due to the nonlinear nature of the mathematical models that represent natural systems, the uncertainties due strictly to boundary conditions, initial conditions, and model parameters are difficult to distinguish and therefore quantify. However, to the capture these uncertainties together, a Monte Carlo-based uncertainty analysis tool has been added to HEC-HMS to quantify both knowledge uncertainty and natural variability. It includes the ability to statistically sample model parameters using analytical distributions, with an option for the distribution to be a function of the month of the year. It also can link a dependent parameter to a previously sampled parameter through a relationship that includes an error term.

OVERVIEW OF NEW HEC-HMS CAPABILITIES

The hydrologic modeling software, HEC-HMS, is used for dam and levee safety studies, flood damage reduction studies, real-time operations, and general planning studies. The latest version of HEC-HMS now has an integrated uncertainty assessment capability to allow for the development of probabilistic results for key metrics such as total runoff volume or maximum reservoir pool elevation.

The HEC-HMS uncertainty analysis features the ability to assign probability distributions to hydrologic model parameters such as soil loss rates, unit hydrographs, baseflow, and channel routing. Current available analytical distributions that can be assigned to parameters include beta, exponential, gamma, log normal, normal, triangular, and Weibull. Random numbers are generated using the Well19937c generator (Panneton, L'Ecuyer, and Matsumoto, 2006). Output includes the sampled parameters, key metrics, and selected time-series. As an example, the key

metrics can be processed to obtain histograms (Figure 1) or estimate the 90 percent non-exceedance value.

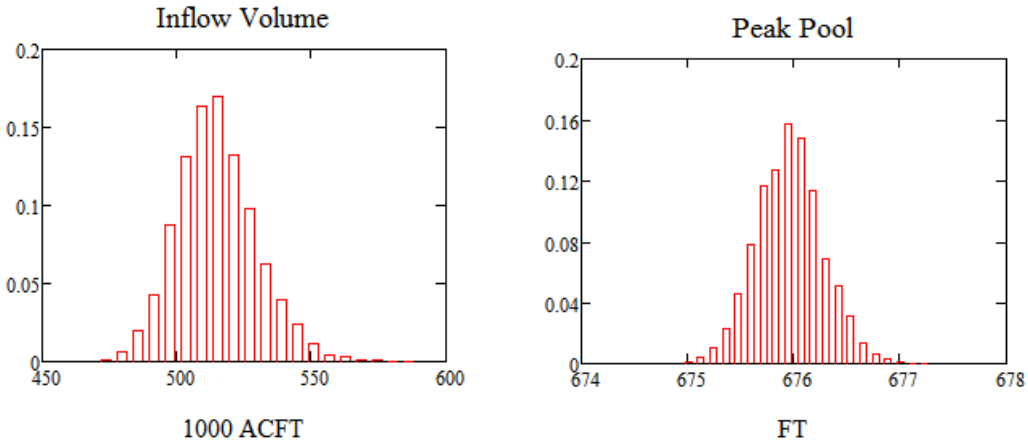

Figure 1 Example of Distribution of Inflow Volume or Peak Pool Results

IMPACT OF STOCHASTIC ANALYSIS ON POOL STAGE FREQUENCY

A study was conducted to compare a deterministic estimate of a reservoir pool stage frequency curve to an estimate generated from the new uncertainty assessment feature in HEC-HMS. The deterministic case assumed fixed parameters for loss rates while the uncertainty assessment used probability distributions estimated from calibration data. The minimum, mean, and maximum pool stage frequency curves from the uncertainty analysis are shown in Figure 2, along with the deterministic estimate. This case shows the deterministic estimate above the mean, notably so in the lower probability range which is an area of interest when performing a risk assessment for dams. Although the deterministic estimate is within the confidence limits computed from the minimum and maximum of the uncertainty analysis, the difference between the deterministic and mean stochastic estimates was profound in this study. The loss rates used in the deterministic model lie in the 'less probable' (and low soil loss) region of the estimate for the soil loss uncertainty distribution. By incorporating the estimated distribution of loss rates into the final pool stage frequency curve, a wider range of soil loss is sampled, thereby reducing the amount of runoff and peak pool stage.

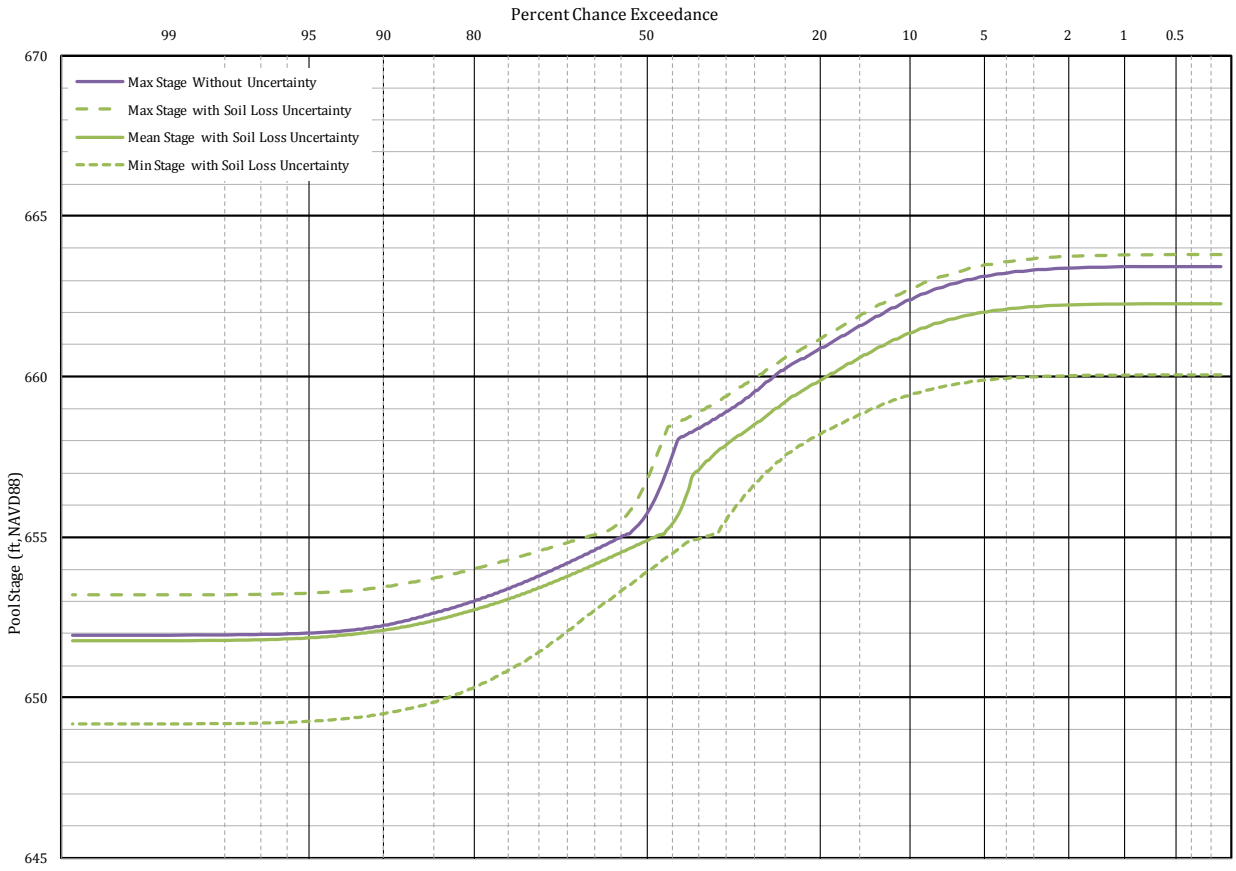

Figure 2 Pool Stage Frequency Example

EVOLUTION OF PROBABILITY DISTRIBUTIONS FOR HYDROLOGIC MODELING PARAMETERS

The most critical requirement for capturing knowledge uncertainty and natural variability in pool stage frequency curves or inflow volume is having the tools to account for the uncertainties in the parameters and having the probability distributions of the parameters themselves. Little work has been done to capture the probability distributions in hydrologic modeling parameters such as soil loss rates or unit hydrographs. Perhaps one reason this work has not been done is that up until now there has been a lack of tools that can integrate the information into the simulation process. The availability of uncertainty assessment capability in a commonly used and widely available tool such as HEC-HMS will hopefully serve as a catalyst for deeper study on expected or reasonable probability distributions of hydrologic modeling parameters in various regions around the world.

Abstract

Watershed models are evaluated through calibration and validation processes. However, sediment model parameters and observed data for calibration are often expensive and difficult to collect. Where sediment data is limited, sensitivity analysis can identify the most influential parameters in the model. Identifying sensitive input parameters is critical for model development and application. This paper aims to improve understanding of the sensitivity of the sediment input parameters in the Hydrologic Engineering Center's Hydrologic Modeling System (HEC-HMS 4.0).

Historically, HEC-HMS was focused on modeling rainfall-runoff processes using a full range of components for meteorology, canopy, soil, surface runoff, baseflow, channel routing, reservoirs, and diversions. Recently, components have been added for representing land surface erosion, channel erosion and transport, and lake turbulent settling. A sensitivity analysis evaluated model parameters required by these new sediment capabilities. Sensitivity analysis results were then compared with observed data to identify sensitive parameters and their relative influence. These results can support HEC-HMS sediment model development in locations with little to no observed data.

INTRODUCTION

The Hydrologic Engineering Center's Hydrologic Modeling System (HEC-HMS) sediment transport module (STM), including surface erosion, in-stream sediment routing, and reservoir sediment routing modeling capabilities was released in December 2013 (USACE 2013). The STM was designed based on applicable knowledge of geomorphology, hydrology, hydraulics, and concepts of surface and sediment transport.

In addition to the implementation of the new STM into HEC-HMS, the HEC-HMS team conducted a detailed sensitivity analysis of the HEC-HMS sediment model to assess the overall influence of sediment input parameters on the computed total cumulated sediment loads. Sensitivity analysis evaluates the relative model response as a function to changes in model input

parameters (Nearing et al. 1990). The evaluation process includes three steps according to Nearing et al. (1990):

- Calibration and validation of the model to measured data
- Sensitivity analysis of the model response to input parameters
- Evaluation of confidence limits for the model prediction

Sensitivity analysis was conducted on selected input parameters of the three main elements (sub-basin, reach, and reservoir) of the HEC-HMS sediment model. The sensitivity analysis used a calibrated and validated HEC-HMS model that consisted of a two-year simulation period (1 January 1995 through 31 December 1996).

HYDROLOGY AND SEDIMENT MODEL OVERVIEW

The study site selected for the sensitivity analysis consists of a 921 km^2 (356 mi^2) watershed called the Upper North Bosque River. The Upper North Bosque River Watershed (UNBRW) is located in Central Texas (Figure 1). UNBRW is a headwater watershed in the North Bosque River basin. Elevation in the watershed ranges from 299 m to 495 m (981 ft to 1624 ft) above sea level. The mean annual precipitation is 750 mm and dominant soil type is fine sandy loams with sandy clay subsoil, calcareous clay, and clay loams in the watershed (Saleh and Du 2004). The HEC-HMS model included 68-subbasin, 40-reservoir, and 84-reach elements based on five gage locations, land use, soil, and topographic information (USACE 2014).

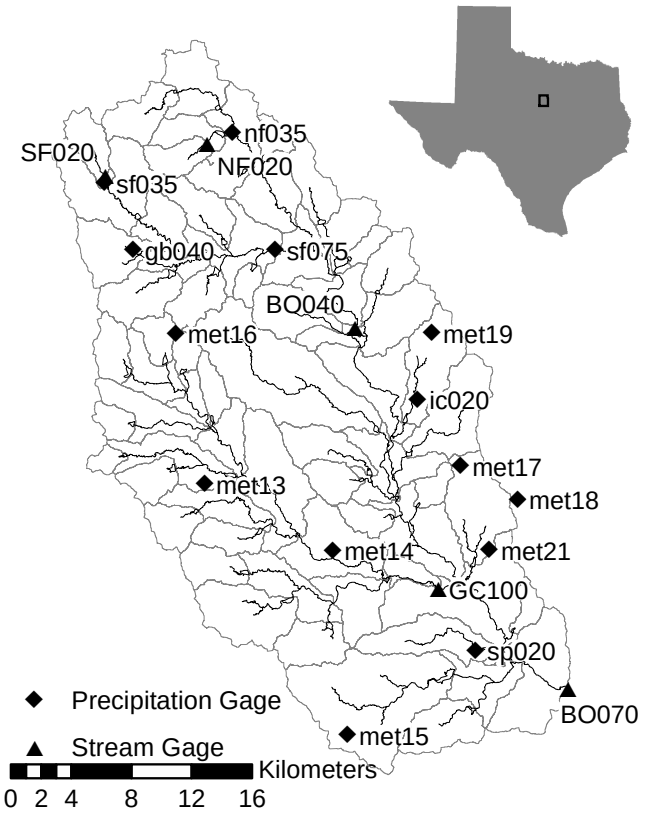

Figure 1 Project Location map including gauged locations for UNBRW

The selection of modeling methods and initial input parameters relied heavily on the data available and appropriateness for hydrology and sediment models. The model was calibrated to observed hydrologic and sediment data from 1 January 1995 to 31 December 1996 by adjusting model parameters to minimize the difference in computed and measured flow and sediment at five gage locations (NF020, SF020, BO040, GC100, and BO070) as shown in Table 1. Unlike the calibration period, the validation of the model required observed data from 1 January 1997 to 31 December 1998 (USACE 2014). Using the calibrated and validated hydrology/sediment model, a sensitivity analysis was conducted by changing one of the selected sediment model parameters or methods and fixing others as based values during the calibration period.

Table 1 Measured and computed results of daily flow and TSS loading.

		Calibration Period (01Jan1995 to 31Dec1996)					
		Hydrology (ft^3/s)			Sediment (tons)		
		Mean	Standard Deviation	Mean Error	Mean	Standard Deviation	Mean Error
NF020	Measured	1.06	4.94	N/A	2.66	23.12	N/A
	HMS	1.41	6.36	0.35	2.67	32.24	0.01
SF020	Measured	1.41	7.77	N/A	1.32	15.00	N/A
	HMS	1.77	9.89	0.35	1.32	12.79	-0.01

	HMS	108.06	423.07	6.00	100.03	890.15	0.33

METHODOLOGY

A linear sensitivity model was selected for sensitivity testing of HEC-HMS sediment model. The sensitivity parameter (S) is computed using equation (1).

$$S = \frac{\left(\frac{O_2 - O_1}{O_{12}}\right)}{\left(\frac{I_2 - I_1}{I_{12}}\right)} \quad (1)$$

Where;
I_1: the least value of input parameter
I_2: the greatest value of input parameter
I_{12}: the average value of I_1 and I_2
O_1: the output value of I_1
O_2: the output value of I_2
O_{12}: the average value of O_1 and O_2

The dimensionless sensitivity parameter (S) quantifies the sensitivity of the input parameter by comparing the relative normalized output change to a normalized input change. McCuen and

Snyder (1983) discuss limitations of the linear sensitivity analysis used in this paper. One of the biggest limitations of the linear sensitivity equation (1) above is that, equation 1 yields a single sensitivity parameter value instead of a distribution of outputs as a function of the input parameter distribution. Describing the sensitivity parameter as a distribution instead of a single value will better describe sensitivity of the parameters.

In this sensitivity analysis, wide ranges of input parameters were selected for the subbasin, reach, and reservoir elements (Table 2). Generally, one selected parameter was varied and other parameters were fixed as base values.

Table 2 Parameters and method selected for Sensitivity Analysis

Element	Parameter/Method
Subbasin Element	Enrichment Ratio
	Sand
	Silt
	Clay
	MUSLE (Cover Factor)
Reach Element	Fraction of Gravel
	Channel Width
	Active Layer Factor
Reservoir Element	Fall Velocity Method

SENTIVITY TO SEDIMENT METHODS AND PARAMETERS

The particle size distribution of source material in the subbasin (on the land surface) is generally much coarser than the stream channel sediment at the basin outlet due to changing hydrodynamic forces as water flows over the land surface and concentrates within streams and channels. The clay and silt enrichment in the suspended sediment is largely the result of preferential deposition of the courser fraction during the transport and delivery of sediment from its source to basin outlet (USACE 2014). The enrichment ratios for each particle class converted the watershed particle-size distribution to an outlet particle-size distribution: The enrichment ratio is defined in equation (2) below.

$$ER = \frac{\%\ sediment\ in\ a\ given\ size\ class\ in\ outlet}{\%\ sediment\ in\ a\ given\ size\ class\ in\ watershed} \quad (2)$$

Where, ER is the enrichment ratio. The numerator, % sediment in a given size class at the outlet, can be determined from a suspended sediment sample near the subbasin outlet. The denominator, % sediment in a given size class in watershed, comes from the SSURGO soil data. The ER was a calibration factor in the original model.

The ERs were computed by varying enrichment ratios ~ ±15% from calibrated values, for each grain class (sand, silt and clay) while fixing the base values for other parameters. The differences of sediment yields from calibrated model results, at each computation point are shown in Figures 2 through 4 for sand, silt, and clay respectively.

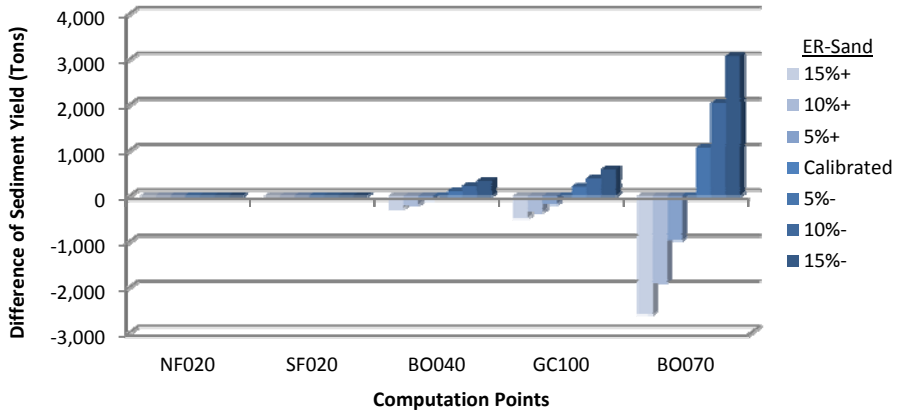

Figure 2 Impact of six selected enrichment ratios of sand on simulated sediment yield for the calibration period (1 January 1995 through 31 December 1996)

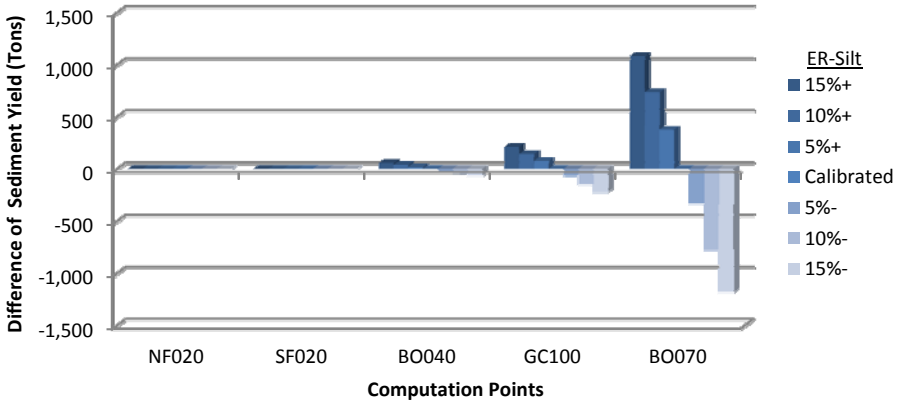

Figure 3 Impact of six selected enrichment ratios of silt on simulated sediment yield for the calibration period (1 January 1995 through 31 December 1996)

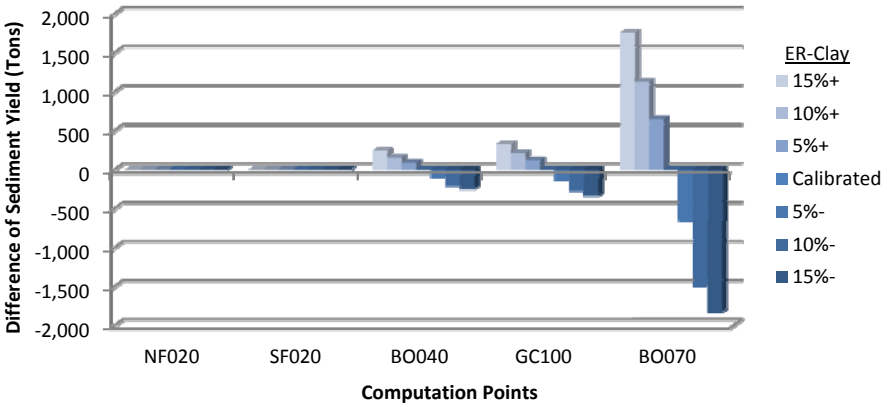

Figure 4 Impact of six selected enrichment ratios of clay on simulated sediment yield for the calibration period (1 January 1995 through 31 December 1996)

MUSLE cover factor sensitivity was determined by varying the cover factor ~ ±50%, relative to the calibrated parameter. The simulation results, in terms of the differences of sediment yields from calibrated model results at each computation point, are shown in Figure 5.

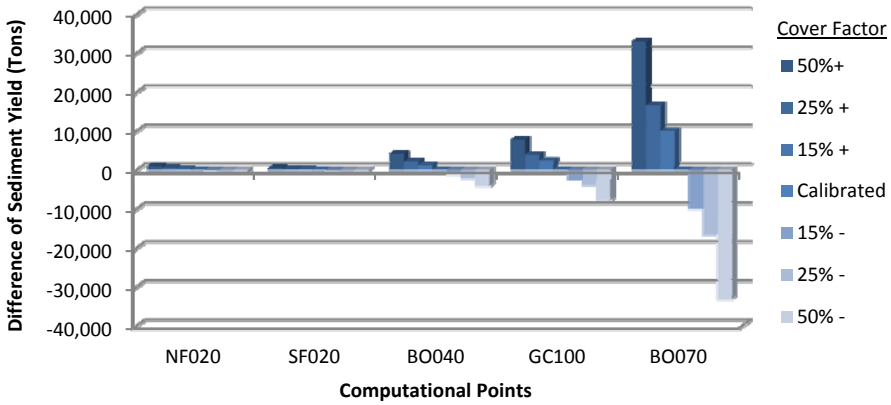

Figure 5 Impact of six selected MUSLE cover factors on simulated sediment yield for the calibration period (1 January 1995 through 31 December 1996)

Sensitivities to the fraction of gravel in the channel bed were determined by varying the gravel fraction from -1% to ~ -25% of the calibrated model parameter, using fixed base values for other parameters. The differences of sediment yields from calibrated model results for these simulations, at each computation point are shown in Figure 6.

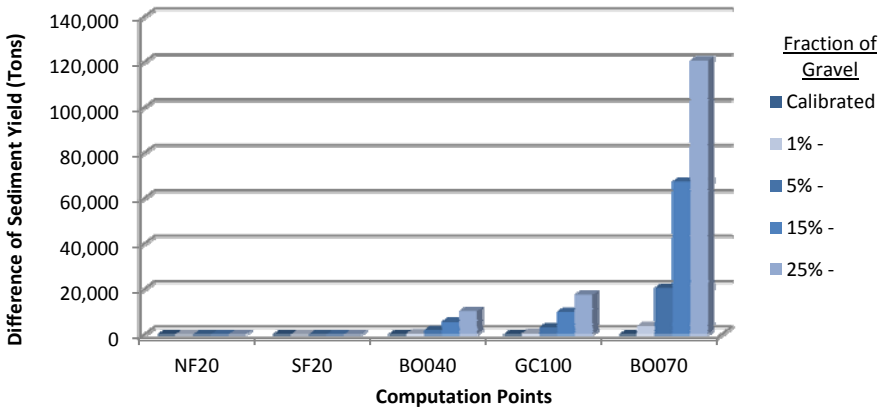

Figure 6 Impact of four selected fraction of gravel for channel gradation simulated sediment yield for the calibration period (1 January 1995 through 31 December 1996)

The channel bed widths were adjusted ~±50% of the calibrated values to test sensitivity to this routing parameter. Simulation results at each computation point are included in Figure 7.

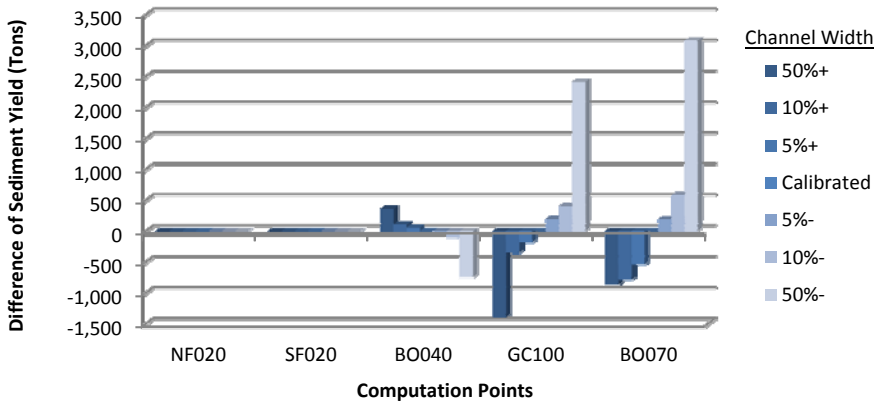

Figure 7 Impact of six selected widths of channel on simulated sediment yield for the calibration period (1 January 1995 through 31 December 1996)

Active layer factor (the thickness of the reach element active layer in multiples of d_{90}) was adjusted from 1 to 3, bracketing the calibrated value of 2. As with the other analyses, the calibration parameters were fixed for all other model variables. Simulation results, in terms of the differences of sediment yields from calibrated model results at each computation point, are shown in Figure 8. Stations NF20 and SF20 results are not sensitive to channel width, gravel content, or active layer thickness because these are directly downstream of a specific subbasin element. There are no reach elements upstream of them for the routing parameters to influence the results.

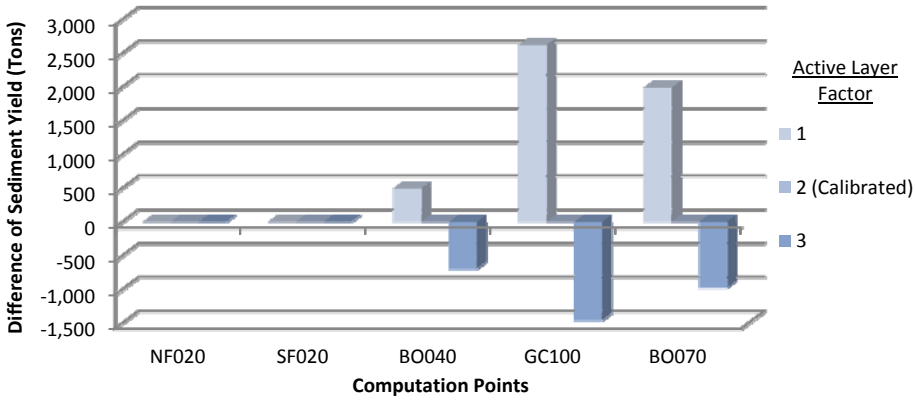

Figure 8 Impact of two selected active layer factors on simulated sediment yield for the calibration period (1 January 1995 through 31 December 1996)

Reservoir fall velocity method sensitivity was evaluated by running the model with all four options available. Results at each computation point are included in Figure 9.

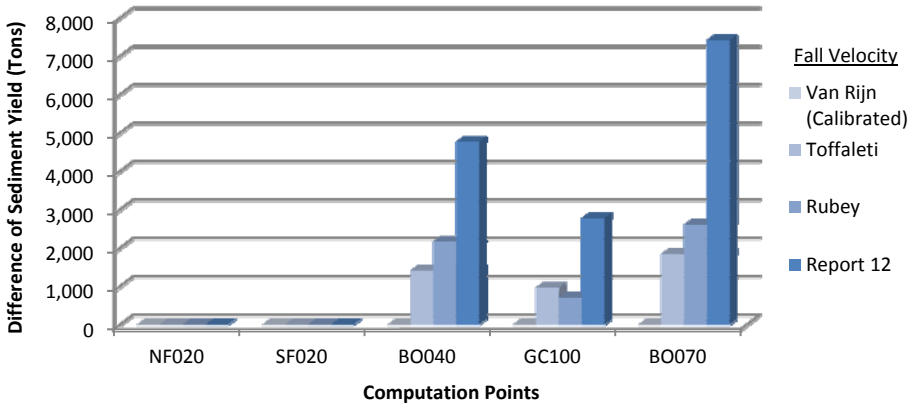

Figure 9 Impact of three selected fall velocity methods on simulated sediment yield for the calibration period (1 January 1995 through 31 December 1996)

RESULTS OF SENSITIVITY ANALYSIS

The parameters tested are listed in Table 3 and include units, base values from calibration, input values, and calculated sensitivity parameter (S) values and rank. Input 1 and Input 2 are the minimum and maximum values, respectively, from the sensitivity analysis. Total accumulated sediment yield was most sensitive to the channel gravel fraction for reach elements and the other two channel parameters (channel width and active layer thickness) were relatively insensitive. The MUSLE cover factor and Sand Enrichment Ratio were sensitive parameters for the subbasin elements. The fall velocity method (especially, Report 12) for the reservoir elements also had some influence on the outlet sediment yields.

Table 3 Summary of Sediment Model Parameters and method used for Sensitivity Analysis

Parameters	Units	Base	Input 1	Input 2	(S)	Rank
Subbasin Element						
Enrichment Ratio[1]						
Sand	Unitless	57.97	54.35	61.04	-0.67	3
Silt	Unitless	29.92	26.69	32.86	0.15	5
Clay	Unitless	12.12	10.55	13.62	0.19	4
MUSLE (Cover Factor) [1]	Unitless	0.011	0.005	0.016	0.91	2
Reach Element						
Fraction of Gravel[2]	Unitless	0.92	0.69	0.91	-3.13	1
Channel Width[2]	(ft)	30.90	15.50	46.40	-0.05	6
Active Layer	Unitless	2.00	1.00	3.00	-0.04	7

[1] – The area weighted average values were used to calculate the sensitivity parameter (S).
[2] – The length weighted average values were used to calculate the sensitivity parameter (S).

SUMMARY AND CONCLUSIONS

This paper presents a sensitivity analysis of the new sediment transport module available in HEC-HMS Version 4.0. The new sediment modeling tool allows the use of HEC-HMS for the assessment of watershed sediment transport. Eight sensitivity tests were developed to evaluate the HEC-HMS watershed sediment model parameters and identify those particularly important to calibrate a sediment model.

The output from an HEC-HMS model with a single perturbed parameter was compared to the calibrated model. This sensitivity analysis indicates the level of sensitivity for each selected parameters and provides guidance to modelers developing watershed surface erosion models with little to no observe data. While this work can inform other studies, sensitivity analysis can be site specific and sensitive parameters in other watersheds may diverge from those identified in the UNBRW study area.

The Hydrologic Engineering Center's Hydrologic Modeling System (HEC-HMS) is a software program used to simulate the hydrologic processes of watersheds. Surface erosion and sediment routing capabilities have recently been added to HEC-HMS version 4.0 (Scharffenberg and Fleming, 2013). These components expand the functionality of HEC-HMS and allow for more diverse applications of the program. This paper demonstrates how the sediment transport capabilities in HEC-HMS version 4.0 can be applied to develop an initial surface erosion and sediment routing model quickly, easily, and cheaply with limited observed data and resources.

The watershed used to demonstrate these capabilities was the House Creek Watershed in Fort Hood, Texas. Fort Hood is an ideal application for the newly released HEC-HMS soil erosion and sediment modeling capabilities. The extensive vehicle maneuver training grounds combined with the installation's highly erodible soils result in impaired lands and degradation of water resources. The project area is approximately 54 square miles and is a sub-watershed of the Cowhouse Watershed. There are two monitoring locations in the main watershed (FH08 and FH01) with an additional monitoring station on Clear Creek, a tributary of House Creek (FH07). The three gages record 15 minute flow data and sediment concentration data for only a few flood events that occurred at irregular intervals.

The HEC-HMS sediment model was developed using a variety of readily available data. Soil Survey Geographic Data Base (SSURGO) data, land use data from the National Land Cover Database 2011, and the USGS 10m DEM were the main data sources for the model. The meteorological model relied on hourly precipitation estimates developed from WSR-88D NEXRAD by the West Gulf River Forecast Center. An analysis period from 1996 to 2001 was established based on the availability of precipitation data, observed flow data, and observed sediment concentration data. Over this period the hydrologic model was roughly calibrated to the limited observed flow data. The surface erosion and sediment routing model was parameterized using SSURGO data, terrain and land use data, and representative soil gradations in order to apply the Modified Universal Soil Loss Equation (MUSLE) to each subbasin (Kelsey and Johnson, 2003). Channel soil gradations from the Upper North Bosque River Watershed were used as representative soil gradations in the Fort Hood model because of the proximity of the watershed and similar soil types. The sediment load output from the model was converted to a sediment concentration, and adjusted to match sediment concentration data observed at FH01, FH07 and FH08.

The limited availability of observed data prevented the traditional approach of calibration followed by a validation period. Instead, the hydrologic model was partially calibrated to two separate time periods that contained significant observed data. The two periods were then evaluated on how closely they reflected observed peak sediment concentrations. The observed sediment concentrations were not continuous data sets, therefore statistics on calibration were not calculated. However, the sedigraphs produced by the HEC-HMS model did provide a reasonable approximation of the observed sediment concentrations. Particularly during the storm event of June 2000 at gage FH01 shown in Figure 4, the peak sediment concentration produced by the HEC-HMS model corresponded with the observed sediment concentration peak. The sedigraphs developed by the HEC-HMS model at gage FH07 shown in Figures 2 and 5 overestimated the sediment concentration compared to the observed data for larger events. This may be due to the fact that the hourly precipitation estimates developed from WSR-88 NEXRAD used in the model have a coarse resolution, and may not accurately define the exact location of high intensity precipitation events in a small watershed like House Creek.

The Fort Hood HEC-HMS surface erosion and sediment transport model confirms that HEC-HMS can be used as a tool to develop a time series of sediment loads in a watershed. In the absence of other sources of data, these sediment loads can be applied as boundary conditions to detailed hydraulic models (Gibson et al., 2010). Often sediment load boundary conditions are estimated through the Universal Soil Loss Equation (USLE) or MUSLE, but this approach requires a separate runoff model and calculation for each event (Gee and MacArthur, 1996). The HEC-HMS sediment transport model provides time series sediment boundary conditions, and may prove computationally faster than other approaches. The HEC-HMS Fort Hood model could be improved by the addition of more observed data. A system of precipitation gages in the watershed would improve the hydrological model by providing detailed, site-specific data. Improved simulation of the precipitation and runoff would improve the accuracy of the soil erosion model. Soil gradations from the channel bed, sediment concentration samples, and additional stream flow gages would all refine the model and allow for more accurate calibration of the sediment transport and hydrologic modeling.

Abstract

St. Croix, U.S. Virgin Islands, has been impacted by 46 hurricanes or tropical storms in the last 141 years. During that time, the island was hit by hurricane force winds every 7.4 years, on average. These large storm events have had a disproportionate impact on the sediment yield of the island, especially on the drier, eastern end. As part of a larger study of hurricane patterns, sediment cores were collected at two lagoons on the eastern end of the island, South Gate Pond and Great Salt Pond. In order to confirm that layers of coarse sediment contained in these cores were from hurricanes, several HMS models were developed. This development included implementation of the newly developed sediment yield routines in HMS. The annual average sediment yield from the HMS model was compared to the volumes of sediment estimated from the sediment cores and showed a good match. Finally, sediment yields were modeled for three hurricanes in the late 1990s: Lenny (1999), Georges (1998), and Mitch (1998). Based on these three events, sediment delivery to the lagoons can contribute almost half of the annual sediment yield in the span of only a few days.

INTRODUCTION

St. Croix is the largest of the U.S. Virgin Islands at 214.7 km^2. It is located at 17° 45' N 64° 45 W. Precipitation varies longitudinally across the island, with the West end being relatively wet and the East end receiving less rain. Due to its location, St. Croix has averaged one hurricane every seven to eight years since the late 19^{th} century.

As part of a larger project to study long-term trends in hurricane frequency, sediment cores were collected in two lagoons on the eastern end of St. Croix. South Gate Pond is located on the north side of the island and Great Salt Pond is located on the south side. Both of these ponds are depositional lagoons that act as sediment sinks and may preserve records of sediment delivery due to hurricanes.

METHODS

This study focused on the creation of models for the South Gate Pond and Great Salt Pond watersheds on St. Croix. Neither of these watersheds, however, contains a USGS gage with a long-term record. In order to ensure that the relevant parameters of the hydrology models were realistic, a third model was also created for the Jolly Hill watershed. This watershed contains the only USGS gage on the island with a significant record length. USGS Gage #50345000 (Jolly Hill Gut at Jolly Hill) has continuous 15-minute data available from 1986 through 2006 and was used for calibration. The locations of all three watersheds, as well as the USGS gage, are shown in Figure 1.

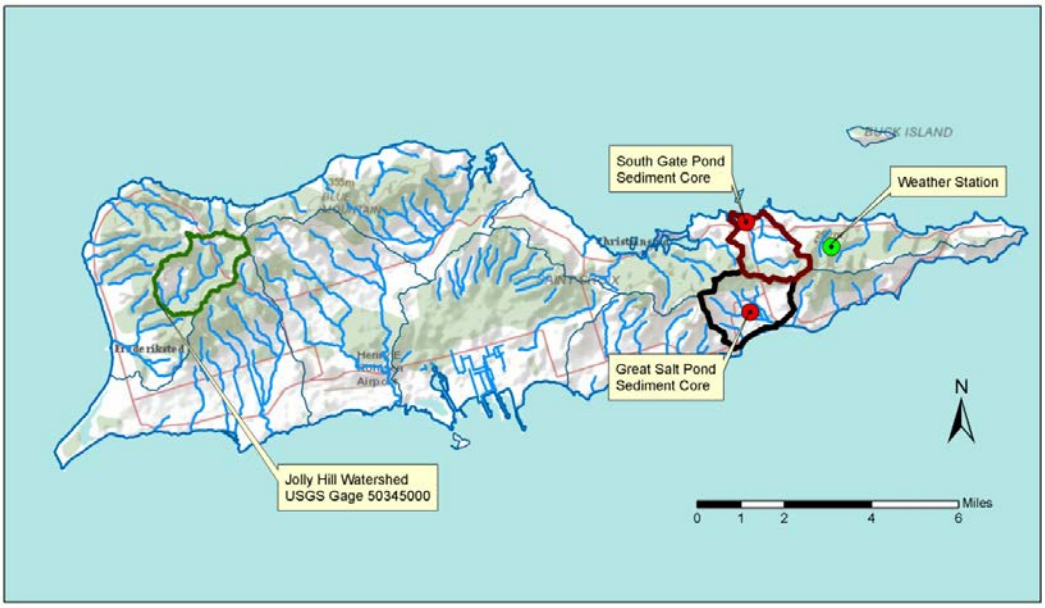

Figure 1 Watershed and time series data locations

HEC-HMS 4.0 Alpha was selected for use in modeling the target watersheds. This decision was based on balancing data requirements, ease of model setup, and the implementation of sediment yield routines in the model.

Data gathered for use in the model included the USGS gage flows, topography, soils, and weather information. The soils in the target watersheds are very coarse, primarily gravelly loam. The primary source of meteorological data was a weather station (Christiansted Station; GHCND #VQW00011624) just east of the Great Salt and South Gate Ponds. The weather station records included precipitation data from 1953 to present.

The hydrology model for Jolly Hill on the west side of St. Croix was developed first in order to take advantage of its 20-year flow record. Hydrology models can be very sensitive to certain variables, such as the percentage of impervious surface area and infiltration. For the Jolly Hill watershed model (see Figure 4), calibration was obtained only when a percolation loss of 0.07 $m^3/s/1000\ m^2$ was used, which represents a losing stream condition. Prior to adding the percolation rate the modeled stream overpredicted flow under very small precipitation events.

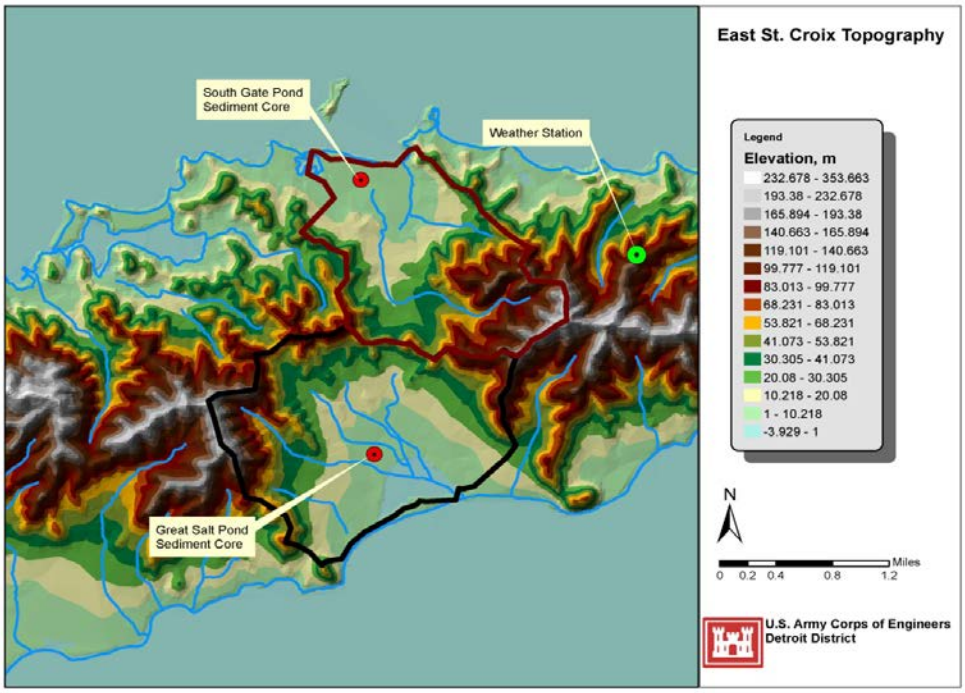

Figure 2 Eastern St. Croix Topography

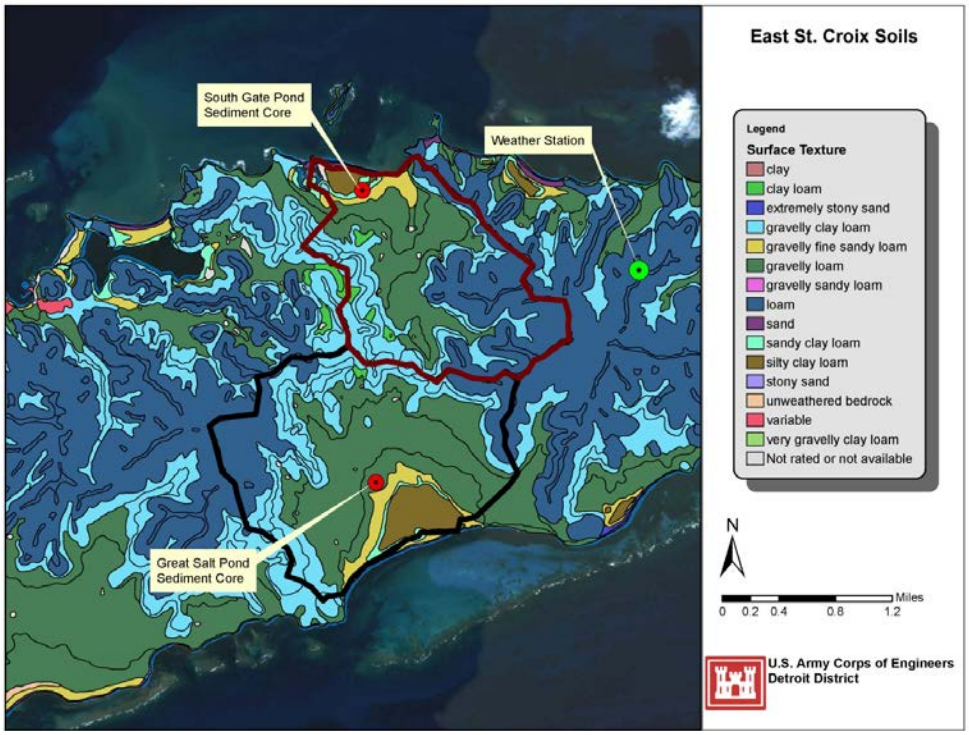

Figure 3 Eastern St. Croix Soils

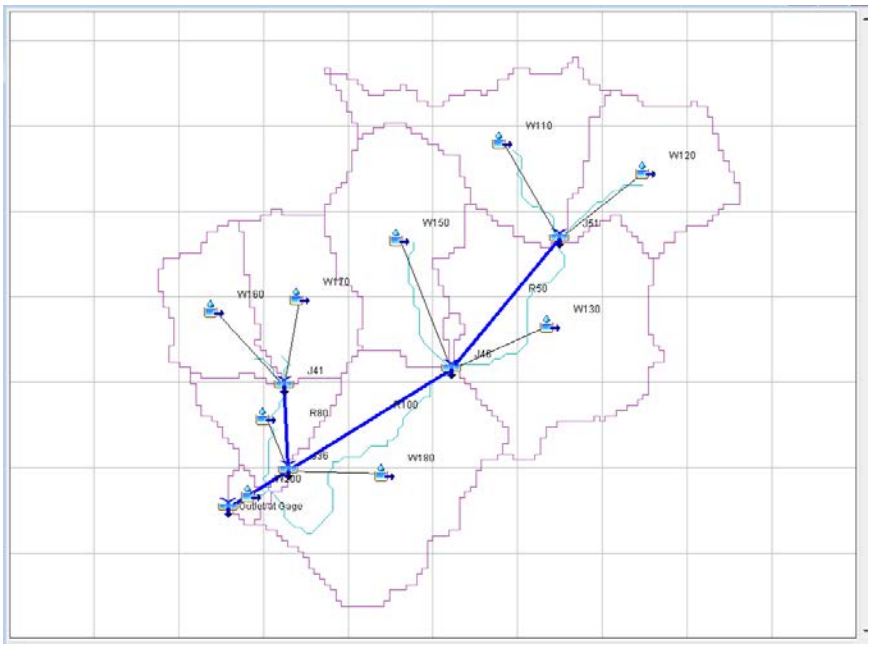

Figure 4 HEC-HMS Model Schematic for Jolly Hill (USGS Gage 50345000)

The year 2001 was selected for calibration of the Jolly Hill model. This year had extreme, moderate, and small events, as well as a complete flow and precipitation record. Figure 5 shows the output of the calibrated hydrology model for this basin.

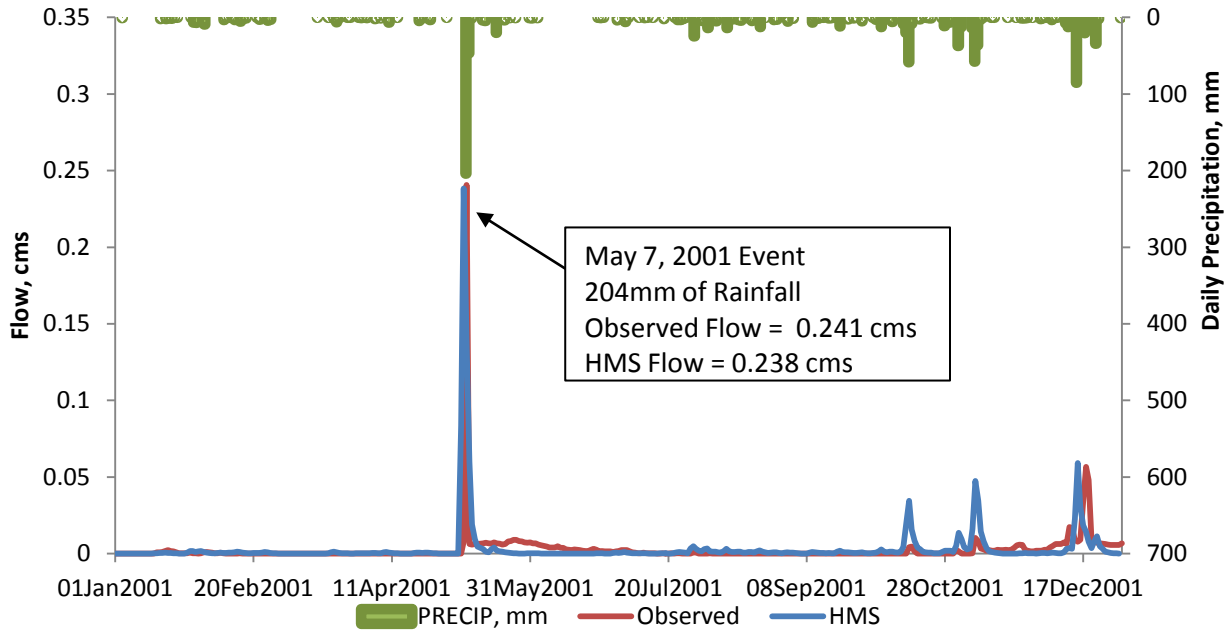

Figure 5 Calibrated Hydrology Model of Jolly Hill Watershed (USGS Gage 50345000)

The calibrated hydrologic parameters from Jolly Hill were then used in the development of sediment yield models in an Alpha version of HEC-HMS 4.0. The Great Salt Pond and South Gate Pond watersheds were both modeled for hydrology and sediment yield/delivery dynamics. The calibration parameters for the hydrology of the Jolly Hill watershed were used due to its proximity and similarity of the topography, geology, and soil types. The HEC-HMS model layouts for Great Salt Pond and South Gate Pond are shown in Figures 6 and 7, respectively.

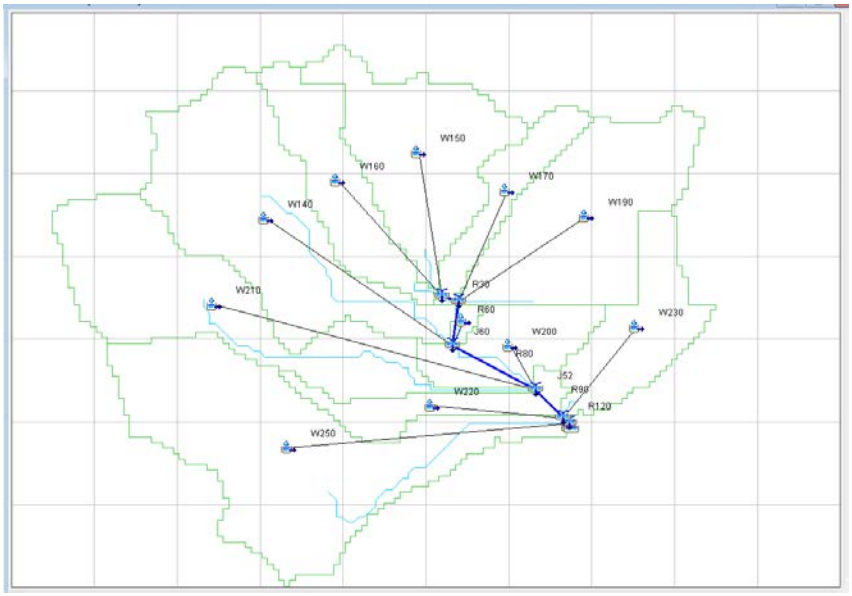

Figure 6 HMS Model Schematic for the Great Salt Pond Watershed

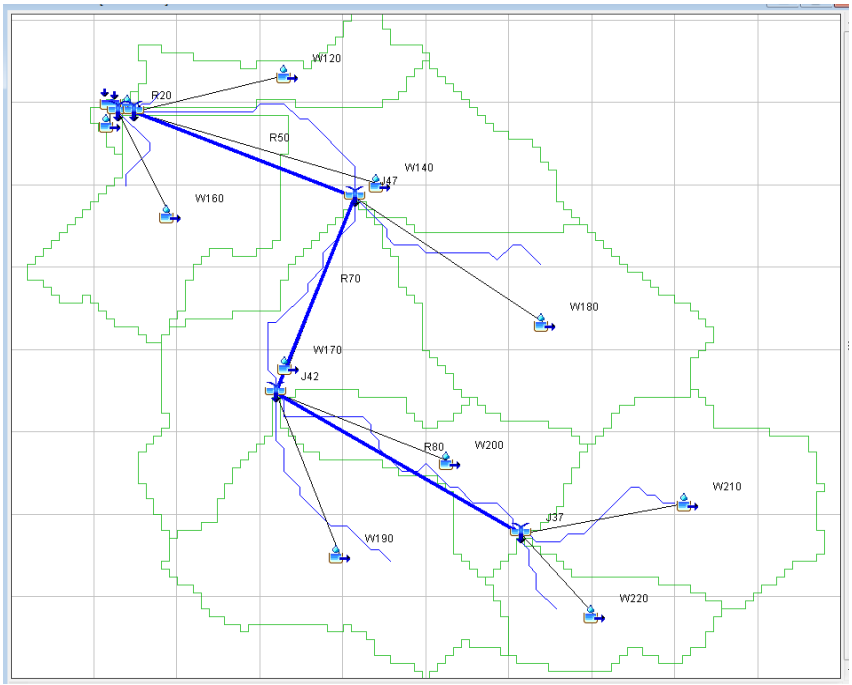

Figure 7 HMS Model Schematic for the South Gate Pond Watershed

The sediment calibration was based on long-term sediment accumulation rates obtained from the sediment cores collected in each lagoon. The physical variables associated with the annual sediment delivery to each lagoon are summarized in Table 1, below.

Table 1 Sediment Calibration Data

	Great Salt Pond	South Gate Pond
Lagoon Area	275,000 m^2	131,000 m^2
Annual Vertical Sediment Accumulation Rate (from Cores)	0.33 cm/yr	0.38 cm/yr
Annual Sediment Accumulation (Volume)	907 m^3/yr	498 m^3/yr
Porosity of Sediment (Assumed)	0.53	0.53
Calculated Annual Sediment Yield	1,274 tonnes/yr	699 tonnes/yr

The Great Salt Pond and South Gate Pond HEC-HMS model were divided into 17 annual models from 1986-2005. Calendar years 1989, 1990, and 1994 were excluded from the modeling effort due to insufficient precipitation data. Several other years also had a few days of missing data, although they were not excluded from the modeling. All missing precipitation data were assumed to be 0 mm. The annual sediment yields from the HEC-HMS model are summarized in Table 2.

The average modeled sediment delivery to Great Salt Pond over the 17 selected years was 1,385 tonnes per year. This closely approximates the sediment delivery calculated from the cores of 1,274 tonnes per year. The modeled sediment delivery to South Gate Pond of 542 tonnes per year was comparable to the 699 tonnes per year estimate based on the sediment cores. The sediment yield models for both watersheds were determined to be calibrated based on these results.

Four modern hurricanes were specifically identified as likely signatures in the sediment core record:

1. Hurricane Marilyn – September 14-15, 1995
2. Hurricane Georges – September 19-23, 1998
3. Hurricane Mitch – October 22-23, 1998
4. Hurricane Lenny – November 17, 1999

Upon investigation of the available data for each of these storms, only Hurricane Lenny, Georges, and Mitch were modeled. During Hurricane Marilyn the precipitation gage appears to have malfunctioned and the record does not contain any precipitation. This also leads to an underestimation of the sediment yield associated with the year 1995 in Table 2.

Table 2 Sediment Delivery to Great Salt Pond based on HEC-HMS Sediment Model

Year	Christiansted Precipitation, mm	Great Salt Pond Sediment Yield, tonnes	South Gate Pond Sediment Yield, tonnes
1986	919.7	1,361	530
1987	1,280.8	1,643	638
1988	1,151.3	1,032	411
1989		*Insufficient Precip Data*	*Insufficient Precip Data*
1990		*Insufficient Precip Data*	*Insufficient Precip Data*
1991	625.8	618	237
1992	957.5	1,443	563
1993	937.6	1,042	407
1994		*Insufficient Precip Data*	*Insufficient Precip Data*
1995	860.3	1,462	568
1996	1,353.2	2,782	1108
1997	809.6	1,089	422
1998	1,080.7	1,363	534
1999	1,029.7	1,568	615
2000	773.8	937	367
2001	1,068.5	1,905	747
2002	550.3	489	191
2003	1,428.2	2,283	895
2004	989.5	1,375	531
2005	897.3	1,150	447
Average	**983.2**	**1,385**	**542**

RESULTS

The HEC-HMS models were run separately for each of the three selected hurricanes: Lenny, Georges, and Mitch. The sediment yields resulting from these events, as well as the annual sediment yield for the corresponding year of the calibration runs, are shown in Tables 3 and 4.

Table 3 Sediment Modeling Results for Great Salt Lagoon for Selected Hurricanes

Hurricane	Year	Annual Sediment Yield, tons	Hurricane Precipitation, mm	Hurricane Sediment Yield, tons	Percent of Total Annual Sediment Yield
Georges	1998	1,363	100.1	209	15.3%
Mitch	1998	1,363	158.8	499	36.6%
Lenny	1999	1,568	186.9	667	43.0%

Table 4 Sediment Modeling Results for South Gate for Selected Hurricanes

Hurricane	Year	Annual Sediment Yield, tons	Hurricane Precipitation, mm	Hurricane Sediment Yield, tons	Percent of Total Annual Sediment Yield
Georges	1998	534	100.1	82.2	15.4%
Mitch	1998	534	158.8	195.3	36.6%
Lenny	1999	615	186.9	264	43.0%

Since Hurricanes Georges and Mitch occurred approximately one month apart, it is likely difficult to isolate these as two separate events in the sediment record of the cores. Instead, these combined storms may be viewed as yielding 51.9% of the total sediment in calendar year 1998 for both ponds. Figures 8 and 9 show the continuous sediment yield record from the HEC-HMS model for calendar years 1998 and 1999, respectively for the Great Salt Pond. Figures 10 and 11 show the continuous sediment yield record for the South Gate Pond for years 1998 and 1999, respectively.

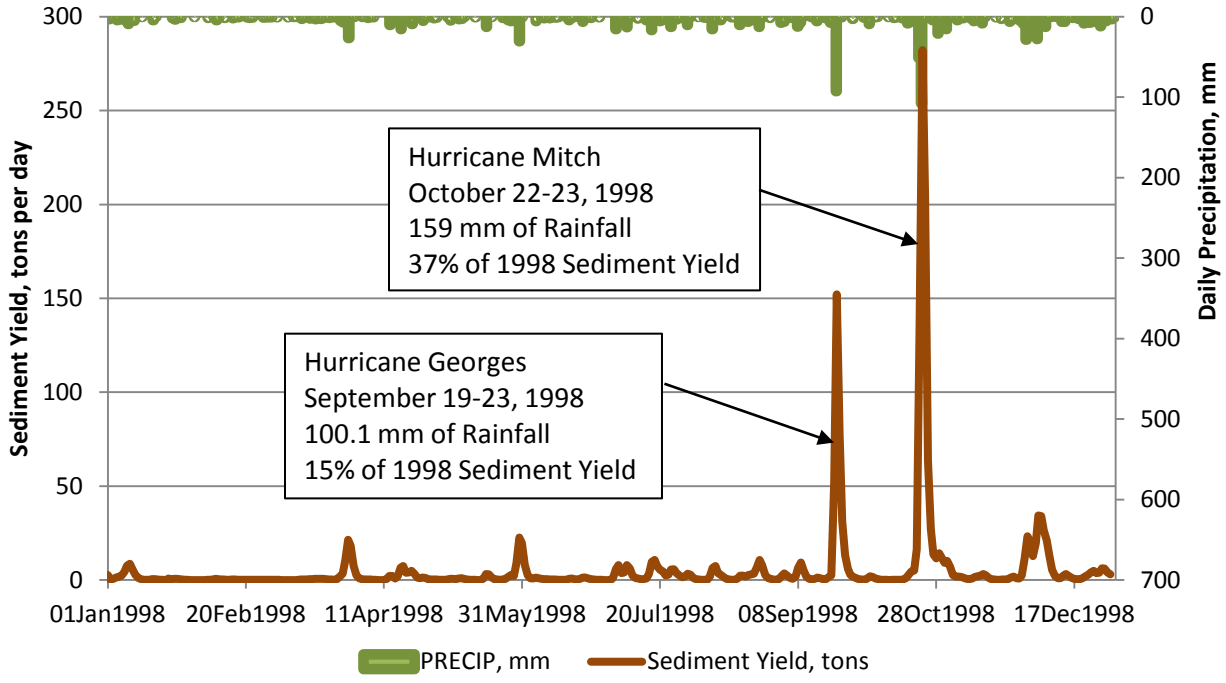

Figure 8 Great Salt Pond- Calibrated HMS Sediment Yield (1998)

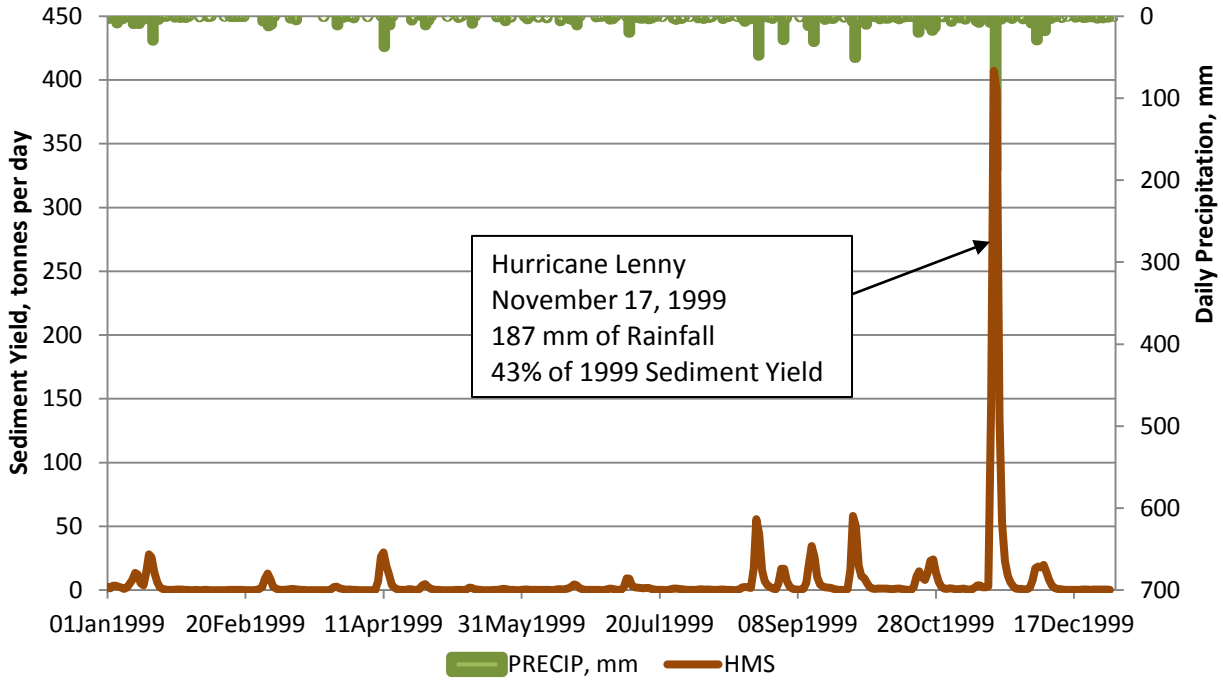

Figure 9 Great Salt Pond- Calibrated HMS Sediment Yield (1999)

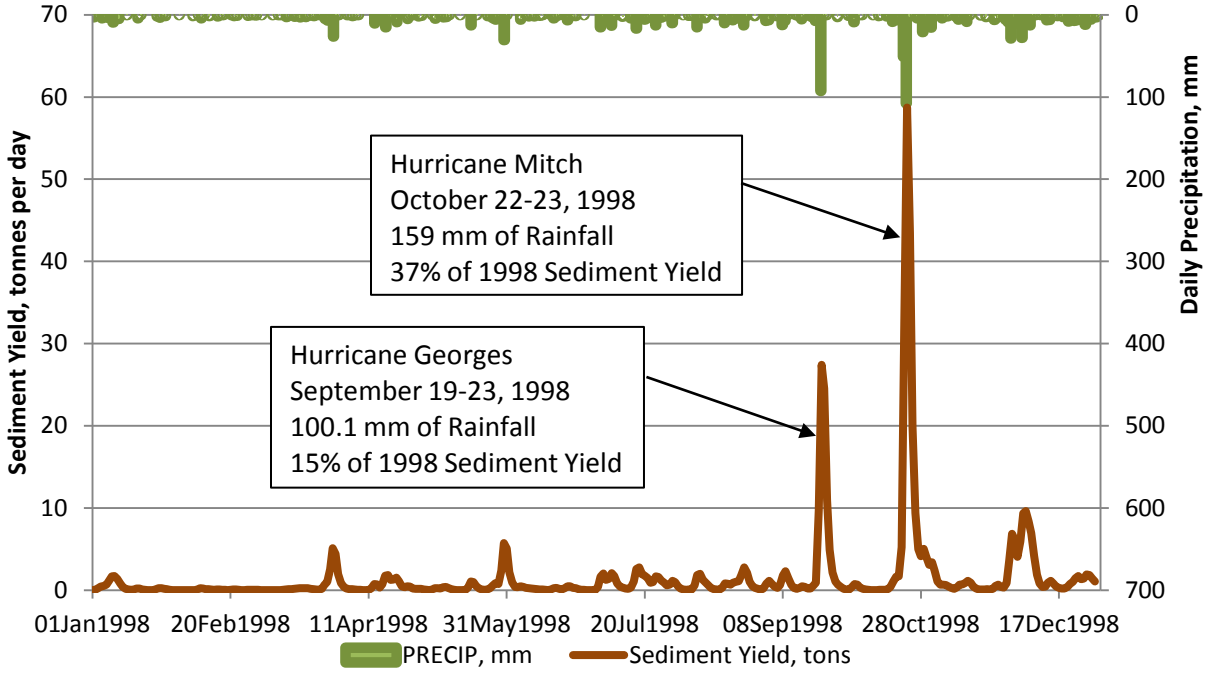

Figure 10 South Gate Pond- Calibrated HMS Sediment Yield (1998)

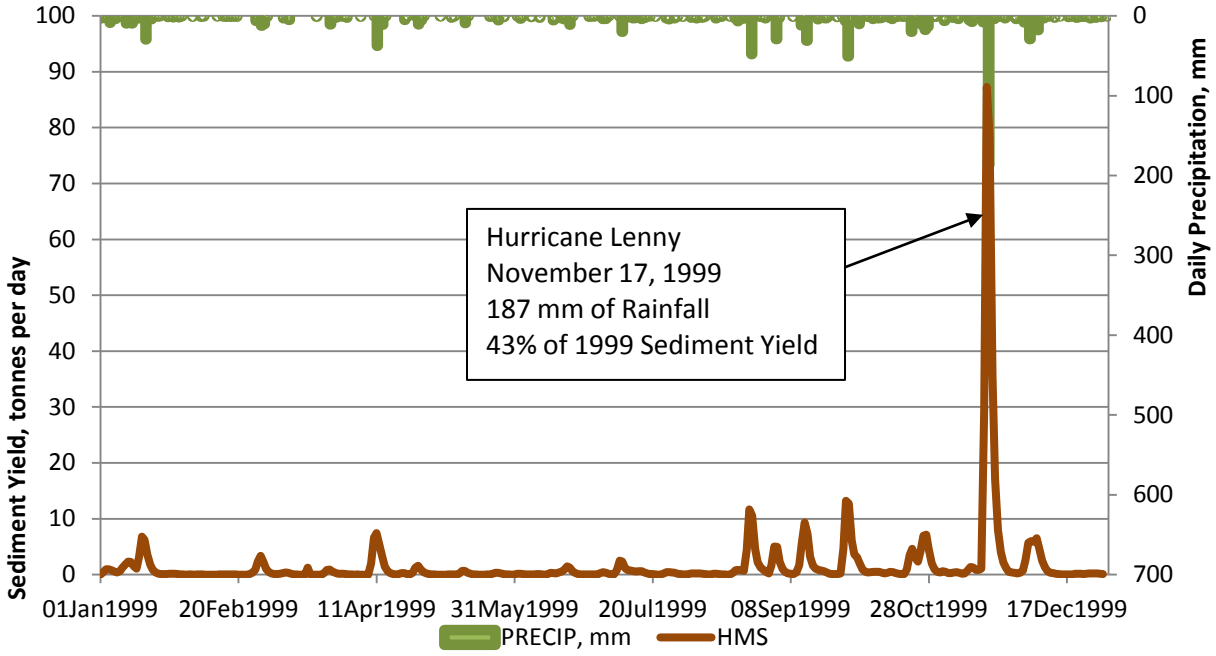

Figure 11 South Gate Pond - Calibrated HMS Sediment Yield (1999)

It should be noted that years with high sediment loads did not necessarily have hurricanes passing directly over the island. In 1996, for instance, Hurricane Hortense did not pass directly over the island but the rainfall generated by the storm still produced a significant portion of the sediment for that year. In 2001, however, a storm in May resulted in a large sediment load. Roughly a third of the modeled years with above average sediment were not the result of hurricanes.

In the sediment yield/sediment routing model, an assumed gradation was provided. The gradation included silts, sands, and gravels. Figure 12 shows the output of the cumulative sediment deposition in the Great Salt Pond by grain class.

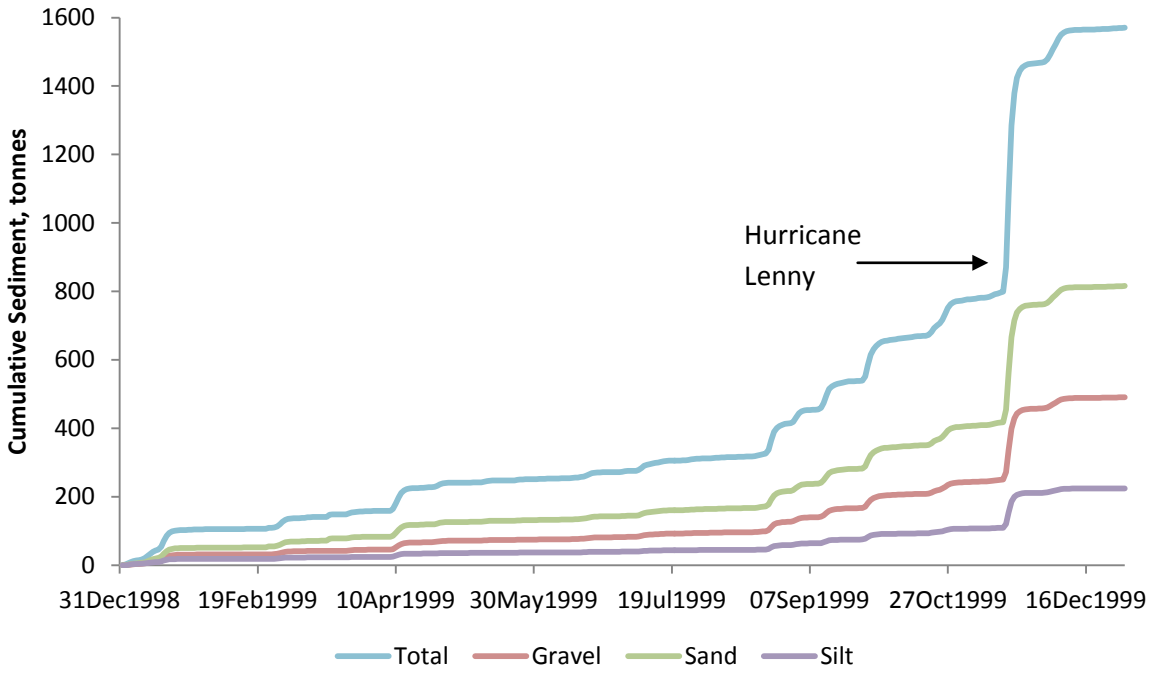

Figure 12 Cumulative Sediment Yield in Great Salt Pond Watershed by Grain Size for the 1999 Hurricane Season

Figure 13 shows the output of the cumulative sediment deposition in the South Gate Pond by grain class. Based on the model, there is approximately an equivalent amount of sediment load for the sand, silt, and gravel grain sizes, although there is slightly more sand (approximately 40% sand, 31% silt, and 29% gravel). This is a finer gradation than the Great Salt Pond, even though the same assumed gradation was supplied to the model for the channel bed and parent material in the watershed. This observation (finer sediment in the South Gate Pond) is consistent with observations of the sediment cores at the two lagoons.

Figures 12 and 13 both show the dramatic increase in sediment due to the impact of a hurricane on St. Croix. These sharp changes in sedimentation should be visible in cores taken from the lagoons.

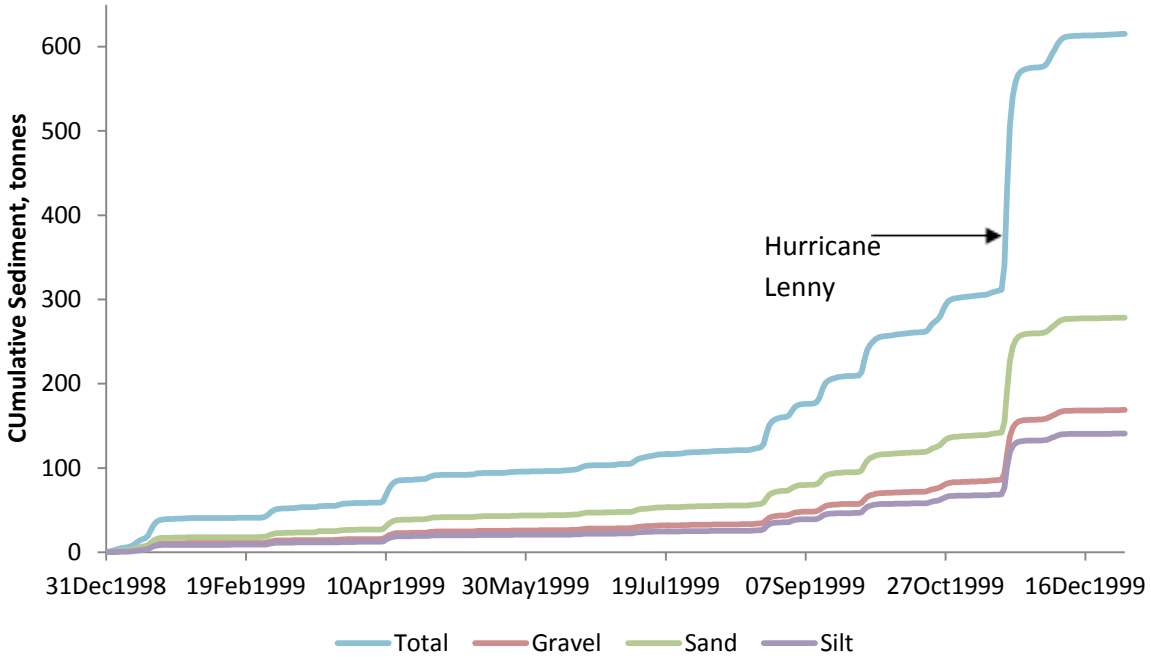

Figure 13 Cumulative Sediment Yield in South Gate Pond Watershed by Grain Size for the 1999 Hurricane Season

CONCLUSIONS

The modeling for the St. Croix watersheds yielded calibrated results for both flow and annual sediment yields in Great Salt Pond and South Gate Pond. It was found from the three hurricanes modeled that the sediment yields associated with a single named storm can contribute almost 50% of the annual sediment yield in that year. In these cases, sediment signatures associated with individual hurricane events may be extracted from sediment cores. Of the sediment that is delivered to the Lagoons, the majority (approximately half) is classified as sand, although the uncertainty associated with this conclusion is relatively high due to lack of sediment gradation data in the stream and in the watershed. The calibrated hydrology and sediment yield model can now be used to answer specific sediment loading questions from other design storms, output from climate change models, or other historic hurricane events. This modeling study demonstrates that the presence of sizeable, distinct layers in cores extracted from Great Salt Pond and South Gate Pond may be good indicators of hurricanes impacting St. Croix.

Extending WEPP Technology to Predict Fine Sediment and Phosphorus Delivery from Forested Hillslopes

Abstract: In many watersheds, including the Great Lakes and Lake Tahoe Basins, two basins where the land cover is dominated by forests, the pollutants of concern are fine sediments and phosphorus. Forest runoff is generally low in nitrogen, and coarse sediment does not adversely impact the quality of lake waters. Predictive tools are needed to estimate not simply sediment, but fine sediment ($\leq$10 μm) and phosphorus delivery from forested hillslopes. We have been developing methods for making such predictions with the Water Erosion Prediction Project (WEPP) model. WEPP is a physically-based hydrology and erosion model that runs on a daily time step, with sub-daily runoff, erosion and sediment delivery predictions. The fine sediment delivery for forested hillslopes is relatively easy to estimate because WEPP provides a breakdown of primary particles (clay, silt and sand) and aggregates (silt size aggregates (30 μm) and sand size aggregates (300 μm)). The size distribution of eroded sediment is disaggregated to determine the amount of fine sediment below a user-specified size in each of the particle classes. Phosphorus transport is complex, as research has shown that in steeper forested watersheds, the dominant hydrologic flow paths are lateral flow and base flow. Surface runoff and sediment delivery are generally minimal unless the site has been disturbed by logging or fire, or the soil layer is thin (shallow to impermeable bedrock). Thus, in an undisturbed forest, the main phosphorus pathway will likely be in subsurface lateral flow as soluble reactive phosphorus (*SRP*), whereas in a disturbed forest, the dominant pathway may be in surface runoff as *SRP*, or as particulate phosphorus adsorbed to eroded sediment. Prediction is further complicated as research has shown that the *SRP* concentration in the soil water may be higher in undisturbed forests than in burned or harvested forests. Delivered sediment also is complicated in that preferential particle size sorting may occur, increasing the content of clay and organic matter in delivered sediment and thereby increasing the phosphorus concentration in delivered sediment above that in the forest. We have developed a way to use the current predictions within the WEPP technology to estimate not only the surface runoff and sediment delivery, but also delivery of fine sediment below a user-specified threshold, and phosphorus through both surface and subsurface lateral flow pathways.

BACKGROUND

In recent years, watershed managers have been challenged to determine the role of forest watersheds in generating phosphorus. Recent examples where watersheds with a significant fraction of the area in forests have concerns about phosphorus delivery include: Lake Tahoe (EPA, 2014), the Great Lakes (EPA, 2012), Big Bear Lake, CA (EPA, 2007), and Cascade Reservoir, ID (Idaho Division of Environmental Quality, 1996). In all of these cases, watershed managers were unable to evaluate the role of forests and forest management on phosphorus

delivery from the forested parts of the watershed. Within the Lake Tahoe Basin we have received funding for three projects to develop phosphorus management tools to address these concerns. This paper focuses on the development of those tools for the Lake Tahoe Basin, but the principles can be applied to forested watersheds anywhere.

Phosphorus pathways in agricultural watersheds are associated mainly with surface runoff, detached sediments, lateral flow and tile drainage water (Sharpley et al., 1994). The dominant pathway in most cases is associated with detached sediments, while phosphorus dissolved in surface runoff and tile drainage are usually lesser important. Agricultural phosphorus delivery models have tended to focus on how management practices such as manure spreading, application of chemical fertilizers and minimum tillage affect the availability of soluble reactive phosphorus (*SRP*) for runoff, and the concentration of phosphorus adsorbed to soil aggregates and particles (particulate phosphorus, *PP*) (Sharpley et al., 1994). The concentrations of phosphorus in eroded sediments, surface runoff, and drain tile flows are then used in runoff and erosion models to predict phosphorus delivery (Withers and Jarvie, 2008).

In forested watersheds, surface runoff and erosion are frequently minimal, and generally are associated with wildfire. In the absence of wildfire, the dominant flow paths for water entering streams are either subsurface lateral flow or base flow (Elliot, 2013; Srivistava et al., 2013). Phosphorus concentrations in forest soils are usually much lower than in agricultural settings. Recent research has found that the concentration of *SRP* in the upper layers of soil water that are the source of shallow lateral flow are much greater than is measured in surface runoff (Miller et al., 2005). These observations suggest that a phosphorus delivery model is needed for forest watersheds that can include the current surface runoff and sediment delivery vectors, as well as delivery from shallow subsurface lateral flow.

In order to develop a model that can predict phosphorus delivery with lateral flow, a hydrologic model that includes shallow lateral flow as well as surface runoff and sediment delivery is needed. The Water Erosion Prediction Project (WEPP) model has such a capability (Dun et al., 2009; Srivistava et al., 2013). WEPP is a physically-based distributed hydrology and erosion model, and it uses a daily time step to predict evapotranspiration, plant growth, residue accumulation and decomposition, deep seepage, and shallow lateral flow. Whenever there is a runoff event from precipitation and/or snowmelt, WEPP predicts infiltration, runoff, sediment detachment and delivery (Flanagan and Nearing, 1995). WEPP has both a hillslope version and a watershed version. In recent years, the predicted deep seepage has been used to estimate groundwater base flow (Elliot et al., 2010, Srivastava et al., 2013), further increasing the model's hydrologic capabilities.

In addition to phosphorus, stakeholders in the Lake Tahoe Basin also are concerned about fine sediment delivery (Coats, 2004). In this context, "fine sediment" is generally considered to be sediment particles and aggregates less than 10 - 20 μm in diameter. Such particles can remain suspended in lakes for a considerable period of time as vertical currents due to surface wind shear and temperature gradients are sufficient to prevent the particles from settling (Coats, 2004). It is these small particles combined with increased algal growth due to phosphorus enrichment that have caused the lake to lose some of its clarity in recent decades.

This paper describes research and development activities that are ongoing to develop phosphorus and fine sediment prediction capabilities from forested watersheds using the WEPP model.

THE WEPP MODEL

The WEPP model was originally developed to predict surface runoff, upland erosion and sediment delivery from agricultural, forest and rangeland hillslopes and small watersheds (Laflen et al., 1997. Inputs for the model include daily climate, soil, topographic, and management or vegetation information. Within the model, WEPP completes a water balance at the end of every day by considering infiltration, runoff, deep seepage, subsurface lateral flow, evapotranspiration, and soil depth and horizon properties. Surface runoff is estimated on a sub-daily time step using an input hyetograph based on the daily precipitation depth, duration, and peak intensity and the soil water content, using a Green and Ampt Mein Larson infiltration algorithm (Flanagan and Nearing, 1995; Dun et al., 2009). The deep seepage is estimated when the soil exceeds field capacity for multiple soil layers, if desired, using Darcy's law. Evapotranspiration is estimated using either a Penman method or Ritchie's model. The lateral flow is estimated for layers that exceed field capacity using Darcy's law for unsaturated conditions as downslope conditions may not be saturated (Dun et al., 2009; Boll et al., 2015). Duration of surface runoff is dependent on storm duration and surface roughness (Flanagan and Nearing, 1995) and lateral flow duration is assumed to be 24 h on days when lateral flow is estimated. If requested by the user, WEPP generates a daily "water" file that contains modeled precipitation and snow melt, surface runoff, lateral flow, deep seepage, and soil water content (Flanagan and Livingston, 1995).

Table 1 shows part of the water file for the Tahoe City, CA climate for Julian days 70-78 (March 11-19). On day 70, precipitation (*P*) was all rain, with no snowmelt; on day 71 rainfall combined with melting snow, and days 77 and 78 were snowmelt only days. Daily runoff (*Q*) occurred only on day 78, while lateral flow occurred every day. The soil exceeded field capacity on day 72 so that deep percolation (*Dp*) began. During these 9 days, the total precipitation was 32 mm, total surface runoff was 15 mm, lateral flow was 19 mm, deep percolation was 0.1 mm, the soil water

Day=julian day; P= precipitation; RM=rainfall +snowmelt; Q=daily runoff; Ep=plant transpiration; Es=soil evaporation; Dp=deep percolation; latqcc=lateral subsurface flow; Total-Soil Water=unfrozen water in soil profile; frozwt=frozen water in soil profile; SWE=snow water equivalent on the surface

content increased by 77.38 mm and the snow water equivalent on the surface decreased by 106 mm. Development is ongoing to add the deep seepage to a temporary groundwater reservoir, and from that to use a linear reservoir model to predict base flow from a sub-watershed as a fraction of the volume of that reservoir (Elliot et al., 2010; Srivastava et al., 2013).

WEPP predicts delivered sediment in five classes: primary clay, silt and sand particles, small aggregates made up of clay, silt and organic matter, and larger aggregates consisting of all three primary particles and organic matter. The sediment size classes and properties are summarized in Table 2 for a coarse sandy loam soil that is widespread in the Lake Tahoe Basin. The fraction of sediment in each size class delivered from a hillslope or a watershed is presented by WEPP. In addition, WEPP calculates a specific surface enrichment ratio (*SSR*), which is the ratio of the sediment surface area in the clay and organic matter fraction in the delivered sediment divided by this value for the soil on the hillslope. This ratio was intended to be used to assist water quality modelers in determining the increase in concentration of a pollutant in the delivered sediment compared to the sediment on the hillslope (Sharpley et al., 1994). For example, if the phosphorus content in the soil was 500 mg kg^{-1} and the enrichment ratio was 2.2, the concentration of phosphorus in the delivered sediment would be 1100 mg kg^{-1}.

THE LAKE TAHOE BASIN

Figure 1 is a map of the Lake Tahoe Basin showing the dominant geologic influences. The largest tributary is the Upper Truckee River flowing into the lake from the south. The overflow for the lake is in the northwest corner, where the Truckee River routes the overflow north, and then east toward Reno, NV. The dominant geologic processes in the basin were volcanic in the north and west, and decomposing granite in the south and east. There are also significant areas of exposed rock outcrops, particularly in the southern part of the basin. Some of the lower elevation lower gradient segments of the stream tributaries are alluvial. The lake has 63 tributaries, and the lake itself accounts for 38 percent of the total watershed area (Coats, 2004). Forests cover 57 percent of the watersheds, and shrubs 31 percent (Greenburg et al, 2006).

ESTIMATING PHOSPHORUS CONCENTRATIONS

Phosphorus delivery from a hillslope either will be adsorbed to eroded sediment (particulate phosphorus, or *PP*) or will be dissolved in surface runoff, subsurface lateral flow, or base flow (soluble reactive phosphorus, or *SRP*). Concentration of phosphorus in sediment depends on the

Table 2 For a forest sandy loam soil, properties of sediment size classes in eroded sediments estimated by the WEPP model.

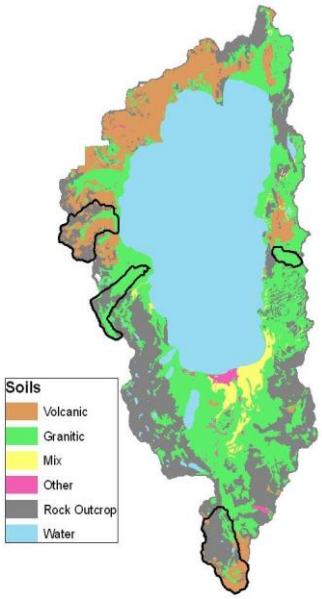

Figure 1 Major geologic categories within the Tahoe Basin.

mineralogy and particle size of the soil. Phosphorus dissolved in solution depends on the geology and the flow pathways (surface, lateral or base flow) that water follows.

For this paper, we focused on developing PP and SRP concentrations that are typical of the Lake Tahoe Basin. A similar procedure can be applied to other watersheds. Within the Lake Tahoe Basin, there is a long history of measuring total phosphorus (TP), SRP and suspended sediment concentration (SSC) in streams discharging to the lake. The number of water quality samples collected from the 13 major streams that flow into Lake Tahoe between 1989 and 2003 range from 129 samples collected from Trout Creek to 1414 at Incline Creek (Figure 2). The largest stream, the Upper Truckee, was sampled at multiple points within the watershed, and Incline Creek has two sample sites within its watershed (Figure 2) whereas the other streams were only sampled near their outlets. The analyses are available from the USGS (http://waterdata.usgs.gov/nwis/rt). Using observed TP (mg L^{-1}), SRP (mg L^{-1}) and SSC (mg L^{-1}) concentrations we calculated the Concentration of phosphorus sorbed to the suspended sediment (mg kg^{-1}) using equation 1.

$$\text{Concentration} = \frac{\text{TP}-\text{SRP}}{\text{SSC}} 10^6 \qquad (1)$$

As seen in Figure 2, the median Concentration from each of the major stream in the Lake Tahoe Basin have a distinct regional pattern with Concentrations ranging from 1000 mg kg^{-1} in the wetter, western streams in the basin to ~1500 mg kg^{-1} delivered from the northern streams, to 1850 mg kg^{-1} from the high elevation streams in the southern setcion of the basin. These regional trends are likely associated with the underlying geology and the characteristics of the delivered sediment.

In order to capture seasonal trends in SRP delivered from Lake Tahoe streams, we applied a USGS model, LOADEST (Runkel et al., 2004), to the observed SRP data. The LOADEST model transforms point data into continuous time series of P loading and concentration as a function of stream flow and time using regression techniques. As seen in Figure 3, the SRP concentrations in Lake Tahoe streams vary seasonally with the highest concentrations (~0.022 mg L^{-1}) during low flow conditions in the fall and lowest concentrations (~0.015 mg L^{-1}) in the late spring during snowmelt. The LOADEST model was able to match these monthly trends fairly well (Figure 3).

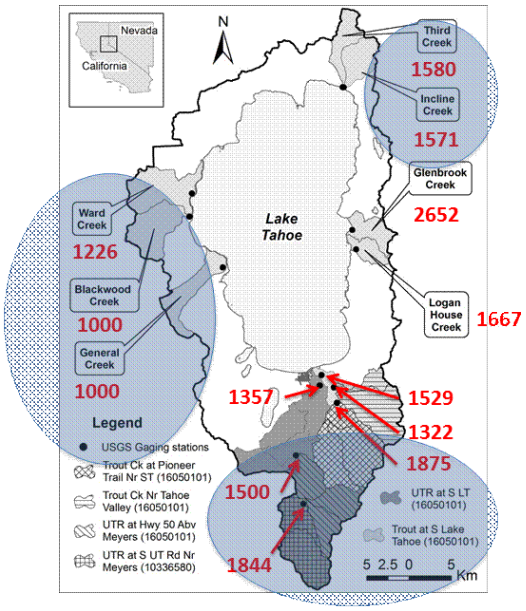

Figure 2 Concentration of phosphorus (mg kg^{-1}) adsorbed to delivered sediment from watersheds within the Lake Tahoe Basin shown in red. The concentrations tended to break down into three distinctive sets as shown by the gray circles, with the granitic soils in the Upper Truckee Basin having the larger concentrations, whereas the volcanic watersheds on the western side had lower concentrations of adsorbed *P*.

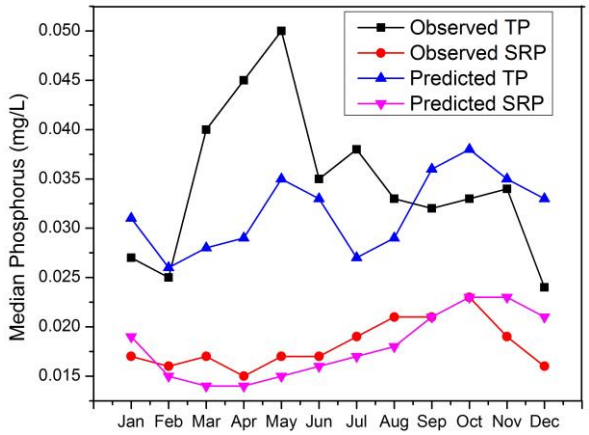

Figure 3 Observed and predicted phosphorus concentrations averaged across all years and all watersheds.

We also attempted to predict monthly TP concentrations with the LOADEST model; however the agreement was quite poor. Since the LOADEST model was not developed to use SSC as an independent variable in the regression analysis, but rather attempted to predict TP based on flow and time, it was not surprising the monthly TP concentrations simulated by LOADEST did not agree with observed patterns. This suggests that the TP concentration is largely influenced by the PP in the delivered sediment.

In addition to the sample concentrations we also generated daily hydrographs for each of the sampled streams. Figure 4 is a hydrograph for Blackwood Creek in which we have estimated the relative contribution of each of the flow paths (surface, lateral and base) using the WEPP model water file coupled to a linear groundwater flow model. Figure 4 shows that the base flow is the dominant flow path from July until snowmelt the following April, that surface runoff occurs only at times of peak flow rates, and that lateral flow is the dominant flow path during higher stream

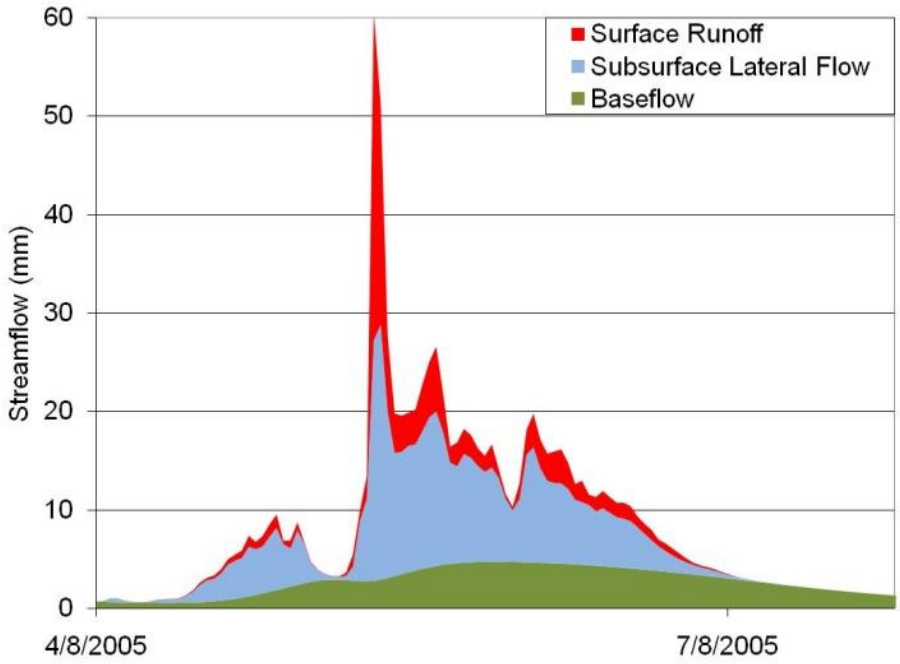

Figure 4 Example hydrograph based on WEPP hydrology for Blackwood Creek (Elliot et al., 2010).

flow rates in the late spring. Combining this information with the results shown in Figure 3, it is apparent that the SRP in surface runoff is likely less than 0.01 mg L^{-1}, whereas SRP concentrations in lateral flow and base flow are likely to be around 0.02 mg L^{-1}. Concentrations are the lowest during March and April when surface runoff is contributing to runoff and diluting lateral and base flow, but higher from June onward when lateral flow and base flow are the main sources of water in the stream system. Total phosphorus delivered, however, is likely to be the highest during the peak flow times associated with snow melt in April and May, which coincides with the greatest sediment transport as well.

ESTIMATING FINE SEDIMENT DELIVERY

The distribution of particle size delivery from hillslopes or watersheds given in the WEPP model output file can be parsed to determine the amount of each textural fraction in each particle size category by summing the delivery of a given size primary particle with the fraction of that particle contained in the aggregates. In WEPP, clay primary particles are ≤ 4 μm diameter, and silt particles are 4 - 62.5 μm diameter. To simplify modeling, we assumed that within the silt textural category the distribution of particle sizes was linear. Thus if the user needed to know the amount of sediment ≤ 10 μm, the number could be determined by adding all of the clay fraction as primary particles and in aggregates to the (10-4)/(62.5-4) fraction of the silt delivered as primary particles and in aggregates.

INTERFACES

In order to make this technology useful to managers, an interface was developed similar to the Forest Service Disturbed WEPP online interface for the WEPP model (Elliot, 2004). Figure 5

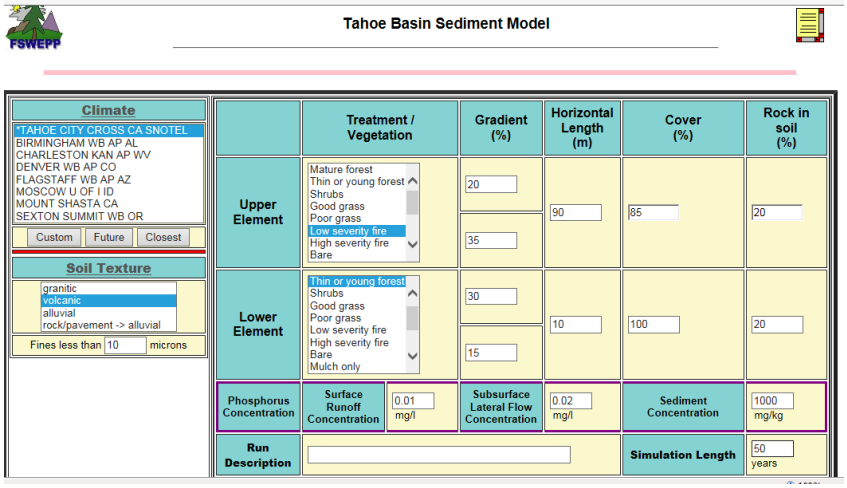

Figure 5a Input screen for the Tahoe Basin Sediment Model using a SNOTEL station from within the Lake Tahoe Basin for the weather and phosphorus concentrations from Figures 2 and 3.

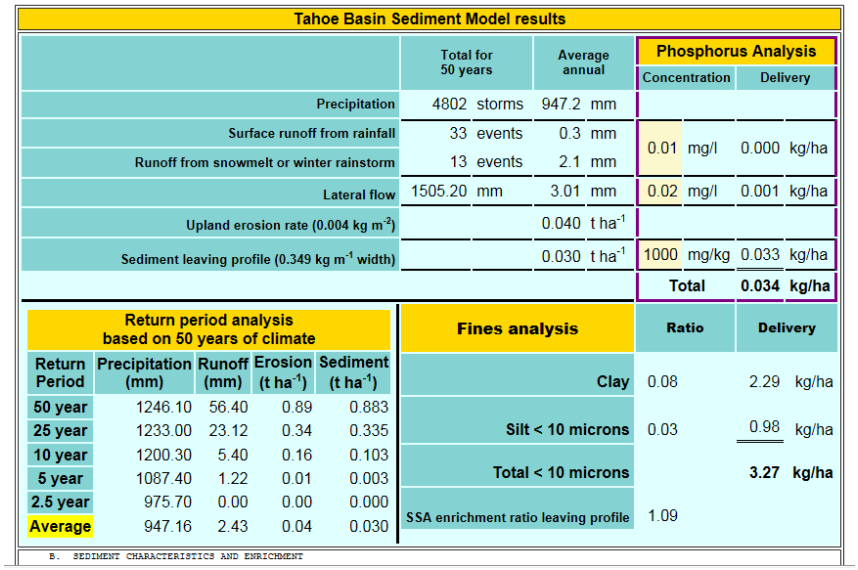

Figure 5b Output screen for the Tahoe Basin Sediment Model.

shows the input and output screens for the Tahoe Basin Sediment Model (TBSM, http://forest.moscowfsl.wsu.edu/fswepp). The user is asked to select a climate, dominant geology, vegetation conditions for the upper or treated part of a hill, and lower or stream side buffer part of the hill. In the case of an undisturbed condition, or a post-wildfire condition, the upper and lower portions of the hill may have the same vegetation.

The climate database for the TBSM includes one NOAA station within the Lake Tahoe Basin as well as five nearby weather stations. In addition, climate statistics have been added to the database for seven NRCS Snow Telemetry (SNOTEL) stations located within the Basin. Another feature unique to the TBSM interface is that future climate scenarios are available for the seven SNOTEL stations and the one NOAA station within the Basin.

The user is asked to provide the phosphorus concentrations in the surface runoff, lateral flow, and sediment. Earlier versions of the interface were designed for the user to enter the phosphorus concentration in the soil, and the model would then adjust this value using the specific surface enrichment ratio from the WEPP output. We found, however, that it was easier to obtain the concentration of total and soluble reactive phosphorus from in-stream monitoring rather than

concentrations of phosphorus in the soils themselves, so the current interface is designed to use the concentrations shown in Figure 2 based on in-stream data. The interface could be altered for other applications where on-site particulate phosphorus concentrations are readily available and be designed to use delivered sediment with a delivery ratio as previously discussed.

Figure 5b shows the output screen for the TBSM. Each phosphorus path (sediment, surface runoff and lateral flow) is presented so that users will be able to determine the dominant pathway for the condition they are modeling. In the example shown in Figure 5b for a prescribed burn with a buffer, the greatest source of phosphorus is in the delivered sediment. This is often the case in disturbed forests (Stednick, 2010). In undisturbed forests, the greatest source of SRP is likely to be in the shallow subsurface lateral flow (Miller et al., 2005).

The fine sediment category between 4–62.5 μm is specified on the input page (Figure 5a) and the total delivery per unit area is calculated from the predicted sediment delivery, and presented on the output page.

DISCUSSION

This approach to modeling phosphorus and fine sediment delivery was developed for the Lake Tahoe Basin. The principles that are described here for estimating delivery of phosphorus can be applied to any condition where the input variables are known. For conditions where P concentrations are not known, sampling of a streams may be necessary to estimate the PP and SRP concentrations and their variability to apply this tool. The Tahoe Basin Sediment Model (TBSM) interface assumes a particulate phosphorus (PP) concentration attached to stream sediment. In other conditions, it may be more appropriate to link the PP concentration to the onsite concentration, and apply a specific surface enrichment ratio to the delivered sediment. With this interface, using the large PP concentrations in stream sediments (1000 – 2500 mg/kg), we may be over-predicting the delivery of PP to the stream. Elliot et al. (2012) reported onsite concentrations of 4–22 mg/kg and concentrations on coarse sediments collected from rainfall simulation of 160–475 mg/kg. The increasing concentrations of PP from soil to upland eroded sediments to stream sediments is due to the specific surface enrichment, and further work on the interface may be necessary to make sure the high instream concentrations are linked to the delivery of clay-size material. In the Tahoe basin, clay generally accounts for around 2 percent of the soil fraction.

An interesting hydrologic feature of coarse forest soils is that unless the soils are highly disturbed, there is little surface runoff. Comparing the hydrograph in Figure 4 to the SRP concentration variability in Figure 3 suggests that when surface runoff does occur, SRP concentrations are low, but when lateral flow or subsurface flow dominate the runoff, SRP concentrations increase. The net effect of integrating the runoff and concentration values in these two figures suggests that total SRP delivery is the greatest when runoff is the greatest. It also suggests an interesting twist to managers: if managers seek to minimize surface runoff, subsurface lateral flow is likely to increase (Srivastava, 2013), and so will the concentration of SRP leaving the hillslope. Surface runoff itself will deliver less SRP, but it will also be the mechanism that delivers sediment, so that PP will likely dominate the total phosphorus (TP) budget when there is surface runoff.

The TBSM does not consider channel processes. In steep forest watersheds, stream channels and banks tend to be coarse, minimally adsorbing or desorbing TP. Forests with finer textured or higher organic materials in stream beds or banks are more likely to influence TP delivery, adding to SRP during times of low stream SRP concentration and reducing SRP during times of high concentration (Withers and Jarvie, 2008).

The interface clearly shows the link between sediment delivery and TP delivery. Past watershed research has shown that sediment budgets from forest watersheds are dominated by wildfire, with sediment delivery following wildfire being as much as 100 times greater than that associated with undisturbed forests (Elliot, 2013). Such sediment pulses will likely dominate delivery of phosphorus in the same way as they dominate the sediment budget. Managers need to consider the effects of forest practices not only on immediate phosphorus delivery, but also on the effects that forest practices may have on phosphorus delivery following wildfire (Elliot, 2013).

If applying this tool to other basins, users need to be aware of several features of this interface that were customized for the basin. The soil categories, granitic, volcanic, alluvial and rock/pavement would correspond to coarse sandy loam, sandy loam, loam and rock/pavement in other watersheds. The PP concentrations were for sediment transported by suspension through the Tahoe Basin stream system, and not necessarily the concentration of eroded sediment leaving a hillslope. Careful thought needs to be given to decide whether to use the approach described here for suspended sediment, or to use the PP concentration in the field, and apply the specific surface enrichment ratio is PP concentrations of the soil are available. In impaired watersheds, however, it is often easier to obtain TP and SSC than it is upland soil concentrations and therefore use the interface in its current form.

CONCLUSIONS

We have described an approach to using the WEPP model to aid in predicting phosphorus and fine sediment delivery from steep forested watersheds. The approach is limited to hillslope processes, and does not consider channel impacts on phosphorus delivery. The tool that was developed, however, can be useful in aiding forest managers in evaluating the effects of forest management, including wildfire, on delivery of fine sediments and phosphorus.

POTENTIAL INSIGHTS INTO PHYSICAL CHARACTERISTICS OF SEDIMENT FROM SIMULTANEOUS OPTICAL SIDE SCATTER AND BACK SCATTER TURBIDITY MEASUREMENTS

Barbra Utley, Ph.D., Application Specialist, Campbell Scientific Inc., Logan, Utah, barb.utley@campellsci.com; Boyd Bringhurst, Water Resources Market Manager, Campbell Scientific Inc., Logan, Utah, boyd@campbellsci.com

Abstract: Turbidity is one of the most common surrogate measurements for suspended sediment concentrations (SSC) in natural systems. One weakness of turbidity measurements is that the data collected provide no information regarding the size or shape of the particles. The Campbell Scientific OBS500 measures both side scatter and back scatter simultaneously. Normally side scatter (SS) measurements are considered more accurate at lower turbidities (0.4-1000 TU) while back scatter (BS) measurements are regularly calibrated from 0.4-4000 TU and possibly up to 10000 TU in the future. Campbell Scientific Inc. (CSI) has noticed at multiple testing locations that SS and BS measurements often track closely both in magnitude and relative change, while in other systems the measurements track with regards to relative change but are offset by 10-30 turbidity units.

CSI hypothesized that the difference in measurement magnitude is tied to size, shape, color, absorption, biological matter or other physical attributes of the water. CSI paired a controlled laboratory study with field data from two deployment locations (Spring Creek near Mendon, UT and the Wilmington River near Priest's Landing, GA) to determine the impact of mineralogy on the SS and BS measurements. Sediment samples from both field sites will be analyzed for mineralogy and morphology by DCM Sciences in Denver, CO.

The controlled laboratory study completed simultaneous SS and BS measurements at multiple concentrations over the shared calibration range of the SS and BS sensors (0-1000 TU). Six different mineral suspensions were tested at each of the six concentrations (0, 10, 100, 250, 500, and 1000 mg/L). The mineral suspension included multiple size fractions – mineral combinations of kaolinite, bentonite, quartz, feldspar, mica, and anthracite (Mica 700, Mica 2400, Mica 4000, 200 Mesh Feldspar, 325 Mesh Feldspar, Bentonite, Calcined Kaolinite, Georgia Kaolinite, Natural Brown Sand, Utah Coal, and Wyoming Coal). Also quartz suspensions at the six concentration levels were created from sieved art sand. The colors tested included white, blue, red, green, and black to determine if SS, BS, or their interaction were significantly different for the same mineral and particle size but different colors. In total SS and BS data were collected for 96 suspensions by three OBS500 sensors. A total of 600 data points were collected per treatment level.

The data collected during the laboratory study were used to develop a multivariate, linear regression model to predict concentration (mg/L) as a function of SS, BS, and particle size. This model was then tested with an independent set of laboratory data. The verification test was completed using known concentrations of natural sediments from the Spring Creek field site near Mendon, UT. Five concentrations were chosen randomly over the modeled concentration range of 0-1000 mg/L. The prediction model was also tested with the long-term turbidity data collected at the two field sites and their sediment mineralogy and morphology.

EVALUATING TURBIDITY AND SUSPENDED-SEDIMENT CONCENTRATION RELATIONS FROM THE NORTH FORK TOUTLE RIVER BASIN NEAR MOUNT ST. HELENS, WASHINGTON: ANNUAL, SEASONAL, EVENT, AND PARTICLE SIZE VARIATIONS - A PRELIMINARY ANALYSIS

krspicer@usgs.gov

INTRODUCTION

Regression of in-stream turbidity with concurrent sample-based suspended-sediment concentration (SSC) has become an accepted method for producing unit-value time series of inferred SSC (Rasmussen et al., 2009). Turbidity-SSC regression models are increasingly used to generate suspended-sediment records for Pacific Northwest rivers (e.g., Curran et al., 2014; Schenk and Bragg, 2014; Uhrich and Bragg, 2003). Recent work developing turbidity-SSC models for the North Fork Toutle River in southwestern Washington (Uhrich et al., 2014), as well as other studies (Landers and Sturm, 2013; Merten et al., 2014), suggests that models derived from annual or greater datasets may not adequately reflect shorter term changes in turbidity-SSC relations, warranting closer inspection of such relations.

In-stream turbidity measurements and suspended-sediment samples have been collected from the North Fork Toutle River since 2010. The study site, U.S. Geological Survey (USGS) streamgage 14240525 near Kid Valley, Washington, is 13 river km downstream of the debris avalanche emplaced by the 1980 eruption of Mount St. Helens (Lipman and Mullineaux, 1981), and 2 river km downstream of the large sediment retention structure (SRS) built from 1987–1989 to mitigate the associated sediment hazard. The debris avalanche extends roughly 25 km down valley from the edifice of the volcano and is the primary source of suspended sediment moving past the streamgage (NF Toutle-SRS). Other significant sources are debris flow events and sand deposits upstream of the SRS, which are periodically remobilized and transported downstream. Also, finer material often is derived from the clay-rich original debris avalanche deposit, while coarser material can derive from areas such as fluvially reworked terraces.

Data Collection, Sampling, and Processing: Unit value (15-minute interval) turbidity values were collected and processed according to established USGS procedures (Wagner et al., 2006), using a Forest Technology Systems DTS-12 sensor oriented vertically in a standpipe on the left bank of the river. Sensors were calibrated in standards (i.e., solutions of known turbidity) before and after deployment periods. Data corrections were applied based on the calibration results. All turbidity sensors have a maximum threshold recording level. For the DTS-12 the threshold is approximately 2,500 Formazin Nephelometric Units (FNU). Turbidity values above the DTS-12 maximum in water year (October to September) 2013 were estimated from a Hach Solitax sensor located adjacent to the DTS-12. Solitax sensor values are measured in Formazin Backscatter Ratio Units (FBRU) up to a maximum value of about 20,000 FBRU; observed values were reasonably consistent with DTS-12 values below about 2,500 FNU. Turbidity data from sensors reporting in different units should not be used interchangeably (Anderson, 2005). Solitax FBRU data in water year 2013 were used only as a visual guide to estimate discrete values of DTS-12

turbidity in FNU for the SSC samples collected above the DTS-12 threshold. Also for water year 2012, some turbidity values above the sensor threshold were estimated by extending the slope of the DTS-12 rise and fall graph line and interpolating the appropriate turbidity value at the time of the sample.

Manual cross-sectional depth-integrated and bankside automated-pumping samples were collected using standard USGS samplers and methods. The manual method used was the Equal Discharge Increment method or EDI, in which a separate sample of the same volume is collected from each centroid in the cross-section. Each centroid has a calculated percentage of flow whose locations are determined by a discharge measurement (Edwards and Glysson, 1999). Samples were analyzed for SSC and many for particle size distribution (Guy, 1977). Sediment particle size is defined by the diameter, such that a diameter smaller than 0.062 millimeters (mm) is considered fine-grained sediment. Coefficients, calculated from a concentration ratio, were applied to correct pump samples to the manual cross-section mean SSC. For example, if an SSC from a manual sample was 120 milligrams per liter (mg/L) and the pump samples collected directly before and after the manual sample were each 100 mg/L, the pump SSCs would be multiplied by 1.2 to obtain a corrected value.

REGRESSION ANALYSIS

Datasets of the sample SSC, concurrent in-stream turbidity, and percentage of fine sediment were compiled for 2010–2013 water years. Datasets were then divided by year, season, and specific high-turbidity events. Regression models were developed from these subsets and results were compared from year-to-year and season-to-season, along with evaluations for groups of high-turbidity events. Models were also developed by categorizing the data by specific groups of particle size distribution, or percentage of fine-grained sediment. Samples were categorized in two groups: less than or greater than 60 percent fines. Regression equations and model results were evaluated for each category.

The regression analysis used the power equation form, such that SSC is equal to a x Turbidity ^{b}, where a is the y-intercept and b is the slope. The coefficient of determination (R^2) and sum of squares error of prediction (SSE) values, shown on most figures, are statistical and comparative diagnostics used in regression modeling to evaluate accuracy (Helsel and Hirsch, 2002; Uhrich et al., 2014). In general, the higher the R^2 the better the model fits the data, although there are exceptions and the R^2 should be evaluated with other model statistics and plots of the residual values. The SSE is a measure of variation in the model or its deviation from the mean, hence the lower the SSE the less the variation and tighter fit of the model.

Annual Regressions: Annual turbidity-SSC models can provide adequate results for most Pacific Northwest streams (Bragg et al., 2007) but might not be suitable for the North Fork Toutle basin near Mount St. Helens due to its variable sediment sources and erosional conditions. The analysis of North Fork Toutle River turbidity and SSC data, under varying time scales, reveals how a single turbidity value can have varying SSC and/or sediment-size fraction values associated with it.

Annual data were grouped by water year. The 2010 dataset, a partial year from May to September, was combined with the 2011 water year. The number of samples collected for the 2010–2011, 2012, and 2013 datasets were 653, 509, 408, respectively, totaling 1,570 turbidity-SSC pairs available for analysis (figure 1). Ordinary least-squares regression models, developed for each water year, yielded an equation to estimate SSC from turbidity (Helsel and Hirsch, 2002; Uhrich et al. 2014). SSC was first computed using the 2010–2011 regression equation, for a range in turbidity values from 100 to 2,000 FNU. This turbidity range was the most common amongst all years in matched turbidity with sample SSC, although in 2013 the paired turbidity with SSC was higher, due to the use of the Solitax sensor. The 2010–2011 computed SSC, for the selected turbidity range values, had a percent difference of 5 to 32 percent higher than the 2012 equation estimates, for the same range of turbidity values, with a 54 to 65 percent difference higher than the 2013 equation estimates. For example, a turbidity value of 100 FNU equated to 835 mg/L for the 2010–2011 model. The same turbidity value equated to 795 mg/L and 385 mg/L for the 2012 and 2013 models, respectively. A turbidity value of 1,600 FNU equated to 7,360 mg/L for 2010–2011. The same value equated to 5,150 and 2,630 for 2012 and 2013, respectively. Turbidity values above 2,000 FNU, which were associated with the SSC samples, occurred in 2013 and exhibited slightly greater differences in SSC.

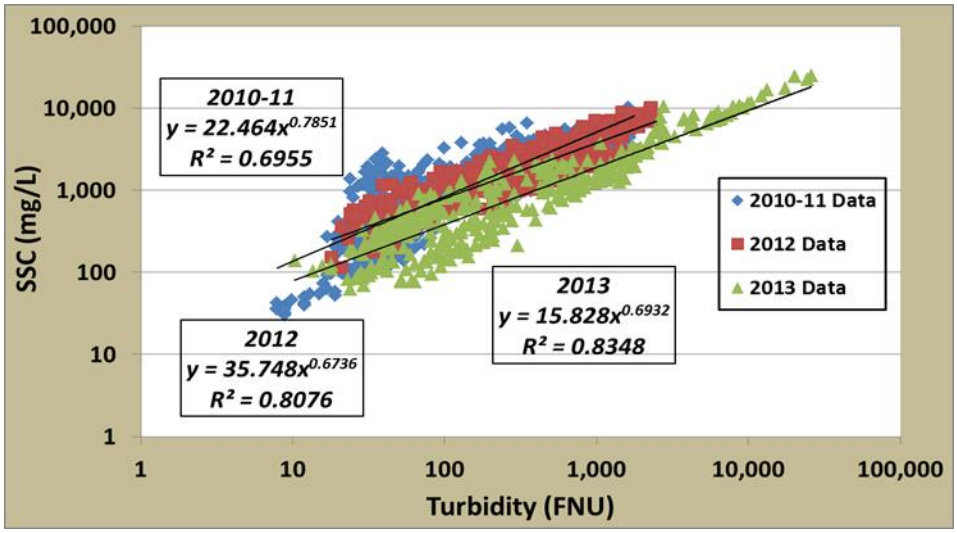

Figure 1 Ordinary least-squares regressions of turbidity and SSC for the USGS streamgage 14240525 North Fork Toutle River below SRS near Kid Valley, Washington, using 2010–2013 turbidity and SSC data pairs.

The large differences between 2013 and the other water years were largely caused by the reconstruction of the SRS spillway, about 2 km upstream from the streamgage. The spillway was raised by over 2 m in October 2012, thereby impounding greater amounts of suspended sediment and limiting downstream transport. Also in 2012, as a precursor to the spillway raise, grade-building structures and diversion channels were placed upstream of the SRS to impede and trap sediment movement. Hence, there was a significant change to turbidity-SSC relations from 2010–2011 and 2012 water years to the 2013 water year. This demonstrates that annual turbidity-SSC models for the North Fork Toutle River must be checked year-to-year as changes are

inevitable in this basin due to the ubiquitous and dynamic nature of a natural and managed sediment regime.

Seasonal Regressions: Seasonal differences are also evident. Seasons were differentiated into 4 groups comprising 3 months each: October-December, January-March, April-June, and July-September. These monthly groupings were further simplified to fall, winter, spring and summer, respectively. Regression equations were generated for each season in each year (figure 2).

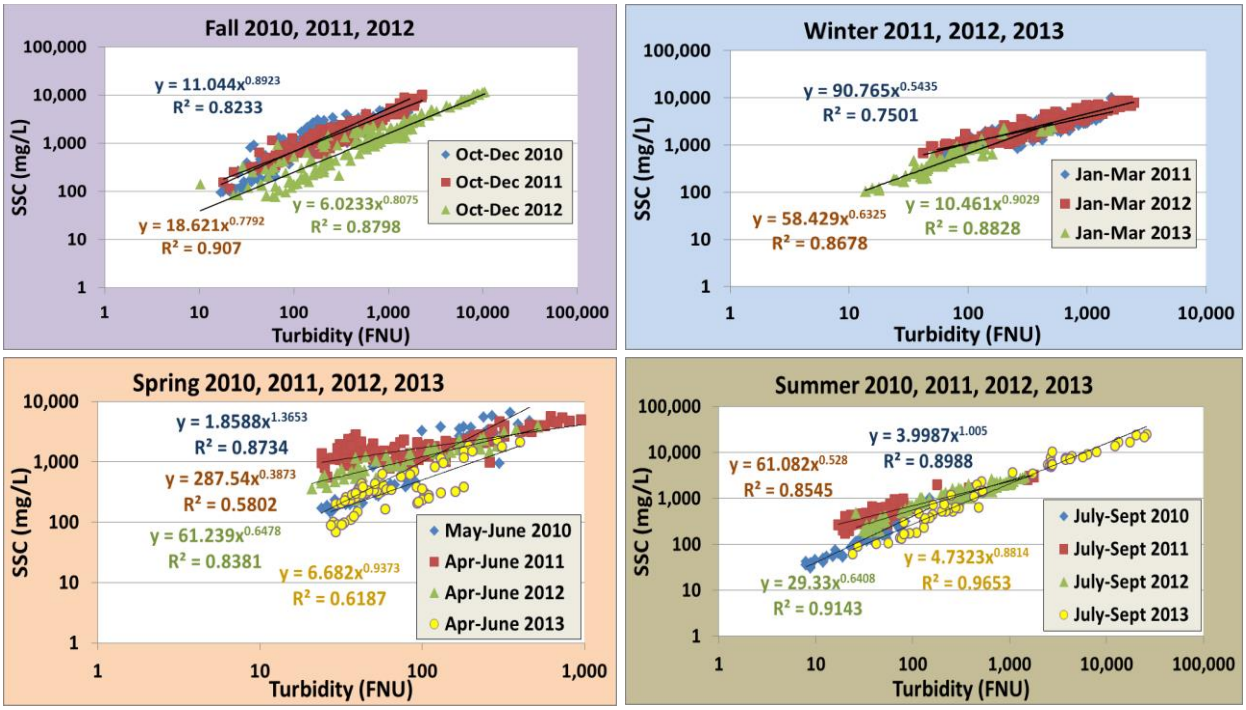

Figure 2 Seasonal regression models for the NF Toutle-SRS streamgage using 2010–2013 data.

Similar to the annual computational method, a range of turbidity values from 100 to 2,000 FNU was used to estimate seasonal SSC. The regression analysis showed that a low turbidity of less than 200 FNU with a relatively low estimated SSC occurred in the seasons of summer 2010 and 2013 and fall 2012. Seasons with high turbidity, greater than 1,200 FNU, having a low estimated SSC also occurred in fall 2012 and summer 2011, 2012, and 2013. The seasons of fall 2012 and summer 2013 had low SSC despite the turbidity level (table 1). Hence, low turbidity in the North Fork Toutle basin with a relative low SSC are indicative of late summer and early fall low flow conditions, where sediment transport is minimal. High turbidity with low SSC can result when the sediment supply is limited and may also occur in conjunction with the low flow, and low turbidity-SSC condition.

A low turbidity less than 200 FNU having a relative high SSC occurred in the two adjoining seasons winter and spring in the years 2011, 2012 (table 1). Also, spring 2010 had low turbidity with a high SSC. There was no data available for winter 2010 to determine if this year followed a similar trend as 2011 and 2012. A season having high turbidity with a high estimated SSC occurred in the 3 adjoining seasons: Spring, summer, and fall 2010. Also, there was a relative

high SSC for a high turbidity for fall 2011, and the 2 adjoining seasons of winter and spring in 2012 and 2013.

Table 1 Seasonal regression computed SSC for selected turbidity values.

Turbidity 100 to 2,000 FNU	Low SSC	High SSC
Low Turbidity (*less than 200 FNU*)	Summer 2010 Fall 2012 Summer 2013	Spring 2010 Winter 2011 Spring 2011 Winter 2012 Spring 2012
High Turbidity (*greater than 1200 FNU*)	Summer 2011 Summer 2012 Fall 2012 Summer 2013	Spring 2010 Summer 2010 Fall 2010 Fall 2011 Winter 2012 Spring 2012 Winter 2013 Spring 2013

Some high SSC conditions may be sediment-transport capacity limited, such that the sediment supply is abundant but the capacity to transport it is restricted. Low turbidity and high relative SSC conditions are indicative of high flow, and/or high sediment-transport conditions and often occur in conjunction with high turbidity-SSC seasons. Overall though, each of the seasonal differences can be attributed to a variety of sediment source, erosion, and streamflow conditions, as well as sediment-particle size, and can shift back-and-forth from a sediment supply limited to sediment-transport capacity limited system.

The seasons with the highest slope and lowest y-intercept were the two adjoining seasons spring 2010 and summer 2010. The seasons with the lowest slope and highest y-intercept were the two adjoining seasons winter 2011 and spring 2011. This shows there was a significant shift in turbidity-SSC relations from 2010 to 2011, although all data from 2010 were not available. These seasonal differences document how suspended-sediment transport can shift within a specific year and how one season can vary from another, and from the same season in different years. Hence, for the highest accuracy, turbidity-SSC model development in the North Fork Toutle basin should follow more seasonal than annual time scales.

Event Regressions: There were several events during the 2010–2011 to 2013 water years that had a distinct turbidity-SSC signature. Twenty-one major events were selected for analysis, which were determined by a rise in streamflow and/or turbidity that increased by at least 100 percent from its previous level, and with an event duration of less than 8 days. There may have been several peaks in streamflow or turbidity during a particular event period. A turbidity-SSC regression model was generated for each of the 21 events. These were categorized into 4 main event groups (A, B, C, D) based on a given turbidity, from a 100 to 2,000 FNU range of values, and a computed SSC from the regression models that was within an average 30 percent

difference for all groups. Each event group also had a similar slope and y-intercept within a 30 percent range. A second regression model was then generated for each of the 4 groups (figure 3).

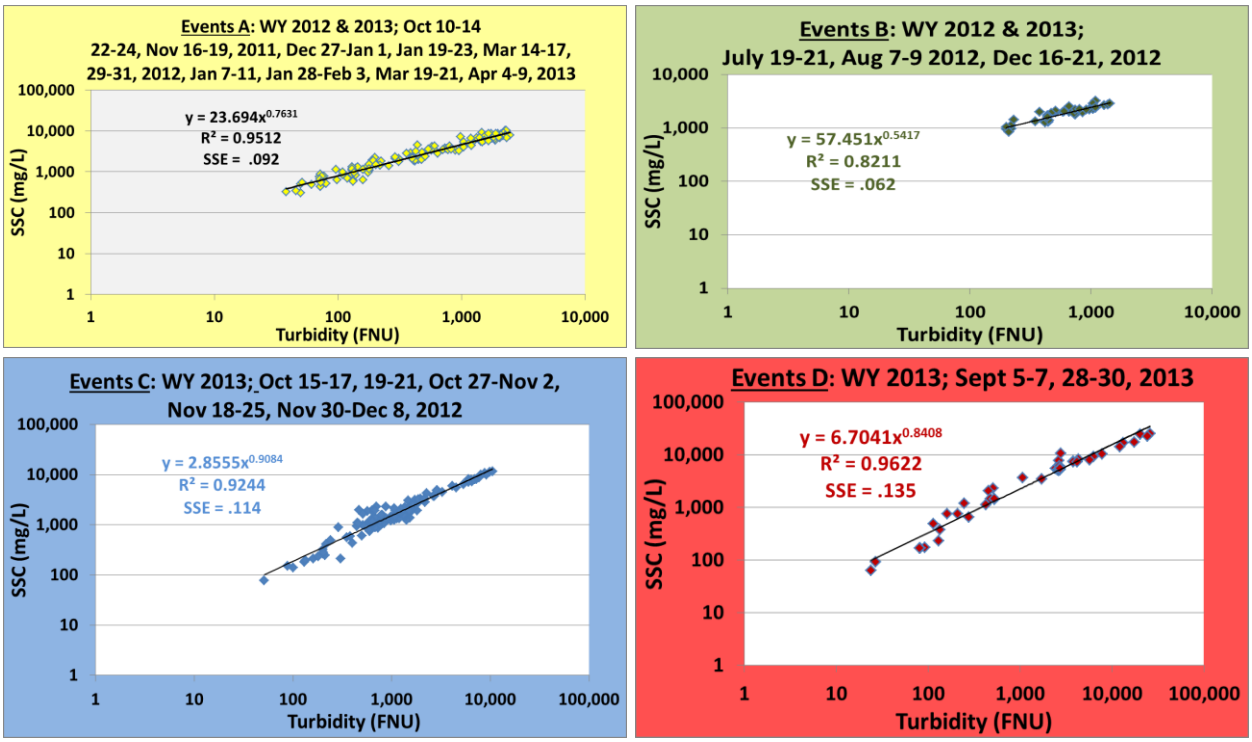

Figure 3 Event regression models for the NF-Toutle-SRS streamgage.

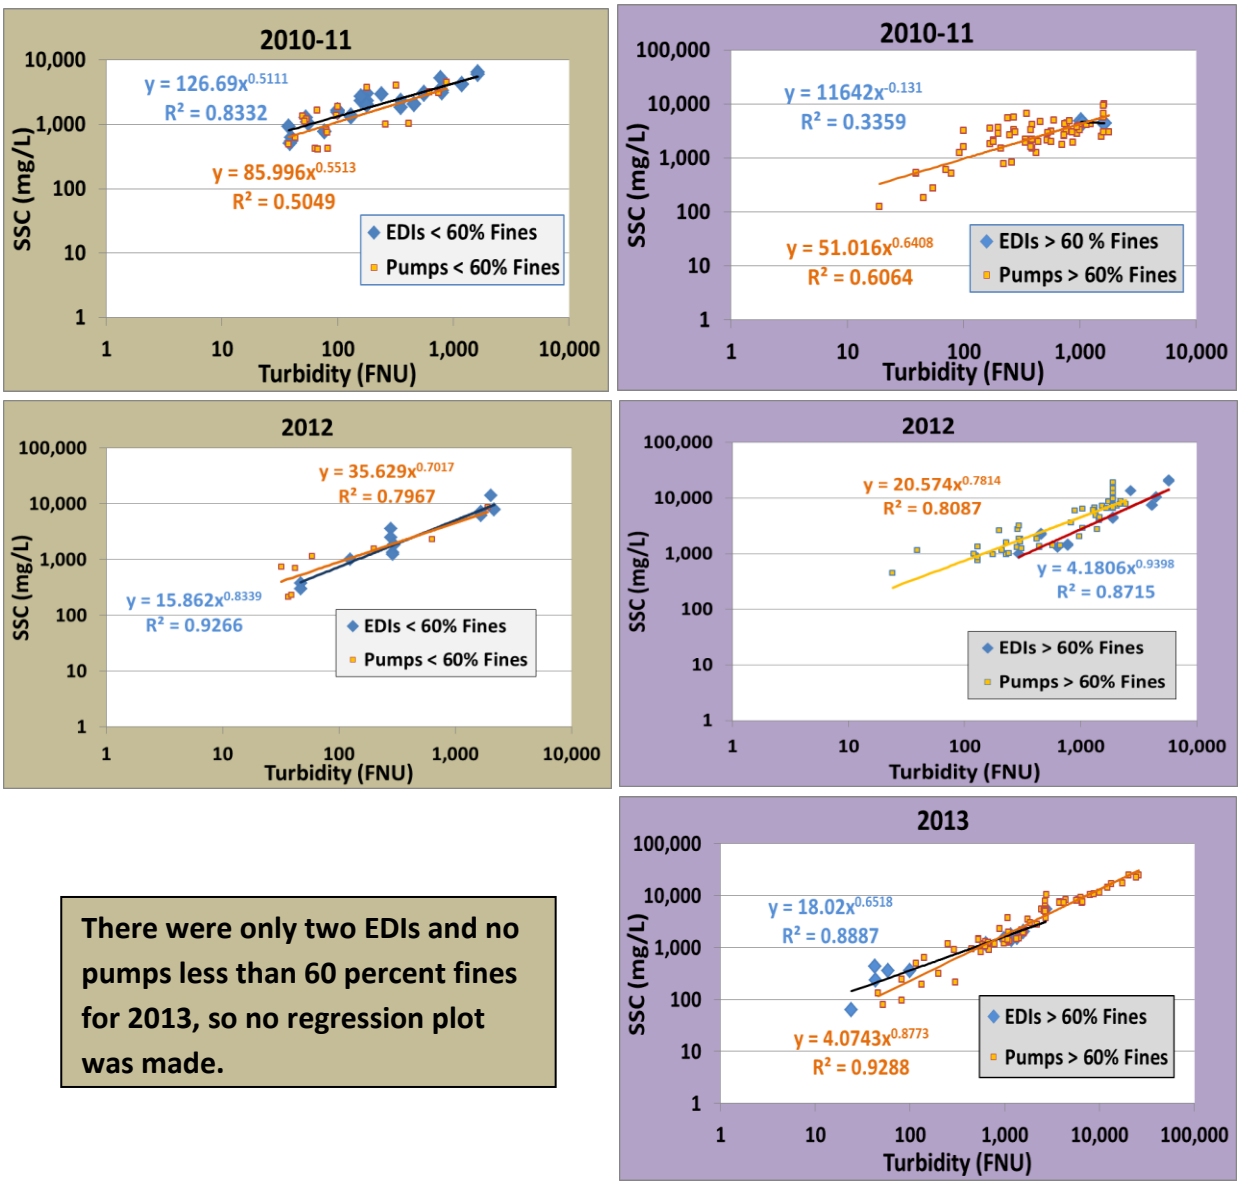
Event group B had the lowest slope and highest y-intercept, which was indicative of low flow, summertime conditions and first-flush autumn events where, in this case, the turbidity peaks precede the streamflow peaks. Event group C had the highest slope and lowest y-intercept, which occurred entirely during the fall of 2012 where the turbidity peaks lagged the streamflow peaks. Event group A was wedged between groups B and C and had a wide-range of events extending through several time spans, occurring primarily from November to March. This is reasonable considering most sediment transport is a combination of both conditions in groups B and C, and in slope and y-intercept. Event group D is comprised of two abnormally large peaks in September, normally the driest month of the year.

Creating separate event models enabled a more accurate SSC estimate for these periods, as compared to the annual and seasonal models, as reflected by the high R^2 and low SSE values in figure 3. Hence, it is possible to fine-tune regression models to smaller time scales for specific events in order to more appropriately approximate an SSC from turbidity for these periods.

Particle-Size Regressions: There were 317 samples available with particle size data for the entire 2010–2011, 2012, and 2013 datasets. As with the previous regression models the turbidity and SSC data with particle-size data were assembled as one dataset. The data points were then separated into two groups by particle size distribution. One group consisted of all samples with 60 percent of total material smaller than sand (<0.062 mm in diameter); the other group had 60

percent of total material larger than sand. Within each group, EDI cross-section samples and pump samples were differentiated.

Similar to the annual and seasonal regressions, a range of different turbidity values from 100 to 2,000 FNU was input to each of the particle-size equations for each year (figure 4). Comparisons were made within each year and from year-to-year for the EDI and pump groups of 60 percent finer than sand. The comparisons between years showed that average particle size decreased from 2010-11 to 2013. The 2010-11 pump sample group greater than 60 percent fines (mostly fine material) showed higher SSC by an average 63 percent difference as compared to 2013 for the turbidity values input to equations.



There were only two EDIs and no pumps less than 60 percent fines for 2013, so no regression plot was made.

Figure 4 NF Toutle-SRS particle-size regressions for 2010-11, 2012, and 2013.

There were no EDI samples in 2010-11 that were greater than 60 percent fines, although from 2012 to 2013, in this greater than 60 percent fines category (mostly fine material), the EDI and pump concentrations, estimated from the range of turbidity values, decreased an average 26 and 64 percent difference, respectively. Hence, the concentration of fine material for a given in-stream turbidity, transported downstream past the SRS, was lower in 2013 than 2012. Also in 2012, the EDI particle-size concentrations that were less than 60 percent sand (mostly coarse material), for the 100-2,000 range in turbidity, were all higher than the 2012 greater than 60 percent finer than sand group (mostly fine material) by an average 48 percent difference. Hence, all EDI suspended-sediment concentrations in 2012 were primarily SSCs with coarser-grained sediment than in 2013. The pump samples in 2012 did not have as much or as consistent a difference.

There also were differences between EDI and pump estimates based on particle size. In 2010-11 the EDI concentrations for a given turbidity in the less than 60 percent fines group (coarser material) had an average 12 percent difference higher than the pump concentration for the same group. Yet in 2012 the EDI concentrations were much lower than pump concentrations, especially for samples grouped as greater than 60 percent fine material, which averaged a 56 percent difference lower. For coarse material, less than 60 percent fines, the concentrations of EDIs and pumps varied in 2012, such that at low turbidity pump SSCs were higher and at high turbidity the EDIs SSCs were higher.

The 2013 estimated SSCs, for the range in turbidity values, also varied between the EDIs and pumps, although the reverse occurred in 2013 such that, at low turbidity the EDI SSCs were higher and at high turbidity the pump SSCs were higher. In 2013, there were only values for EDI and pump samples that were greater than 60 percent fines (mostly fine material), with no values for less than 60 percent fines (mostly coarse material), so no comparisons could be made for the coarser material. Hence, the EDI finer-grained SSCs for a given turbidity were usually lower than the pump SSCs, particularly in 2012. The EDI and pump differences may be due to the mechanics of pumping sediment up a stream bank, through a hose to a sampler, as opposed to directly collecting into a sampler by manual cross-sectional methods, through the water column, and at the same velocity as the stream. Auto-pump samplers tend to collect more fine sediment than coarse particles due to these restrictions, so even though the pump concentrations can be corrected to the EDIs the particle size distribution cannot. These discrepancies should be considered in deciding which samples to select for developing turbidity-SSC regression models, especially in any type of particle-size analysis.

DISCUSSION

These analyses are not the final regression equations, but were developed to demonstrate the general turbidity-SSC relations in the North Fork Toutle River basin. Also no bias correction factors were applied to the regression equations, which are used to correct for any shift in converting log values back to linear space (Helsel and Hirsch, 2002; Uhrich et al., 2014). The bias correction factors usually alter the equations only slightly so were not considered in presenting preliminary turbidity and SSC relationships. Also, the Solitax high-end turbidity sensor was used as a guide to fill in missing flat-line DTS-12 threshold periods for the 2013 data.

The estimated data was applied from the start to the stop point of the flat-line DTS-12 threshold period.

The logical next step with this preliminary analysis is to develop final regression equations, incorporating a suite of elements to fine tune the models, such as bias correction factors, and developing a separate Solitax to DTS-12 regression. Also, multiple regression models for the North Fork Toutle basin have been shown to more accurately predict SSC from turbidity by using streamflow and a lag of turbidity as added explanatory variables (Uhrich et al., 2014). The final test would be to compute a sediment record using the regression-model approach and compare the results to the conventional sample-based approach.

Fine- and coarse-grain sediment will have fluctuating turbidity and SSC, based on seasonal and rise/fall periods, which can be grouped into defined categories. Model R^2 and SSE values will usually improve with concentrations having finer particle sizes. Hence, suspended-sediment discharge can be differentiated by particle-size distribution. Defining these hysteresis effects improves resource planners' and stakeholders' understanding of fluvial sediment transport and subsequent deposition in the studied lower basins. In the lower Toutle and Cowlitz River channels, aggradation of coarse-grain sediment has significant effects on flood inundation risk to surrounding communities, and in the Columbia River it affects river navigation and shipping commerce by large deep-draft, commercial ocean-going vessels.

SUMMARY

Annual regression models are used for many Pacific Northwest streams to estimate SSC from turbidity. For the North Fork Toutle River an annual time span may not be appropriate, as episodic erosional events and changing sediment sources require shorter time scale models to accurately predict SSC from turbidity. Evaluating sediment transport using seasonal time frames is one method in which this could be achieved, as precipitation patterns in the Pacific Northwest lend themselves to predictable occurrences during certain times of the year. Although seasonal approaches offer improved accuracy over annual models the time scale may not capture shorter-term events that can occur within each season. Shorter-term models for specific events and time scales provide improved accuracy over longer-term turbidity-SSC models. Monitoring of turbidity and sediment transport can vary by particle size. The selection of samples as EDI or auto-pump is important as there can be distinct differences between the collection methods. Once representative samples are selected, it is possible to develop regression models based on sediment-size data from the sample analysis. These particle-size models can be used to predict not only the concentration but also the type of sediment in transport.

EVALUATION AND APPLICATION OF REGIONAL TURBIDITY-SEDIMENT REGRESSION MODELS IN VIRGINIA

EXTENDED ABSTRACT

INTRODUCTION

Conventional thinking has long held that turbidity-sediment surrogate-regression equations are site specific and that regression equations developed at a single monitoring station should not be applied to another station; however, few studies have evaluated this issue in a rigorous manner. If robust regional turbidity-sediment models can be developed successfully, their applications could greatly expand the usage of these methods. Suspended sediment load estimation could occur as soon as flow and turbidity monitoring commence at a site, suspended sediment sampling frequencies for various projects potentially could be reduced, and special-project applications (sediment monitoring following dam removal, for example) could be significantly enhanced.

The objective of this effort was to investigate the turbidity-suspended sediment concentration (SSC) relations at all available USGS monitoring sites within Virginia to determine whether meaningful turbidity-sediment regression models can be developed by combining the data from multiple monitoring stations into a single model, known as a “regional” model. Following the development of the regional model, additional objectives included a comparison of predicted SSCs between the regional models and commonly used site-specific models, as well as an evaluation of why specific monitoring stations did not fit the regional model.

METHODS

All USGS Virginia Water Science Center monitoring stations with paired turbidity (measured with a YSI 6136 sensor) and SSC data were retrieved from the USGS National Water Information System database and considered for this analysis. Data from 64 stations were initially retrieved; however, the data were filtered to ensure that only sites with sufficient observations and only sites with sampling over an extended range of hydrologic conditions were considered. A total of 29 stations met the project-assigned criteria of (1) at least 24 paired turbidity-suspended sediment concentration measurements, and (2) water-quality sampling over most of the observed range of hydrologic conditions (Table 1).

Table 1 Turbidity monitoring station identifiers, names, and watershed areas.

Station identifier	Station name	Watershed area (mi^2)
02042500	Chickahominy River near Providence Forge, VA	251
02041650	Appomattox River at Matoaca, VA	1,342
01627500	South River at Harriston, VA	212
01634000	NF Shenandoah River near Strasburg, VA	770
01631000	SF Shenandoah River at Front Royal, VA	1,634
01668000	Rappahannock River near Fredericksburg, VA	1,595
01632900	Smith Creek near New Market, VA	94
01626000	South River near Waynesboro, VA	127
02035000	James River at Cartersville, VA	6,252
02037618	James River at Boulevard Bridge at Richmond, VA	6,776
01621050	Muddy Creek at Mount Clinton, VA	14.32
01671020	North Anna River at Hart Corner near Doswell, VA	462
02024752	James River at Blue Ridge Pkwy near Big Island, VA	3,076
02054750	Roanoke River at Route 117 at Roanoke, VA	352
01667500	Rapidan River near Culpeper, VA	468
03524740	Clinch River at Route 65 at Dungannon, VA	820
0165389480	Accotink Creek Below Old Lee Hwy at Fairfax, VA	4.87
02055080	Roanoke River at Thirteenth St Bridge at Roanoke, VA	390
01654000	Accotink Creek near Annandale, VA	23.87
01673000	Pamunkey River near Hanover, VA	1,078
01646305	Dead Run at Whann Avenue near Mclean, VA	2.05
01646000	Difficult Run near Great Falls, VA	58
01656903	Flatlick Branch above Frog Branch at Chantilly, VA	4.20
01645762	SF Little Difficult Run above Mouth near Vienna, VA	2.71
01654500	Long Branch near Annandale, VA	3.72
01645704	Difficult Run above Fox Lake near Fairfax, VA	5.49
01674500	Mattaponi River near Beulahville, VA	602
02034000	Rivanna River at Palmyra, VA	663
01658500	SF Quantico Creek near Independent Hill, VA	7.62

This collection of 29 stations represents a diverse group of sites (Figure 1) that provide a range of watershed areas (from 2.05-6,776 sq miles) and locations throughout the state, which allows for a reasonable investigation of whether a regional model can be developed for the state of Virginia.

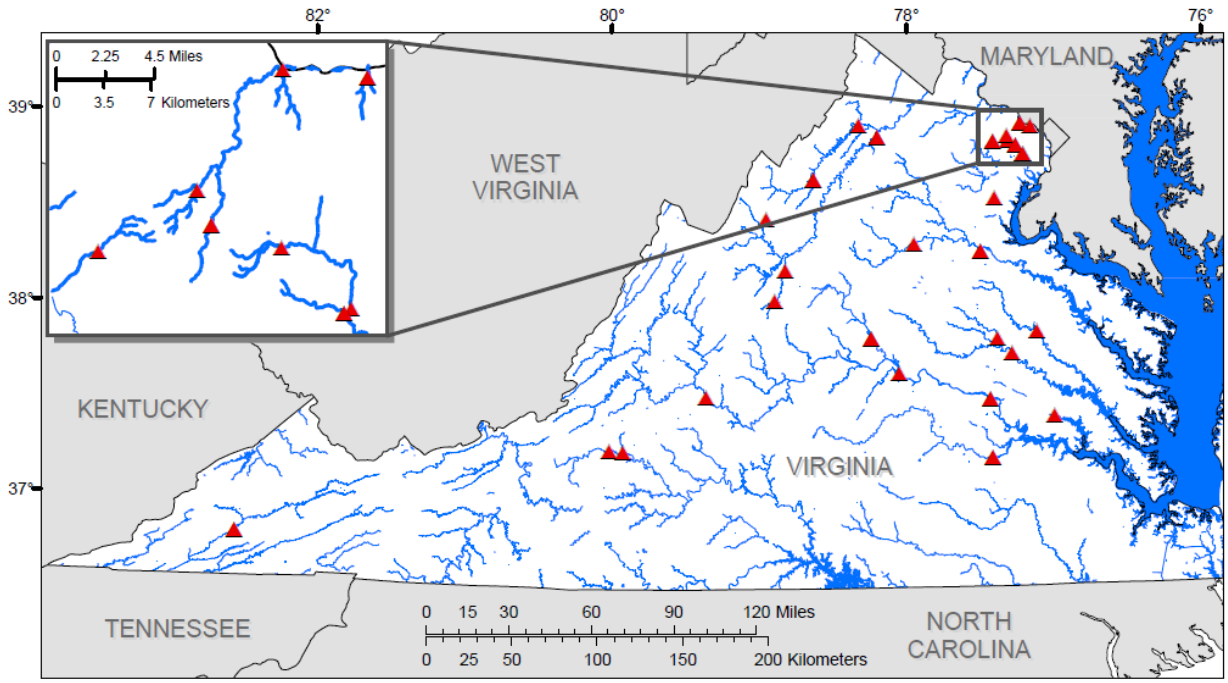

Figure 1 Map of turbidity-monitoring stations included in the study analysis.

For all 29 sites, simple linear regression models to predict SSC from turbidity were developed following standard methods for the development of regression models (Helsel and Hirsch, 2002; Jastram and others, 2009). Because of skewed distributions, both the turbidity and SSC variables were natural log transformed prior to the development of the regression models. All developed models were inspected to ensure they met the assumptions of simple linear regression.

RESULTS

Statistically significant, site-specific regression models were developed for all 29 stations (Figure 2); regression strength and quality varied among regression models. Most coefficients of determination (R^2) ranged from 0.80 to 0.95, with greater and lesser values being observed for some stations. Particularly low R-squared values were noted for station 02042500, Chickahominy River near Providence Forge, VA, and station 02041650, Appomattox River at Matoaca, VA. The Chickahominy River is a typical Coastal Plain blackwater river, with an extremely low river gradient, a broad floodplain, and extensive wetlands that yield low, and relatively uniform turbidity levels and SSCs. The Appomattox River station is located 2.2 miles downstream of a major dam, which likely acts as a sink for sediment, and causes a highly variable turbidity-sediment response.

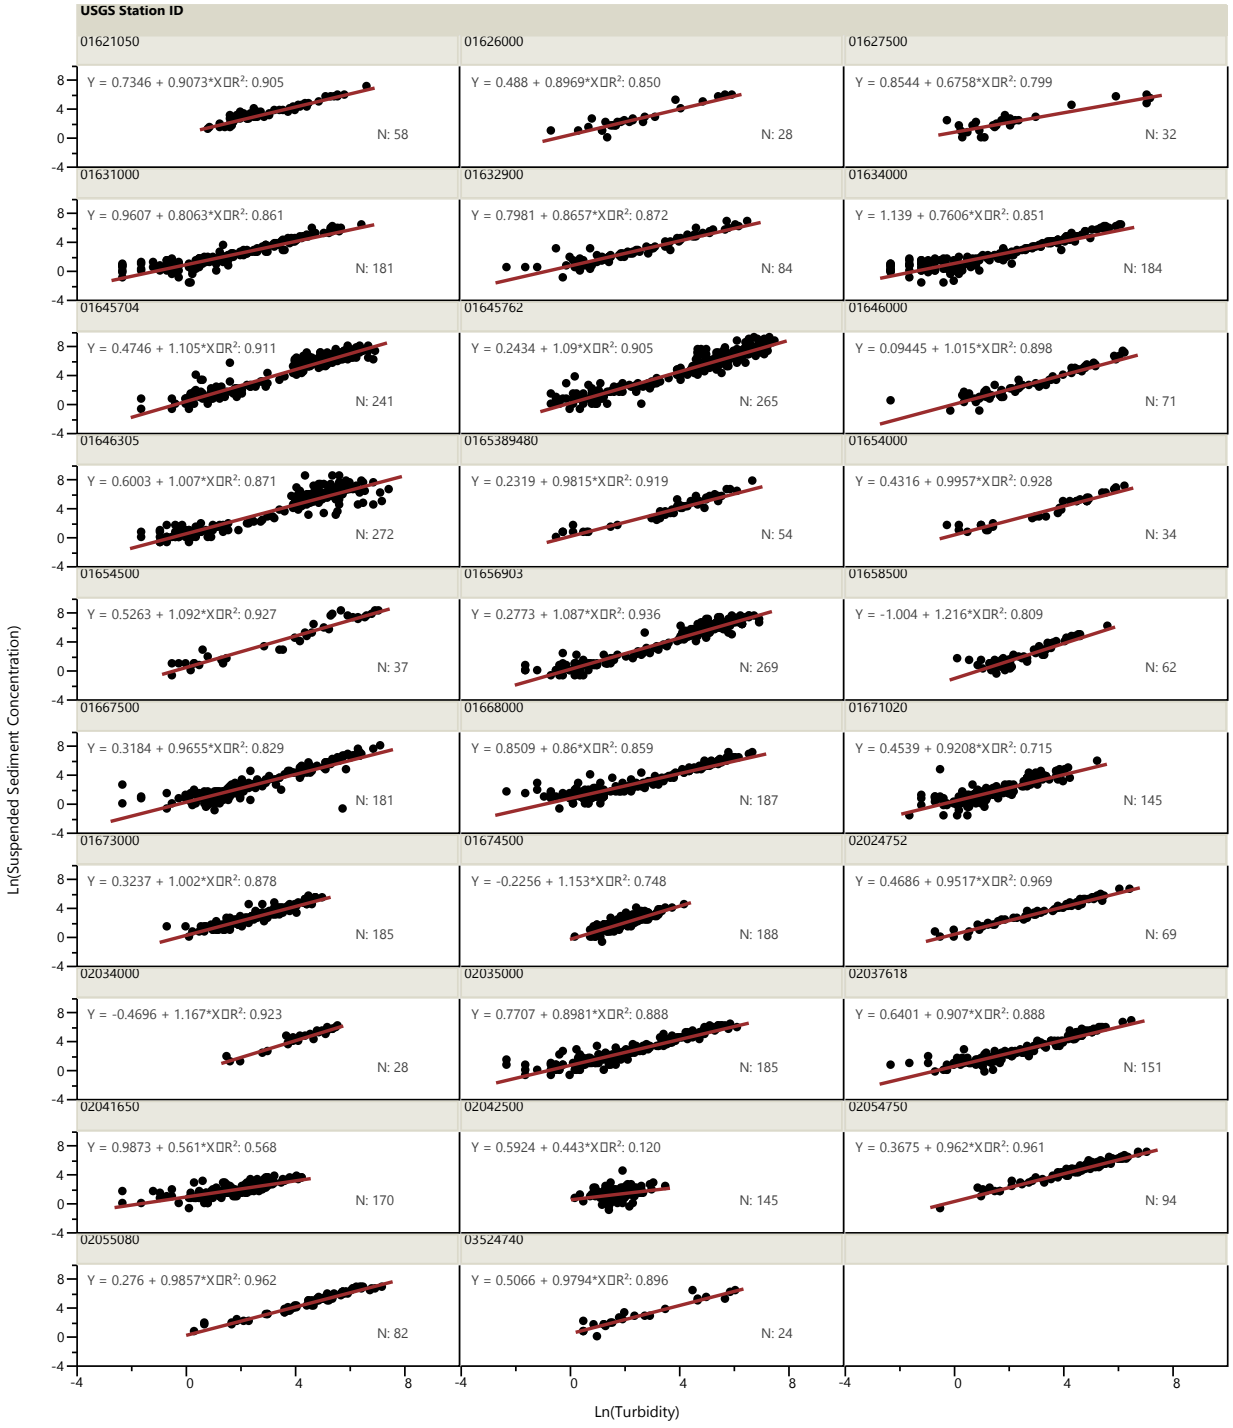

Figure 2 Site-specific turbidity-sediment regression equations for 29 monitoring stations, including model equation, the coefficient of determination (R^2) for each model, and the number of observations (N).

A single robust regional model was desired for the group of site-specific regression models that had relatively similar slope and intercept terms, so a comparison of these terms for all 29 stations was performed. The 99-percent confidence interval (CI) for the slope and intercept for each site-specific model was compared to the 99-percent CIs of the overall mean slope and intercept values for the collection of the 29 site-specific models (Figure 3). Sites where both the slope and intercept CIs of the site-specific model intersected the CIs of the overall mean slope and intercept were deemed not significantly different from the overall mean – effectively an analysis of covariance – and were included in the computation of a new regional turbidity-SSC model. A total of 19 monitoring stations (colored red in Figure 3) were included in the regional turbidity-SSC regression model for the combined data set from all 19 sites. A statistically significant regional model was developed, having an R^2 of 0.89 (Figure 4). Overall, the regional model demonstrates a strong correlation between turbidity and SSC for a diverse range of monitoring stations, however, subsequent comparisons between the regional- and site-specific models were performed.

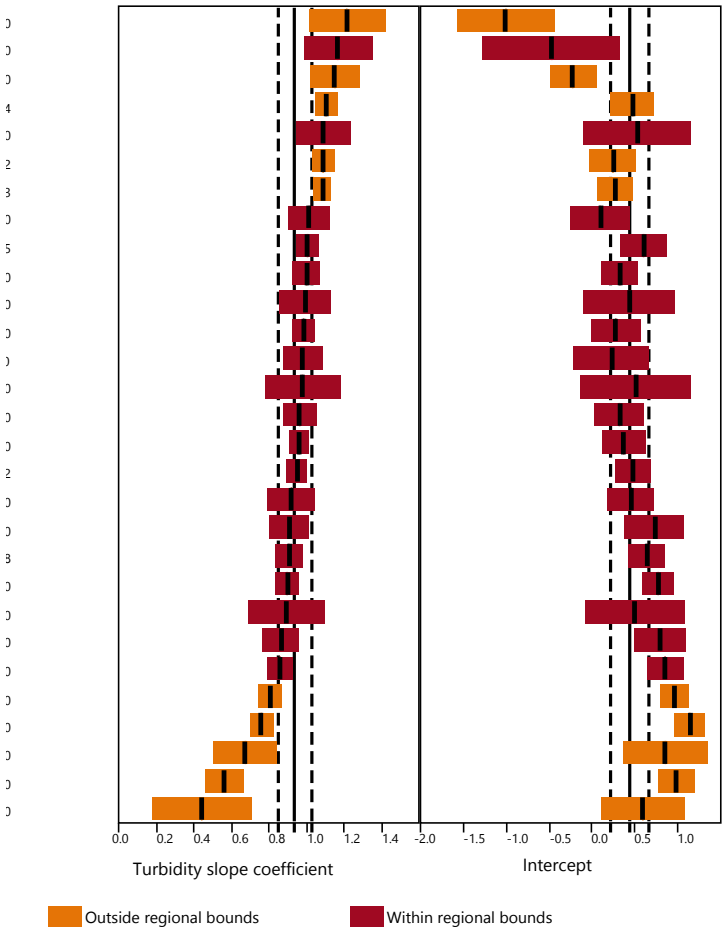

Figure 3 Site-specific model slope and intercept coefficients with 99-percent confidence intervals for 29 stations evaluated, and overall mean slope and intercept (solid line) and 99-percent confidence intervals (dashed lines).

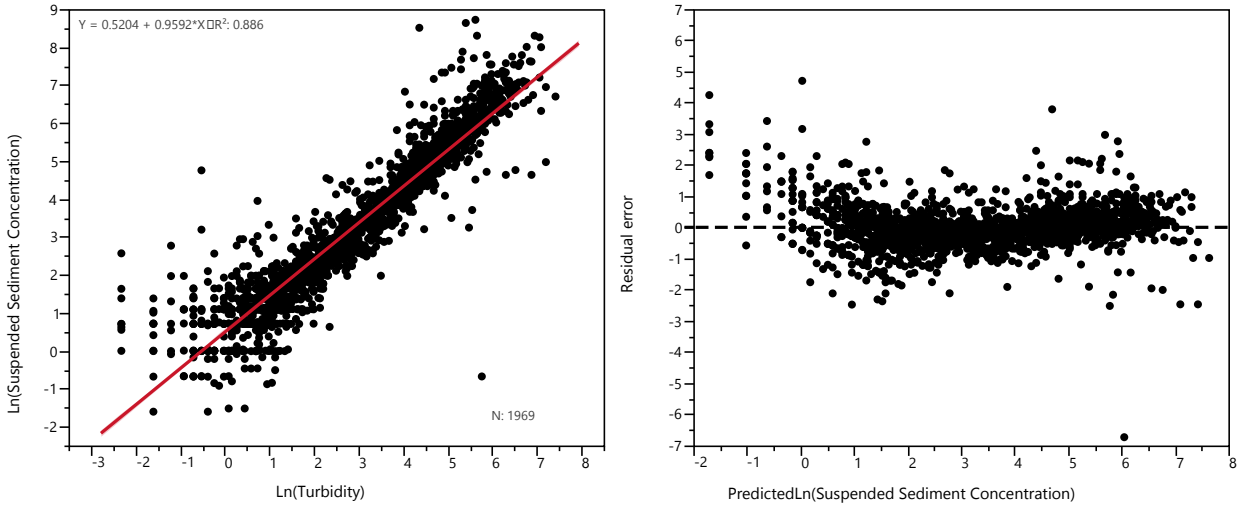

Figure 4 The regional turbidity-suspended sediment model and residuals, based on the combined datasets from 19 monitoring sites.

Direct comparisons of the predicted values between the regional- and site-specific regression models demonstrate good agreement between both models (Figure 5). Comparison of model errors demonstrates that while the regional model has slightly higher mean square error (MSE) in a few cases, overall the MSEs are comparable, regardless of model used (Figure 6).

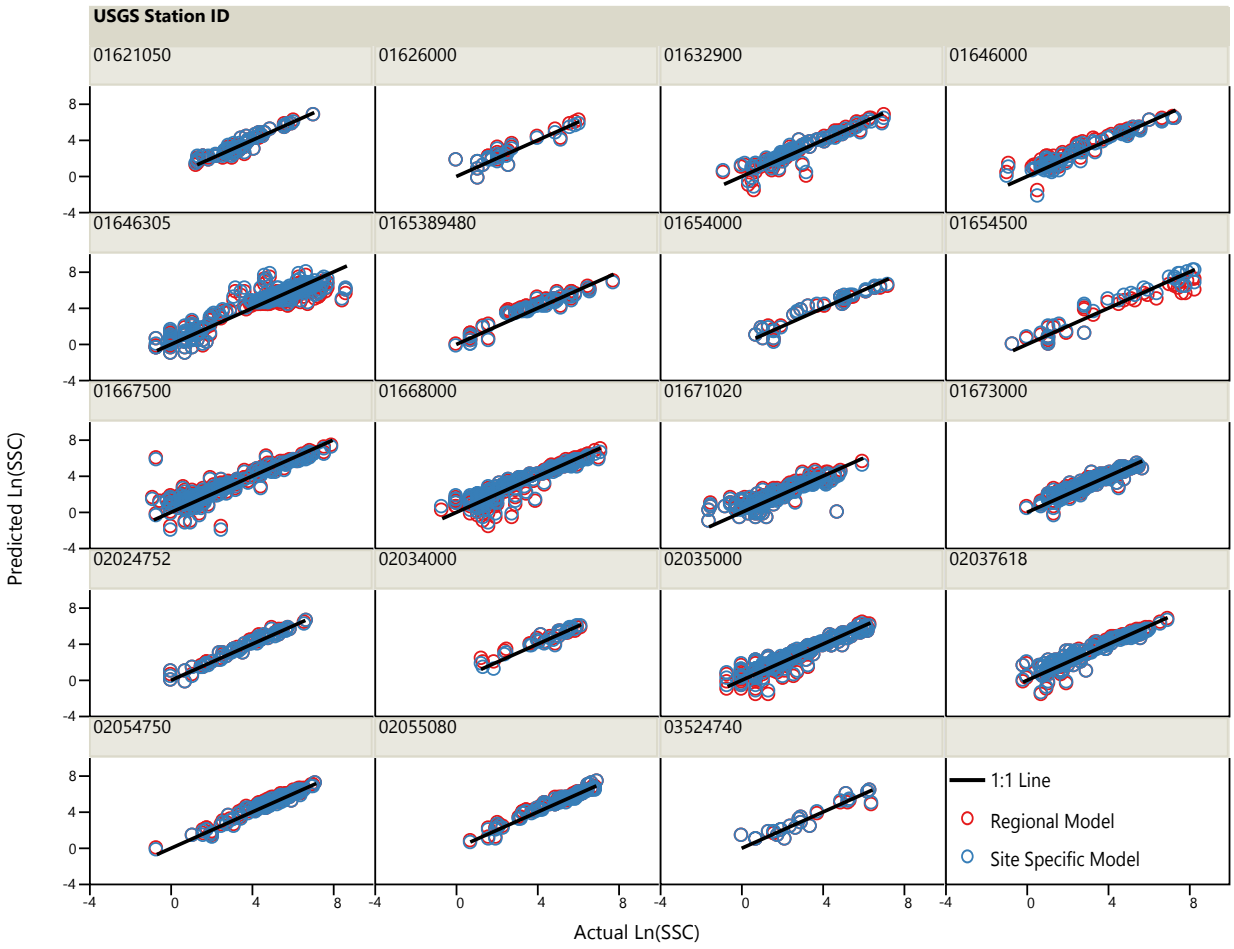

Figure 5 A comparison of actual and predicted values between the site-specific and regional models.

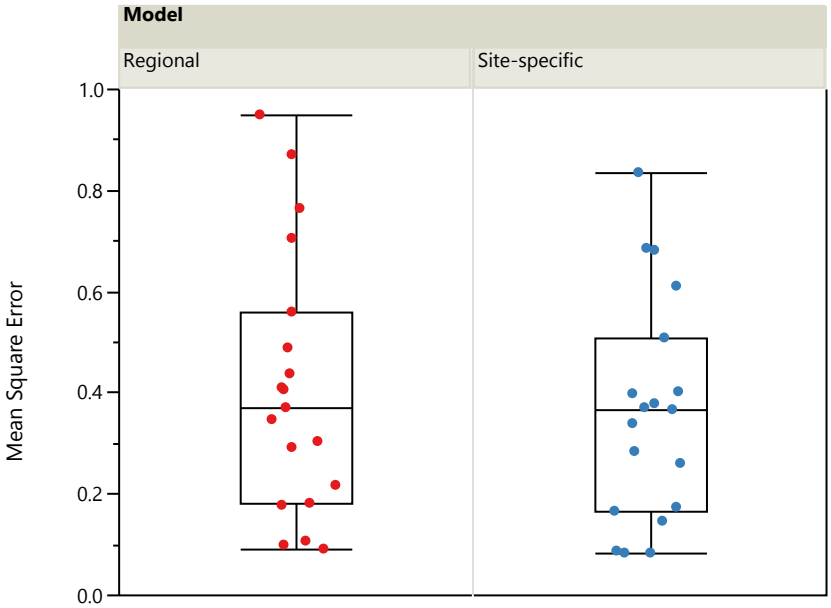

Figure 6 A comparison of the mean square errors between the site-specific and regional turbidity-sediment models.

Ten stations were not included in the regional model because their site-specific regression models were significantly different from the overall mean of the slope and intercept coefficients. The reasons for these differences are still under investigation, but are generally believed to be related to transport processes and physical characteristics of the available sediments, which may be further related to, and modeled by, watershed characteristics such as soil type, basin slope, and land-use. Overall, the sites with elevated slope coefficients generally had smaller intercept values (see the sites at the top of Figure 3) than sites with lesser slopes. These elevated slopes indicate that such streams are moving relatively more sediment per unit of turbidity than the regional model, which would be indicative of higher gradient streams, with greater energy for entrainment of sediments, flowing through more erodible soils or soils with physical characteristics that impart less turbidity per unit mass (coarse particles). The smaller intercepts of these models indicate that these are clear waters with little to no suspended material present at the low end of the turbidity range. Conversely, the sites with smaller slope coefficients had larger intercept values (see the sites at the bottom of Figure 3). These smaller slopes are indicative of streams which are moving relatively less sediment per unit of turbidity than the regional model and the greater intercepts indicate that there is some amount of fine suspended material or other turbidity-causing substance, such as organic matter, present at the low end of the turbidity range. Such streams would be expected to have lower gradients, with less energy for entrainment of sediments, to be flowing through soils less available for entrainment or that impart greater turbidity per unit mass (fine particles), or have controls on sediment transport such

as dams. Both the Chickahominy River and the Appomattox River, the sites with the poorest turbidity-sediment model fit, are in this category, and both generally move less sediment than other rivers included in the regional model. Future work will continue to explore, in more detail, how improved models could be developed to regionally model these 10 stations that were not included in the initial regional model.

SUMMARY

A robust regional turbidity-SSC regression model has been developed from data collected from 19 diverse watersheds across Virginia, supporting the idea that regional turbidity-SSC models can be developed in many areas. Subsequent investigations are planned to explore why some sites did not fit the regional model, and whether a regional model can be expanded beyond Virginia, perhaps to the entire Chesapeake Bay Watershed. Potential future applications of the regional turbidity-SSC regression model are promising, given that most of the existing streamgages within Virginia do not currently have continuous turbidity monitors or suspended sediment sampling. As sediment management strategies are implemented and regulators require reduced sediment loadings to major rivers, more efficient sediment monitoring and load estimation techniques are required to track progress towards these goals, and the use of regional turbidity-SSC models could both increase the efficiency and decrease the cost of such efforts.

IN-STREAM LASER DIFFRACTION FOR MEASUREMENT OF SUSPENDED-SEDIMENT CONCENTRATION AND PARTICLE-SIZE DISTRIBUTION IN RIVERS

EXTENDED ABSTRACT

Laser-diffraction technology has recently been adapted for in-stream measurement of fluvial suspended sediment concentrations (SSCs) and particle-size distributions (PSDs) as a streamlined (SL), isokinetic version of the Laser In-Situ Scattering and Transmissometry (LISST). The LISST-SL instrument is capable of at-a-point measurements of volumetric SSC and PSD ranging from 1.8–415 μm in 32 log-spaced size classes at a temporal resolution of 2 seconds.

As with any new sediment-measurement or sediment-surrogate technology, the LISST-SL must be rigorously tested with respect to accuracy and reliability in different physiographic environments, and its performance must be compared to concurrent measurements using traditional methods to identify and minimize bias and changes in precision between the old and new technologies (Gray and Gartner, 2009). To this end, we have collected 22 datasets of sediment and streamflow measured concurrently by using a physical sampler, LISST-SL, and acoustic Doppler current profiler (262 samples in all) during 2010–2012 at 16 U.S. Geological Survey streamflow-gaging stations in Washington and Illinois with basin areas ranging from 38 to 69,264 km^2. A detailed description of the methods, results, and discussion of this comparative study has been published by Czuba et al. (2015); herein the major findings are summarized and potential future work is discussed.

As laser diffraction measures volumetric SSC, these measurements must be converted to mass SSC measurements before they can be compared to the data from physical measurements. The conversion from volumetric SSC to mass SSC requires a measurement or assumption of the sample effective density. For fully dispersed quartz grains, the effective density is typically around 2.65 g/mL and for 23 of the physical samples, the effective density varied from 2.56–2.87 g/mL with an average of 2.67 g/mL. In contrast, an unrealistically low computed effective density (mass SSC/volumetric SSC) of 1.24 g/mL (95% confidence interval: 1.05–1.45 g/mL) provided the best-fit value (R^2 = 0.95; RMSE = 143 mg/L) for accurately converting volumetric

SSC to mass SSC for over two orders of magnitude of SSC (12–2,170 mg/L measured by the physical sampler; covering a substantial range of SSC that can be measured by the LISST-SL). These unrealistically low values for the computed effective density suggest something systemic is happening where the LISST-SL is overestimating the volumetric SSC. Explanations for such a low computed effective density have typically pointed to flocculation. However, PSD measured by the LISST-SL and in physical samples (which are dispersed before analysis) were similar, thus ruling out particle flocculation as a major factor.

For now, obtaining accurate mass SSC measurements with a LISST-SL in the fluvial environment requires applying an effective density much less than the density of the sediment particles. Either a best-fit effective density of 1.24 g/mL can be applied, or mass SSC measurements can be made to compute a site-specific effective density for converting volumetric SSC to mass SSC.

The results (Czuba et al., 2015) suggest that the most likely issue is the shortcoming of the laser-diffraction method in only being able to account for irregular particles through the irregular particle kernel matrix (Agrawal et al., 2008). Irregular particles are defined here, following the definition by Agrawal et al. (2008), as rounded or angular particles with particle axes approximately equal. The term "irregular" is used to denote a difference in particle shape from that of spheres but this definition does not include particles that are elongated or flaky. This definition is used because these were the shapes of particles used by Agrawal et al. (2008) in developing the irregular particle kernel matrix. The irregular particle kernel matrix is used to convert "raw" laser-diffraction measurements into concentrations of particles in different size classes. Any elongated (e.g., feldspar) or flaky (e.g., mica) particles present in suspension can create a strong bias in SSC without such an effect on PSD when applying the irregular particle kernel matrix to these particles (Felix et al., 2013). This suggests that a new "fluvial particle kernel matrix" may need to be developed that can account for elongated and flaky particles that may be present in suspension, although more research is needed to confirm that this is the causative factor.

Future work should focus on assessing the suitability of the irregular particle kernel matrix (Agrawal et al., 2008) for actual suspended fluvial material by obtaining suspended material directly from the river and considering the full distribution of fine and coarse material to assess if a different particle kernel matrix would better represent what the LISST-SL is measuring in the fluvial environment. More detailed analysis of the suspended material should be performed using a microscope to assess particle shape and surface characteristics. The characteristics of any organic material should also be assessed as well as the water chemistry affecting potential flocculation. These more detailed measurements at a few sites should provide further insight into the causative factor or factors responsible for the unrealistically low computed effective densities. If this is the case then it will be possible to reprocess all 262 LISST-SL measurements from this study to verify that any new kernel matrix is suitable for the fluvial environment.

HISTORY OF THE FEDERAL INTERAGENCY SEDIMENTATION PROJECT, PART V

J.R. Gray, Scientist Emeritus, U.S. Geological Survey, Reston, Virginia, graysedimentology@gmail.com, and
M.N. Landers, Chief, Federal Interagency Sedimentation Project, U.S. Geological Survey, Atlanta, Georgia, landers@usgs.gov

Abstract: In the late 19th and early 20th centuries, sediment-sampling activities in the United States increased rapidly to support the civil-works programs of several Federal agencies. These agencies and other domestic and foreign investigators developed and used physical samplers of suspended sediment, bedload, and bed material to collect data needed for specific elements of their missions. Most instruments were designed with limited attention to, or knowledge of, sediment-transport concepts or the influence of the equipment on the local flow pattern. As a result, data obtained by different investigators before the 1940s were neither comparable nor could their accuracy be evaluated.

The Federal Interagency Sedimentation Project (FISP) was created in 1939 to unify and standardize fluvial sediment-data-collection instruments and methods used by several Federal agencies. The priorities and thrusts of the FISP have evolved throughout its history in the wake of its accomplishments and in response to the needs of the Federal community for the quantifiably accurate characterization of fluvial sediment concentrations, size distributions, and fluxes. The FISP conducts and supports applied research in topics covering the range of its mission, which includes physical-sampler design, testing, quality assurance, and supply; field methods; computational methods; laboratory analytical methods; and indirect (surrogate) methods.

The priorities of the FISP, along with oversight of its activities, are provided by a Technical Committee comprised of representatives from the supporting Federal agencies. The results of applied research conducted by the FISP appear in over 60 FISP reports, industry standards, and many related journal articles, agency reports, and proceedings papers such as this.

This paper uses and expands upon summaries of the FISP published in 1950, 1963, 1965, 1976, 1979, and 1989 to describe the origins of the FISP, and its six principal phases from 1939-2014. Mission-specific endeavors and their products are highlighted, and potential future research endeavors are summarized.

INTRODUCTION

When the Federal Interagency Sedimentation Project (FISP) was formed in 1939, the objective(s) of most fluvial-sediment measurements focused on the potential for or presence of sediment deposition in reservoirs and in navigation and irrigation channels. The list of sediment-related concerns subsequently has expanded to include bridge scour, erosion of agricultural lands, turbidity-induced aquatic ecosystem degradation, loss of spawning substrate due to fine-grained sediment infilling, reduction in primary productivity, decreases in biotic diversity, and effects from sediment-associated chemical constituents (Larsen et al., 2010). Even reduced sediment-transport rates are now recognized as having deleterious morphologic and economic consequences associated with some of the world's impounded rivers, receiving estuaries, and coastal systems starved of their natural/historical fluvial-sand supplies (Collier et al., 1996; Osterkamp and Gray, 2003).

In 2010, the physical, chemical, and biological damages attributable to fluvial sediment in North America were estimated to range from $20 billion to $50 billion annually (Larsen et al., 2010). Because effective remediation of sediment damages is predicated on the availability of demonstrably credible statistics describing rates of fluvial-sediment transport and deposition, the need for reliable, temporally and spatially consistent sediment data today is paramount. Additionally, a 21st century renaissance in sediment-surrogate technologies is revolutionizing the acquisition of fluvial-sediment data (Rasmussen,

2008; Gray and Gartner, 2009 and 2010a, b; Gray et al., 2010; Voichick and Topping, 2014; Gray and Landers, 2014). Hence, the importance of the FISP's mission – to unify and standardize fluvial-sediment research and development activities of participating Federal agencies – arguably has never been greater.

Skinner's (1989) "History of the Federal Interagency Sedimentation Project," organized into three phases, followed – but did not list as references – at least five previous historical perspectives on the FISP, to wit:

- Nelson and Benedict (1950), "Measurement and Analysis of Suspended Sediment Loads in Streams."
- FISP (1963), "A Summary of the Work of the Inter-Agency Sedimentation Project."
- Witzigman (1965), "A Summary of the Work of the Inter-Agency Sedimentation Project."
- Holeman (1976), "History of the Sedimentation Committee."
- Benedict (1979), "Equipment for Investigations of Fluvial Sediment."

Nelson and Benedict (1950) is the first-such summary of the entity now known as the FISP. Witzigman (1965) is identically titled to, and evidently based on FISP (1963). Thus, Witzigman (1965), which lists four FISP phases, and FISP (1963) together are construed to be the second FISP history. Holeman (1976) is less a historical perspective than a snapshot of the functions and activities of the FISP. Because it was deemed by the authors to add little in the way of historical perspective, it was excluded from this list of FISP histories. Thus, Benedict's (1979) and Skinner's (1989) contributions are considered to be the third and fourth histories of the FISP, respectively – all to the best knowledge of the authors.

This fifth installment weaves information gleaned from the aforementioned publications with other cited sources and contemporary recollections. The latter include contributions from co-author and current FISP Chief Mark N. Landers; perspectives shared by former FISP Chief C. Wayne O'Neal; and those of the principal author based on his 36-year association with the FISP as a customer, contributor, and former U.S. Geological Survey (USGS) representative to and twice-Chairman of the Technical Committee that provides oversight, guidance and programmatic priorities to the FISP.

The intent of this contribution is threefold: Summarize and expand on some of the information contained in the contributions of Nelson and Benedict (1950), FISP (1963), Witzigman (1965), Holeman (1976), Benedict (1979), and Skinner (1989); describe FISP endeavors and accomplishments from 1989-2014; and "peer into the crystal ball" as intrepid soothsayers in an attempt to identify potential future challenges for and directions of the FISP.

BACKGROUND, FORMATION, LOCATION, LEADERSHIP, AND OVERSIGHT

In the late 19th and early 20th centuries, sediment-sampling activities increased rapidly to support civil-works programs in several agencies of the United States (U.S.) Government. These agencies and other domestic and foreign investigators developed and used physical samplers of suspended sediment, bedload, and bed material (FISP, 1940a; b) to collect data needed for specific elements of their missions. Most instruments were designed with limited attention to, or knowledge of, sediment-transport concepts or the influence of the equipment on the local flow pattern (Glysson 1989). Consequently, data obtained by different investigators before the 1940s were neither comparable nor could their accuracy be verified.

By the late 1930s, Federal managers realized that, "…the accuracy of sediment data was affected by lack of standardization in equipment and techniques" (Skinner, 1989). This led to a proposal by G.A. Hathaway of the U.S. Army Corps of Engineers (Corps) and E.W. Lane of the Iowa Institute of Hydraulic Research to form, "a[n interagency] project…to remedy the situation" (Skinner, 1989). The proposal was endorsed by the U.S. Geological Survey, U.S. Department of Agriculture, Bureau of Reclamation, Office of Indian Affairs, Tennessee Valley Authority, and the Corps, and led to the formation of an Intergovernmental Committee under the general supervision of E.W. Lane of (and at) the University of Iowa's Institute of Hydraulic Research in 1939 (Nelson and Benedict, 1950; Brown, 1965; Benedict, 1979). This committee was charged with sponsoring, "an exhaustive study of all problems encountered in collecting sediment data and, eventually, to standardize accepted methods and equipment" (Nelson and Benedict, 1950).

In April 1946, the "activities and functions of the committee were transferred to the Subcommittee on Sedimentation of the Federal Inter-Agency River Basin Committee…which [coordinates] hydrologic activities of the Federal Departments through the assistance of several subcommittees" (Witzigman, 1965). In June 1948 the project was transferred to the St. Anthony Falls Hydraulic Laboratory of the University of Minnesota under the leadership of the Corps' Byrnon C. Colby (Holeman, 1976).

In 1956, the Subcommittee on Sedimentation reorganized the project and named it the Federal Inter-Agency Sedimentation Project, a title – minus the hyphen and either referred to as "the project" or identified by the acronym "FISP" – that remains today. Since 1956, the project has been overseen and sponsored by a Technical Committee comprised of representatives from FISP-member agencies (see the attachment, "A brief history of the Federal Inter-Agency Sedimentation Project").

The USGS's John V. Skinner succeeded Byrnon Colby as project chief and served in this capacity until his 1992 retirement. That year, the project was transferred to the Corps' Waterways Experimentation Station in Vicksburg, Mississippi. The USGS's Dallas Childers led the project in an acting capacity after John Skinner's retirement until C. Wayne O'Neal became FISP Chief by or before 1994.

About two years prior to O'Neal's 2005 retirement, the project's inventory and functions to procure, quality assure, supply, and repair physical sediment samplers and supporting instrumentation were transferred to the USGS's Hydrological Instrumentation Facility (2015) in Bay St. Louis, Mississippi, where those FISP functions continue to be successfully performed today. The project retained its in-house instrument development role. However, by then a sea change in the capabilities and means for acquiring fluvial-sediment data was well underway, to wit: From routine, periodic and/or episodic collection of physical samples, to continuous in situ monitoring of selected sedimentary characteristics using surrogate technologies field-calibrated with FISP physical samplers and sampling techniques.

Upon C. Wayne O'Neal's 2005 retirement, the USGS's Broderick C. Davis became project chief and led the project until his 2012 retirement. By the time the USGS's Mark N. Landers became project chief in 2012, the FISP business model of in-house research and development lasting seven decades had largely yielded to a proposal-driven business model that took advantage of the broad-based experience and expertise in surrogate means for monitoring suspended sediment, bed material, and bedload.

The above-cited sources contain information that resolves a 2-decade-old "chicken-or-the-egg" controversy among FISP personnel and then-members of both the Technical Committee and Subcommittee on Sedimentation that included more than a modicum of jingoism: Which came first, the FISP (and Technical Committee), or the Subcommittee on Sedimentation?

A sedimentation project was formed in 1939 and managed until April 1946 by an "Interdepartmental Committee." That year, oversight authority of the project was transferred to the Subcommittee on Sedimentation of the Federal Inter-Agency River Basin Committee.

In 1956 this Subcommittee, which today is known as the Subcommittee on Sedimentation of the Advisory Council on Water Information (2015), "reorganized the project and called it the Federal Inter-Agency Sedimentation Project" (Witzigman, 1965). Since 1956, the project has been overseen and sponsored by a Technical Committee comprised of representatives from FISP-member agencies.

Thusly is the "chicken-or-the-egg" controversy answered: The Federal Interagency Sedimentation Project was so named, and the Technical committee formed, in 1956. This was at least a decade after the project was referred to as the Subcommittee on Sedimentation.

However, the FISP's mission and operational perspectives can be summarized by its 1939 formative charge which remains more-or-less relevant today, "to study problems in collecting sediment data and to develop, improve, and standardize methods and equipment for determining the quantity and character of sediment carried by streams" (Witzigman, 1965). It is referred to as "the project" in virtually all historical writings. Undoubtedly the aforementioned "basic purpose" of the FISP extends continuously from its

inception to the present, regardless of its title or that of its oversight committee. Ergo, save for any gain or loss of bragging rights, the chicken-or-the-egg question is rendered an immaterial historical footnote.

An epilogue to this story occurred in 2004 when the Subcommittee on Sedimentation was reorganized under the Advisory Committee on Water Information, a public-private entity governed by the Federal Advisory Committee Act. The expectation – subsequently borne out – that non-Federal organizations would join the Subcommittee raised the potential of non-funding organizations to exert influence on the FISP's mission and priorities. This concern, coupled with other factors, resulted in the Subcommittee's decision to formally sever its linkage with the FISP. The FISP's stand-alone status with oversight by the Technical Committee remains extant today.

SIX PHASES OF THE FEDERAL INTERAGENCY SEDIMENTATION PROJECT

With due consideration to the contributions by Nelson and Benedict (1950), FISP (1963), Witzigman (1965), Benedict (1979), and Skinner (1989), the authors determined that the history of the FISP can be summarized as occurring in six phases: Developing,

I. Manual Samplers for Collection of Physical Sediment Samples
II. Sediment-Analytical Instruments
III. Automatic Samplers
IV. Automatic Sediment Gages
V. Manual Samplers for Collection of Trace-Element Water-Quality Samples
VI. Sediment-Surrogate Technologies

Although summaries of all six phases follow, the reader is directed to Nelson and Benedict (1950), FISP (1963), Witzigman (1965), Benedict (1979), and Skinner (1989), for more in-depth descriptions of phases I-IV. Emphases in the ensuing summaries are placed on successes or lack thereof, expressed in terms of knowledge gained, and the instruments and/or methodologies approved and rendered publically available.

Phase I: Manual Samplers for Collection of Physical Sediment Samples, 1939-1980s* Phase I addressed two challenges: An insufficient understanding of the physics of the motion and distribution of sediment particles in suspension and as bedload, and a lack of standardization of samplers and sampling techniques. Research on sedimentary physics in the early years of the FISP led to the recognition of the need for, design, and development of isokinetic samplers and sampling procedures to address deficiencies associated with surface-grab or weighted-bottle samplers. An outstanding body of FISP literature on this topic is available at the FISP web site (water.usgs.gov/fisp) as part of FISP report Nos. 1-14 and A-TT.

Research and development efforts focused on samplers and sampling techniques for collection of representative sediment samples for subsequent laboratory analyses in three categories: In suspension (suspended sediment); rolling, sliding, or saltating on the bed (bedload); and stationary (bed material). Davis (2005) lists most of the FISP samplers described in the following sections. Edwards and Glysson (1999), Nolan et al. (2005), Gray and Landers (2014) and Gray and O'Halloran (2015) describe FISP- and USGS-approved sampler-deployment techniques. Three of the samplers developed as part of Phase I appear in figure 1.

Selected Rigid-Bottle Samplers Developed During FISP Phase I

US DH-48

US DH-59

US D-74

Figure 1 Examples of suspended-sediment samplers developed during Phase I of FISP.

Today there are 16 models of suspended-sediment samplers (table 1 and figures 1 and 2), including those also capable of sampling for trace elements (figure 2); two models of bedload samplers (table 2); four models of bed-material samplers (table 3); and a suite of passive single-stage suspended-sediment samplers developed as part of Phase I. These samplers are described in detail on the FISP web site catalog along with their specifications, operational limits, and links to operator's manuals. The nomenclature for FISP sediment-sampling instruments (tables 1, 2, and 3) denotes the series, type, and year that sampler development started (Davis, 2005). All are available for purchase through the FISP or authorized private-sector firms.

FISP samplers not only are used by several Federal agencies and other organizations in the U.S., but in a number of countries around the world on every continent except Antarctica (Gray and Demas, in press). The simplicity and minimal moving parts of FISP isokinetic samplers, strong theoretical underpinnings supported by laboratory and field-based research, and still-water calibrations impart general confidence in the representativeness of the samples produced.

*The US P-6 point-integrating suspended-sediment sampler (figure 2), which was designed to replace the US P-61, was approved by the Technical Committee in 2012. It cannot be used to collect contamination-free samples for trace-element analyses.

Phase II: Sediment-Analytical Instruments, 1940s-70s Witzigman (1965) and Benedict (1979) describe several laboratory-analytical instruments, some of which remain in use by USGS and other sediment laboratories. Several reports on this subject can be found at FISP (2015).

The bottom-withdrawal tube was developed to determine the size distribution of material up to 0.7 millimeters in diameter in suspended-sediment samples. Only the USGS Louisiana Water Science Center sediment laboratory continues to use this instrument, and only for samples submitted by the Corps' New Orleans District (Cheryl Joseph, USGS written commun., 2015).

The visual-accumulation tube method was developed to determine the size distribution of sand-size material in suspended-sediment, bed-, and beach-material samples. This method remains in use in several USGS fluvial-sediment laboratories.

Investigations into the use of X-rays to quantify particle-size distributions resulted in the development and commercial availability of the Sedigraph in or about 1967. Only one USGS production sediment laboratory – located at the Cascades Volcano Observatory in Vancouver, Washington – continues to use a Sedigraph (Dan Gooding and Julie Nason, USGS, written commun., 2015).

At least two other sediment-analyzing methodologies were investigated: Turbidity and ultrasonics. Turbidity is an optical water-quality characteristic affected by several factors including the color and size of the sediments and the color of the fluid in which they are suspended, in addition to sediment concentration. The ultrasonic method was developed to determine concentrations and size distributions of sediments ranging from 0.040-1.0 millimeters. A laboratory instrument was considered to operate well, but was not considered "competitive" with existing laboratory equipment. No contemporary USGS production sediment laboratory uses ultrasonics to analyze sediment samples.

Phase III: Automatic Samplers, 1940s-60s The FISP developed and produced two types of automatic samplers after the midpoint of the 20th century: Passive single-stage samplers, and the US PS-69 pumping sampler. As designed, both types of samplers drew water from a fixed point in the stream (in the case of the US PS-69, with or without a strainer affixed to the intake orifice).

[1]Samplers designated in *italics* may also be used for collection of trace-element samples as described in the USGS National Field Manual for the Collection of Water Quality-Data (USGS, 2014).

[2] For rigid-bottle samplers, the maximum recommended velocity for sampler deployment is based either on measured isokinetic limitations or on the maximum velocities used in isokinetic and stability tests. Bag samplers were determined to retain isokinetic characteristics at the highest velocities tested.

[3]The 3/16-inch-diameter nozzle is more sensitive to velocity and temperature effects than larger-diameter nozzles, and only should be used when necessary to sample greater depths with these bag samplers.

[4] The minimum isokinetic velocities for the US D-99 sampler at water temperatures greater than 10°C and less than 10°C are 0.91 m/s (3.0 ft/s) and 1.1 m/s (3.7 ft/s), respectively, unless the 0.48-mm (3/16-in) nozzle is used, in which case it is 1.22 m/s (4.0 ft/s).

Table 2 Designations for and Characteristics of FISP Manually Operated Bed-Material Samplers (Davis, 2005).

Sampler Designation	Description	Sampler Weight (pounds)	Maxi-mum Sampler Pene-tration (inches)	Maxi-mum Sample Volume (cubic inches)
US BMH-53	Hand-held, 2-inch diameter, piston-type bed-material sampler.	7.5	8	25
US BM-54	Cable-suspended, spring-loaded scoop, bed-material sampler	100	2	18
US BMH-60	Cable-suspended, spring-loaded scoop, bed-material sampler	32	1.7	11
US RBMH-80	Hand-held rotary-scoop bed-material sampler	8	1.8	15

Table 3 Designations for and Characteristics of FISP Manually Operated Bedload Samplers (Davis, 2005).

Sampler Designation	Description	Sampler Weight (pounds)	Nozzle Width X Height (inches)	Maximum Velocity (feet per second)
US BL-84	Cable-suspended, mesh bag bedload sampler	32	3 x 3	9
US BLH-84	Hand-held, mesh bag bedload sampler	10	3 x 3	**
Bed Load Trap	Portable mesh bag, fixed location bedload sampler	32	12 x 8	variable

**rod-deployed either by wading or from above the stream; maximum velocity is probably 9 ft/s.

A U-series single-stage sampler (FISP, 1963; Witzigman, 1965; Benedict, 1979; FISP, 2015) collects samples of near-surface water on the rising hydrograph. They are typically deployed in a series of samplers affixed at different elevations to a pier, wingwall, or other stable structure. When the total head incident on the intake orifice results in water cresting inside the intake-tube weir, stream water siphons into a sample bottle and the displaced air vents through an exhaust tube. When the sample rises to the elevation of the exhaust pipe's orifice inside the bottle, an airlock forms and sample collection should cease. However, in practice, sample recirculation sometimes occurs, preferentially enriching the sedimentary content of the sample. Additional unreliability could result from a presumed inability to representatively capture sand-size material. In spite of these drawbacks, the FISP U-series samplers and other types of passive automatic samplers that they inspired, including a design by Gray and Fisk (1991) that precludes the potential for sample recirculation, remain in use at some field sites.

Skinner (1989) describes the PS-69 pumping sampler, which the FISP developed and produced to collect fixed-point samples at gaging stations on relatively "flashy" streams and at those that could not be adequately sampled by an observer. FISP-produced prototypes include the PS-62, PS-66, and PS-67 pumping samplers, which, along with the PS-69, were field tested in the 1960s in Maryland (Yorke, 1976). Desirable features of the PS-69 included a 12-volt power system; sample rack that held 72 quart-size containers; and an intake-line backflush system using an in-gage reservoir that was refilled after each backflush cycle. Its drawbacks included its large size and power requirements, complexity with many moving parts, and lack of reliability in the challenging field environment. The FISP ceased to supply and support the PS-69 samplers some years after the first commercial pumping samplers made by Manning Environmental Corporation, and ISCO Corporation became available by the early 1980s.

Phase IV: Automatic Sediment Gages, 1950s-80s FISP (1963), Skinner and Beverage (1976), and Skinner (1989) summarized FISP endeavors to automate the collection of suspended-sediment data in the field and laboratory. They describe investigations in radiant energy (acoustic and electromagnetic, including gamma rays), applied forces (a densimetric technique), a vibratory technique as part of a U-tube, and electrical conduction. The latter takes advantage of a disparity in the conductivity of river water to that of the entrained sediments. In retrospect, the FISP was ahead of its time in this pre-microcomputer age. None of these efforts resulted in the wide-scale field-deployment of "automated sediment gages."

Phase V: Manual Samplers for Collection of Trace-Element Water-Quality Samples, 1990s-2006 In the 1980s, a need for trace-element data at parts-per-billion-level concentrations (as opposed to the parts-per-million-level concentrations measurements for suspended sediment and many chemical constituents including nutrients and common ions) presented the prospect of contamination from the sampling apparatus, particularly for samples collected for trace-metal analyses. A decision to simply coat FISP suspended-sediment samplers used to collect trace-element samples with white marine epoxy paint proved disastrous from a data-quality perspective. Much of the derived dissolved trace-element data were rendered unreliable due to contamination from the sampler in spite of the epoxy coating (USGS, 1991).

Rigid-Bottle Samplers Developed During FISP Phase V

Figure 2 Examples of suspended-sediment samplers developed during Phase V of FISP (the US P-6 cannot be used to collect samples for trace-element analyses).

Phase VI: Developing Sediment-Surrogate Technologies, approximately 2004-present By the arrival of the third millennium, the availability of hardware and relatively robust software that postdated FISP's Phase III automated sediment gage-development efforts were being exploited by a number of researchers and some private-sector firms to develop surrogate means for measurements of suspended-sediment concentrations and size distributions, bedload-transport rates, and bed-material size distributions. Their primary focus was on bulk-optic, laser-optic, acoustic, and pressure-differential surrogate metrics capable of providing high-temporal – and in some cases also high-spatial – resolution time-series data (Gray and Gartner, 2009). When calibrated to sediment characteristics using concurrently collected physical samples, these surrogate methods provide substantial improvements in the acquisition and accuracy of the data produced, primarily due to the temporal continuity afforded by in situ surrogate instruments. Moreover, these surrogate methodologies promise to lower monitoring costs in the medium-to-long term.

By 2004, after its successful decade-long, primary focus on development of trace-element samplers, the FISP found itself in need of expertise and momentum if it hoped to take on a leadership role in the burgeoning field of sediment-surrogate technologies. By then, bulk optics (turbidity) had matured as a surrogate metric for suspended-sediment concentration and was being integrated into selected operational programs (Rasmussen et al., 2008). With the publication of the USGS-produced and -sanctioned technique for converting continuous turbidity measurements to mass-concentration values (Rasmussen et

al., 2009), the FISP subsequently refrained from supporting turbidity research projects in lieu of other compelling but inadequately resolved sediment-surrogate technologies.

The initial Phase VI surrogate technology to be evaluated by the FISP was laser scattering (Gray and Gartner, 2009). Laser scattering provides at-a-point values for volumetric concentrations back-calculated from the sum of particles measured volumetrically in 32 size classes. The FISP has funded research projects to evaluate the LISST-SL, an isokinetic laser-scattering instrument (Czuba et al., 2015). This research led to the FISP's sanctioning laser-diffraction analyzers for environmental volumetric measurements for both suspended-sediment concentrations and particle-size distributions, albeit with important caveats (FISP, 2013).

FISP is currently funding sediment-acoustic research. Sediment acoustics was deemed by Gray and Gartner (2009) to be the most promising for meeting the needs of large-scale fluvial-sediment monitoring programs, a contention reiterated by the authors today. The use of manually deployed or in situ acoustic Doppler current (ADCP) meters, in particular, shows considerable potential as a surrogate technology for suspended-sediment concentration and possibly also to quantify particle-size classes, to wit:

1. ADCPs already are used extensively for streamflow monitoring and provide river-velocity data,
2. A direct measure of the cross-sectional variability in sediment concentrations is provided,
3. The technology is not as susceptible to biofouling as other surrogate technologies, such as turbidity sensors,
4. The technology measures a larger volume than other surrogate technologies, and
5. Acquisition of sediment-size information is possible using multiple acoustic frequencies.

FISP continues to fund evaluations of a densimetric technology that exploits the differences in the pressures simultaneously sensed by precision pressure transducers at two in situ orifices separated by a fixed distance in a water column. The technology's performance theoretically improves with increasing suspended-sediment concentrations exceeding some 10-20 grams per liter. The densimetric technology was evaluated by the USGS in Puerto Rico, Arizona, and, most recently and successfully, at New Mexico's Rio Puerco, a tributary of the middle Rio Grande renowned for conveying highly sediment-laden flows (Brown et al., 2015).

FUTURE CHALLENGES AND DIRECTIONS

The purpose of the FISP continues to be driven by the need for reliable sediment-monitoring equipment and methods in a world where the relevance of sediment information continues to increase. The future directions of the FISP – in response to known and emerging challenges – involve a growing knowledge of and improved methods for physical sampling and for continuous sediment monitoring using surrogate technologies. Primary focus areas and concomitant challenges for the FISP in the foreseeable future may include the following:

- Develop and improve operational instrumentation and methods to monitor suspended-sediment characteristics (concentrations, loads, particle-size distributions) using acoustic backscatter at high-temporal and/or high-spatial resolution.
- Develop and improve operational instrumentation and methods to monitor bedload using acoustic and other surrogates at high-temporal and/or high-spatial resolution.
- Obtain improved understanding and characterization (including sampling accuracy) of physical sediment samplers, particularly bag-type samplers, using computational fluid dynamic modeling and field verification.
- Evaluate and improve instruments and methods for physical bedload sampling.
- Continued evaluation and development of new technologies including those based on laser-diffraction and densimetric principals.
- Evaluate technologically advanced methods for fluvial-sediment laboratory analyses and records processing.

The foci and thrusts of the FISP have changed in response to member-agency needs and evolving capabilities over its ¾-century existence. The authors hope to read a "FISP History Part VI" before the cessation of their respective dotages – perhaps to commemorate the FISP's centennial in 2039.

ACKNOWLEDGEMENTS

The veracity and content of this contribution benefited considerably from peer reviews provided by Jerry Bernard (retired) and Marie Garsjo (retired), Natural Resources Conservation Service; C. Wayne O'Neal (retired), FISP; and Robert Hilldale, Bureau of Reclamation. The artistic prowess of the USGS's Annette Goode toward formatting of the tables and figures in this manuscript was greatly appreciated.

ATTACHMENT

A BRIEF HISTORY OF THE FEDERAL INTER-AGENCY SEDIMENTATION PROJECT*

(unattributed and undated, inferred from content to have been written in or after 1956)

In 1939, representatives of several Federal Agencies met to discuss ways of improving methods for measuring the quantity and characteristics of sediment that is transported in rivers. These representatives organized an Interdepartmental Committee to standardize methods and equipment for collecting sediment data. The following agencies supported the standardization effort: Corps of Engineers of the Department of the Army; Flood Control Coordinating Committee of the Department of Agriculture; U.S. Geological Survey; Bureau of Reclamation; Office of Indian Affairs of the Department of Interior; and the Tennessee Valley Authority. The Iowa Institute of Hydraulic Research cooperated in the work which was performed at the Hydraulic Laboratory, State University of Iowa, Iowa City, Iowa.

From 1939 to 1942 the project was under the general supervision of Professor E. W. Lane. From July 1942 to July 1945, the project was supervised by M. E. Nelson, Army Corps of Engineers, and L. C. Crawford, Geological Survey; the research work was conducted by personnel from both agencies.

In April 1946, the Interdepartmental Committee transferred its authority the Subcommittee on Sedimentation of the Federal Inter-Agency River Basin Committee. The River Basin Committee was composed of representatives from the Department of the Army, Department of the Interior, Department of Agriculture, Department of Commerce, Tennessee Valley Authority, and Federal Power Commission. The main objective of the Committee was to coordinate all Federally sponsored hydrologic studies.

In June 1948, the Subcommittee on Sedimentation moved the project from the Iowa Institute of Hydraulic Research to the St. Anthony Falls Hydraulic Laboratory at the University of Minnesota in Minneapolis, Minnesota. From 1946 to 1955, project activities were under the general supervision of M. E. Nelson, Army Corps of Engineers, and P. C. Benedict, U.S. Geological Survey. Mr. B. C. Colby directed the research work.

In 1956, the Subcommittee reorganized the project and called it the Federal Inter-Agency Sedimentation Project. The Subcommittee also adopted a formal Guidance Memorandum that described the project's objectives and organization.

Since 1956, the project has been sponsored by a Technical Committee composed of representatives from Federal Agencies that are involved in sediment studies. Major policies that affect the project are made by the Sedimentation Committee of the Interagency Advisory Committee on Water Data of the Water Resources Council. The project's staff conducts basic and applied research and also develops, tests, and calibrates sediment equipment.

Currently, agencies represented on the Technical Committee are: Army Corps of Engineers, U.S. Geological Survey, Bureau of Reclamation, Agricultural Research Service, U.S. Forest Service, Federal Highway Administration, and the Bureau of Land Management.

**This title and ensuing text reflects verbatim the contents of an unattributed, undated 2-page FISP "history" discovered by John R. Gray (USGS Scientist Emeritus) when G. Douglas Glysson (USGS, retired) cleaned the last USGS office that Glysson occupied on the 5th floor of the USGS National Center, Reston, Virginia, in late 2014. The file was scanned by Annette Goode, USGS Office of Surface Water, in December 2014. It was subsequently reformatted to fit on one page as it appears above.*

Although the veracity of this "history" has not been unequivocally verified, some parts are undoubtedly correct based on Gray's knowledge of the Project, and on histories published by Witzigman (1965) and Skinner (1989). Coupled with the circumstances under which it was found, there is little doubt that it is authentic and reliable. Thus it is hereby included as part of the permanent FISP record by John R. Gray, 2015

ONE-STOP SHOPPING FOR FLUVIAL-SEDIMENT DATA: THE USGS SEDIMENT-DATA PORTAL

EXTENDED ABSTRACT

Casey Lee, U.S. Geological Survey National Water Quality Assessment Program; 4821 Quail Crest Place, Lawrence, KS; cjlee@usgs.gov
Meredith Warren, U.S. Geological Survey Center for Data Analytics; 8505 Research Way Middleton, WI; mwarren@usgs.gov

Since the first samples on the Rio Grande in 1889, the U.S. Geological Survey (USGS) has been collecting information on sediment transport in streams and rivers across the United States. Although the USGS maintains an extensive database of sediment and related data through the National Water Information System (NWIS), these data can be difficult to utilize because:

1. It can be challenging to ascertain where and when suspended-sediment data have been collected.
2. It can be difficult to determine if non-representative sampling methods have left suspended-sediment and associated data are prone to bias.
3. There has been limited aggregation of information needed to interpret sediment data, such as information on sediment grain size, streamflow, and landscape conditions.

In 2013, the USGS National Water Quality Assessment Program (NAWQA) took an initial step toward minimizing these problems through release of the USGS Sediment Data Portal (Figure 1). The portal improves the utility and accessibility of USGS suspended-sediment data by providing tools to visualize, filter, and download discrete and daily suspended-sediment data and sampling site characteristics.

Data served through the portal represent the best available compendium of suspended-sediment data for streams and rivers in the United States, serving results from more than 600,000 discrete sediment samples and more than 10,000 years of daily sediment data. An accompanying USGS Data Series Report, "Compilation, Quality Control, Analysis, and Summary of Discrete Suspended-Sediment and Ancillary Data in the United States, 1901-2010" describes methods used to recover and quality control existing USGS suspended-sediment data, and summarizes suspended-sediment and selected ancillary data across the United States with respect to time, streamflow, and landscape condition.

The USGS Sediment Data Portal can be accessed at: http://cida.usgs.gov/sediment.

Abstract The fully electronic Sediment Data and Information Web-based (SEDWE) application enables use of a range of hand-held platforms to efficiently and accurately record U. S. Geological Survey (USGS) fluvial-sediment sample and ancillary data before departing the sediment-monitoring site. The field data are subsequently transferred to the USGS National Water Information System (NWIS) and USGS Sediment Laboratory Environmental Database System (SLEDS) via the USGS Sediment-sample LOGIN (SedLOGIN) application. The ensuing permanent NWIS record includes all relevant field data conveyed via SEDWE and sample-analytical results conveyed via SLEDS.

SEDWE provides a standardized paperless alternative for documenting fluvial-sediment data collected in the field, while retaining relevant metadata. The application, which functions on smart phones, tablets, and personal computers, is anticipated to become a standard tool for use by the USGS to capture, store, and share a more useful and explanatory record of fluvial-sediment sample and ancillary data.

INTRODUCTION

The U.S. Geological Survey (USGS) Sediment Data and Information Web-based Application (SEDWE) enables field-data collectors to efficiently and accurately record and store USGS fluvial-sediment and related ancillary data at a sediment-monitoring site (hereafter referred to as a "USGS sediment station"). These data are recorded on a hand-held electronic device in the field, and subsequently uploaded to the USGS National Water Information System (NWIS) (USGS, 2015) through the intermediary Sediment-sample LOGIN (SedLOGIN) application (USGS, 2010). The ensuing permanent NWIS record includes all relevant field data conveyed via SEDWE and sample analytical results conveyed via SLEDS.

The fully electronic SEDWE application was designed to increase the efficiency, completeness, and accuracy of field-data collection and subsequent storage in USGS databases. For storage of fluvial-sediment data collected as part of a larger suite of water-quality samples, USGS personnel are encouraged to continue to use the Personal Computer Field Form (PCFF) (Wilde, 2008). The use of the SEDWE and PCFF applications is preferred over paper-based field notes. SEDWE is anticipated to become a standard tool for use by the USGS to document a more useful and explanatory set of ancillary data associated with collection of fluvial-sediment samples.

Background Sediment-discharge measurements in the U.S. began in 1938 when Captain Talcott sampled the Mississippi River (Skinner, 1989). The formation of the Federal Interagency Sedimentation Project (FISP, 2015; Gray and Landers, 2015) in 1939 led to the development of quality-assured fluvial-sediment data-collection instruments and methods that remain in use today (Diplas and others, 2008). FISP instruments and methods are widely used for collecting fluvial-sediment data by most Federal agencies; many Tribes, States, and local governments;

and many countries around the world (Gray and Demas, in press). Sediment data produced by the USGS are collected, analyzed, and stored following guidelines and policies described by Porterfield (1972), Johnson (1997), Edwards and Glysson (1999), Nolan and others (2005), Koltun and others (2006), Diplas and others (2008), and Gray and Landers (2014), and Gray and O'Halloran (2015).

Until 2010, the only formal requirement for storage of data associated with USGS sediment stations included mean-daily values of streamflow, time-weighted suspended-sediment concentration, and suspended-sediment discharge, along with discrete particle-size data (if analyzed). In 2010, the USGS issued mandatory guidelines for storing a larger suite of discrete fluvial-sediment data and associated ancillary information. In addition to water-sediment samples collected manually or automatically in the field, ancillary parameters required by the SedLOGIN application include information on water temperature, sampler type, and method of deployment (USGS, 2010).

The SedLOGIN application was released in February 2010 as part of USGS policy to facilitate recording and storage of discrete sediment and ancillary data collected at USGS sediment stations. Its purpose is to assist USGS field personnel with database entry of fluvial-sediment sample information.

Once data are entered in SedLOGIN, a Sediment Laboratory Analytical Request (SLAR) form is automatically generated, printed, and included with the samples shipped to the sediment laboratory. The sample data and associated field parameters are automatically transferred from SedLOGIN to both the Sediment Laboratory Environmental Database Systems (SLEDS), and QWDX (the water-quality data transfer system). Results of sample analyses are also transferred by the laboratory into QWDX, from which the sample-associated data are transferred to the QWDATA module of the NWIS.

All new data derived from fluvial-sediment (discrete suspended-sediment, bedload, and bottom-material) samples collected must be stored in QWDATA using methods described by Johnson (1997), Edwards and Glysson (1999), Nolan and others (2005), Diplas and others (2008), and Gray and Landers (2014), and selected metadata as described by the USGS (2010). These storage requirements also include results of analyses of replicate samples identified by appropriate medium codes as environmental and/or quality-control samples. Data associated with physical samples collected by hydrographers, observers, and by automated means are also stored.

Entry of selected ancillary data to QWDATA prior to the aforementioned 2010 mandate was encouraged but not compulsory. Until the development of SEDWE, a limiting factor had been that SedLOGIN (or direct entry of data into QWDATA) required manual data entry using an office computer with appropriate USGS-access rights. In the past, paper forms or non-standardized electronic notes were used to record information in the field for subsequent largely manual transcription to standardized electronic media upon return to the office (Figure 1).

Figure 1 Schematic of procedure for collecting and recording fluvial-sediment data prior to the availability of the SEDWE application.

ATTRIBUTES OF SEDWE ELECTRONIC FIELD NOTES

SEDWE enables one-time electronic recording of fluvial-sediment and ancillary data for subsequent entry to the SedLOGIN application (Figure 2). The use of SEDWE has advantages over paper-based record keeping, including:

1. a reduction in arithmetic and recording errors,
2. elimination of the need to produce and archive paper notes,
3. improved consistency in, and more complete capture of field observations,
4. decreased project costs by reducing time spent on data entry and management, and
5. an increase in the overall quality and reliability of the sediment-station records concomitant with a decrease in the requisite time and effort to produce the records.

SEDWE enables USGS field hydrographers and sediment-station observers to accurately enter, view, modify, submit and print ancillary data associated with fluvial-sediment samples in accordance with USGS data-collection, management, and storage protocols (Porterfield, 1972; Koltun and others, 2006; USGS, 2010). SEDWE guides the user through a step-by-step process to complete all data entry successfully. SEDWE is secure, available any time, and can help expedite the sharing of USGS data.

SEDWE can be used in "offline mode" when the recording platform is not connected to the Internet, allowing the user to view and edit the recorded fluvial-sediment and ancillary data before submission. The available features, while on offline mode, include recording of fluvial-sediment sample data, and some tutorial information. External links and upload functionality are enabled when Internet access is restored.

Figure 2 Schematic of steps for collecting and recording sediment data using SEDWE.

SEDWE User Environment SEDWE is a field- and web-based system which operates on a variety of devices such as a PC, tablet, or smartphone. The application provides an independent platform for field-client operations. It was developed using Hypertext Markup Language 5 (HTML), jQuery mobile, Cascading Style Sheets (CSS) and PHP programming languages. USGS users can access SEDWE using any of the following browsers: Mozilla Firefox®, Apple Safari®, and Google Chrome® (use of firm or brand names is for information only and does not constitute endorsement by the U.S. Government).

Overview of SEDWE Interfaces The SEDWE application consists of three interfaces selectable based on the type of user: Observer, Hydrographer, and Administrator. The Observer Interface only is accessible to USGS sediment-station observers. The Hydrographer Interface only is accessible to USGS personnel who collect and process fluvial-sediment data, or their designees. These interfaces are used for recording pertinent data before departing the USGS sediment station. The Administrator Interface is accessible by any registered USGS Hydrographer who has access rights in QWDX/SedLOGIN. It is used for configuring the SEDWE users and their designated USGS sediment stations. Hydrographers who access the Administrator Interface will share the same access rights as the SEDWE Administrator within the Administrator Interface at the USGS Water Science Center level.

Hydrographer and Observer Interface The Observer and Hydrographer interfaces require USGS user authentication. The application will display the corresponding USGS sediment stations assigned to a particular user. The assigned stations are registered and set by a USGS administrator in the Administrator Interface. Observers and Hydrographers are able to add, modify, and delete records prior to submitting the data via an email containing the XML data file to a designated reviewer (QWDX-authorized user). Once reviewed, the XML file can be imported into SedLOGIN. Until further notice, the XML file will be delivered by email for later processing into SedLOGIN.

The Open XML option allows the user to view data stored in an XML file generated by other users. When the data stored in the local cache of the device are cleared, the user can open a previously generated XML file. Once the data are loaded into SEDWE, the user can either review or continue editing the data.

The Observer and Hydrographer Interfaces include three links or tabs, which are referred to as Shipments Manager, Manage Images, and Tutorials (Figure 3). Depending on the type of user (either Observer or Hydrographer), the corresponding form for recording sediment-sample data is shown. In each category the user enters the sediment data into a custom-designed electronic spreadsheet for each set or group of samples until all metadata are entered for later processing.

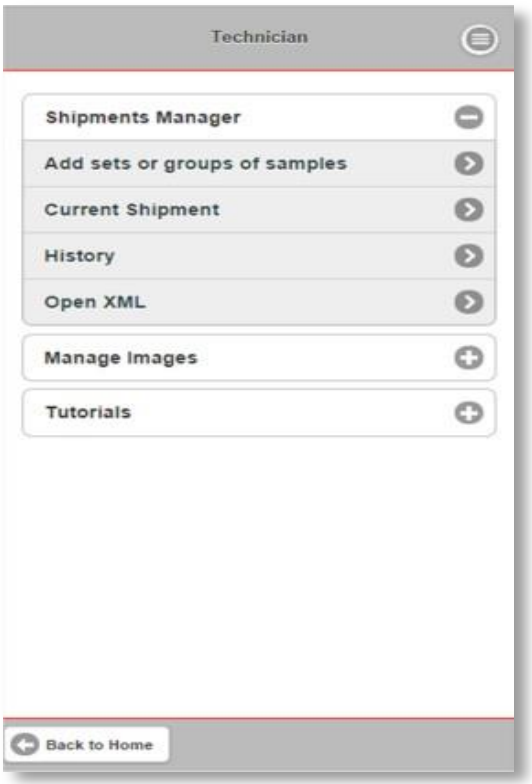

Figure 3 SEDWE main menu screen for the Observer and Hydrographer Interfaces.

The Shipments Manager tab allows the user to record data by selecting the "Add sets or groups of samples" button, and to edit or review the recorded data with the "Current Shipment" button, both of which use the same Data Recording screen (Figure 4).

The Manage Images screen (Figure 5) allows the user to send an image of field conditions at the sediment station to the designated hydrographer by selecting it from the device picture gallery or by taking the picture using a camera-equipped device. The Tutorial includes a user's manual and helpful links, videos, and educational resources about field sediment-sampling protocols and procedures.

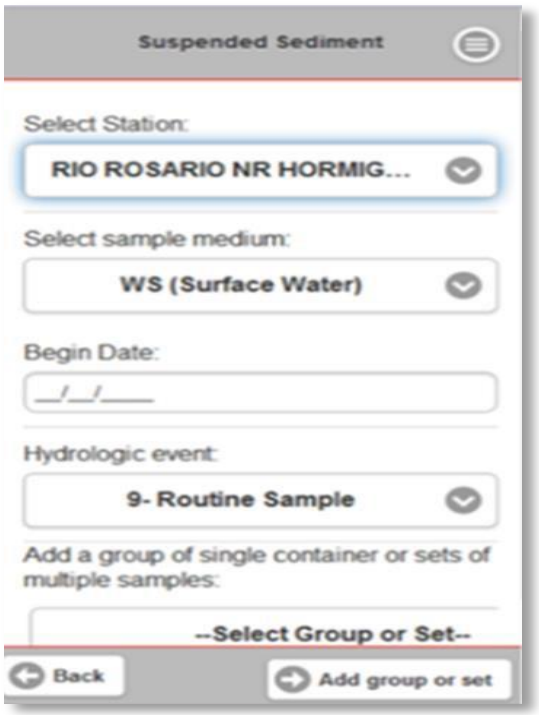

Figure 4 SEDWE Data Recording screen.

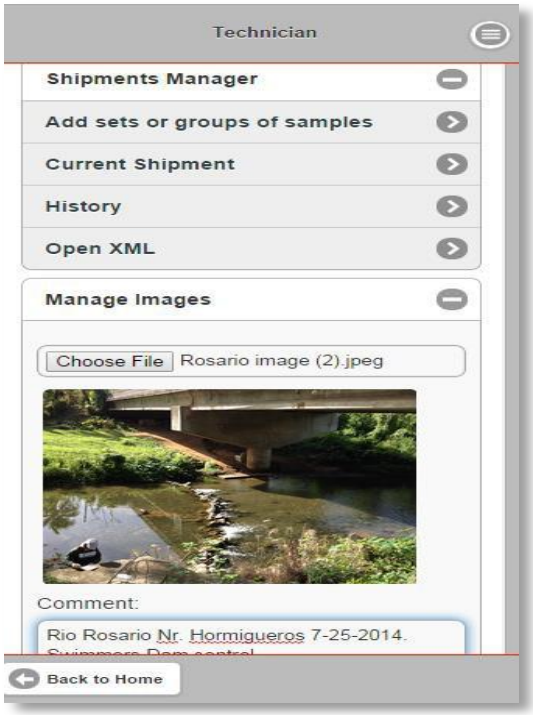

Figure 5 SEDWE Manage Images screen.

Administrator Interface The SEDWE Administrator Interface stores information related to users and stations for use by the SEDWE application. The SEDWE Administrator Interface consists of three main screens: Users, Stations, and Import from SedLOGIN. The Users and Stations screens allow the Administrator and the registered Hydrographer to query the Users and Stations stored in the SEDWE database, and to add a new user or station. The Users and Stations functionalities include:

1. add a new user or station,
2. modify an existing user or station, and
3. delete an existing user or station.

The Import from SedLOGIN screen allows a user to specify project(s) in SedLOGIN from which to import one or both of the project's stations or the project's users into the SEDWE database.

Connecting to SedLOGIN Programing codes, parameters, and validation in SEDWE prevents errors because the same codes, parameters, and validation are used by SedLOGIN. Hydrographers must log into SedLOGIN to import the XML file from SEDWE, and can import SEDWE data into any SedLOGIN project that the hydrographer is authorized to access. SedLOGIN will enforce data validation if there are any missing required parameters. Hydrographers can review and edit an XML file before importing the file into SedLOGIN by using the "Open XML" option in SEDWE.

SUMMARY

The SEDWE application serves as a standardized USGS resource to document ancillary data associated with fluvial-sediment sample collection prior to departing a USGS sediment station. SEDWE was designed to interface with other USGS sediment software to accomplish efficient transfer and accurate storage of these data. A range of electronic, hand-held platforms are supported to record and store USGS data associated with fluvial-sediment samples. The data subsequently can be transferred to the NWIS database, and to the USGS SLEDS application through the SedLOGIN application, and ultimately to the QWDATA database of the NWIS. SEDWE electronic forms serve to standardize and facilitate capture of ancillary data associated with fluvial-sediment sample collection. Benefits of using SEDWE include reductions in transcription errors due to one-time data entry; elimination of the need to archive paper records; improved data consistency and capture; decreased project costs; and an overall increase in the quality and reliability of USGS sediment-station records.

CHARACTERIZING AND SIMULATING SEDIMENT LOADS AND TRANSPORT IN THE LOWER PART OF THE SAN ANTONIO RIVER BASIN EXTENDED ABSTRACT

J. Ryan Banta, jbanta@usgs.gov; **Darwin J. Ockerman**, ockerman@usgs.gov; **Cassi L. Crow**, ccrow@usgs.gov; and **Stephen P. Opsahl**, sopsahl@usgs.gov.

INTRODUCTION

This extended abstract is based on the U.S. Geological Survey Scientific Investigations Reports by Crow et al. (2013) and Banta and Ockerman (2014). Suspended sediment in rivers and streams can play an important role in ecological health of rivers and estuaries and consequently is an important issue for water-resource managers. The quantity and type of suspended sediment can affect the biological communities (Wood and Armitage, 1997), the concentration and movement of natural constituents and anthropogenic contaminants (Moran and others, 2012), and the amount of sediment deposition in coastal environments (Milliman and Meade, 1983). To better understand suspended-sediment characteristics in the San Antonio River Basin, the U.S. Geological Survey (USGS), in cooperation with the San Antonio River Authority and Texas Water Development Board, conducted a two-phase study to (1) collect and analyze sediment data to characterize sediment conditions in the San Antonio River downstream of San Antonio, Texas, and (2) develop and calibrate a watershed model to simulate hydrologic conditions and suspended-sediment loads for four watersheds in the San Antonio River Basin, downstream from San Antonio, Texas.

METHODS

Sediment Characterization: The study area consists of approximately 2,150 square miles. The upstream boundary of the study area coincides with USGS streamflow-gaging station 08181800 San Antonio River near Elmendorf, Tex. (hereinafter referred to as the "SAR Elmendorf gage") and USGS streamflow-gaging station 08185000 Cibolo Creek at Selma, Tex. (hereinafter referred to as the "Cibolo Selma gage"). The downstream boundary of the study area is the confluence with the Guadalupe River. During 2011–13, suspended-sediment samples were collected at 10 sites for the analysis of suspended-sediment concentration and particle size distribution. In addition, samples of bedload material were collected at six sites for the analysis of bedload mass and particle-size distribution. Samples were collected over a variety of hydrologic conditions ranging from a minimum streamflow of 1.9 cubic feet per second (ft^3/s) at the Cibolo Selma gage on September 17, 2012, to a maximum streamflow of 10,600 ft^3/s at the same site on May 25, 2013. To estimate suspended-sediment loads, log-linear regressions were developed to estimate suspended-sediment concentration based on streamflow at five sites for which sufficient data (including historically collected data) were available (see Figure 1 for example). The suspended-sediment concentrations were used in conjunction with streamflow to calculate estimated suspended-sediment loads.

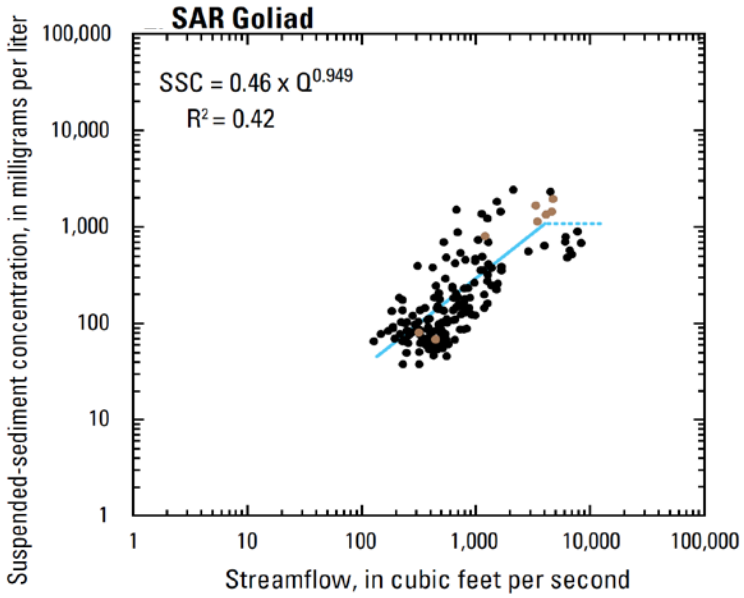

Figure 1. Example of relation between suspended-sediment concentration and streamflow at the SAR Goliad gage (USGS station 08188500 San Antonio River at Goliad, Tex.) (Modified from Figure 5 in Crow and others, 2013).

HSPF Model Development: In 2010, the U.S. Geological Survey (USGS), in cooperation with the San Antonio River Authority, the Evergreen Underground Water Conservation District, and the Goliad County Groundwater Conservation District, developed a Hydrological Simulation Program – FORTRAN (HSPF) model for the San Antonio River Basin to simulate hydrology only (hereinafter referred to as the "USGS–2010 model") (Lizarraga and Ockerman, 2010). In 2012, URS Corporation developed an updated version of the San Antonio River Basin HSPF model (hereinafter referred to as the "URS–2012 model"), which was based on the USGS–2010 model. For this study, the USGS developed an updated version of the HSPF model, based on the URS–2012 model, to simulate hydrologic conditions and suspended-sediment loads in the San Antonio River Basin during 2000–12 (hereinafter referred to as the "USGS–2014 model").

Because of the large size, the study area in the San Antonio River Basin was divided into four watershed models: (1) San Antonio River upstream from Cibolo Creek, (2) Cibolo Creek, (3) Ecleto Creek, and (4) San Antonio River downstream from Cibolo Creek. Input data for the HSPF model included spatial and time-series data. Spatial data included geology, soils, land-cover, topography, and drainage characteristics such as subwatershed boundaries and stream-reach length and cross-section data. Time-series data included meteorological data (rainfall and potential evapotranspiration), streamflow data, and suspended-sediment load data. The ranges of expected soil erosion rates were used as guidance for establishing targets for model simulation of sediment yields for different land-cover types. Sediment-related HSPF model parameters were adjusted so that simulated soil erosion rates approximated the reported soil erosion rates by land-cover type.

RESULTS AND CONCLUSIONS

Sediment Characterization: The samples collected during 2011–13 represent a wide range of SSCs, including some of the largest concentrations ever collected at some of the sites. Suspended-sediment concentrations (SSCs) in 67 samples collected during 2011–13 ranged from 14 milligrams per liter (mg/L) during base-flow conditions at USGS streamflow-gaging station 08183500 San Antonio River near Falls City, Tex. (hereinafter referred to as the "SAR Falls City gage") on August 19, 2011, to 4,480 mg/L during a stormflow event at the same site on January 26, 2012. The instantaneous suspended-sediment loads (SSLs) computed from 67 SSC samples collected during 2011–12 ranged from 0.36 tons per day at the Cibolo Selma site during base-flow conditions on September 17, 2012, to 47,800 tons per day at the SAR Elmendorf site during a stormflow event on January 25, 2012. These SSLs were used as either inputs to the HSPF model or as calibration targets for simulated model loads.

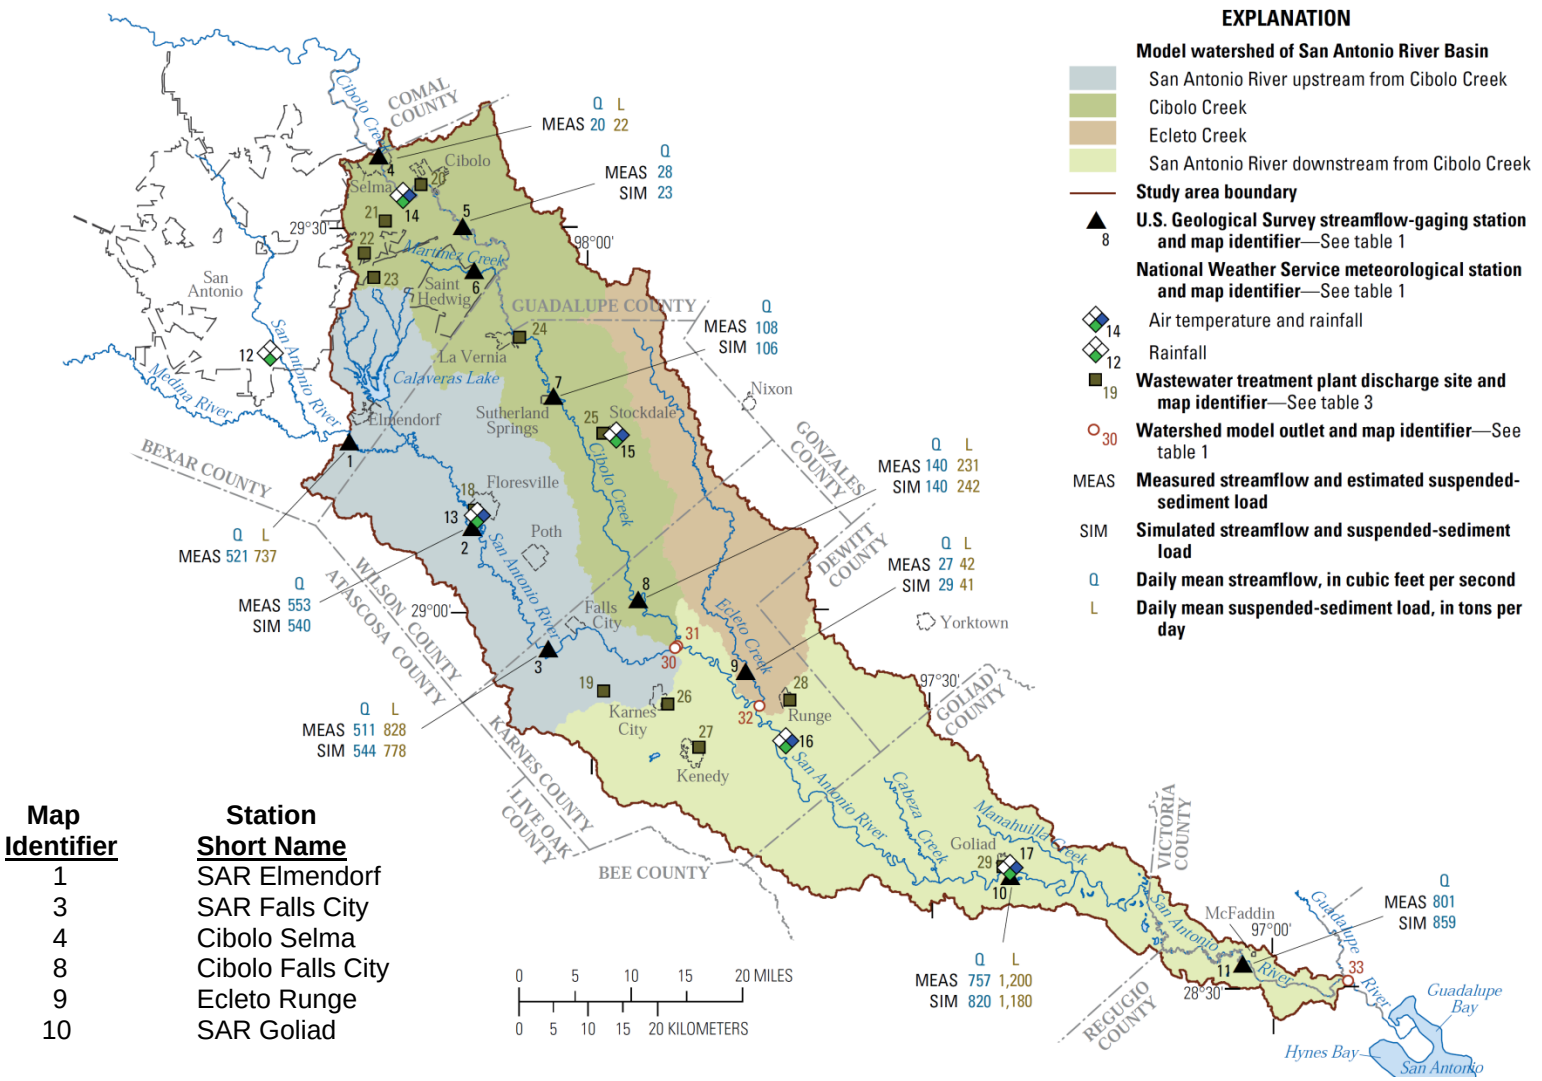
HSPF Model: The calibrated model of the study area in the San Antonio River Basin was used to simulate hydrologic conditions and suspended-sediment loads for 2000–12, as well as to simulate sediment production by various land types within the study area. Taking into consideration the model-fit statistics and graphical comparisons (Moriasi and others, 2007; Donigian, 2002; U.S. Environmental Protection Agency, 2000 and 2006), the watershed models simulated the observed streamflow within the "good" to "very good" categories during the calibration period (2006–12), with the exception of the Ecleto model. The calibration process also included a separate, post-calibration test of the model fit during 2000–2005. Simulations during the testing period had similar model-fit statistics as during the calibration period, with the exception of the USGS streamflow-gaging station 08186000 Cibolo Creek near Falls City, Tex. (hereinafter referred to as the "Cibolo Falls City gage"). One possible reason for weaker testing results (compared with calibration results) is the quality of available rainfall data for 2000–2005. During the entire 2000–12 simulation period, the model-fit statistics at each of the four primary calibration gages indicate "good" to "very good" fits (Banta and Ockerman, 2014).

Similar to the hydrology calibration, the suspended-sediment load model-fit statistics also were evaluated during the testing period at the SAR Falls City, Cibolo Falls City, and USGS streamflow-gaging station 08188500 San Antonio River at Goliad, Tex. (hereinafter referred to as the "SAR Goliad gage"), resulting in "good" to "very good" fits (Banta and Ockerman, 2014). Overall, model-fit statistics and graphic evaluations from the calibration and testing periods, provided multiple lines of evidence indicating the USGS–2014 model simulations of suspended-sediment conditions were mostly "good" to "very good," except for Ecleto Runge, which is considered unsatisfactory to fair (Banta and Ockerman, 2014).

The daily mean estimated suspended-sediment loads were 737 tons per day (tons/d) and 22 tons/d, respectively, at the SAR Elmendorf and Cibolo Selma gages during 2006–12 (Figure 2). At the outlet of the study area, the confluence of the San Antonio River with the Guadalupe River, the simulated daily mean suspended-sediment load during 2006–12 was 1,230 tons/d (Figure 2). These model results indicate that 759 of the 1,230 tons/d (approximately 62 percent) of the suspended sediment being delivered to the Guadalupe River originated upstream from the study area, mostly upstream from the SAR Elmendorf gage. Sample analyses and model results indicate that most of the suspended-sediment load in the study area consists of silt- and clay-

sized particles (less than 0.0625 millimeters). At the confluence of the San Antonio River with the Guadalupe River, approximately 98 percent of the total simulated suspended-sediment load was composed of silt and clay.

The Cibolo Creek watershed was the largest contributor of suspended sediment from the study area. The higher suspended-sediment yields in the Cibolo Creek watershed are likely because of steeper topography, more developed and cropland land cover, and more runoff than the other watersheds. For the entire study area, open/developed land and cropland exhibited the highest simulated soil erosion rates; however, the largest sources of sediment from the study area (by land-cover type) were pasture and forest/rangeland/shrubland, which account for about 80 percent of the study area and contributed about 70 percent of the suspended-sediment load.



Map Identifier	Station Short Name
1	SAR Elmendorf
3	SAR Falls City
4	Cibolo Selma
8	Cibolo Falls City
9	Ecleto Runge
10	SAR Goliad

DEVELOPMENT OF A VELOCITY-BASED QUANTITATIVE DESIGN METHODOLOGY FOR BENDWAY WEIRS

Nathan Holste, Hydraulic Engineer, Bureau of Reclamation, Denver, CO, nholste@usbr.gov

INTRODUCTION

Transverse features such as bendway weirs have become a popular alternative to traditional bank protection methods in recent years because they offer more environmental benefits and often have a lower cost. Bendway weirs are river training structures that redirect flow and energy throughout a channel bendway while moving the thalweg and most severe hydraulic forces away from the outer bank. Installation consists of a discontinuous field of multiple transverse structures placed in series and angled into the flow. A flat crest slope and low crest elevation distinguish bendway weirs from other transverse features such as spur dikes (flat, high crest elevation near top of bank) and vanes (upward sloping crest from low instream tip elevation to near top of bank). Scour at the weir tips due to flow acceleration shifts the thalweg toward the channel center. Eddies between the weirs may encourage variable depth, velocity, and sediment deposition that is favorable to aquatic species. Geometric based design guidelines are available in the existing literature such as HEC-23 (Lagasse et al., 2009) and NCHRP 544 (McCullah and Gray, 2005); however, no methodology exists to quantify the effects of bendway weirs on channel hydraulics.

A new method is presented that supplements existing geometric guidelines with an equation to predict velocity at inner, center, and outer channel locations as a function of bendway weir geometry. This equation was developed by researchers at Colorado State University (CSU) (funded by the Bureau of Reclamation) from data collected during a series of laboratory physical model tests. A group of physically significant terms was analyzed to develop the empirical, statistically-derived velocity ratio equation. The proposed method is illustrated with a design example for a project constructed in 2013 on the Rio Grande north of Albuquerque, New Mexico. Bendway weirs were implemented at this site to restore habitat in an incised river while stabilizing the eroding outer bank. A floodplain bench was also designed and constructed within the weir field to provide riparian habitat with energy dissipation at high flows. The combination of bendway weirs and a floodplain bench provides increased lotic and riparian habitat diversity and complexity at multiple flow stages while reducing hydraulic forces at the outer bank.

INITIAL ASSESSMENTS

Prior to beginning a detailed bendway weir design, an interdisciplinary project team should be assembled. Purpose, need, goals, and objectives must be well thought out, and a list of several alternatives should be developed and assessed. Typical considerations include fluvial geomorphology, engineering, ecology, economics, and constructability. A project that addresses the causes of channel instability and is compatible with the desired river form and function will be the most effective. The selected alternative is the option that best accomplishes the project team's goals within the identified constraints. The remainder of this paper assumes that bendway weirs have been selected as the preferred alternative, although some of the initial assessments described below should be completed during the alternatives evaluation.

Conduct Geomorphic Analysis: It is important and often difficult to distinguish local instability from system instability. A dynamically stable system will still exhibit local adjustments such as channel lengthening through bank erosion in growing meander bends that is offset by cutoffs at other bends. Local instability exists where there are adjustments at individual locations, while reach-averaged parameters such as hydraulic geometry and slope remain steady. Conversely, system instability propagates throughout a stream network as a result of water and sediment discontinuity, changes to downstream base level, and land use changes. System instability is visible through reach-wide aggradation, degradation, or

planform metamorphosis (Watson et al., 2007). Transverse features such as bendway weirs may not be appropriate or effective if reach-wide instability exists.

For the Rio Grande project site, it was determined that the eroding bank was not the result of system instability, thus suggesting that goals could be achieved through a local project without being jeopardized by reach-scale factors. Historical aerial photos were used to calculate reach sinuosity over time compared to the local sinuosity trends. Cross section surveys, longitudinal profiles, and a low flow specific gage analysis (i.e., stage vs. specific discharge at a nearby gaging station) showed that the reach bed elevation had been relatively stable over time. Other important geomorphic factors that were considered include hydrology, sediment supply, bed and bank material, channel width, and slope.

Determine Hydraulic Conditions: Hydraulic modeling is recommended as a component of a robust bendway weir design methodology. Depending on project goals, risks, and resources, multi-dimensional modeling can provide significant benefits when evaluating hydraulics associated with transverse features. However, 1-D models have the advantage of less intensive data requirements and can be set up and run relatively quickly. Executing a hydraulic model requires the selection of flow rates that are important for the design and analysis. The design flow will depend on individual project conditions and is typically specified with a return period or frequency. Appropriate design flows for bendway weirs often have a return period between five and twenty-five years. The following hydraulic conditions at the design flow should be determined for use in the CSU velocity ratio equation: (1) bend-averaged, cross section averaged channel velocity, (2) bend-averaged channel top width, (3) bend-averaged maximum channel depth, (4) bend-averaged water surface elevation, and (5) bend-averaged channel cross-sectional flow area. Main channel values should be used instead of the entire cross section values because bendway weir performance is primarily affected by main channel hydraulics, and the CSU physical model was not constructed to include a floodplain. The mean annual peak flow and base flow, and their associated water surface elevation and depth, are also needed for the geometric design guidelines.

Determine Rock Size: Transverse, discontinuous features are subject to more direct and severe hydraulic forces than longitudinal, continuous methods of protection such as traditional riprap revetments. A comprehensive, quantitative method for determining rock size of transverse features is not available in the existing literature. However, de Almeida and Martin-Vide (2009) performed an experimental study to compare riprap stability for transverse, longitudinal, and continuous protection methods. They tested a transverse bed sill structure and proposed a range of discontinuity factors to increase riprap size based on protrusion height above the bed and length of protection. The discontinuity factor allows riprap sizing results from the Maynord equation (Maynord et al., 1989) to be converted to a transverse rock size. For the Rio Grande project site, a bendway weir D_{50} rock size of 24 inches was determined by applying a discontinuity factor of 2.5 to a calculated riprap revetment size of 9.6 inches.

It should also be noted that NRCS (2007) recommends that the riprap size of stream barbs should be twice the size determined from standard riprap sizing criteria. NCHRP 568 (Lagasse et al., 2006) evaluated seven of the most commonly used revetment riprap sizing equations and recommended the EM 1601 equation (USACE, 1994) on the basis of discriminating between stable or failed riprap, bank and bend correction factors, and the reasonableness of safety/stability factors. The EM 1601 equation is similar to the Maynord 1989 equation with additional safety and correction factors.

Estimate Scour Depth: Properly estimating and designing for scour is an important element of any stream erosion countermeasure project. Transverse features such as bendway weirs typically experience the largest scour (depth and volume) near the tip or nose of the structure. Scour holes that form adjacent to or underneath bendway weirs will cause riprap from the structures to launch into the scour holes, potentially leading to failure. The goal of this design component is to provide enough riprap volume so that the bendway weirs can adjust to any scour without compromising their function. More specifically,

the crest elevation and tip location should be maintained after some of the sacrificial riprap falls into the scour hole. Bendway weirs can be keyed into the bed if practicable to account for scour, but this is difficult unless construction occurs in dry conditions.

An extensive, but not exhaustive, review of scour equations was conducted to identify several methods that would be appropriate for the Rio Grande project site. The selected scour equations can be categorized as a mean velocity equation, regime equations, bend equations, and a transverse structure equation. Table 1 presents the calculated scour results along with notes describing specific methods. The equations are generally empirical and were developed from lab or river measurements for a given set of conditions. Most of the equations represent a best-fit curve, although the USACE (1994) method is an upper envelope curve designed to overpredict scour for about 95 percent of the data.

Table 1 Scour equation results (at design flow of 14,200 cfs).

		Regime Equations[1]			Bend Equations			
	Mean Velocity[1]	Neill (1973)	Lacey (1930)	Blench (1969)	Maynord[2] (1996)	Zeller[2] (1981)	USACE[3] (1994)	Blench[4] (1957)
Total Scour[5]	5.43	5.61	3.88	4.31	5.21	7.57	9.67	5.65
Total Scour (w/SF = 1.1 if applicable)	5.97	6.17	4.27	4.74	5.21	7.57	9.67	6.21
Average = 6.23 ft		Median = 6.07 ft		**Design Scour Depth = 7 ft**				

[1]Reference: Pemberton and Lara (1984)
[2]Developed for sand bed rivers, assumed conservative for gravel bed (no safety factor)
[3]Upper envelope curve (no safety factor)
[4]Cox (2005) compared 10 equations to lab bendway weir results and found that the Blench (1957) equation had the best prediction of observed scour depths
[5]Includes general, bend, and thalweg scour components. No long term scour component was included because of reach bed stability.

The design scour depth can be used to estimate the riprap volume needed to protect bendway weirs from failure due to scour. As a means of simplifying the analysis of a complex three-dimensional process, the scour pattern was examined within the context of a typical cross section view of the bendway weir tip. It is assumed that riprap will launch into the scour hole at the angle of repose and form a type of revetment that is similar to longitudinal, continuous bank protection. USACE (1994) and NCHRP 568 (Lagasse et al., 2006) recommend a revetment thickness of $1.5*D_{50}$ or D_{100}, whichever is greater. The D_{100} is largest for the example project, resulting in a 4-ft revetment thickness. At the angle of repose, a simplified parallelogram representing the launched riprap has a top and bottom width of 6 ft, resulting in an area of 42 ft^2 at the design scour depth. Incorporating a safety factor of 1.5 to account for uncertainties during the launching process yields a cross-sectional area of 63 ft^2 at the tip that should be available for scour. This is in addition to the area required to maintain the design crest elevation and tip location, which can be calculated based on a minimum a crest width of at least $1* D_{50}$ (2 ft) after scouring occurs. The cross-sectional area is a function of the crest width, weir height, and side slope angle. (Bottom width is also governed by crest width, weir height, and side slope.) The constructed bendway weir cross section side slopes were set at 1.5H:1V (34°), which is slightly flatter than the riprap angle of repose for increased stability.

INITIAL GEOMETRIC DESIGN

After completing the initial assessments, the next phase of the proposed design methodology is to incorporate established geometric design guidelines for bendway weirs. The most important geometric parameters that govern bendway weir function and effectiveness are length, planform angle, spacing, and

crest elevation (height). Other bendway weir variables that must be specified in the design include top width and key length. HEC-23 (Lagasse et al., 2009) and NCHRP 544 (McCullah and Gray, 2005) provide recommendations for determining these geometric components. A range of values is determined for each geometric parameter and the CSU velocity ratio equation is subsequently used for optimization.

Sketch Desired Thalweg and Bank Line Location: An important conceptual factor when designing a bendway weir field is the location of the bendway weir tips. Derrick (2012) recommends laying out the desired thalweg relocation throughout the bend and then placing the stream ends of the bendway weirs just short of the anticipated thalweg realignment. Smooth upstream and downstream transitions should be included, and different attack angles at a variety of flow stages should be considered. If a floodplain bench is included such as for the Rio Grande example project, this alignment should be determined as well. Historical aerial photos provide a useful tool for laying out the thalweg and floodplain bench location, and a previously observed stable channel alignment may be a helpful template for the new alignment.

Determine Key Length: Bendway weirs must be keyed into the bank to prevent the structures from being flanked if lateral erosion continues at the site. The Rio Grande bendway weir design is slightly unusual because a majority of the total bendway weir length is buried within the floodplain bench, which can be considered as part of the key. GIS was used to draw the alignment of the key terminus using the following two methods, and the most conservative length was selected at each bendway weir location.

(1) Assuming that all of the floodplain bench fill material is eroded, HEC-23 states that the key length should not be less than 1.5 times the total bank height. For a nominal bank height of 10 ft the required key length is 15 ft, so the existing top of bank was offset by this distance.
(2) The maximum probable erosion based on historical aerial photographs was estimated to be 85 ft, so the floodplain bench bank line was offset by this distance.

It should be noted that HEC-23 also provides a method to estimate key length as a function of weir length and spacing, and this result should be compared to the above methods after the final geometry is determined.

Determine Weir Crest Width: HEC-23 and NCHRP 544 both recommend a crest width of (2 to 3)*D_{100}. Therefore, a range of recommended crest widths between 8 and 12 ft corresponds to the selected riprap size (D_{100} of 4 ft). A crest width of 8 ft was chosen for the portion of the weir buried within the floodplain bench and 12 ft was selected for the weir tip exposed to the flow to accommodate the required scour volume.

Determine Weir Length: Bendway weir length can be defined as the length along the crest axis, measured horizontally from water's edge at the design flow. (Effective length is a different parameter that also incorporates planform angle and is measured perpendicular to the bank tangent.) Both HEC-23 and NCHRP 544 recommend a minimum and maximum weir length as a function of stream width as shown in Table 2. The bend-averaged channel top width is 202 ft, which was calculated by averaging the bank-to-bank widths at cross sections within the bend. A range of bendway weir lengths between 20 ft and 100 ft was considered when analyzing geometry effects with the CSU equation.

Table 2 Recommended bendway weir length.

Design Guideline	Minimum	Maximum
HEC-23	Tw/10 = 20 ft	Tw/3 = 67 ft
NCHRP 544	Tw/3 = 67 ft	Tw/2 = 101 ft

Determine Weir Planform Angle: Bendway weirs are angled upstream so that flows over the top of the structure are redirected away from the outside bank and toward the channel centerline. HEC-23 states that

the angle of projection between the bendway weir axis and the upstream bankline tangent typically varies from 60 to 80 degrees. The NCHRP 544 planview diagram shows potential angles ranging from 45 to 90 degrees measured from the upstream bankline tangent. NCHRP 544 states that the most common and preferred angles are between 70 and 80 degrees. Therefore, angles from 60 to 80 degrees were considered for the Rio Grande bendway weir design.

Determine Weir Spacing: Bendway weir spacing is the distance between the centerline axes of two consecutive weirs as measured along the bankline. Spacing is determined by the radius of the bend and the length of the bendway weirs. HEC-23 provides two equations (S_1 and S_2) that establish a range of feasible weir spacing values and a third equation (S_{max}) to calculate the maximum spacing. All three equations are a function of weir length so results are dependent on whether the maximum or minimum length is used. NCHRP 544 outlines a simpler approach where only one recommended equation is provided to calculate spacing as a multiple of weir length. All of these equations and the calculated results are summarized in Table 3. The spacing values considered for additional analysis with the CSU equation varied between 85 ft and 190 ft for the Rio Grande project. Given the length of the bend to be protected (~760 ft), the total number of weirs could be as many as 9 (spacing ~85 ft) or as few as 4 (spacing ~190 ft). Increasing the number of weirs to 10 or more results in only small changes in spacing for each additional weir and was not cost effective.

Table 3 Recommended bendway weir spacing.

Design Guideline	Minimum*	Maximum†
HEC-23	$S_1 = 1.5L\left(\frac{R_c}{T_w}\right)^{0.8}\left(\frac{L}{T_w}\right)^{0.3} = 24ft$ $S_2 = (4\ to\ 5)L = 81ft$ $S_{max} = R_c\left(1-\left(1-\frac{L}{R_c}\right)^2\right)^{0.5} = 119ft$	$S_1 = 1.5L\left(\frac{R_c}{T_w}\right)^{0.8}\left(\frac{L}{T_w}\right)^{0.3} = 115ft$ $S_2 = (4\ to\ 5)L = 337ft$ $S_{max} = R_c\left(1-\left(1-\frac{L}{R_c}\right)^2\right)^{0.5} = 210ft$
NCHRP 544	$S = 1.5L = 101ft$	$S = 1.5L = 152ft$

*from HEC-23 (L_{min} = 20 ft) and NCHRP 544 (L_{min} = 67 ft) minimum lengths
†from HEC-23 (L_{max} = 67 ft) and NCHRP 544 (L_{max} = 101 ft) maximum lengths

Determine Weir Height: As discussed, bendway weirs are low elevation structures where the crest must be overtopped to work as designed. Weir height is not clearly defined in the existing literature because all typical cross section schematics show a flat riverbed. In field applications, the riverbed undulates significantly in both the transverse and longitudinal directions. For this reason it is easier to define a weir crest elevation rather than a weir height. Therefore, the existing height recommendations should be converted to a difference between the crest elevation and water surface, rather than a height above the bed.

HEC-23 recommends that weir height should be 30 to 50 percent of the depth at the mean annual high water level. It is not clear if the depth at mean annual high water level is the maximum depth (thalweg depth) or average depth (hydraulic depth). The suggested interpretation of this guideline is that the weir crest elevation should be the water surface at the mean annual peak flow minus 70 to 50 percent of the bend-averaged maximum channel depth. It is assumed that HEC-23 refers to maximum depth because it also states that bendway weirs should cross the stream thalweg. NCHRP 544 shows that the crest elevation should be within (+/–) 1 ft of the typical base flow water surface elevation. Table 4 presents the results as interpreted from HEC-23 and NCHRP 544 and converted to a crest elevation. Crest elevations between 5505 ft and 5510 ft were analyzed for the Rio Grande site. The crest elevation of 5510 ft was

included based on the alternate HEC-23 interpretation using hydraulic depth, which results in recommended elevations that are about 2.5 ft higher than what is shown in the table for HEC-23.

Table 4 Recommended bendway weir crest elevation.

Design Guideline	Minimum	Maximum
HEC-23	(0.3H) → $WSE_{m.a.p.} - 0.7 \times D_{m.a.p.} = 5505.4\ ft$	(0.5H) → $WSE_{m.a.p.} - 0.5 \times D_{m.a.p.} = 5507.5\ ft$
NCHRP 544	$WSE_{base} - 1ft = 5507ft$	$WSE_{base} + 1ft = 5509ft$

FINAL VELOCITY-BASED DESIGN

The goal of a bendway weir field for bank protection projects is to minimize lateral erosion by reducing velocity and shear stress along the outer bank. Over the course of several years, CSU performed physical modeling of transverse structures in a trapezoidal, rigid bed channel as detailed by Heintz (2002), Darrow (2004), and Schmidt (2005). The model includes two distinct channel bends and was constructed at an undistorted, 1:12 Froude scale based on geometry of the Rio Grande. Scurlock et al. (2012) performed a statistical regression analysis of hydraulic results from 130 unique tests to develop predictive equations for maximum velocity ratio (MVR) and average velocity ratio (AVR). Channel planform zones were delineated as outer (o), center (c), and inner (i) locations throughout the bend so that MVR and AVR equations could be developed for each of the three locations. MVR is defined as the maximum velocity for a given channel location with structures installed divided by the bend-averaged velocity without structures ($MVR = Vmax_{structures}/Vavg_{baseline}$). AVR is defined as the average velocity for a given channel location with structures installed divided by the bend-averaged velocity without structures ($AVR = Vavg_{structures}/Vavg_{baseline}$).

The CSU velocity ratio equation is robust, but is also affected by significant limitations. The equation is generalized for all transverse features rather than being specific to bendway weir hydraulics. Spur dikes and vanes are included in the database because there were not enough bendway weir tests to generate a valid regression equation. Important elements of natural geometry and topography such as the pool depth ratio and cross-sectional transverse bed slope are also neglected because the modeled channel is prismatic. Therefore, it is not surprising that the trapezoidal equations have been found to underpredict outer bank maximum velocity for a channel with natural topography (Baird, 2014). Scurlock et al. (2012) also note that "maximum velocity data are difficult to capture spatiotemporally, and may behave erratically; therefore, the concept of AVR may represent a more reliable predictive method." There are currently a limited number of native bed model runs with bendway weirs, and the data are insufficient to develop a new regression equation. Equation 1 and Table 5 present the regression coefficients used to predict velocity values for the Rio Grande design project. Scurlock et al. (2014) have since revised the coefficients based on a new statistical regression that excludes certain outlier points from the original dataset. The velocity ratio equation is comprised of dimensionless terms that represent the following parameters: an area contraction ratio, a spacing ratio, a channel curvature ratio, a lateral contraction ratio, a submergence ratio, and a planimetric angle ratio.

$$MVR, AVR = a_1(A^*)^{a_2}\left(\frac{L_{arc}}{T_w}\right)^{a_3}\left(\frac{R_c}{T_w}\right)^{a_4}\left(\frac{L_{w-Proj}}{T_w}\right)^{a_5}\left(\frac{D_B}{D_B-\Delta Z}\right)^{a_6}\left(\frac{\theta}{90}\right)^{a_7} \quad (1)$$

where:

$a_1, \ldots, a_7$ = regression coefficients

A^* = percent of baseline channel cross-sectional flow area blocked by transverse structure [percent]

L_{arc} = arc length (spacing) between centerline of structures, measured along bankline [ft]

T_w = bend-averaged baseline channel top width [ft]

R_c = centerline radius of curvature of channel bend [ft]
$L_{w\text{-}Proj}$ = projected length of structure into channel, measured horizontally from water's edge along perpendicular channel cross section at design flow [ft]
D_B = bend-averaged maximum cross-section baseline flow depth [ft]
Δz = elevation difference between water surface and structure crest at the tip [ft]
θ = structure planview angle, measured from upstream line tangent to bank [degrees]

Table 5 Coefficients for MVR and AVR regression equations (all data) (Scurlock et al., 2012).

Ratio Location	R^2	*MA%E*	a_1	a_2	a_3	a_4	a_5	a_6	a_7
MVRo	0.8429	20.8533	0.0068	0.0000	0.5546	0.3846	–2.1431	0.7003	0.3824
MVRc	0.8011	4.3100	0.3773	0.2695	0.0000	0.1973	–0.1563	0.0467	0.1155
MVRi	0.6087	4.4433	0.3400	0.3404	–0.1116	0.1065	–0.2084	0.0445	0.1580
AVRo	0.4861	40.7230	0.0138	0.0000	0.5917	0.7439	–1.1451	0.4629	0.5996
AVRc	0.7255	4.0327	0.3615	0.2710	–0.0739	0.1850	–0.1412	0.0536	0.1158
AVRi	0.7530	3.9452	0.1315	0.4894	–0.1308	0.1770	–0.4098	0.1170	0.1266

Determine Permissible Velocity: In order to use MVR and AVR to predict the physical effects of bendway weirs, the ratios must be analyzed within the context of existing baseline velocity and permissible velocity. Once the baseline velocity, MVR, and AVR are known, the predicted velocities with bendway weirs can be compared to the permissible velocities to determine if erosion is expected to continue at the site. Permissible velocity is primarily a function of the bed and bank material in addition to vegetation characteristics. It is expected that bank erosion would be greatly reduced if the predicted maximum and average velocities with bendway weirs are less than the permissible velocities along the outer bank. Channel centerline and inner bank velocities are important to the river conditions downstream of the protected bend and to the point bar across from the bendway weirs. As flow velocity is reduced along the outer bank due to bendway weir installation, it is likely that velocity will increase along the channel centerline and inner bank. This may cause erosion of the point bar and increased velocity downstream. Table 6 summarizes the maximum and average permissible velocity ratios at the outer, center, and inner channel locations for the Rio Grande example project. The bend-averaged baseline velocity at the design flow (5.81 ft/s) was used to convert permissible velocities to corresponding velocity ratios. Several references such as Kilgore and Cotton (2005) and Fischenich (2001) provide methods to determine permissible velocity as a function of soil and vegetation characteristics. Rock stability at the weir tips is a consideration when selecting center permissible velocity, and the inner permissible velocity will depend on the desired point bar characteristics and historical lateral migration. Downstream effects should also be considered when selecting inner and center velocities. Average velocities can be set at an appropriate ratio of maximum permissible velocities (e.g., 75 percent) based on local conditions.

Table 6 Permissible velocity ratios for Rio Grande bendway weir design.

MVRo = 0.34	AVRo = 0.26
MVRc = 1.72	AVRc = 1.29
MVRi = 2.07	AVRi = 1.55

Use Velocity Equation to Iterate Range of Geometric Parameters: A median or most recommended value should be selected for each of the primary geometric parameters in addition to the range described above. The median value for three of the parameters can be held constant while varying the fourth parameter over the complete range determined from the geometric guidelines. These predicted velocity results should then be plotted and compared to the permissible velocity to examine the sensitivity and effect of each parameter. Figure 1 shows the results from the Rio Grande design project. The y-axis is percent difference compared to the permissible velocity, and the x-axis is the value of the geometric

parameter that is being adjusted. A negative percent difference means that the predicted velocity with bendway weirs is less than the permissible velocity. A positive percent difference means that the predicted velocity is greater than the permissible velocity and erosion would be expected. All of the recommended geometric parameters from HEC-23 and NCHRP 544 yield acceptable velocities for this example, except for very short weir lengths (less than about 38 ft). It should be noted that weir lengths less than about 30 ft for this site fall outside the bounds of configurations tested in the laboratory. The weir angle results are somewhat counterintuitive because of the relationship between angle and projected length. After completing the graphs, the desired velocity reduction and safety factor should then be used to select a narrowed range of parameter values for final analysis. This narrowed range is represented by vertical lines in the plots shown below.

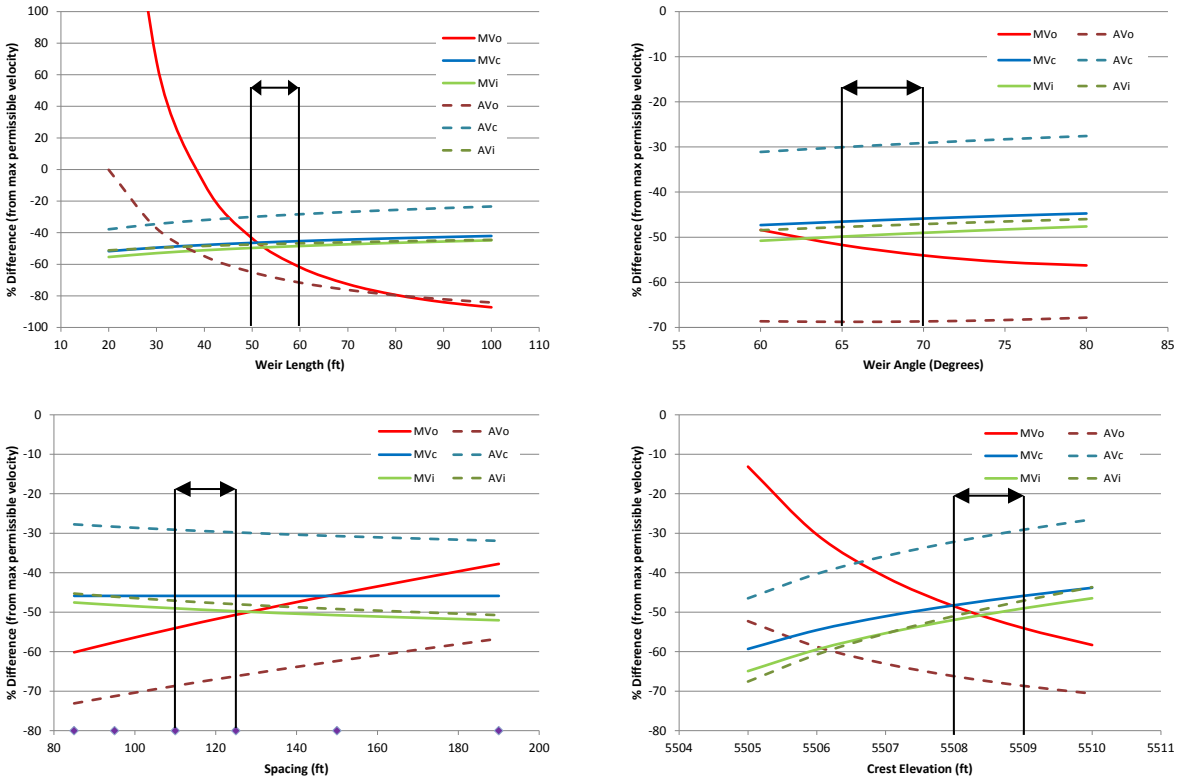

Figure 1 Velocity comparison as a function of weir length, angle, spacing, and height.

Finalize Bendway Weir Geometry: A matrix of potential final geometric values should be developed from a narrowed range based on the initial velocity calculations. The construction precision should also be accounted for, such as specifying elevation to the nearest 0.5 ft or 1 ft and specifying angles to the nearest 5°. For the Rio Grande project, the matrix consisted of 24 possible combinations based on 3 length values, 2 angle values, 2 spacing values, and 2 height values. The predicted velocities were then recalculated for every combination and plotted on a new graph. This is different than the initial iterations where only one geometric parameter was changed at a time. The selected values result in predicted maximum outer bank velocities that vary from 28 to 62 percent below the maximum permissible outer bank velocity. MVc, MVi, AVc, and AVi all remain fairly constant, but increase slightly as MVo and AVo are reduced. The final design is summarized in Table 7 and was selected based on: (1) a predicted MVo at least 50 percent smaller than the permissible MVo, (2) a balance of MVo reduction without an excessive increase in MVc and MVi, and (3) compatibility with existing bendway weirs installed further downstream in 2007. There is a balance between obtaining the greatest outer bank velocity reduction

while minimizing the amount of rock that is used for construction. Specifying a predicted MVo that is 50 percent less than the permissible MVo is similar to a safety factor of 2, although the difference in raw velocity values is only 1 ft/s.

Table 7 Design summary of final bendway weir geometric parameters.

	Exposed (active) Length*	Buried (key) Length	Total Weir Length	Angle	Spacing	Crest Elevation†	Top Width
Weir #1	37 ft	94 ft	131 ft	70°	105 ft	5509 ft	12 ft (exposed section); 8 ft (buried section)
Weir #2		98 ft	135 ft				
Weir #3		98 ft	135 ft				
Weir #4		123 ft	160 ft				
Weir #5		107 ft	144 ft				
Weir #6		90 ft	127 ft				
Weir #7		90 ft	127 ft				

*Original design length of 55 ft was modified to allow for placement of additional floodplain bench material so that final cut and fill volumes are balanced (see next section)

†On average, the modeled WSE drops about 0.6 ft between Weir #1 and Weir #7

Design Complementary Project Features: Bendway weir function and performance can be greatly improved with the addition of other compatible project features. Three additional components were included for the Rio Grande design example: point bar excavation, floodplain bench construction, and willow pole planting. Other features that should be considered are longitudinal stone toe, bioengineering, and locked logs. It may also be possible to retrofit existing projects with bendway weirs to improve aquatic habitat, relocate the thalweg, and manage energy throughout the bend. Although bendway weirs are low elevation structures, they block a portion of the main channel flow area and could reduce the effective channel width so excavating from the inner bend prevents channel narrowing. Maintaining sufficient channel width is important because a wider, shallower channel results in lower velocity and shear stress than a deep and narrow channel. Excavating the point bar at two different depths provides effective water and sediment transport with variable habitat over a range of flows. For the Rio Grande project, the upper point bar surface was also set at an elevation that promotes wetland establishment.

Creating an inset floodplain bench accomplishes the dual purpose of providing a cost effective method of disposing of the excavated material while offering significant hydraulic and environmental benefits. Reestablishing a floodplain surface allows higher flows to spread out at a shallower depth, thereby reducing velocity. Also, eddies that occur between the bendway weirs will cause scalloping of the floodplain bench rather than eroding the existing bankline. Figure 2 and Figure 3 illustrate the final design for the Rio Grande example project. An iterative process was used to design the floodplain bench and bar excavation elevation and alignment. The primary considerations while determining the floodplain bench elevation included depth to groundwater, typical inundation duration, and locations of existing willows near the site. A Reclamation biologist helped evaluate these factors and an average elevation of 5510.5 ft was selected for the floodplain bench. This is about 2.5 ft above the assumed groundwater table (base flow elevation) and corresponds to a river discharge of 3,500 cfs (1.25-yr return period). Balancing cut and fill volumes required a wider floodplain bench than originally estimated, thereby shortening the bendway weir length protruding into the flow. A final iteration was performed with the CSU velocity equations to refine the bendway weir layout based on the final floodplain bench design. A grid of coyote willows is included on the floodplain bench to stabilize the soil and create additional habitat. Vegetation provides increased hydraulic roughness to further reduce flow velocity and potentially encourage sediment deposition. Planting the willows in a grid pattern ensures that the technique will be effective regardless of flow rate and direction. It is essential that willow poles reach and maintain contact with groundwater to provide the best opportunity for survival.

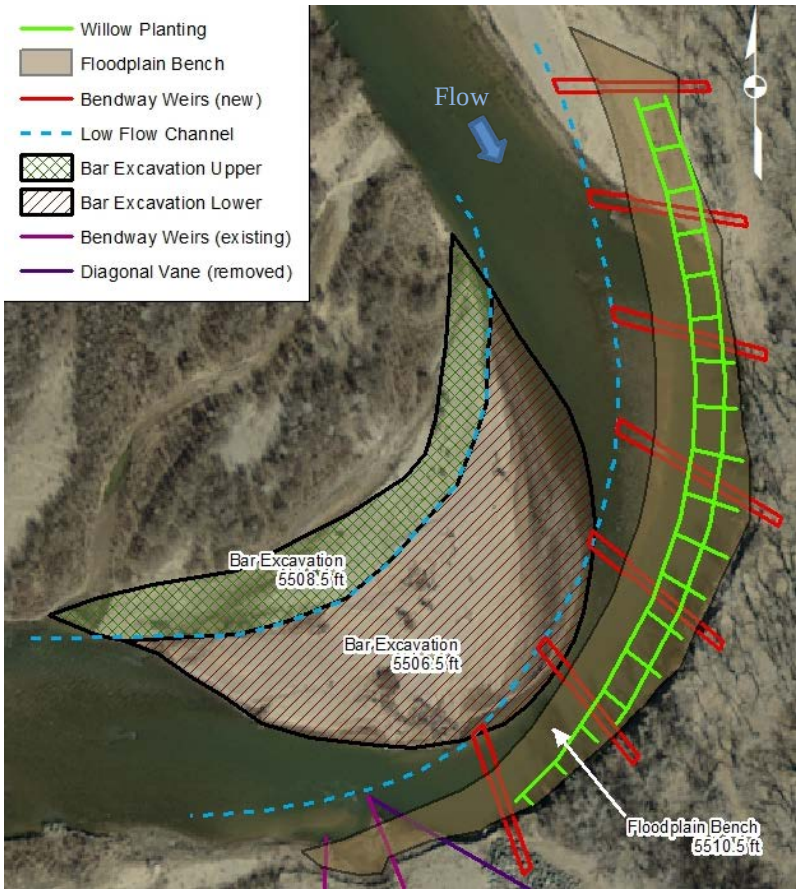

Figure 2 Site Plan with final location of project features.

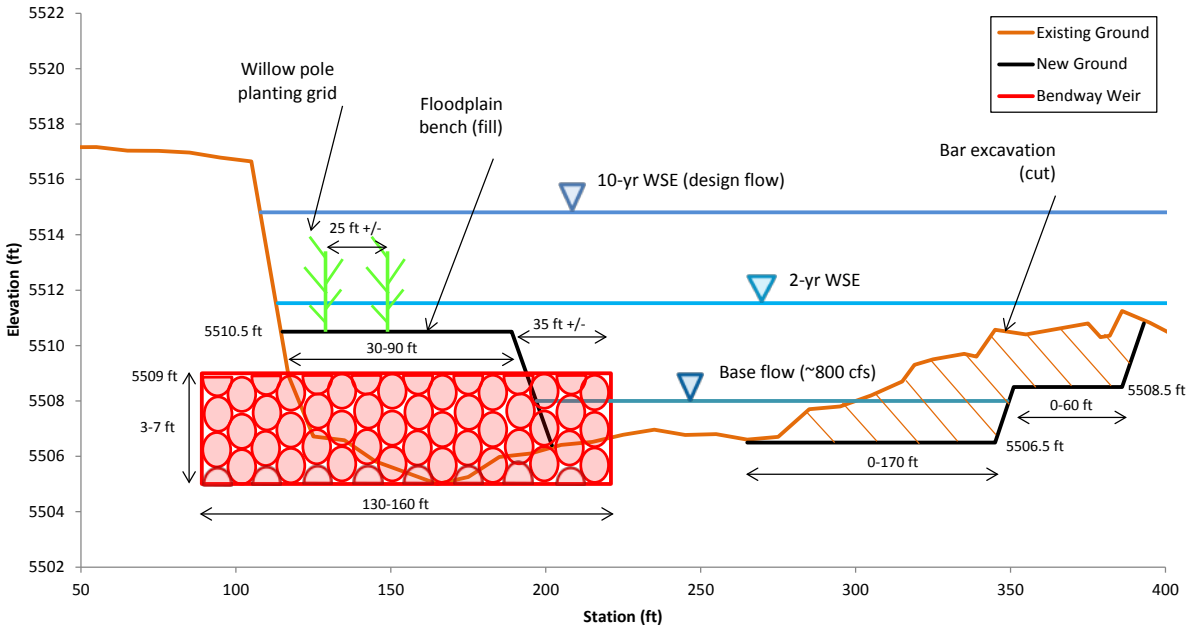

Figure 3 Typical cross section (looking downstream) with dimensions.

Summary and Recommendations: A bendway weir design methodology was described and illustrated with an example project that was constructed in 2013 on the Rio Grande north of Albuquerque, New Mexico. This project has only experienced two low spring runoff years since construction, but there have been a few high flow monsoon events. Sediment has been deposited along the bendway weirs and on the floodplain bench, indicating that the project has been effective so far. Existing guidelines were used near the beginning of the design process to establish a framework of feasible values for important geometric parameters. The existing guidelines do not quantify the effect of bendway weirs on channel hydraulics. However, they are based on field experience and designs of previous projects and should not be discounted. The CSU velocity ratio equation allows channel velocity to be predicted as a function of different bendway weir configurations. Comparing predicted velocities to the permissible velocity provides a method to estimate if the bendway weirs will be effective in preventing future bank erosion. Scurlock et al. (2012 and 2014) should be reviewed for a more detailed description of the velocity ratio equation including the range of applicability. This is an area of ongoing research by CSU for the Bureau of Reclamation, which includes the development of a 3-D numerical model.

It is recommended that an as-built survey be completed soon after construction to document field conditions of completed projects. This is important regardless of the design methodology and provides a reference for evaluating future adjustments. Bendway weir projects should be monitored for performance over time, particularly during and after high flow events. The level of monitoring can range from visual observations to more sophisticated data collection techniques. Surveys of the river channel and banks can be compared to as-built data to evaluate erosion and deposition patterns. Monitoring bendway weir tip location, crest elevation, and crest width will indicate if the riprap has been mobilized and if the structures are still functioning as intended. Measuring velocity and water surface elevation throughout the bend during high flow events will provide valuable hydraulic information that can be used to evaluate the CSU equations and the effects of bendway weirs on the flow.

PERFORMANCE OF LOG CRIBS FOR BLUFF STABILIZATION

Ben Lee, Hydraulic E.I.T.,' Inter-Fluve, Madison, Wisconsin, blee@interfluve.com; Marty Melchior, Regional Director, Inter-Fluve, Madison, Wisconsin, mmelchior@interfluve.com; Andy Selle, Hydraulic Engineer and Fisheries Biologist, Inter-Fluve, Madison, Wisconsin, aselle@interfluve.com; Ben Swanson, Ph.D, Fluvial Geomorphologist, Inter-Fluve, Madison, Wisconsin, bswanson@interfluve.com

INTRODUCTION

Erosion of valley walls and terraces associated with channel migration often produce high, steep erosional features, known as bluffs, along channels. In some rivers and streams, bluff erosion can add a disproportionate volume of sediment to the overall load, creating a host of ecological and sediment conveyance problems (Fitzpatrick et al., 1999; Belmont et al., 2011). A range of stabilization techniques are applied to bluffs with various levels of success. An approach that targets the toe of the bluff using natural log materials, often available on site, appears to be a low cost and effective approach to stabilization.

The technique involves constructing a log crib that mimics natural wood accumulation and provides the foundation for a floodplain bench at the toe of the bluff. The wood forms a rigid, structural treatment while also providing organic material and complexity similar to habitat features in natural streams. The creation of a floodplain bench above the wood impedes rotational failure of the upper bluff and allows recruitment of vegetation that will provide long-term stabilization. The bench also catches material that erodes from the untreated upper bluff. The approach is being applied to streams in the Midwest as (1) the benefits of woody material in streams have been shown to improve aquatic and riparian habitat (Flebbe, 1999; Zorn and Nuhfer, 2007; Kratzer and Warren, 2013), (2) it works with a natural process whereby eroding bluffs in forested watersheds contribute woody debris that impedes further erosion of the toe, and (3) the method is relatively cost effective as materials can be locally sourced and the upper bluff is not directly stabilized.

The installation and performance of the log crib and bench approach has not been well documented. While the log crib approach has been used in the past, it has been primarily used for stabilizing eroding banks rather than higher terraces or bluffs (Krymer and Robert, 2013). Furthermore, these designs have been based on a symmetrical form rather than one that mimics natural debris accumulations. We have developed an approach using log cribs with a bench that is based on more natural wood recruitment patterns to improve fish habitat while also providing bluff stabilization.

Clark Creek is a small, step-pool and plane-bed stream that meanders through glacial sands and gravels. The channel contains cold water and provides habitat for native brook trout (*Fontinalis salvelinus*). Avulsion and channel migration during floods in recent decades have resulted in stream migration toward bluffs at the edge of the valley, creating sedimentation problems and impacting aquatic and riparian habitat. To address these problems while improving aquatic habitat, we have installed log cribs and monitored their performance. Construction occurred in October, 2013, and subsequent surveys continue to provide information on the performance of the design.

REGIONAL SETTING

Clark Creek lies along the north-facing slope of the Baraboo Hills in south-central Wisconsin. The headwaters of the stream consist of hillslope debris overlying Baraboo Hills quartzite bedrock (Clayton and Attig, 1990). The middle of the watershed is located in a glacial ice-margin lake basin that filled a valley within the Baraboo Hills as the Green Bay Lobe of the Wisconsin Glaciation prevented drainage to the north. The lower watershed is located in glacial till (Clayton and Attig, 1990). Sediments throughout the middle and lower part of the watershed are primarily sand with some gravels, cobbles and localized varved clay deposits.

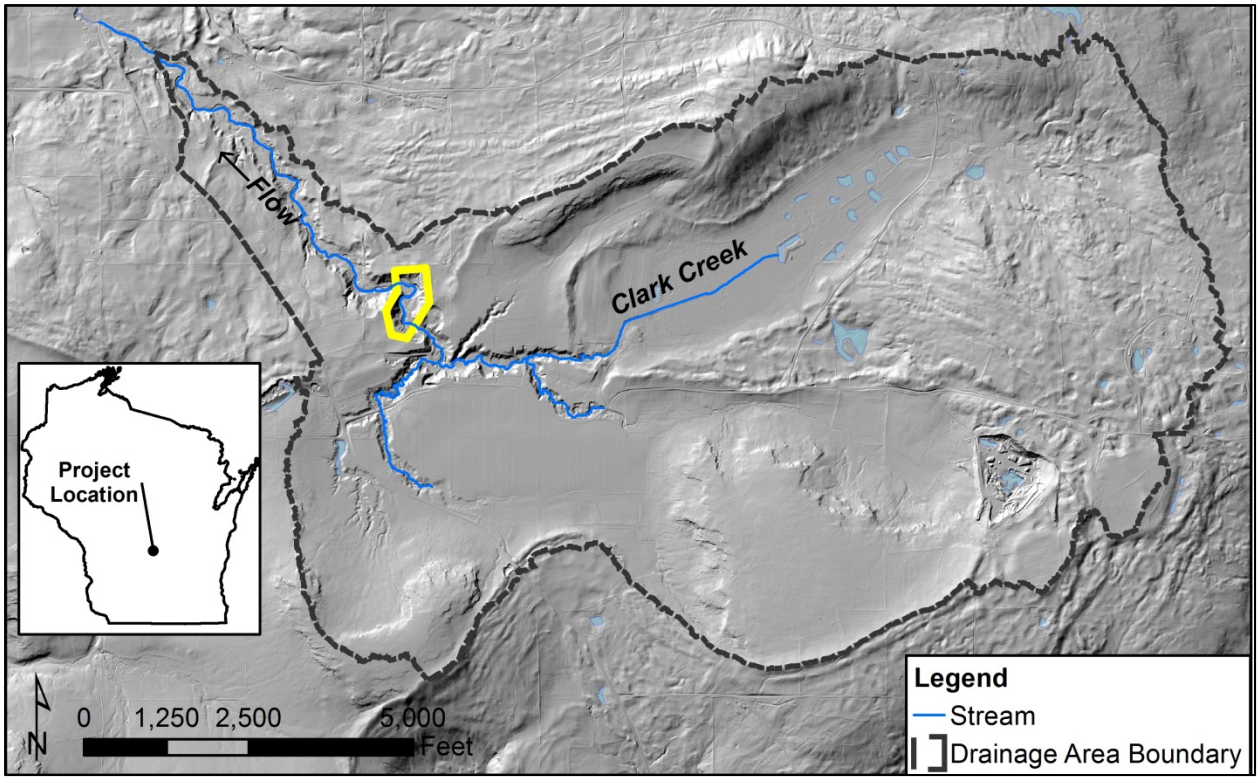

Figure 1 Clark Creek location, watershed topography and perennial flow reaches (blue lines).

GEOMORPHIC HISTORY

Clark Creek runs through a relatively confined valley in the transitional area between the glacial ice-margin lake and tills. Valley widths through the site average 150 feet. Longitudinal valley slopes are 1-2%.

Large flood events in 1993 and 2008 initiated incision and channel avulsion (Figure 3). The 1993 flood was estimated to have a recurrence interval of 500 years and the 2008 flood was estimated to have a recurrence interval of 100 years (Montgomery Associates, 2011). Based on evidence from former channel locations and an abandoned culvert, bed elevations dropped three to five feet. Incision was greatest in the eroded bluff reach due to the removal of riparian vegetation within the last century. In less disturbed reaches, riparian vegetation and other roughness features provided natural resiliency that impeded further incision.

In 2013, channel slopes varied depending on location relative to the bluffs. Adjacent to the eroding bluffs, the channel had a step-pool morphology with slopes up to 7%. Between the bluffs, the channel had a plane-bed morphology with gradients around 1-2%. The steeper slopes developed as cobbles and boulders in the glacial till comprising the bluffs deposited at the toe. This larger material, lag, was immobile and allowed the grade to steepen as fine sediment transported downstream. Despite the coarse material contributed to the channel by the bluffs, the majority of the material in the bluffs consists of sand (see Figure 2).

Reaches downstream of the eroding bluff reach did not experience the same depth of incision. The bankfull channel appeared to be adjusted to recent discharge and sediment supply regimes. Relatively low benches had formed adjacent to the channel which supported vegetation at least three years old and some minor sand deposition. The average width of the channel in this reach was around 16 ft with a depth of 1.5 ft.

Figure 2 Photo of Bluff 1 in April, 2013 (looking upstream). Note the coarse lag material deposited in the channel and bluff toe that has formed steps. Exposed sediments along the inside of the bend are from the 2008 flood.

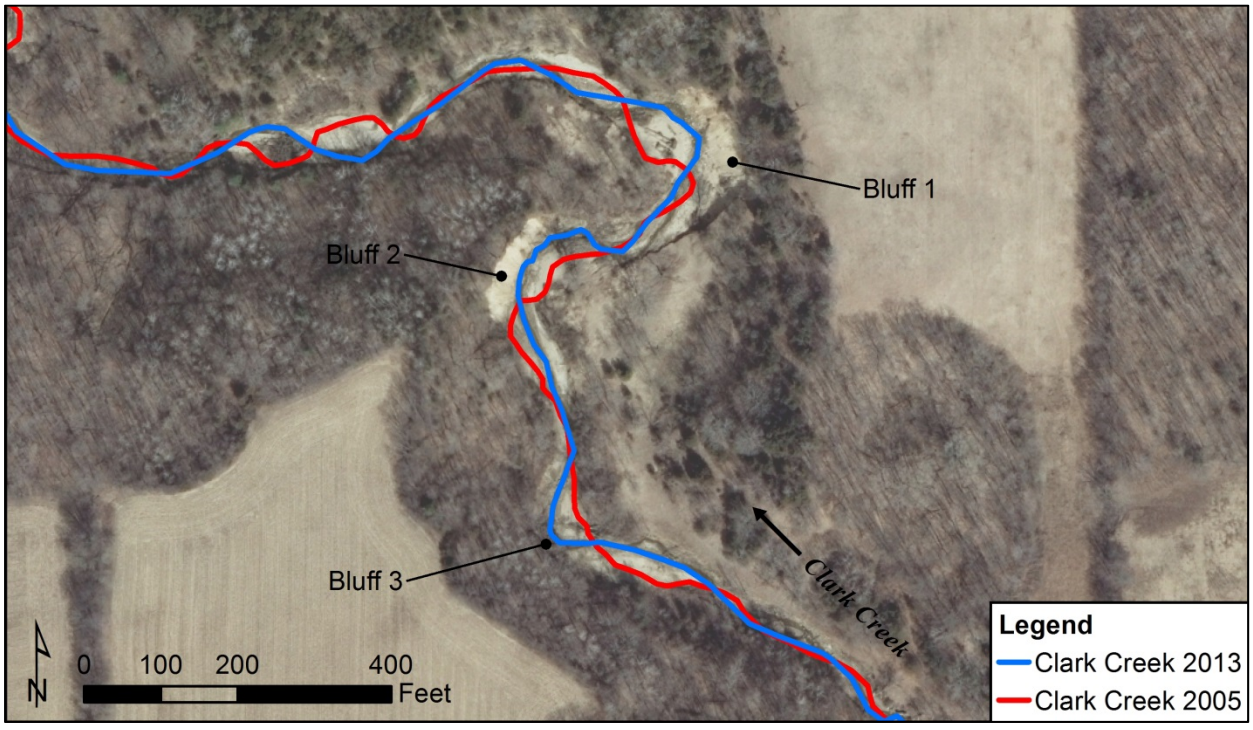

Figure 3 Channel alignments in 2013 and in 2005 before the 2008 flood event that created multiple avulsions.

PROJECT DESIGN

Stabilization of the bluffs involved three major design components: (1) re-aligning the channel away from the bluff toe, (2) building a log crib as the foundation for a floodplain bench at the toe of the bluffs, and (3) re-building the channel with native stone.

Channel Design

The channel was re-located away from each bluff toe to accommodate the log crib and bench (Figure 4). The width of the bankfull channel was based on the 16 ft average width observed along the downstream reference reach. The design called for a bank height along the log crib side of the channel of 3 ft; however, this value varied at Bluffs 2 and 3 where heights around 5 and 4 ft were constructed, respectively. The higher banks were due to the larger diameters of logs available to construct the cribs. Opposite the bluffs, channel bank heights were 1.5 ft, similar to the downstream reference reach.

Log Crib Design

Log cribs were constructed to impede erosion of the banks near the bluffs and provide a framework to contain soil for the constructed bench at the bluff toe. The benches were designed to (1) catch eroded material from the upper bluff, (2) create an area for vegetation establishment, and (3) resist rotational failure of the bluff. Constructed bench widths were approximately 23 ft at Bluff 1, 18 ft at Bluff 2, and 14 ft at Bluff 3. Each log crib was built at least 3 ft deeper than the channel bed elevation to account for local scour and additional minor incision that could occur in the future (Figure 4).

The cribs were comprised of four to five layers of logs. The angle of the logs in each layer was varied to provide habitat complexity and to better replicate the configuration of a natural log jam. Slash was incorporated into the jams to provide smaller interstitial spaces and additional organic substrate for macroinvertebrates and small fishes. Logs were sourced from nearby uplands and varied in diameter from 1 to 3 ft with lengths between 20 and 35 ft.

Channel Substrate Design

Stone from the original channel, supplemented with rock from nearby farm fields, was utilized for construction of the new channel. The median grain size of the existing channel bed material was 0.16 ft in plane-bed reaches and most stones in the step-pool reaches had diameters between 1 and 2 ft. The incipient grain size for the designed channel was 0.8 ft during the 100-year flood (Bathurst, 1987), thus imported stone had diameters between 1 and 2.5 ft to ensure stability. Natural steps in step-pool channels were replicated with the imported rocks. The stones were also extended laterally into the floodplain opposite each log crib to provide resistant material should the channel migrate. The constructed channel slope was 4.1% at Bluff 1, 3.0% at Bluff 2, and 2.5% at Bluff 3. Distances between the steps averaged 15 ft at Bluff 1, 19 ft at Bluff 2, and 22 ft at Bluff 3. These distances were consistent with the existing channel and other comparable streams (Chin et al., 2009).

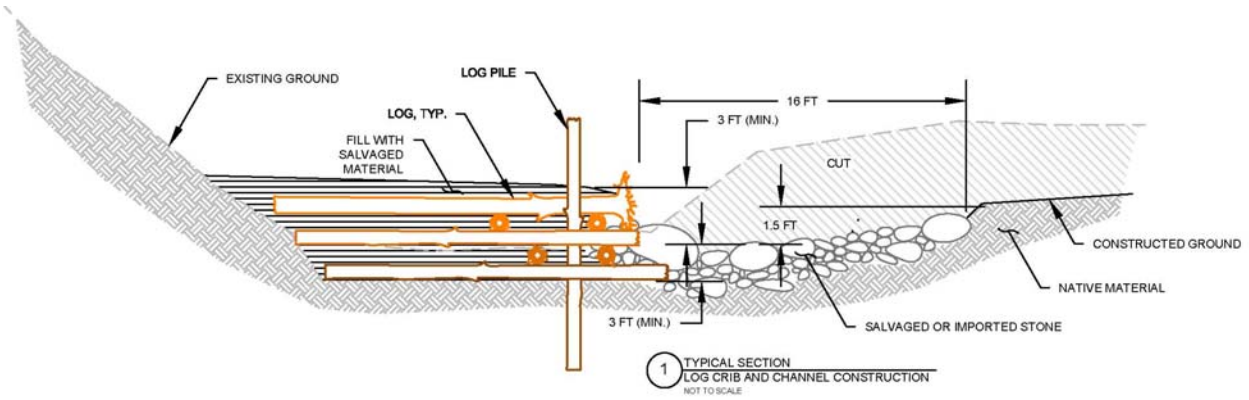

Figure 4 Typical cross section detailing the dimensions and materials used for construction of the log cribs, benches and channel.

Figure 5 Upstream view of Bluff 1 in November, 2013, immediately after construction. Logs with root wads form one side of the channel and steps and pools were constructed in the channel.

MONITORING METHODS

The topography of the bluffs and channel were surveyed at each of the three sites with a survey grade real time kinematic global positioning system. An as-built survey was completed in November, 2013, immediately after

construction. In June, 2014, a post-construction survey was completed to document changes following a six month period that included a flood with a 2.5-year recurrence interval. A final survey was completed in November, 2014, one year after construction. The final survey did not include complete coverage of Bluff 1 as snowfall inhibited characterization of the site.

Each survey included sufficient detail to construct a three dimensional surface model of the sites. The surveys included all breaks in grade along the channel, banks, adjacent floodplain, and the crib bench. With these data, triangulated irregular network (TIN) surface models were built in AutoCAD® Civil 3D®. Geomorphic changes between each survey were analyzed by creating volumetric TIN models that subtracted one survey from the previous. Geomorphic units were delineated in the models to quantify erosion and deposition patterns.

RESULTS

Bluff 1 experienced the greatest geomorphic change between November, 2013 and June, 2014 with about 60 cubic yards of material eroded from the left floodplain (Figure 6). The sandy sediments from the un-vegetated floodplain transported downstream during the 2.5-year flood and a new side channel formed. The eroded and designed channels conveyed water during base flow conditions in June. The extension of the rock steps into the left floodplain limited further downcutting into the floodplain. Within the main channel, 13 cubic yards of material deposited in pools while 18 cubic yards of material was eroded as the left bank adjusted. The bench above the crib experienced 36 cubic yards of deposition and 31 cubic yards of erosion. The erosion was likely a result of fill material settling after construction and the freeze-thaw cycle during the winter. Deposited material originated from erosion of the upper bluff.

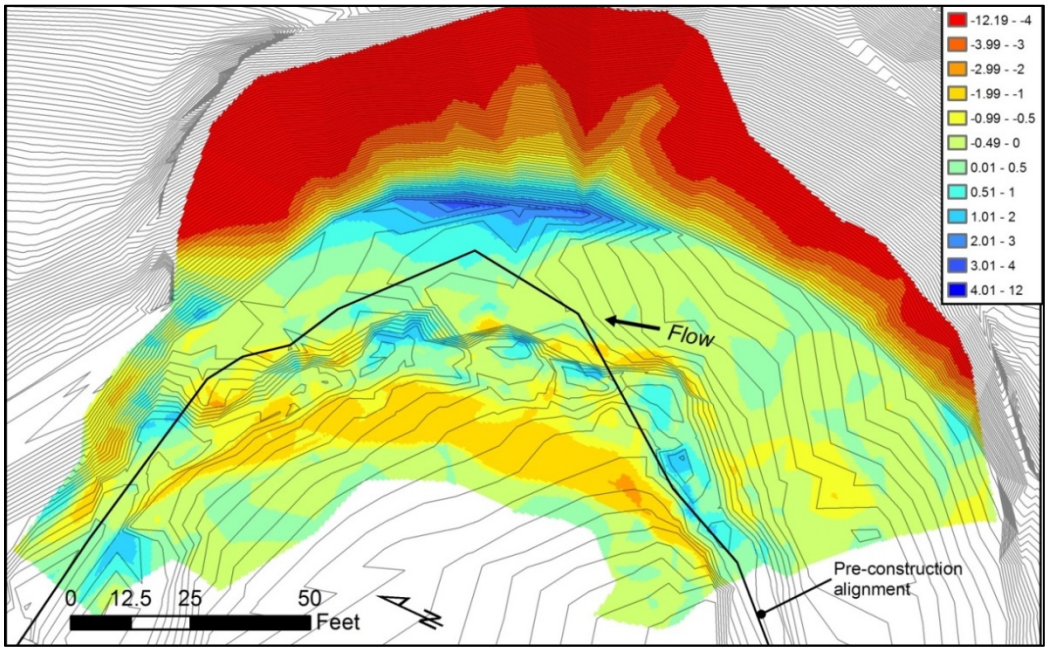

Figure 6 Erosion (red) and deposition (blue) at Bluff 1 between November, 2013, and June, 2014 (in feet). The 0.5 ft contours (gray lines) represent the November, 2013 topography integrated with LiDAR data. Note the erosion of the deposition of eroded upper bluff material on the bench. Deposition is also evident in the channel pools. Along the inside of the bend, up to 3 ft of erosion occurred.

At Bluff 2, 25 cubic yards of sediment filled the pools in the channel between November, 2013 and June, 2014 (Figure 7), and 22 cubic yards of material eroded from the channel as the right bank adjusted. Along the log crib toe,

11 cubic yards of deposition occurred. The constructed bench experienced 19 cubic yards of erosion and 12 cubic yards of deposition. The right floodplain had 58 cubic yards of erosion and 3 cubic yards of deposition.

A total of 35 cubic yards eroded from the site and 86 cubic yards deposited between June, 2014 and November, 2014. The bench at the bluff toe experienced 39 cubic yards of deposition, the channel experienced 11 cubic yards, and the right floodplain experienced 26 cubic yards.

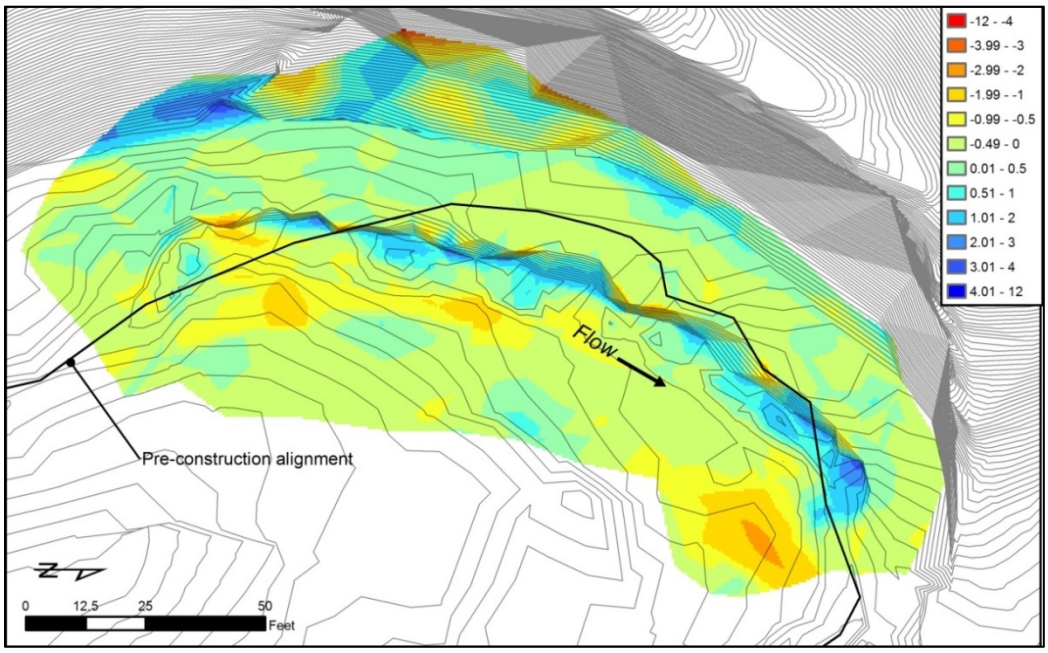

Figure 7 Erosion (red) and deposition (blue) at Bluff 2 between November, 2013 and June, 2014 (in feet). The 0.5 ft contours (gray lines) represent the November, 2013 topography integrated with LiDAR data. Sediment deposited in the channel pools and at the toe of the log crib. Erosion occurred along the inside bend floodplain.

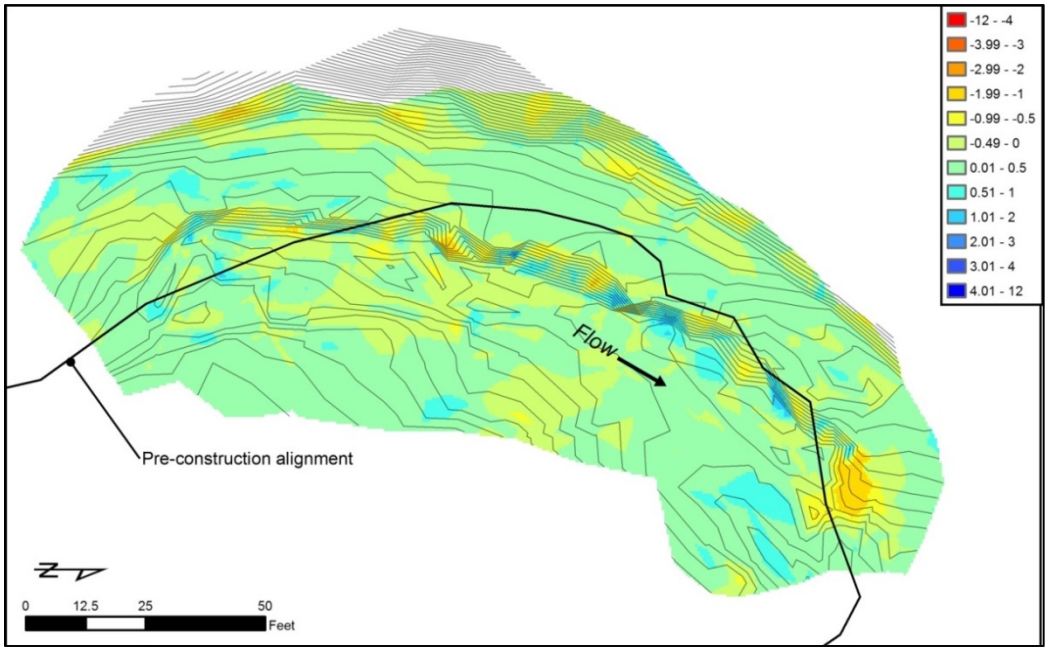

Figure 8 Erosion (red) and deposition (blue) at Bluff 2 between June, 2014 and November, 2014. The 0.5 ft contours (gray lines) represent the June, 2014 topography. Relatively little erosion and deposition took place during this time period compared to the previous 6 months.

At Bluff 3, pools in the channel and the log crib toe experienced 25 cubic yards of deposition between November, 2013 and June, 2014. Some erosion occurred just upstream of the log crib along the channel banks. The right floodplain generally degraded during this time period except for the furthest upstream area. Three logs were placed on the floodplain at this location to provide roughness and to impede avulsion.

Between June, 2014, and November, 2014, the channel accumulated 15 cubic yards of sediment and the right floodplain accumulated 30 cubic yards of sediment.

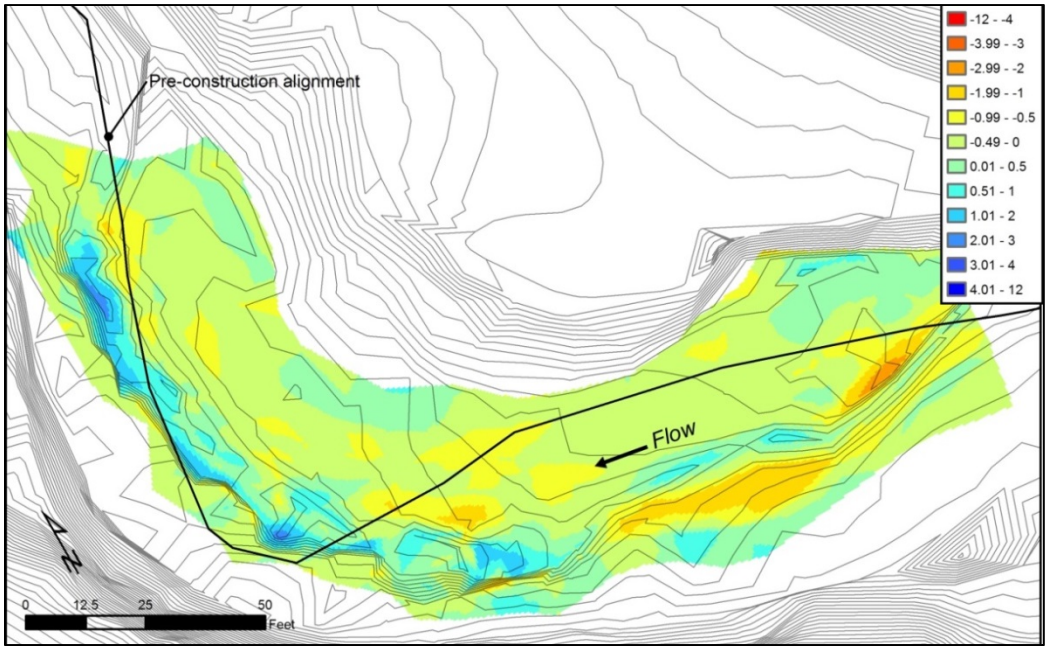

Figure 9 Erosion (red) and deposition (blue) at Bluff 3 between November, 2013 and June, 2014. The 0.5 ft contours (gray lines) represent the November, 2013 topography integrated with LiDAR data. Sediment deposited in the channel pools and at the toe of the log crib.

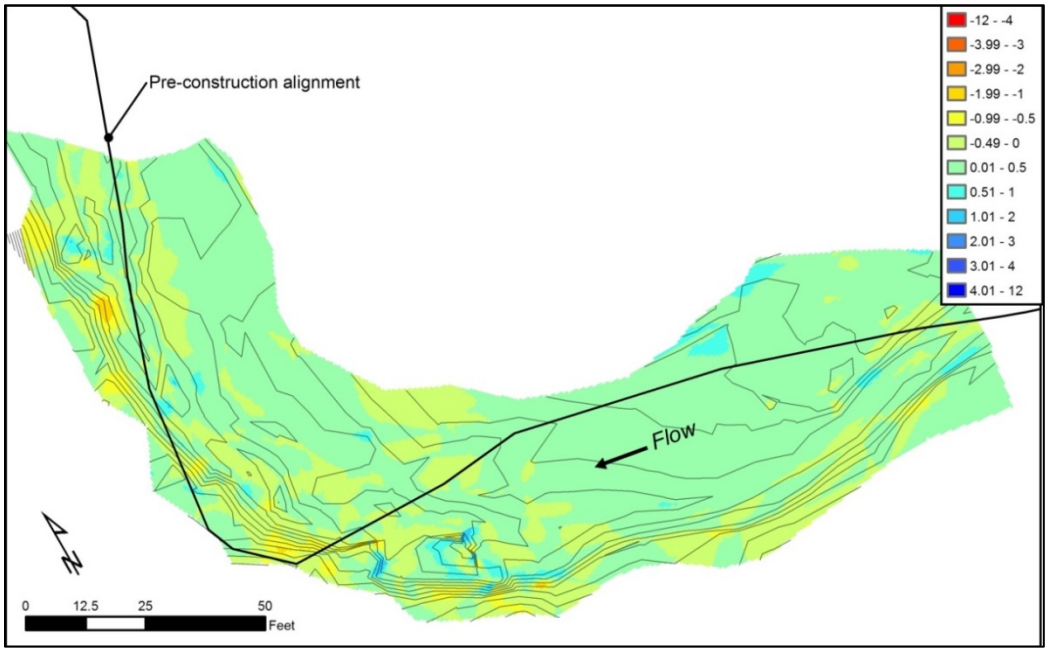

Figure 10 Erosion (red) and deposition (blue) at Bluff 3 between June, 2014 and November, 2014. The 0.5 ft contours (gray lines) represent the June, 2014 topography.

DISCUSSION

The log cribs and benches performed as designed during the first year after construction. Material eroded from the upper bluffs was deposited on the benches (Figure 12). Most of the geomorphic change occurred between November, 2013 and June, 2014 indicating that more material eroded from the upper bluff during spring thaw rather

than precipitation-induced erosion in the summer. Similarly, we noted active erosion at all of the bluff sites the previous year in April, 2013.

Soil contained in the log crib remained in place and provided resistance against channel migration. In addition, the roughness provided by the logs and root wads promoted some deposition around the toe of the structure.

The quantities and locations of erosion and deposition varied between the bluff sites. The bench at Bluff 1 experienced the greatest accumulation of sediment. This was probably due to the larger exposed area and the greater bluff height compared to Bluffs 2 and 3.

Vegetation on the benches grew closer to the channel bank where deposition did not occur (Figure 12). Additional monitoring will continue to provide information on the sustainability of vegetation in this depositional area.

Figure 11 Photo of the Bluff 1 immediately after construction in October, 2013 (looking downstream).

Figure 12 Photo of Bluff 1 in June, 2014 from the same location as Figure 11. Note the deposition on top of the bench and the secondary channel along the inside of the bend.

Channel change was relatively rapid within the first six months of construction. Sand filled in pools and deposited at the toe of the logs. Pool deposition was expected as they were over-excavated to ensure larger, immobile bed material would not limit depths. Nevertheless, the filling of the pools probably reduced the habitat available for macroinvertebrates by creating unstable substrates and for fish by concealing boulders that provided cover. Deposition around the log banks also filled in areas of habitat complexity. The sediment accumulations did not appear to be systemic as the reaches up- and downstream did not have noticeable changes. Instead, the channel form adjusted to match local hydraulics.

The lack of vegetation cover on the floodplain opposite the log cribs contributed to instability. Late autumn construction did not provide sufficient time for vegetation growth. Funds for construction and worker availability were limited to this time frame, however. The deposition surrounding the logs on the floodplain at the upstream end of Bluff 3 provides a useful reference for stabilization in these situations. Additional placement of logs throughout the floodplain would impede erosion until vegetation establishes to provide erosion resistance during floods.

CONCLUSIONS

The log cribs and benches have performed as designed after one year of construction. The benches provide a trap for sediment falling from the upper bluff while also providing an area for vegetation to establish and provide long-term lateral stability for the channel. The log cribs have impeded channel migration into the bluffs during a flood with a 2.5-year recurrence interval. The project, however, has not been tested by a significant flood event and performance measures are ongoing.

Channel adjustments have suggested improvements to the design. Placement of logs throughout the floodplain would impede erosion and maintain primary flow in the constructed channel. It is also possible that occluding some flow on the floodplain with the logs would force larger pools in the channel to minimize localized aggradation. Creating a relatively stable channel is important for bluff stability in Clark Creek. Avulsion instigated bluff erosion during the floods of 1993 and 2008. An unstable floodplain in the years immediately following construction could

lead to the initiation of bluff erosion in other areas should a large flood occur. In addition, part of the reason for utilizing a log crib was to improve aquatic habitat. Creating a channel that maximizes the habitat potential should therefore be considered an important part of the design.

ABSTRACT

Stream degradation often has its roots in problems found in the upper watershed. These areas can be degraded by gully erosion, by the prior installation of surface drainage ditches, or by the formation of a defined channel on a site that was previously vegetated with no channel. The resultant lowering of the hydraulic grade line causes a lowering of the local groundwater table, reduced flood connectivity, and, in some cases, the loss of wetland hydrology. On sites where gully erosion is still active, the channel may be actively degrading with an advancing headcut. In other cases, the gully may have reached a state of stability, but the site has lost its original hydrologic functions. Excess sediments are supplied to lower areas in the watershed and base flows are reduced. If these upper areas are not adequately addressed, the benefits of restoration efforts in the lower portions of the watershed can be limited. A stream corridor approach is needed.

The presentation will discuss the use of a systematic approach to applying vegetation and low-head structures to restore these areas. This approach results in raising the groundwater table, increasing the frequency and extent of surface inundation, increasing upland sediment deposition, and stabilizing advancing headcuts. This low impact and cost effective approach has been applied in some wetland restoration projects but has seldom been effectively applied as part of a stream restoration. The presentation will discuss benefits, design issues, construction and maintenance. Example applications will be addressed.

ESTIMATING CHANGES IN RIPARIAN AND CHANNEL FEATURES ALONG THE TRINITY RIVER DOWNSTREAM OF LEWISTON DAM, CALIFORNIA, 1980 TO 2011

Jennifer Curtis, Geomorphologist, U.S. Geological Survey, Eureka, CA, jacurtis@usgs.gov

Abstract: The Trinity River Restoration Program, one of the nation's largest adaptively managed river restoration programs, requires periodic assessments to determine the effectiveness of management actions in restoring channel dynamics and habitat features. This study documents the evolution of the intensively managed 65-km restoration reach downstream of Lewiston Dam, California during the period spanning 1980 to 2011. The nature and extent of riparian and channel changes were characterized using a series of geomorphic feature maps constructed from orthorectified photography acquired at low flow conditions in 1980, 1997, 2001, 2006, 2009, and 2011. Since 1980 there has been a general conversion of riparian to channel features and expansion of the active channel area. The primary mechanism for expansion of the active channel area was bank erosion from 1980 to 1997 with channel widening being well distributed longitudinally throughout the study reach. The primary period of bar accretion occurred from 1997 to 2001 and was followed by slightly higher rates of bar scour from 2001 to 2006. In comparison, post-2006 bank and bar changes were spatially limited to reaches with sufficient local transport capacity or sediment supply supported by gravel augmentation, mechanical channel rehabilitation, and tributary contributions to flow and sediment supply. A series of tributary floods in 1997, 1998 and 2006 were the primary factors leading to documented increases in channel complexity and floodplain connectivity. During the post-2006 period managed flow releases, gravel augmentation and mechanical restoration caused localized increases in sediment supply and transport capacity, which led to small but measurable increases in channel complexity and floodplain connectivity. Significant channel widening and muted geomorphic response of channel rehabilitation sites to post-2006 management highlights the need for continued monitoring and assessment of the magnitude, duration, and timing of prescriptive gravel augmentation, flow releases, and associated geomorphic objectives.

INTRODUCTION

Completion of the Trinity River Diversion in 1964 enabled the transfer of 75 to 90 percent of the upper Trinity River flows into the upper Sacramento River. Subsequent declines in salmon and steelhead populations prompted a series of studies (Trinity River Taskforce, 1970; USFWS, 1980; USFWS and HVT, 1999) that culminated in the Record of Decision (USDOI, 2000) and organization of the multi-agency Trinity River Restoration Program (TRRP). The Record of Decision (ROD) authorized management actions to restore salmon and steelhead populations to pre-dam levels downstream of Lewiston Dam, California. The TRRP, a collaborative partnership, is responsible for implementing ROD-mandated restoration and adaptive management for one of the largest river restoration programs in the nation.

The Trinity River is the largest tributary to Northern California's Klamath River. The study reach extends 65 kilometers along the upper main stem from Lewiston Dam downstream to the confluence with the North Fork Trinity River (Figure 1). The restoration reach is a partially confined gravel-bed river with a nearly constant bedrock-controlled slope of 0.002. The channel pattern is primarily single-thread and the dominant channel type is pool-riffle with intermittent

plane-bed and bedrock-controlled canyon reaches. Restoration efforts began in the 1970s and included: construction of spawning beds, side channels and channel complexity features, as well as riparian berm removal and re-contouring of channel margins, pool dredging, bridge replacement, installation of engineered log dams, and prescriptive gravel augmentation and flow releases.

The goal of this study was to quantify ecologically significant measures of geomorphic change, relevant to Trinity River fisheries restoration, and to evaluate the cumulative effects of natural and managed drivers of change during the period spanning 1980 to 2011.

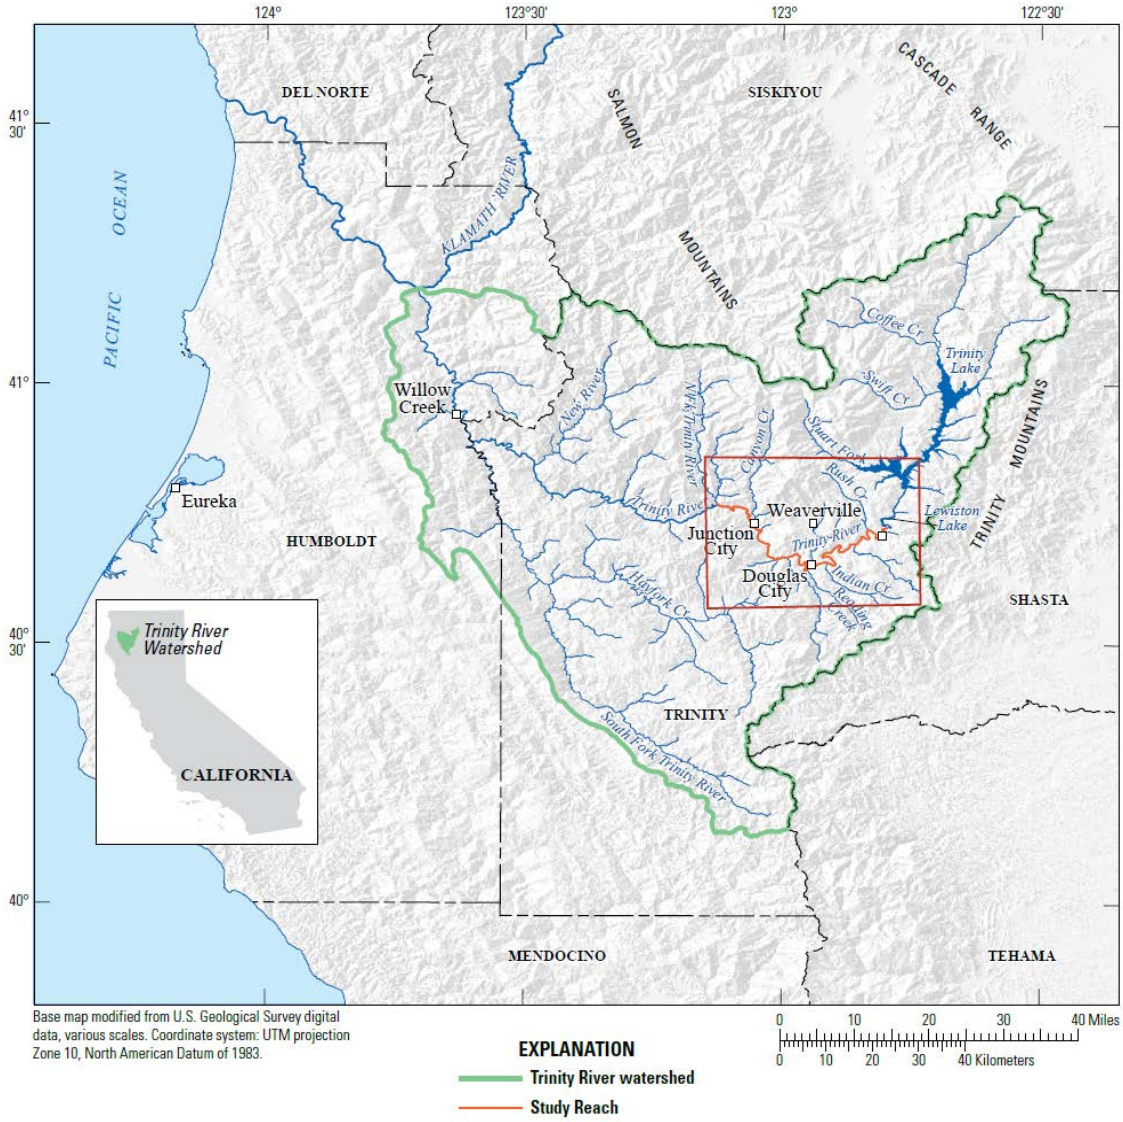

Figure 1. Map showing study area with the 65-km study reach shown in red located along the Trinity River downstream of Lewiston Dam, California.

METHODS

Six discrete geomorphic maps were created from rectified orthophotographs (1980, 1997, 2001, 2006, 2009, and 2011). Riparian and channel features larger than 30 m^2 were digitized at a scale of 1:1,000 into an ARCMap (v.10.0) geodatabase (Curtis and Guerrero, pending approval). Channel features included: the primary baseflow wetted channel, secondary water features (alcoves, wetlands, side-channels and split-flow channels), active and stable alluvial bars, and bedrock outcrops. Riparian features included: islands, wetlands and three floodplain types. Floodplain types included: a relatively continuous high-elevation pre-dam floodplain, a series of mid-elevation floodplains constructed by mechanical surface lowering, and lower elevation post-dam topographic benches composed of coalesced bars that were stabilized by 1975. The geomorphic maps were used to estimate spatial and temporal changes in ecologically significant riparian and channel features relevant to Trinity River fisheries restoration (Curtis and others, pending approval). The study reach is divided into upper, central, and lower river segments and sub-divided further into thirteen geomorphic reaches for the presentation of results. The upper river includes geomorphic reaches 1 to 5, the central river includes reaches 6 to 8, and the lower river includes reaches 9 to 13.

RESULTS

Since 1980 the general trajectory of change within the study area has been the conversion of riparian to channel features and expansion of the active channel area, which includes the baseflow wetted channel and morphologically active channel margins characterized by bedload transport. The primary mechanism for active channel area expansion was bank erosion from 1980 to 1997 (Figure 2B). The primary period of bar accretion from 1997 to 2001 was followed by slightly higher cumulative bar scour from 2001 to 2006 (Figure 3A). In comparison, smaller post-2006 bank and bar changes were spatially limited to reaches with sufficient local transport capacity or sediment supply supported by post-ROD gravel augmentation (upper river only), mechanical channel rehabilitation, and tributary contributions to flow and sediment supply (Figures 2 and 3).

Scour and deposition produced by tributary floods in 1997, 1998 and 2006 (Figure 4) were the primary factors leading to increases in the active channel area, channel complexity and floodplain connectivity. Channel complexity was characterized by the areal extent of secondary water features (alcoves, side-channels, split-flow channels and wetlands) and active alluvial bars. Increases in floodplain connectivity were characterized by the areal extent of constructed floodplains. Managed flow releases after 2006, in the absence of tributary flooding, combined with gravel augmentation and mechanical restoration caused localized increases in sediment supply and transport capacity. This led to additional increases in the active channel area, channel complexity and floodplain connectivity.

In 1980 the diversity of channel features was greatest in the upper and central river (Figure 5) where channel complexity features (active alluvial bars and secondary water features) represented approximately 12 percent of the active channel area. From 1980 to 2001 the active channel area increased by 20 percent. By 2001 channel complexity features comprised 17 percent of the active channel area. From 2001 to 2011 the active channel area increased by about

5 percent and in 2011 channel complexity features again occupied 17 percent of the active channel area.

In 1980 post-dam topographic benches comprised 94 percent of the riparian environment (Figure 6). By 2001 floodplain construction had increased riparian diversity and the proportion of post-dam benches declined to 86 percent. By the end of the study period in 2011, the relative proportions of post-dam benches, constructed floodplains, and stabilized bars were 60, 27, and 10 percent respectively.

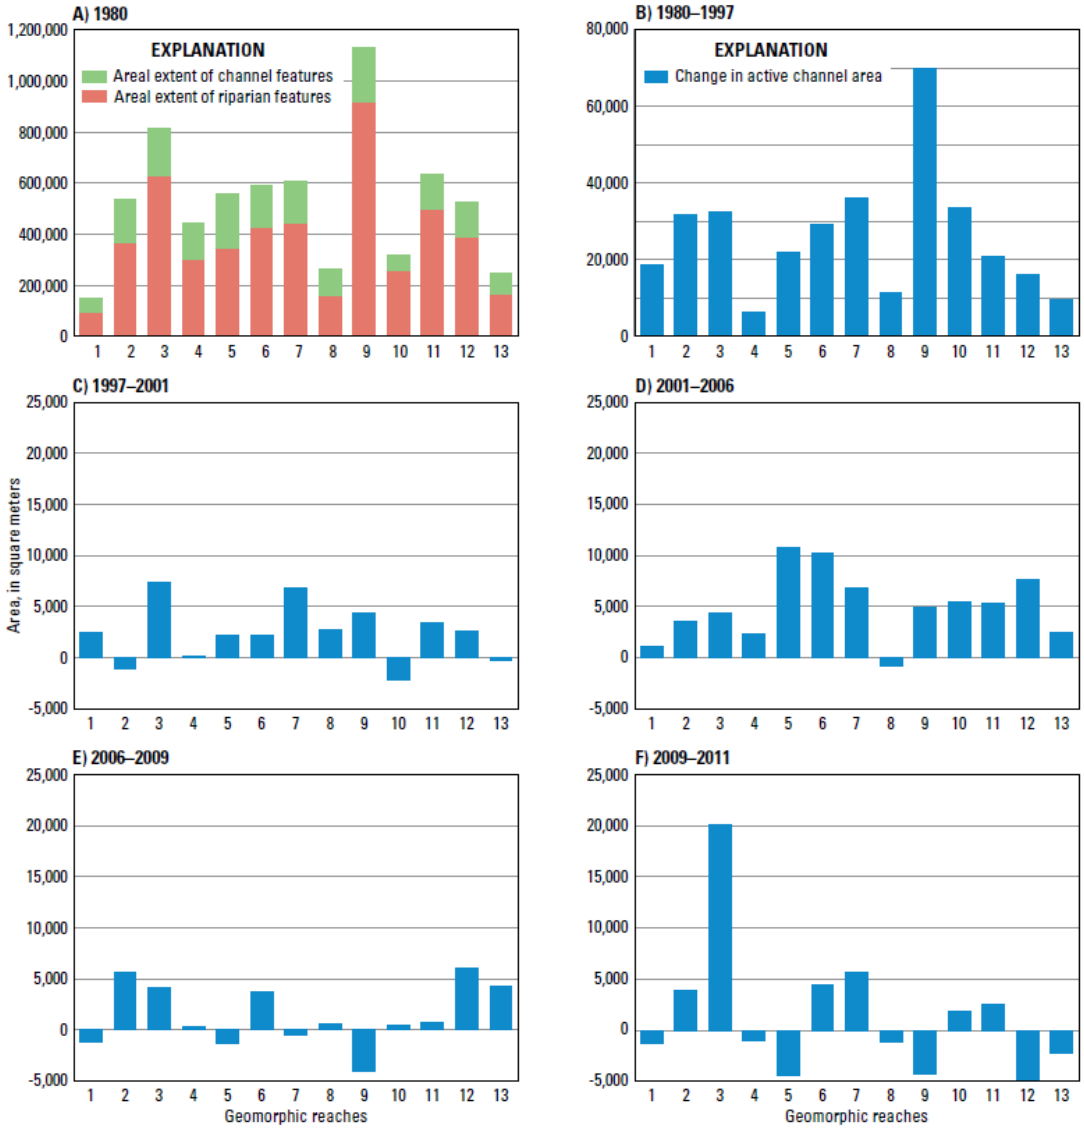

Figure 2. Graphs showing areal extent of riparian and channel features within thirteen geomorphic reaches along the Trinity River downstream from Lewiston Dam, California, A) in 1980, and change in active channel area for five periods from B) 1980 to 1997, C) 1997 to 2001, D) 2001 to 2006, E) 2006 to 2009, F) 2009 to 2011. Note the change in scale.

CONCLUSIONS

Intrinsically the upper river has a low potential for change because dam construction and flow diversions decreased the transport capacity and sediment supply. Numerous management actions were implemented during the study period to resolve the lack of capacity for maintaining a

dynamic alluvial river with desirable habitat features. These management actions included channel rehabilitation, gravel augmentation and alterations in the size and timing of prescriptive flow releases.

In 1980 the study reach possessed a static channel form but the tendency toward stable alluvial features was disrupted by the 1997, 1998, and 2006 tributary floods. Channel widening from 1980 to 1997 represented a system-wide threshold disturbance that was followed by bar accretion (1997 to 2001) and bar scour (2001 to 2006). The geomorphic effectiveness of the post-2006 prescriptive flows and gravel augmentation was small in comparison to pre-2006 precipitation-driven tributary flows that generated higher and longer duration main stream flows (Curtis and others, pending approval). Pre-1997 studies determined that 80 percent of the low-flow channel margin was mobilized during a peak flow release of 6,000 ft^3/s (TRA, 1993; Wilcock and others, 1995; MT, 1997). More recent studies (HVT and others, 2011) indicate prescriptive flows did not produce expected scour, mobility, or channel maintenance targets at many rehabilitated sites. These observations suggest that channel widening could have altered local hydraulics such that prescriptive flows may need to be increased to achieve the TRRP's restoration goals. The muted geomorphic response of channel rehabilitation sites to the post-2006 flows highlights the need for continued monitoring and assessment of the magnitude, duration, and timing of prescriptive gravel augmentation, flow releases and associated objective for channel scour, mobility, and maintenance. Achieving the TRRP goal of a downscaled dynamic river may come with the unexpected consequence of a larger active channel area that requires larger maintenance flows.

INTRODUCTION

This study evaluates the use of future climate projections to assess the potential impacts of climate change on the operation of a USACE multipurpose reservoir in east-central Iowa. The Coralville Reservoir, on the Iowa River just above Iowa City, IA, has been in operation since 1958. The two largest floods during the period of operation have occurred in the last 25 years, with the largest occurring during the Midwest Flood of 2008.

Climate conditions in the Iowa River basin have changed significantly since the reservoir was placed into operation. Analysis of historical precipitation and flow data demonstrate increased reservoir inflow volumes compared to pre-project conditions upon which the project was originally designed. Observed changes in reservoir inflow have resulted in periodic modifications to the water control plan; however, the threat of continued climate change in the future, and the uncertainty associated with those changes, has the potential to result in increased future risks to meeting project purposes.

Using a calibrated hydrologic model of the Iowa River basin and dynamically-downscaled climate data, the risk to the reservoir system associated with future climate scenarios was analyzed. Reservoir operations for a number of future climate scenarios were simulated in order to test the robustness of the reservoir system to potential climate change effects and to identify potential adaptation strategies.

The study concludes that the numerous limitations associated with climate and hydrologic modeling makes it difficult to fully assess the risks for a project due to climate change using modeling tools alone. A project-based resilience-robustness approach that considers the vulnerabilities of the project to changes in climate, such as the approach by Brown et al. [2011], gives a better picture of the climatic risk for a project. Specific to reservoir management, this study concludes that long-term reservoir planning is not as valuable a tool to meeting the missions of a reservoir as short-term weather forecasting and a framework that allows for real-time, risk-based, decision making for reservoir operations.

BACKGROUND

Study Area: Coralville Dam (Figure 1) is a 1,400 ft long, 100 ft high rolled earthfill dam impounding Coralville Reservoir on the Iowa River located 83.3 miles above its confluence with the Mississippi River and 5 miles above Iowa City, IA. There are 3,115 mi^2 of mainly row-cropped agricultural land draining into the Iowa River above the dam. An additional 9,400 mi^2 of uncontrolled drainage (below Coralville Reservoir) flows from the Iowa-Cedar watershed to the Mississippi River.

Figure 1 Coralville Dam During Midwest Flood of 2008

The primary purpose authorized by Congress (PL 75-761) is flood risk management for areas below the lake on the Iowa and Upper Mississippi Rivers. Other congressionally

authorized purposes include low flow augmentation, fish and wildlife management (PL 85-624), and recreation (PL 78-534). Construction on the dam began in July 1949 but was delayed by the Korean Conflict. The reservoir began operation in September 1958.

The reservoir is regulated by a gated conduit outlet with a discharge capacity of 20,000 cubic feet per second (cfs) at full flood control pool (712 ft NGVD). At pool elevations above full flood control pool the emergency spillway is activated and uncontrolled release begins. The 500 ft long uncontrolled concrete chute spillway has a discharge capacity of 244,000 cfs. The spillway has been activated twice in the history of the project, once each during the 1993 and 2008 floods.

During normal (non-flood or drought) operations the reservoir is regulated to maintain a seasonal conservation pool elevation (see table 1). During flood operations, the release schedule for the reservoir changes based upon forecasted pool elevations (i.e., storage utilized) and downstream constraints to control flooding. When the pool elevation is forecast to exceed elevation 707 ft (NGVD) major flood operations are initiated, and flows are regulated to maximize use of the remaining storage. During non-major flood operations, maximum releases are controlled by downstream constraints, including seasonal constraints due to agricultural production and river stage control points on the Iowa River (at Lone Tree, IA, and Wapello, IA) and the Mississippi River (at Burlington, IA). Additionally, releases are temporarily reduced in order to manage flash flood flows at Iowa City.

When reservoir inflows fall below minimum conservation releases, the reservoirs drought contingency plan is activated providing for low-flow augmentation of releases with the highest priority given to meeting downstream water supply requirements.

Table 1 Coralville Lake Seasonal Conservation Pool Elevations

Date	Regulation (Elevation ft NGVD)	Action Purpose
15 Feb – 20 Mar	Lower from 683 to 679	Increase storage for spring snowmelt
20 Mar – 20 May	Hold elevation 679	Duration of spring snowmelt period
20 May – 15 Sep	Hold 683	Storage for low-flow augmentation
15 Sep – 15 Dec	Hold 683-686	Increase in lake area for migratory waterfowl
15 Dec – 15 Feb	Hold 683	Storage for low-flow augmentation

Current Climate: Iowa City, just downstream of Coralville Dam, has a mean annual temperature of 50 °F and averages about 34.9 inches of precipitation per year [cumulative data since 1893 from Iowa Environmental Mesonet AgClimate data]. Near the headwaters of the Iowa River basin is Northwood, IA, which has a mean annual temperature of 44 °F and averages about 32.2 inches of rainfall per year. The climate across the basin is generally homogeneous as it lacks significant topography to affect precipitation and temperature patterns. The basin has a humid continental climate, which is characterized by large seasonal temperature differences including hot, humid summers and cold, sometimes frigid, winters.

Average annual temperature, total annual precipitation, and the number of days per year with precipitation have increased in Iowa from the late 19th to the early 21st century, and at the Iowa City gauge within the Iowa River basin, these trends are statistically significant at 95% confidence. Since 1893, mean annual temperature has been rising at an average rate of 0.32°F per decade at Iowa City. Prior to 1960, only 6 years out of 67 (9%) measured a mean annual temperature at or over 52 °F, but 1960 and later, 24 of 52 years (46%) have met or exceeded that threshold.

In Iowa, the biggest changes in temperature are due to wintertime and nighttime temperature increases. There are more frost-free days per year (about 5 more at the start of the 21st century than in the mid 20th century, and about 8-9 more than beginning of the 20th century). Warmer temperatures increase the length of the growing season, due to fewer days of frost. There is also earlier seasonal snowmelt, and lakes and streams remain frozen for less time. There has been a decrease in the number of extreme high temperature events (days above 100°F). Increased summer precipitation and soil moisture have suppressed surface heating and reduced daytime summer maximum daytime temperatures. From the Climate Change Impacts on Iowa 2010 report:

> *If Iowa were to experience a severe drought, as has occurred frequently in the past, the slow and steady rise in statewide annual mean temperature, now masked in summer by moist surface*

conditions, could lead to an abrupt switch to extreme summer heat comparable to the summers of 1983 or 1988.

On average, annual total precipitation has been rising by 0.43 inches per decade. There has been an increase in year-to-year variation in annual total precipitation as well, with an increase in 30-year coefficient of variation (CV) in annual precipitation from around 0.11-0.17 in the early 20th century to around 0.19-0.24 in the early 21st century.

On average, there has been one more rainy day per year every 6.4 years. While currently there are not as many rainy days as the late 1940s, total annual precipitation has increased steadily, which is due to a combination of more rainy days and increased frequency of moderate to intense rainfall.

Streamflow is largely driven by rainfall, although for any one event antecedent conditions play an important part in runoff-generating processes. Over time there has been an increase in average annual streamflow volume on the Iowa River as well as an increase in annual peak discharge. The 15-day peak discharge past Marengo is an important inflow metric for operations at Coralville Reservoir on the Iowa River, and its trend is shown in Figure 2. There is a clear increase in the average annual 15-day maximum flow, as well as an increase in the interannual variation for that parameter.

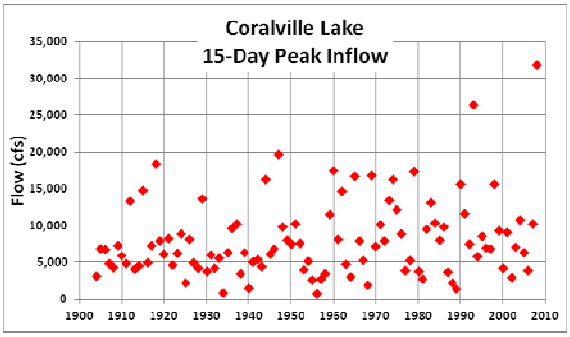

Figure 2 15-day Peak Discharge, Iowa River at Marengo

Current Problem/Concern: Historical Iowa River flows into Coralville Lake show an increase in the mean and variance of annual 15-day peak discharge between the design period (pre-reservoir streamflow records) and the period over which the reservoir has been in operation (1959-present). Of particular significance are the Floods of 1993 and 2008, which both exceeding the largest historical event upon which the original water control plan was developed. The largest historical floods available in the record at the time of project design were predominately spring snowmelt (or rain on snow) driven events, whereas the record flooding in 1993 and 2008 resulted from persistent late spring and summer thunderstorms occurring over a heavily saturated watershed. Increased total precipitation has led to higher soil moisture content, which has runoff implications both through affecting antecedent conditions preventing infiltration, and an increase in the installation of agricultural tile drains.

The floods of 1993 and 2008, coupled with significant flooding in 2010, raised questions regarding the operation of Coralville Reservoir and (from the public's perspective) whether the reservoir was giving adequate weight to the risk of urban flooding from major flooding versus favoring protection to downstream agricultural areas during minor flood events. Public and community interest led the State of Iowa's Governor to formally request that the Corps of Engineers conduct a re-evaluation of the water regulation procedures at each of the four large flood risk management reservoirs operated by the U.S. Army Corps of Engineers within Iowa. Uncertainty in future climate conditions has the potential to be a major risk driver in the evaluation of alternative water management strategies to better manage future flood risk in the Iowa River Basin.

Purpose and Scope: The study is concentrating on the following central question: "How do we incorporate climate change considerations into reservoir operating policies that will be robust and adaptive to potential climate changes in the interest of long term management of risks to project operating purposes?"

Previous Studies: This pilot study is the first attempt at evaluating the potential effects of climate change on the operation of Coralville Lake or on hydrology in the Iowa River basin. However, other studies have been completed that evaluate the regulation plan for the lake in response to past floods. In 1997, a Section 216 (Review of Completed Works) study was completed for Coralville Lake and its regulation plan. Several alternative initiatives were proposed in order to enhance benefits at the lake, but none garnered a Federal interest.

Methodology and Approach: The study utilized the following approach*:*

1) Investigate original design assumptions for the dam and determine which metrics are sensitive to climate change
   a) Evaluate changes in meteorology from historical to potential future

   b) Examine possible bias or error in GCM/RCM results
2) Obtain downscaled climate data for the Iowa River basin, the area of interest
3) Run observed meteorology and downscaled climate scenarios through a calibrated hydrologic model to obtain flow information at critical locations for a variety of scenarios
4) Use post-processing tools to learn more about the effects of changes in climate and hydrology
   a) Reservoir sedimentation model – how is storage in the reservoir changing due to sedimentation?
   b) Flow routing model – how are the operational conditions for the dam changing?
   c) Reservoir operations model – how much influence does operation have on the possible changes at the reservoir?

The first step in evaluating the potential impacts of climate change for the reservoir was to understand the design parameters and assumptions upon which the original project design and water control plan were based. Using the design documentation and regulation manuals for the project, critical design parameters and assumptions were tabulated (see table 2). These parameters serve as guidance on whether or not the project is currently functioning as intended, and if these assumptions might be violated in the future due to climate change. Tools were developed to answer the question of whether or not these parameters might be sensitive to changes in climate in the future.

Table 2 Design Parameter Matrix

Design parameter	Original Design Assumption	Observation During Operations
Frequency of uncontrolled release over emergency spillway	Uncontrolled release would occur about once in 30 years	2 spillway events since 1958 (~54 years, about 27 year average interval)
Sedimentation/loss of storage space in reservoir	Loss of storage would occur at a rate of about 750-1,200 ac-ft/yr	Average yearly loss of approximately 1,700 ac-ft
Timing/mechanism of annual flood flows	Heaviest floods would occur due to spring snowmelt and flood magnitude would be related to amount of snowpack	Largest floods occurred during the late spring or early summer due to persistent and intense thunderstorm events (e.g. 1993, 2008)
Spillway Design Flood/Dam Safety	The dam was designed with freeboard above a probable maximum flood computed from the transposition of a historical storm during worst case operational conditions, with a peak inflow of 326,000 cfs (top of dam elevation NGVD 743')	Dam has never been overtopped; max pool elevation ~717' (~26' freeboard)
Conservation pool storage volume	Maintain minimum discharge of 150 cfs at Iowa City and Lone Tree from 07/01 – 02/28 (243 days) with strong drought conditions; equating to a volume of 17,000 acre-ft	Due to sedimentation, the elevation of the conservation pool has been increased in order to maintain design volume

Climate change is highly visible in its impacts on hydrology. Changing climate conditions affect the water balance by directly changing the amount of evapotranspiration and precipitation, and timing and type of precipitation that occur. In order to assess these impacts quantitatively, the climate simulations were coupled with a hydrologic model of the study area.

Hydrologic Model: The hydrologic analysis was performed using a quasi-distributed continuous hydrologic model, the Soil and Water Assessment Tool (SWAT) [Neitsch et al. 2009]. It was forced using observed meteorological data and RCM-downscaled results from GCMs. No land use change scenarios were tested for the future cases. The minimum inputs to run SWAT include a digital elevation model, landuse/land cover, soil type and meteorology.

Table 3 Iowa River SWAT Model Input Sources

Input	Source
Land use/land cover	NLCD 2006 (MRLC)
DEM	1 Arc second NED (~30m resolution)
Soil coverage	STATSGO data for the United States included with SWAT model

Meteorology inputs for the model came from a variety of sources in order to have a long enough record of all required forcing variables to calibrate the model. Observed meteorology was necessary in order to calibrate the model to observed streamflow. Once the model was calibrated to match historical rainfall-runoff responses the model was run with downscaled climate data to evaluate the effect of climate change on hydrology.

USDA-ARS SWAT format meteorological data were used in calibration and observed meteorology runs. The data provided from this source were daily maximum and minimum temperature and daily total precipitation. These data span 1/1950-10/2009. Relative humidity, solar radiation and wind speed, in addition to temperature and precipitation, were from Iowa Environmental Mesonet data available over the time period 1/1998-12/2010.

The model was first calibrated for daily discharge at the Marengo, IA gage using historical observed meteorological data. Observed flow and meteorological data are at a daily timestep, and thus the model was run at a daily timestep.

Table 4 SWAT Model Calibration Results

Event	Location	Nash-Sutcliffe	Volume Error	R^2
Calibration (1999-2001)	Marengo	0.85	+5.7%	0.87
Validation (2006-2008)	Marengo	0.80	-7.9%	0.84
Validation (2003-2005)	Marengo	0.64	-0.51%	0.75

While achieving relatively good scores on the selected calibration metrics, one significant weakness of the model is in estimating the highest peak flow values. The model was unable to capture the most extreme flows and the relatively large variance in observed daily streamflow. Baseflow recession and the timing of peak flows were generally well-matched to observed hydrographs; however, the volume error grew with overestimation of baseflow contribution and underestimation of the most extreme peak flows. Additionally, some peak flow events were missed within the simulations (and some existed in model results without corresponding observed peaks) because of the coverage of precipitation gauges.

The daily discharge simulated by SWAT was used in three post-processing routines to gain information about dam sedimentation and reservoir operations.

Sediment Accumulation in Reservoir: Although SWAT has sediment modeling methods included in the model (based on the universal soil loss equation), sparse information for calibration and other factors made it difficult to set up and calibrate the model for sedimentation. An alternative, approximate approach was favored in order to estimate sedimentation rates in the reservoir. A power law relationship between sediment discharge and streamflow modified from USBR [1987] was established using observations at the Marshalltown gauge, upstream of Marengo on the Iowa River. The Marshalltown gauge recorded sediment loading for a short period (less than 10 years). The curve was applied to discharges at Marengo to compute a total sediment inflow to Coralville Lake. A sediment trap efficiency for the dam based on the reservoir capacity and the inflow [Brune 1953, Dendy 1974] was applied to the Coralville inflow hydrograph to compute the amount of sediment accumulating in the reservoir. The results of this method when compared to historical sediment survey results is acceptable for computing an estimate of annual average sediment accumulation.

Flow Routing (Inflow-Pool Elevation-Release Rate Computation): An Excel spreadsheet was created that routes reservoir inflow based on the water control plan in the current regulation manual (January 2001 revision). The model first attempts to discharge enough storage to achieve the seasonal conservation pool elevation, based on the pool elevation of the previous timestep and the inflow to the reservoir. The formal rules for maximum release are checked, including seasonal rules for maximum release (growing vs. non-growing season) and flow at control points downstream on the Iowa River. The action is first checked if informal rules regarding changes in pool elevation and release are being broken, but major flood and drought conditions override any informal rules.

The model gives good results for events where reservoir regulation stayed true to the manual. Some aspects of the water control plan occur variably from year-to-year based on communication with project stakeholders. The spring drawdown and the fall pool raise are variable, so the model acted on the middle date of the available range of dates in the regulation manual. In other historical cases, the reservoir was operated under a temporary deviation to store more water and avoid downstream flooding. Additionally the model could not account for the downstream flow constraints on the Mississippi River, where river stages may dictate a short-term (seven day) reduction in releases from Coralville to reduce peak Mississippi River flooding.

Climate Change Scenarios: The climate data used for the evaluations in this study came from the North American Regional Climate Change Assessment Program (NARCCAP) dataset [Mearns et al. 2007, updated 2012]. The data were processed and exported in SWAT format by Dr Christopher Anderson of Iowa State University.

Emissions Scenario: The greenhouse gas emissions scenario used to force the GCMs in the NARCCAP datasets is the A2 scenario. The A2 emissions scenario is a high-emission Special Report on Emissions Scenarios [SRES; Nakicenovic and Swart 2000] greenhouse gas (GHG) scenario family. It projects vastly increased GHG emissions throughout the 21st century, fueled by continuously increasing human population, an economic (as opposed to environmental) policy focus, and independent, regionally-focused nations. Although the A2 scenario (along with the A1FI and A1B scenarios) is near the highest projected rate of GHG emissions for the early 21st century (according to the SRES), there is evidence that global GHG emissions exceed those scenarios thus far this century [Raupach et al. 2007] The emissions scenario makes up the foundational assumption about the rest of the future climate simulations. It is the driving force behind the GCM simulation and has the greatest influence on the resulting simulations. For this study, A2 was a reasonable "worst case" assumption available at the time.

Global Climate Models: A general circulation model (GCM) is a model that simulates Earth systems, generally the coupled oceanic-atmospheric processes (AOGCM) that most characterize climate. The coupled circulation models for atmosphere, land, ocean, ice, etc. are referred to as Global Climate Models.

In this study two GCMs were used for projections, the CGCM and CCSM models. CGCM is the Meteorological Service of Canada of Environment Canada coupled atmosphere-ocean climate model from the Canadian Centre for Climate Modelling and Analysis (CCCma) Climate Research Branch. CCSM (Community Climate System Model) is the National Center for Atmospheric Research (NCAR) coupled climate model that incorporates four separate climatological models for atmosphere, ice, land and ocean. The version used for the runs in this study is CCSM3, which have since been superseded by CCSM4 as part of the Community Earth System Model.

GCMs are generally run at a coarse scale spatially (on the order of 2°-5° resolution) and temporally (monthly) because of computational limitations. These results are not as useful on a local scale, especially for investigations of climate change impacts on regional or local hydrology, so a method to disaggregate these results needs to be used. Thus the GCM results are downscaled to a finer resolution, in the case of this study ~50km resolution with a daily timestep.

Downscaling Method: The downscaling method in use for the NARCCAP data is dynamic downscaling (not a delta or statistical downscaling method). Here regional climate models (RCMs) are forced by the GCMs to produce finer-scale results. RCMs are higher-resolution numerical weather prediction models that are nested within a GCM, so that the GCM acts as a boundary condition over a focused area. This allows a higher-resolution simulation of local weather process that are often of most interest in understanding regional climate.

For the NARCCAP data, RCM runs are also forced with NCEP reanalysis data for atmospheric conditions for the late 20th century which give an estimate of the best simulation that each RCM can produce. The reanalysis data have the same fluxes and states that GCMs would produce but are based on data assimilation and atmospheric modeling over the 20th century. The data incorporate observed historical data to make a best estimate simulation of atmospheric conditions. Thus the NCEP reanalysis data are a good proxy for actual atmospheric conditions that can be used to force the RCM, which in turn gives a good estimate of the performance of the RCM over the particular application area.

The RCM runs can also produce time series of other fluxes and states (other than temperature and precipitation) that are of interest for modeling. For example, the SWAT model also needs solar radiation, wind speed, and humidity (dew point or relative humidity) data, which are readily available outputs from many RCMs. The regional climate models used for downscaling the GCM outputs in this report are the WRFG and CRCM models.

WRFG (developed by NCAR) is the Weather Research and Forecasting model, using the Grell parameterization scheme (superseding the WRFP, PNNL scheme). CRCM is the Canadian Regional Climate Model developed at the Université du Québec en Montreal.

Downscaled climate simulation results are gridded, so for the purposes of hydrologic modeling the centers of the RCM grid cells were used as gauge stations. Because different RCMs have different grid schemes, the number of gauges used to cover the basin varied between RCMs but there were generally at least six gauges over the basin. The RCM grids are at about 50km resolution. All six forcing variables (T_{max}, T_{min}, P, RH, R_s, W) were read by the model from the downscaled RCM data.

It is important to keep in mind that the resulting downscaled climate data sets are highly experimental and come with their own major limitations and caveats. This study attempted to investigate the utility of these downscaled data as applied to the Coralville project.

RESULTS

Physical System/Climate Findings:

Climate Data and Observed Meteorology: The initial analysis of the downscaled climate outputs revealed some shortcomings in the regional climate model representation of local meteorology. Using the RCM-downscaled NCEP reanalysis data, the precipitation results were compared to observed precipitation using long-term averages. As the reanalysis data acts as a proxy for observed data in place of a GCM, this analysis demonstrates the RCM's best ability to generate local meteorology.

WRFG generally reproduced how precipitation occurs in the study region – the temporal distribution throughout the year was accurate, and it produced storm events consistent with those in the region. It was, however, very dry compared to observation, being low by about 7 in of rain per year while producing about the same number of rain events (see table 5). It appears that the model reduces the amount of moderate precipitation events that occur, resulting in frequent very light or heavy events, with few events of a more moderate intensity.

CRCM performed poorly at simulating local meteorology. CRCM precipitation results were more like Seattle, with most rain coming early in the year and the annual total precipitation coming as a result of a large number of small precipitation events. Intense events were very infrequent, and the annual maximum precipitation was close to constant between years of simulation. CRCM split the precipitation over about 200 days of precipitation a year, where 100-120 is a more reasonable number. The total water balance for CRCM was much closer than WRFG, being slightly wet by about 1 inch per year on average. Brochu and Laprise [2007] similarly documented the observed precipitation biases of the CRCM model over the Mississippi River basin and show a wet bias, as well as a misdistribution of rainfall toward the earlier part of the year.

Table 5 Comparison of Annual Rainfall Statistics for RCMs Forced with Reanalysis Data

	Average Rainy Days Per Year	Annual Average Precipitation	Average Date of 50% Rainfall Accumulation
Observed	109	32.1 in	7/9
WRFG-NCEP	108	25.7 in	7/7
CRCM-NCEP	199	33.1 in	6/24

Future Climate Scenarios: In general, the shift from an RCM-GCM pair from historical emissions to future emissions scenario was not producing changes in extreme precipitation consistent with expectations of climate change in the Midwest. This is likely due to a combination of factors, namely the limitation of the RCMs noted above, as well as the short simulation periods. It is unreasonable to expect to sample events with average recurrence intervals longer than 50 or 100 years in a 25-30 year sample. The resulting data are heavily sampled out of the middle of the distribution of results, which results in very few extreme scenarios (flood or drought) that we are most concerned about.

The underlying biases in the RCMs heavily influence the output results. The WRFG-downscaled GCM results reflect the overall dryness of WRFG, and CRCM-downscaled results have the above noted wet bias and temporal misdistribution of precipitation. Overall the performance of WRFG was limited only by the dry bias; however, CRCM was producing results wholly inappropriate for the region.

The additional limitation of the hydrologic model in simulating the highest peak events meant that climate data representing the middle of the distribution of data was being processed by a model that under-predicted variance and extremes, resulting in rather average-looking flows. This limits the ability to test the operation of the reservoir under events of the most interest (extreme flood and drought). Figure 3 shows the flow-frequency curves for 15-day peak flows for the four future scenarios when compared to observed streamflow. The reduction in variance in the streamflow results creates the reduced frequency of events observed on the tails of the inflow frequency curves. The reduction in variance is due to the forcing climate data and the spatial and temporal resolution of the data used in the hydrologic model.

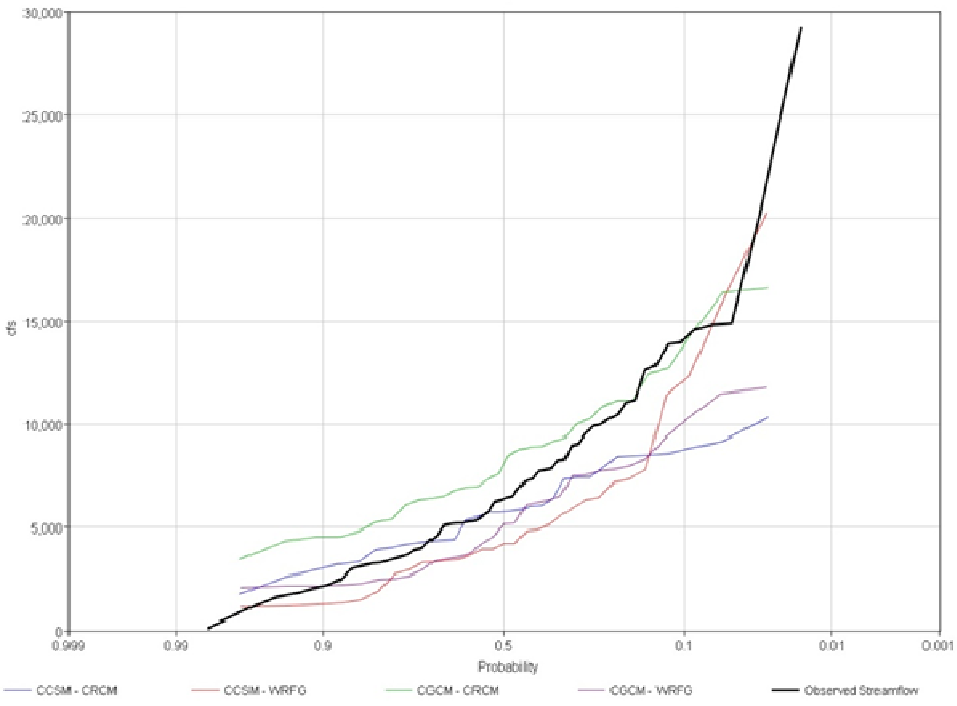

Figure 3 Annual Maximum 15-day Average Flow Past Marengo, Observed and Future Model Projections

Table 6 summarizes the output from the sediment post-processing (annual average sedimentation rate) and the reservoir routing post-processing (amount of time in flood, amount of time in drought, number of spillway events.) Spillway events are classified as being any event where water goes over the spillway, even if this amount is trivial. (This designation has the habit of including some events where the elevation of the pool would likely be very close to going over without any flow being passed by the spillway.)

Table 6 Post-Processed Hydrologic Model Results

RCM	Forcing	Time Period	Years	Average Daily Discharge (cfs)	Average Sed Rate (ac-ft/yr)	% Major Flood	% Drought	Spillway Events	Years With Major Flood
Observed Operations		09/17/1958-12/31/2010	52.3	2055	~1200			2

The resulting simulations did not point toward one clear consensus for the future of inflows to Coralville Lake. When examining the difference between the mid-21st century and 20th century simulations for an RCM-GCM pair, there is no clear picture of the future for the system. The results for the same GCM but different RCM agreed somewhat; the CGCM results forecast an increased flood risk (increase in percent of time in major flood, and total years entering major flood operations) while the CCSM results show a slight decrease in time in major flood but also an additional spillway event.

Table 7 Changes in Hydrologic Modeling Results Due to GCM-RCM Pair

Model pair	Mean discharge	% Major flood	% Drought	Spillway events	Years with major flood
CRCM-CCSM	+31cfs	-0.24%	+0.01%	NC*	-2
CRCM-CGCM	-37cfs	+0.68%	+0.01%	NC	+1
WRFG-CCSM	-7cfs	-0.21%	+0.05%	+1	NC
WRFG-CGCM	+667cfs	+1.26%	-0.03%	NC	+5

NC=No Change

If we consider the result of the simulations without taking into account the limitations in the data and the hydrologic model it appears that modifications to the regulation plan would be sufficient to handle projected climate change. This is not a prudent lesson to take from the study, as the limitations associated with the climate data and the hydrologic model drive the overall results so much as to say the climate data offer us very little with which to try to test adaptation strategies. Thus, caution in the approach of data with such limitations is very important.

Method or Process Used: The methodology used in the study was based largely on what we viewed as a traditional type of climate change impacts analysis for hydrology, in which downscaled climate data were run through a calibrated hydrologic model for a watershed. These runs were done under existing basin conditions, and the resulting climate change scenario results were compared to historical runs and observed hydrology in order to assess the impacts that climate change could potentially have on the hydrology of a watershed. The resulting climate change scenario runs were not as useful for testing the reservoir system's response as we had hoped initially.

We did not observe any emergent processes in the climate change simulations. The streamflow results show about what is expected in terms of increased winter rainfall resulting in streamflow, and reduced spring snowmelt floods. Snowmelt flooding, which dominated the early period of record, has become less prevalent in the Iowa River basin with the largest floods on record (1993 and 2008) resulting from later spring and early summer rains. The simulated increase in flow due to spring and summer storms is consistent with observations during the operational period of the reservoir.

Implications for Future Reservoir Management:

Large Flood Operations: The current water control plan for Coralville Lake is similar to other reservoir projects within the Rock Island District in that the release schedule limits downstream flows to safe discharges (no or minimal damage with limits tied to seasonal agricultural production) until such time that a significant portion of the flood control storage has been utilized. At this point, releases are quickly ramped up to reduce the likelihood of higher, uncontrolled releases that would result when the unregulated spillway is overtopped. The major flood release schedule contained in the current water control plan is based upon an optimization of available reservoir storage to the largest flood that had occurred prior to construction of Coralville Dam.

As observed during the 1993 and 2008 major flood events, flood volumes in excess of the historically observed maximum can and will occur again in the future. The current water control plan, which emphasized optimization of flood volumes to historic events, does not necessarily optimized flood risk reduction during future major floods. In evaluating future climate change scenarios, it was anticipated that additional major flood events would be represented in the model simulations to evaluate alternative water control plans that would improve the risk performance of the reservoir across a wide range of large flood events. As discussed above, the future climate scenarios evaluated failed to produce events at the extremes of the inflow volume-duration-frequency distribution. As a result, the mid-century future climate scenarios evaluated do not provide a basis for defining a new optimized release schedule for future major flood events.

The inability of the future climate scenarios to provide such a basis points to the importance of short term climate forecasts and the need to develop tools capable of informing water managers with risk-based decision criteria to evaluate operational scenarios during major flood events. The required decision support system needs to be capable of incorporating modern forecast information into a risk-based decision tool. Such a system requires a clear set of risk-based criteria, consistent with project authorities, upon which water management decisions will ultimately be made. Further required are tools capable of incorporating the hydrologic, hydraulic, economic, and public health and safety factors into the decision process. The USACE proposed CWMS National Implementation Plan would substantially develop many of these critical tools.

Drought/Low Flow Augmentation: Consistent with the major flood operations discussion, the future climate scenarios evaluated failed to produce events at the extremes of the inflow volume-duration-frequency distribution such that a range of severe drought conditions could be evaluated to identify improvements to the water control plan to improve the robustness of the project to meet future drought conditions. Historically, the greatest threat to being able to meet future conservation needs has been sedimentation of the reservoir. The future climate scenarios indicate (with one exception) that sedimentation rates are likely to increase over historical rates consistent with projected increases in precipitation and stream flow. Historically, the Rock Island District has conducted pool raises to offset anticipated sedimentation and periodically conducts surveys to re-evaluate reservoir storage. Increases in future sedimentation will likely force decisions regarding future conservation pool raises (and the corresponding reduction in available flood storage) earlier than anticipated based upon historical sedimentation rates.

Dam Safety: Increases in temperatures and precipitation patterns from future climate change has the potential to increase maximum probable extreme event precipitation. This has major implications for dam safety if climate

change results in increased probable maximum precipitation estimates. Due to the extreme nature of these design events (having an expected recurrence of approximately once every 10,000 to 100,000 years), it was not unexpected that the 30-year blocks of future climate information do not support a direct analysis of climate change on the adequacy of the project's spillway design flood to meet future climate conditions. Continued monitoring of the trends in extreme precipitation is critical in order to detect changes in the intensity and frequency of heavy rainfall events.

LESSONS LEARNED

Lessons Related to the Physical System and Climate:

Lesson: The dynamically-downscaled NARCCAP dataset was limited in its representation of hydrologic extremes (major flood or drought). This may be due to sampling error (limitation of using 30 years blocks of future climate data to evaluate extreme events having a frequency of significantly greater than once every 30 years), or limitations in the datasets resulting from climate model biases that under represent precipitation variability. The expectation of this kind of climatic shift comes from literature and observed changes in the Midwest; however, we found that the NARCCAP dataset was insufficient for us to test these shifts in our system.

Lesson: It was observed that regional climate models may not adequately represent the local meteorology. The WRFG model performed better in terms of timing and frequency of precipitation, but overall the results were biased on the dry side. The results from CRCM were not at all similar to local weather. We found that screening the RCMs prior to use would have helped guide dataset selection and allowed us to use RCMs more "in tune" with local meteorology if they were available.

Lessons Related to the Methodology and Process Used:

Lesson: The original plan for the study was based on the expectation of greater precipitation and corresponding greater future flood risk (i.e., assumed direction of change). Consequently, the analysis was designed to answer questions specifically related to the expected outcome. We found our questions regarding climate vulnerabilities were too specific, and that more broad questions about these vulnerabilities are warranted. Asking, "How do I deal with greater and more frequent extremes?" is too specific and is biased by expectations about what the climate data will indicate; a broader question to ask is, "What vulnerabilities exist with my project related to future climate variability and how can those vulnerabilities be managed?"

Lesson: Understanding the limitations and biases of downscaled climate data would have changed the path of our study. In addition to broadening the questions that are asked of the climate data, we discovered that the approach to analyzing the climate data would be determined best by first understanding the project's sensitivity and vulnerability to climatic variation and then formulating alternatives to reduce the climate sensitivity (increase robustness) of the project.

Lesson: Hydrologic models as tools for assessing climate change impacts have significant weaknesses, even if calibrated to the system being analyzed. The inability for the hydrologic model used in this study to simulate high peak flows made even the largest precipitation events result in moderate or moderately-high flows. However, a hydrologic model calibrated to simulating peak discharge events will not be able to capture long-term flow parameters important for other reservoir management considerations, such as sedimentation and drought.

Lesson: The inability of the dynamically downscaled climate data to provide a basis for developing regulation procedures to reduce risk in future major flood events emphasizes the importance of short term climate forecasts and the need to develop tools capable of informing water managers with risk-based decision criteria to evaluate operational scenarios during an event. While this implies a level of flexibility in future water management operations that traditionally has not been built into water control plans, any such implementation would need to clearly establish the criteria by which water management decisions will be made. This is consistent with the current USACE national effort to fully develop and deploy the CWMS National Implementation Plan.

ACKNOWLEDGEMENTS

We wish to thank the North American Regional Climate Change Assessment Program (NARCCAP) for providing the data used in this paper. NARCCAP is funded by the National Science Foundation (NSF), the U.S. Department of Energy (DoE), the National Oceanic and Atmospheric Administration (NOAA), and the U.S. Environmental Protection Agency Office of Research and Development (EPA).

USING AN INTEGRATED SURFACE WATER-GROUNDWATER FLOW MODEL FOR EVALUATING THE HYDROLOGIC IMPACTS OF HISTORIC AND POTENTIAL FUTURE DRY PERIODS ON SIMULATED WATER BUDGETS IN THE SANTA ROSA PLAIN WATERSHED, NORTHERN CALIFORNIA.

Joseph A. Hevesi, Research Hydrologist, U.S.G.S., Sacramento, CA, jhevesi@usgs.gov; Linda R. Woolfenden, Research Hydrologist, U.S.G.S., Sacramento, CA, lrwoolfe@usgs.gov; Tracy Nishikawa, Research Hydrologist, U.S.G.S., San Diego, CA, tnish@usgs.gov

Communities in the Santa Rosa Plain watershed (SRPW), Sonoma County, California are experiencing population growth and increasing demand for limited water resources. Streamflow in the SRPW is runoff dominated; however, groundwater also is an important resource in the basin. The watershed has an area of 262 square miles that includes natural, agricultural, and urban land uses. To evaluate the SRPW hydrologic system, an integrated hydrologic model was developed using the U.S. Geological Survey coupled groundwater and surface-water flow model, GSFLOW. The model uses a daily time step and a grid-based discretization of the SRPW to simulate all water budget components of the surface and subsurface hydrologic system, including components of streamflow, recharge, evapotranspiration, unsaturated and saturated groundwater flow, and changes in groundwater storage. Model results were analyzed to assess the effects of historic dry periods on the hydrology of the SRPW. Simulation results indicate significant effects on streamflow and recharge in response to the below-average precipitation that occurred during the dry periods. Although some results for the historic dry periods are similar, differences in the location of gaining and losing stream reaches have changed between earlier and more recent dry periods due to streamflow capture by groundwater pumping that has increased significantly between the two time periods.

The recharge and streamflow distributions simulated for historic dry periods were compared to future dry periods projected from 2 General Circulation Models (GCMs) and two CO_2 forcing scenarios for the 21st century. Decreases in recharge and streamflow or many of the projected dry periods were greater than for the historic dry periods due to a combination of lower precipitation and increases in simulated evapotranspiration for the warmer 21st century climates projected by the GCM realizations. The greatest effect on streamflow for both historic and projected future dry periods is the diminished baseflow simulated for the dry season, from late spring to early fall, with an increase in the percentage of intermittent and dry stream reaches. The results indicate that the coupled model is a useful tool for water managers to better understand the sensitivity of spatially and temporally distributed streamflow and other components of the water budget to potential future dry periods and groundwater pumping.

COLLABORATION ON CLIMATE CHANGE ANALYSIS IN THE PACIFIC NORTHWEST

James D. Barton, P.E., D.WRE, Chief of Columbia Basin Water Management Division, Corps of Engineers Northwestern Division, Portland, OR, james.d.barton@usace.army.mil

ABSTRACT

Climate change is likely to have a significant effect on the future of water management in the Pacific Northwest. Because many dams in this region such as those on the Columbia River are operated as a system and involve many different owners and operators, regional coordination among the various entities is extremely important. This is particularly true on issues like climate change, where the effects may vary considerably in different parts of the region.

In collaboration with the U.S. Bureau of Reclamation, Bonneville Power Administration, and other entities in the region, the U.S. Army Corps of Engineers Northwestern Division recently completed efforts to analyze the effects of climate change on water supply and water management activities in the Pacific Northwest using a regional approach. One of the major goals of this effort was to develop a common set of data, models, and tools that can be used by entities throughout the region to analyze climate change. This information was based on climate projections from the Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment Report produced in 2007. Subsequent to this effort, the IPCC issued their Fifth Assessment Report, and work is now underway by this regional group to update the analysis of the effects of climate change on water management activities. These coordinated efforts are focused on reducing the potential for duplication, overlap, and conflicting results on climate change activities undertaken by the various entities, while at the same time improving regional collaboration and coordination.

The overall approach used in this effort involved the following two main phases of work that will be described in further detail: (1) selection and adoption of future climate and hydrology data that was evaluated and then used to develop water supply forecasts to reflect future hydrologic and climate conditions; (2) simulation of expected future reservoir operations using long-term reservoir models to analyze potential changes in water management planning and operations.

The climate and hydrologic data used in the first phase of this effort was developed by the University of Washington Climate Impacts Group (UW CIG). They produced "downscaled" climate data that was incorporated into a regional hydrology model that was used to produce a set of river flows for locations throughout the Columbia River Basin and associated subbasins. The "downscaling" effort involved refining global climate data into smaller geographic areas, providing usable data that better captured the highly varied mountain and valley regions of the Pacific Northwest. Two future time periods were studied and included the 30-year period surrounding the 2020s (2010 to 2039) and the 30-year period surrounding the 2040s (2030 to 2059).

The study results suggested that the Columbia River Basin annual air temperatures will rise from 1 to 3 degrees Fahrenheit above the historical reference period by the 2020 period and from 2 to

5 degrees Fahrenheit by the 2040 period. This change would affect Columbia River Basin precipitation and snowpack patterns (more rain, less snow), seasonal river flows, hydroelectric generation, demand for electricity, and other key areas. Water temperature was not a part of this study, but may be included in future analysis. Overall, yearly precipitation changes in the study were minimal, averaging a 1 to 2 percent increase. All of the climate change scenarios analyzed exhibited a seasonal shift of higher flows in the winter and lower flows in the summer. This seasonal shift is due in part to more winter precipitation in the form of rain instead of snow and increased snowmelt earlier in the year due to warmer temperatures.

The results of the second phase of this effort that involved simulation of expected future reservoir operations varied depending on the basin or subbasin that was being evaluated. For example, for the overall Columbia River Basin, during the winter-early spring period (January to April) the runoff amounts for the 2020s ranged from 108 to 150 percent of normal for the unregulated flows at The Dalles Dam on the lower Columbia River just upstream of Portland, Oregon. For the 2040s, the runoff amounts for this same period ranged from 95 to 170 percent of normal for unregulated flows. In contrast, during the summer period of June to August, the runoff amounts for the 2020s ranged from 80 to 95 percent of normal for unregulated flows at the Dalles Dam. For the 2040s, the runoff amounts varied from 65 to 95 percent of normal for unregulated flows.

Based on the analysis of the affect of climate change on reservoir operation, it is anticipated that some changes may be needed in reservoir operations. For example, flood risk management procedures will need to account for a projected shift in the timing of the spring runoff, with the average monthly peak runoff shifting from June to May. Related to this, earlier releases of water may be needed from flood risk management projects to capture the early runoff. Also, impacts to the timing of federal hydropower system operations could also impact other operational objectives in the spring and summer such as for fish and wildlife. The increase in the spring flows could results in higher power generation and increased spill of water at many dams. The additional spill could increase total dissolved gas levels, which could negatively impact fish.

ADHydro: QUASI-3D HIGH PERFORMANCE HYDROLOGICAL MODEL

Fred L. Ogden, Professor, fogden@uwyo.edu; Wencong Lai, Post-doctoral Associate, wlai@uwyo.edu; Robert C. Steinke, Research Scientist, rsteinke@uwyo.edu

Abstract: In recent decades, computational models have been developed to solve point-scale process models using physics-based or conceptual approaches. The integration of these processes across space-time has been limited by computational power to either high-resolution over small spatial domains, or coarse resolution over large spatial domains. These modeling approaches have lead to improved understanding at both small and large scales, but have required parameterization of important phenomenon, and the corresponding lack of model sensitivity to changes and uncertainties in parameter values. The CI-WATER project, a cooperative agreement between the US National Science Foundation EPSCoR program and the Utah and Wyoming Ph.D.-granting universities, is developing tools to cross the digital divide that impedes application of high performance computing (HPC) to solve hydrological science, engineering, and management problems. We are developing software tools to ease simulations using HPC resources. These tools include web-aware model setup and visualization tools that will interact with dedicated HPC systems or cloud systems, workflows for model setup, and web services for data provisioning. These tools are being developed with generality in mind, supporting a range of HPC-aware models, including the US Army Corps of Engineers Gridded Surface/Subsurface Analysis (GSSHA) model, and an unstructured mesh high-resolution physics-based hydrological model, called ADHydro. The ultimate objective of ADHydro development is perform multi-decadal simulations of large watersheds such as the Upper Colorado River above Lake Powell (288,000 km^2) in the contexts of land use, water use, and climate changes. We are cooperating with the US Army Corps of Engineers, Engineering Research and Development Center, Coastal and Hydraulics Laboratory, and the National Center for Atmospheric Research, Research Applications Laboratory in linking with their HPC hydrological and atmospheric models. This presentation will showcase our software tools under development.

INTRODUCTION

Physically-based, spatially distributed hydrologic models have been widely used in hydrologic modeling and watershed management, such as SWAT (Arnold et al., 1993), MIKE SHE (Refsgaard and Storm, 1995), and GSSHA (Downer and Ogden, 2004). Applications of such hydrologic models for large watersheds typically use coarse spatial and temporal resolution. Detailed simulation of larger watersheds with hyperresolution hydrological prediction is a grand challenge because significant computational resources and data are required (Wood et al., 2011).

In recent years, a growing number of distributed hydrological models have been developed in parallel computing environments with the advent of high performance computing (Apostolopoulos and Georgakakos, 1997; Cui et al., 2005; Wang et al., 2011; Vivoni et al., 2011; Hwang et al., 2014). HPC hydrological models coupled with meteorological models are capable to model high-resolution long term simulation in large watersheds in order to evaluate the impact of climate and land use changes. HPC hydrological models can be classified into two categories according to their parallel algorithm. One category of such models, for example ParFlow(Ashby and algout, 1996; Kollet and Maxwell, 2006), PFLOTRAN (Mills et al., 2007), PHGS (Hwang et al., 2014), utilize pre-developed HPC packages or libraries for parallel preconditioner and solver.

The other category of models adopt spatial domain decomposition with either sub-basin based (Li et al, 2011; Vivoni et al., 201; Wu et al., 2013) or unit based message passing (Cheng et al., 2005; Liu et al., 2014).

Parallelization of hydrologic models can be implemented using parallel programming standards such as Open Multi-Processing (OpenMP), Message Passing Interface (MPI), grid computing, and other parallel programming toolkit. The PHGS (Hwang et al., 2007) applied OpenMP in the HydroGeoSphere model using parallel matrix solver. The FSDHM model was parallelized using OpenMP by dividing simulation units into hydrologic independent layers (Liu et al., 2014). However, OpenMP only works in shared memory machines. Yalew et al. (2013) parallelized the SWAT watershed model using the distributed grid computing by splitting large scale model into small scale components. As MPI can distribute computing loads and converge results through message transfer and communication between processors, it is the most used technology in parallel hydrologic models for domain decomposition (Li et al, 2011; Vivoni et al., 2011; Wang et al., 2011; Wu et al., 2013). However, using the MPI library for data partitioning and communication is not straightforward. The pWASH123D model (Cheng et al., 2005) utilizes the DBuilder (Hunter and Cheng, 2005) parallel data management toolkit, which hides the MPI scheme for map generating, sending, and receiving between meshes with simple Application Programming Interfaces (API) and embedded ParMETIS partitioner library (Karypis et al., 1997).

The development of the ADHydro model is presented here. The ADHydro model is a high-resolution physics-based distributed hydrological model developed in parallel computing environment. The merits of the model comparing with other HPC hydrologic models include: an innovative method for modeling vadose zone dynamics, a water management module considering reservoirs, diversions and irrigation, a coupled strategy to estimate interception evaporation, and snow processes through the community Noah land surface model with mutiparameterization options (Noah-MP) and the capability to ingest downscaled atmospheric forcing from the Weather Research and Forecasting (WRF) meteorologic model using the CHARM++ parallel programming environment.

GEOSPATIAL DATA AND ATMOSPSHERIC FORCING

The Upper Colorado River Basin above Lake Powell has a watershed area of approximately 288,000 km^2, and total length of streams of 467,000 km. It's located in one of the 21 major geographic regions defined by the USGS hydrologic unit code (Seaber et al., 1987) in the US. In the pre-processing step, topographic base map data were acquired from National Elevation Dataset (NED) 1/3 arc-second Digital Elevation Models (DEMs), and USGS National Hydrography Dataset (NHD) (http://viewer.nationalmap.gov/viewer/). Land cover and land use data were obtained through the 30-meter resolution, 16-class land cover classification National Land Cover Database 2011 (NLCD 2011) (http://www.mrlc.gov/). Soil texture types were aggregated from the NRCS county level Soil Survey Geographic Database (SSURGO) and state-wide State Soil Geographic Database (STATSGO) (http://www.nrcs.usda.gov/wps/portal/nrcs/main/soils/survey/geo/).

The TauDEM tools (http://hydrology.usu.edu/taudem/taudem5/) were used to extract channel

network from NED DEMs. The resulting channel network and NHD were analyzed and processed by ArcGIS to produce shapefiles and steam network connectivity that includes lakes and reservoirs. The shapefiles were used to generate high resolution unstructured 2D triangular mesh using Triangle (http://www.cs.cmu.edu/~quake/triangle.html). A 1D channel network model with mesh size of 100 meters was also generated. River hydraulic geometry were described in the form of power functions of discharge, which scales with drainage area.

Atmospheric forcing for different scenarios was generated using the Weather Research and Forecasting meteorologic model (Michalakes et al., 2004). The WRF model is a mesoscale numerical weather prediction system design to both atmospheric research and operational forecasting needs. Simulation results from WRF, including precipitation, air temperature, air pressure, wind speed, short and long wave radiation and vapor pressure, were used as atmospheric forcing input for ADHydro. The 4 km resolution WRF outputs were downscaled to the high-resolution meshes.

ADHYDRO QUASI 3-D DISTRIBUTED HYDROLOGIC MODEL

The ADHydro is a high-resolution multi-physics distributed model for hydrological and water resources modeling. Major hydrologic processes are considered, including precipitation and infiltration, snowfall and snowmelt in complex terrain, vegetation and evapotranspiration, soil heat flux and freezing, overland flow, channel flow, groundwater flow and water management. These hydrologic components are described below.

The ADHydro model uses the explicit finite volume method to solve conservation laws for overland flow and saturated groundwater flow coupled to river flow. The model has a quasi-3D formulation that couples 2D overland flow and 2D saturated groundwater flow using the 1D Talbot-Ogden finite water-content infiltration and redistribution method (Talbot and Ogden, 2008). This eliminates difficulties in solving the highly nonlinear 3D Richards' equation, while the finite volume Talbot-Ogden infiltration method is computationally efficient, mass conservative, and allows simulation of the effect of shallow groundwater tables on runoff generation.

Interception, Evapotranspiration and Snow Melt: Interception, evapotranspiration and snow melt processes are simulated using the Noah-MP model (Niu et al., 2011; Yang et al., 2011). The Noah-MP model considers biophysical processes such as interactive vegetation canopy, multilayer snow pack and soil, overland runoff, and unconfined aquifer for groundwater storage with a dynamic water table. Its major components include 1-layer canopy, 3-layer snow, and 4-layer soil. In Noah-MP, partitioning precipitation into rainfall and snowfall use surface air temperature as a criterion, the canopy water scheme simulates the canopy water interception and evaporation, and the “semitile” subgrid scheme calculates the skin temperature of the canopy and snow/soil surface separately using an interactive energy balance method. Snow and soil layer temperatures are used to asses the energy for melting and freezing for the snow and soil layers. Noah-MP model input includes static input data (e.g. vegetation and soil data, latitude and longitude) and atmospheric forcing data (e.g. precipitation, air temperature, humidity, radiation).

Overland Flow Routing: The shallow overland flow can be simulated using dynamic wave or

diffusive wave Shallow Water Equations (SWE). The depth-averaged 2D shallow water equations are derived by integrating the Navier-Stokes equations in the vertical direction under the assumptions of hydrostatic pressure distribution and uniform velocity profiles in the vertical direction. The dynamic wave SWE can be written as (Ying et al., 2009):

$$\begin{aligned} \frac{\partial h}{\partial t} + \frac{\partial hu}{\partial x} + \frac{\partial hv}{\partial y} &= q_s \\ \frac{\partial hu}{\partial t} + \frac{\partial hu^2}{\partial x} + \frac{\partial huv}{\partial y} &= g\,h\left(-\frac{\partial Z}{\partial x} - S_{fx}\right) \\ \frac{\partial hv}{\partial t} + \frac{\partial huv}{\partial x} + \frac{\partial hv^2}{\partial y} &= g\,h\left(-\frac{\partial Z}{\partial y} - S_{fy}\right) \end{aligned} \tag{1}$$

where h is water depth, q_s is source/sink term, u and v are flow velocities in x and y directions, respectively, $Z = h + z_g$ is water surface elevation, z_g is surface ground elevation, and S_{fx} and S_{fy} are friction slopes.

Further under the diffusion wave approximation where inertia is not important (Akan and Yen, 1981), the diffusive wave SWE is given as:

$$\frac{\partial h}{\partial t} = \frac{\partial}{\partial x}\left(hk\frac{\partial Z}{\partial x}\right) + \frac{\partial}{\partial y}\left(hk\frac{\partial Z}{\partial y}\right) + q_s \tag{2}$$

where the diffusion coefficient:

$$k = \frac{h^{2/3}}{n}\frac{1}{\left(\partial Z/\partial s\right)^{1/2}} \tag{3}$$

with s is the maximum slope direction, and n is Manning's roughness coefficient. The diffusive wave approximation neglects the local acceleration term and convective acceleration term in the momentum equations, and it is applicable in situations where Froude number is small.

Channel Flow Routing: The dynamic wave governing equations (Saint-Venant equations) for one-dimensional flows in natural rivers include the continuity equation and momentum equation:

$$\begin{aligned} \frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} &= q_s \\ \frac{\partial Q}{\partial t} + \frac{\partial Q^2/A}{\partial x} &= -gA\frac{\partial Z}{\partial x} - gAS_f \end{aligned} \tag{4}$$

where A is cross section area of the channel, and Q is volumetric flow rate. The dynamic wave equations can also be simplified under diffusive wave assumption:

$$\frac{\partial A}{\partial t} - \frac{\partial}{\partial x}\left(\frac{A R^{2/3}}{n}\frac{\partial Z/\partial x}{\sqrt{|\partial Z/\partial x|}}\right) = 0 \tag{5}$$

Level pool routing method is used for lakes and reservoirs:

$$\frac{dS}{dt} = I - O + R - E - S_p + O_l \tag{6}$$

where S is volume of storage in the reservoir, I is inflow, O is outflow, R is rainfall, E is evaporation, S_p is seepage, and O_l is lateral overland flow. Cross-section properties come from empirically-derived scaling relations for the 2-year flow coupled with bankfull cross-section estimators.

Coupling 1D Channel and 2D Overland Flow: A source term based lateral connection between 1D channel and 2D overland flow domain is used. The broad-crested weir discharge is calculated as (Blade et al., 2012):

$$Q_L = \begin{cases} K\,L(z_1 - z_w)\sqrt{2\,g(z_1 - z_w)}, & \frac{2}{3}(z_1 - z_w) \geq (z_2 - z_w) \\ 2.6\,K\,L(z_2 - z_w)\sqrt{2\,g(z_1 - z_w)}, & \frac{2}{3}(z_1 - z_w) < (z_2 - z_w) \end{cases} \tag{7}$$

where z_1 is headwater surface elevation, z_2 is tailwater elevation, and z_w is weir crest elevation, L is the length of 1D channel element in contact with 2D mesh edge, and K is a constant (generally $0.3 < K < 0.6$).

Unsaturated Vadose Zone Flow: The 1D infiltration and redistribution method in the discretized moisture content domain (Ogden et al. 2015b, Talbot and Ogden, 2008), and an optional approximation (Lai et al., 2015) are used to simulate vadose zone flow. The T-O method assumes homogeneous soil, and the water moisture content is discretized into hypothetically interacting bins. The soil moisture characteristic and unsaturated hydraulic conductivity curves are required to discretize the T-O domain. These curves can be described using soil characteristic models such as Brooks-Corey model (1966) or van Genuchten model (1980).

In T-O method, the movement of surface water and groundwater in each bin is simulated, followed by the process of redistribution. The infiltration advancement of surface wetting front in a bin k due to capillary and gravitational forces is given as:

$$\frac{dZ_j}{dt} = \frac{K(\theta_d) - K(\theta_i)}{\theta_d - \theta_i}\left(1 + \frac{|h(\theta_d)| + h_p}{Z_j}\right) \tag{8}$$

where Z_j is position of surface wetting front of bin j, θ_i is initial water content or the water content of the first bin that is not fully saturated from the groundwater table to the surface, θ_d is the water content of the right-most bin in the surface wetting front that contains water, $K(\theta_i)$ and $K(\theta_d)$ are the unsaturated hydraulic conductivity of the θ_i and θ_d bins respectively, h_p is depth of surface ponding, and $h(\theta_d)$ is the capillary pressure of θ_d bin. While the movement of a groundwater wetting front is given as (Ogden et al. 2015a):

$$\frac{dZ_j}{dt} = \frac{K(\theta_j) - K(\theta_i)}{\theta_j - \theta_i}\left(1 - \frac{|h'(\theta_j)|}{D_j}\right) \tag{9}$$

where the hydrostatic capillary height considering a constant surface influx $q_{in} < K_s$:

$$|h'(\theta)| = \frac{|h_b|}{1 - \frac{q_{in}}{K_s}} + \frac{|h(\theta)| - |h_b|}{1 - \frac{q_{in}}{2K(\theta)} - \frac{q_{in}}{2K_s}} \tag{10}$$

The redistribution process sorts the bin depths from deepest to shallowest going from left to right for both the surface wetting fronts and the groundwater wetting fronts. This redistribution scheme moves water at the same elevation laterally, and is similar to the game "Tetris™", but operating horizontally. After redistribution, the length of both surface wetting front and groundwater front decreases monotonically from high capillary suction to low capillary suction.

Saturated Groundwater Flow: The ADhydro model simulates groundwater flow using a quasi-3D unsaturated/saturated flow scheme. Flow in the vadose zone is modeled using the 1D infiltration and redistribution method, and flow in the saturated zone is simulated using the 2D Boussinesq equation. The Boussinesq equation for saturated 2D groundwater flow in unconfined aquifer is given by:

$$S_y \frac{\partial h}{\partial t} = \frac{\partial}{\partial x}\left(K_x h \frac{\partial H}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y h \frac{\partial H}{\partial y}\right) + R \tag{11}$$

where H is total groundwater hydraulic head, h is groundwater depth, K_x are Ky hydraulic conductivity, R is the vertical recharge rate to the saturated surface, and S_y is the specific yield.

Since the amount of water recharge to saturated zone ($W = R\Delta t$) is calculated using the 1D infiltration and redistribution method, to have a more consistent way coupling unsaturated-saturated zone, the saturated flow rate (R') into an element is calculated:

$$R' = \frac{\partial}{\partial x}\left(K_x h \frac{\partial H}{\partial x}\right) + \frac{\partial}{\partial y}\left(K_y h \frac{\partial H}{\partial y}\right) \tag{12}$$

This also allows the saturated flow and unsaturated flow calculated using different time steps. Then the change of groundwater depth can be written as:

$$\Delta h = \frac{R'\Delta t + W}{S_y} \tag{13}$$

The position of groundwater table is used as boundary condition for 1D unsaturated flow. For example, if the total recharge to saturated groundwater is positive ($R'\Delta t + W > 0$), the water table moves upward, the 1D moisture curve should move upward as well using available water from the total recharge.

Coupling 1D Channel and 2D Groundwater Flow: Lateral flow between channel and groundwater is a function of river water surface elevation and groundwater head. The specific flow rate from channel to groundwater can be calculated as (Gunduz and Aral, 2005):

$$q_L = \begin{cases} K_r w_r \dfrac{Z_r - H}{\Delta z_b}, & H > z_b - \Delta z_b \\ K_r w_r \dfrac{h + \Delta z_b}{\Delta z_b}, & H \le z_b - \Delta z_b \end{cases} \tag{14}$$

where K_r is river bottom sediment conductivity, w_r is river bed wetted perimeter, Δz_b is the river bed thickness, Z_r is river water surface elevation, H is groundwater head.

Water Management: A water management model is developed for the Upper Colorado River Basin. Emphasis are placed on the engineered aspects of water management and use, where storage reservoirs, diversions, and irrigation are simulated. Statistical based method and operation rules based optimization method are used. Operational water management rules are explored for the major reservoirs and irrigation districts in the Upper Colorado River Basin from Bureau of Reclamation (http://www.usbr.gov/uc/water/). Typical constrains and rules include maximum and minimum elevations, target elevations for wet and drought seasons, maximum and minimum releases, and contractual, legal, and institutional obligations (Yeh, 1985). The simulation/optimization model determines release decisions for different planning purposes. Interactions between reservoirs and river/aquifer system are also considered.

CHARM++ Parallelization: The ADHydro implementation uses the Charm++ parallel programming system. Charm++ is based on location transparent message passing between migrateable C++ objects. Each object represents an entity in the model such as a mesh element. These objects can be migrated between processors or serialized to disk allowing the Charm++ system to automatically provide capabilities such as load balancing and checkpointing. Objects interact with each other by passing messages that the Charm++ system routes to the correct destination object regardless of its current location.

STORM: A MODEL FOR 2D ENVIRONMENTAL HYDRAULICS

Francisco J.M. Simões, US Geological Survey, Geomorphology and Sediment Transport Laboratory, Golden, CO 80403, frsimoes@usgs.gov

Abstract: A two-dimensional (depth-averaged) finite volume Godunov-type shallow water model developed for flow over complex topography is presented. The model, SToRM, is based on an unstructured cell-centered finite volume formulation and on nonlinear strong stability preserving Runge-Kutta time stepping schemes. The numerical discretization is founded on the classical and well established shallow water equations in hyperbolic conservative form, but the convective fluxes are calculated using auto-switching Riemann and diffusive numerical fluxes. Computational efficiency is achieved through a parallel implementation based on the OpenMP standard and the Fortran programming language. SToRM's implementation within a graphical user interface is discussed. Field application of SToRM is illustrated by utilizing it to estimate peak flow discharges in a flooding event of the St. Vrain Creek in Colorado, U.S.A., in 2013, which reached 850 m^3/s (~30,000 f^3/s) at the location of this study.

INTRODUCTION

Current climate change science and research predictions, such as those identified in the recent Intergovernmental Panel on Climate Change report (IPCC, 2014), indicate the hazards of flooding and their detrimental impacts are becoming more frequent and likely to increase. The need to cope with flooding effects—such as floodplain regulations, insurance, mitigation engineering works, and emergency preparedness—requires tools that can be used to provide accurate predictions of flood timing, duration, and extent. A numerical flow model that solves the shallow water equations (SWEs) and simulates the hydrodynamics of a wide variety of surface flows will be a significant asset in the gamut of tools available to engineers, managers, and decision makers involved in floodplain management. Such a model needs to be accurate, robust, efficient, and be available in a computer environment that facilitates data processing and analysis to reduce project turnaround time.

Moreover, the increased availability of high accuracy digital terrain models (DTMs) over large extents (tens to hundreds of square miles, or more) have created the demand for models that can be used to address inundation events at those scales. These DTMs are often created using remotely sensed terrain data (e.g., Light Detection and Ranging (LiDAR) or interferometric Synthetic Aperture Radar (ifSAR)) with typical horizontal resolutions of 1 m that retain very detailed features, such as individual buildings and roads. Simulating surface flow with this type of spatial accuracy can only be done at high computational cost, requiring computer systems that can accommodate the vast amounts of data in memory and that have fast numerical processors.

In the past decade, Godunov-type schemes using a finite volume formulation have become popular for solving the SWEs (Toro and Garcia-Navarro, 2007; Vazquez-Cendon et al., 2013). This can be attributed to the ability of these schemes to deal with the most complicated shallow water phenomena, such as hydraulic jumps, flow regime change, and the wet-dry interfaces encountered in fast moving catastrophic flooding flows. SToRM (System for Transport and River Modeling) is a model that employs these techniques in two-dimensional (2D) unstructured grids (Simões, 2011), and that is contained in a graphical user environment that provides a number of tools to expedite its use by trained operators.

The purpose of this article is to provide a brief presentation of the computer model SToRM and to explore the use of parallelism to improve computational efficiency in the setting of a desktop workstation. The following sections will present the governing equations and computation methods used to develop the numerical model; how parallelism is employed to move from a single- to a multi-threaded computing environment; and SToRM's implementation in a graphical user interface. Finally, to illustrate the methods in a problem of practical and recent significance, SToRM is applied to estimate peak flood flow rates in a section of the historic flooding that occurred in St. Vrain Creek, Colorado, in September of 2013.

MODEL FORMULATION

SToRM is based on the classical SWEs written in the conservative form (Chaudhry, 1993):

$$\frac{\partial \mathbf{U}}{\partial t}+\frac{\partial \mathbf{F}(\mathbf{U})}{\partial x}+\frac{\partial \mathbf{G}(\mathbf{U})}{\partial y}=\mathbf{S(U)} \tag{1}$$

$$\mathbf{U}=\begin{bmatrix} h \\ hu \\ hv \end{bmatrix},\quad \mathbf{F}=\begin{bmatrix} hu \\ hu^2+gh^2/2 \\ huv \end{bmatrix},\quad \mathbf{G}=\begin{bmatrix} hv \\ huv \\ hv^2+gh^2/2 \end{bmatrix},\quad \mathbf{S}=\begin{bmatrix} 0 \\ gh\left(S_{0x}-S_{fx}\right) \\ gh\left(S_{0y}-S_{fy}\right) \end{bmatrix}$$

where t is time, h is the water depth, g is the acceleration due to gravity, u and v are the depth-averaged flow velocities in the x and y Cartesian directions, S_0 is the bed slope, and S_f is the bottom friction. Integrating equation (1) over a standard control volume Ω and applying the divergence theorem results in

$$\frac{\partial}{\partial t}\int_{\Omega}\mathbf{U}d\Omega+\oint_{\partial\Omega}\left(\mathbf{E}\cdot\mathbf{n}\right)ds=\int_{\Omega}\mathbf{S}d\Omega \tag{2}$$

where $\mathbf{E} = (\mathbf{F},\mathbf{G})^{\mathrm{T}}$ and $\mathbf{n}$ is the outward-pointing unit vector normal to the control volume boundary $\partial\Omega$. SToRM is based on the numerical integration of equation (2) over cell-centered, non-overlapping triangles:

$$\frac{\partial \Omega_i \mathbf{U}_i}{\partial t}=\sum_{k=1}^{3}\mathbf{E}_{ik}\Delta l_{ik}+\mathbf{S}_i\Omega_i \tag{3}$$

In equation (3), $\mathbf{U}_i$ are the average values of the conserved variables over triangle i, $\mathbf{E}_{ik}$ are the inviscid fluxes through triangle edge k, Δl_{ik} is the length of edge k, $\mathbf{S}_i$ contains the source terms, and Ω_i is the triangle's area.

Following the principles of Godunov-type methods, the inviscid fluxes $\mathbf{E}_{ik}$ are numerical fluxes arising from a local Riemann problem at each triangle edge. Here, $\mathbf{E}_{ik}$ are computed using Roe's flux function at those edges (Roe, 1981):

$$\mathbf{E}_{ik}=\frac{1}{2}\left[\left(\mathbf{E}_{ik}^{+}+\mathbf{E}_{ik}^{-}\right)-\mathbf{\Gamma}\left(\mathbf{U}_{ik}^{+}-\mathbf{U}_{ik}^{-}\right)\right]$$

where the '+' quantities are reconstructed at the midpoint of the edge k using data from control volume i and the '-' quantities are reconstructed using data from the adjacent control volume. In SToRM, the up-winding factor $\mathbf{\Gamma}$ can be computed in one of two manners: (1) as in the algorithm of Alcrudo and Garcia-Navarro (1993) or (2) by using Rusanov's (1961) numerical flux. The first approach is more computational demanding (i.e., it requires more computer number crunching), but it has the shock capturing properties needed to compute the flow at discontinuities such as hydraulic jumps and wet-dry fronts, whereas the latter is computationally much simpler and less demanding, but may introduce spurious numerical diffusion into the solution. The decision of which to use is done at each triangle edge: if $|h^{+}-h^{-}|/\mathrm{Max}\{h^{+},h^{-}\} > \delta_s$ then Alcrudo and Garcia-Navarro's method is used, otherwise Rusanov's method is used. A threshold value, δ_s, is used to detect discontinuity across element edges and is usually set to 0.1%, a value found by numerical experimentation.

Second-order accuracy is achieved using a piecewise linear model for the cell variables with the usual MUSCL (Monotonic Upstream-Centered Scheme for Conservation Laws) reconstruction, with limiting to enforce monotonicity near sharp gradients and discontinuities of the dependent variables. The continuously differentiable limiter by Venkatakrishnan (1995) is chosen because it avoids introducing discontinuities to the computation of the reconstructed function and, consequently, to the fluxes, therefore improving the convergence properties of the solver over other commonly used discontinuous limiters. Computation of the gradients is accomplished with a second-order-accurate least-squares technique conditioned by the use of inverse distance weighting.

The friction terms are discretized in a semi-implicit manner:

$$q_{xi}^n = \frac{\underline{q}_{xi}^n}{1 + g\Delta t \underline{S}_{fxi}^n / \underline{u}_i^n}, \quad q_{yi}^n = \frac{\underline{q}_{yi}^n}{1 + g\Delta t \underline{S}_{fyi}^n / \underline{v}_i^n} \tag{4}$$

where $q_x = hu$ and $q_y = hv$ are the components of the unit discharge, the superscript n refers to the time step, and the underlined variables are frictionless-computed quantities. This discretization avoids numerical oscillations in regions of high friction and low water depth, such as in wet-dry fronts, and impacts positively the conditional stability limits of the time-stepping method mentioned in the next paragraph.

The solution is advanced explicitly in time using nonlinear Strong Stability Preserving Runge-Kutta (SSPRK) schemes, also known as Total Variation Diminishing (TVD) Runge-Kutta schemes (Gottlieb et al., 2001). This is done by first rewriting the governing equations, equation (3), as a coupled system of ordinary differential equations:

$$\Omega_i \frac{\partial q_i}{\partial t} = R_i(u, v; t), \qquad i = 1, 2, 3 \tag{5}$$

where R_i is called the residual. Here, a simplified form of the SSPRK schemes is used, in which a m-stage SSPRK method for equation (5) is written in the form

$$\begin{cases} u^{(0)} = u^n \\ u^{(i)} = \sum_{j=0}^{i-1} \alpha_{ij} u^{(j)} + \beta_i \frac{\Delta t}{\Omega_i} R\left(u^{(i-1)}\right), \qquad \alpha_{ij} \geq 0, i = 1, \ldots, m \\ u^{n+1} = u^{(m)} \end{cases} \tag{6}$$

where Δt is the time step size, the superscripts n and $n + 1$ denote the time level, and the parenthetic superscripts denote the Runge-Kutta level. The coefficients α and β are chosen to meet desired criteria. SToRM implements three optimal (in the sense of the Courant-Friedrichs-Lewy CFL stability coefficient θ) SSPRK schemes: first order (m = 1), second-order (m = 2), and third-order (m = 3). Note that these schemes are all subjected to the same stability criterion and have an upper bound for θ.

Boundary conditions are applied at the edges of the model grid using Riemann invariants, i.e., the boundary fluxes are also computed by solving a Riemann problem between the interior states and the "ghost" states outside the computational domain. These "ghost" states are introduced in order to compute the boundary fluxes in a similar and consistent way to the interior fluxes. Here, an approach identical to that of Anastasiou and Chan (1997) is used for solid walls, inflow, and outflow boundaries. However, wetting and drying fronts require a separate treatment.

Wetting and drying occurs not only during the propagation of floods, but also at the edges of any body of water. Thus, the dry-wet front constitutes not only a propagation problem, but also a static boundary condition problem, because it defines the shoreline. It is not easy to include these effects in a straightforward manner in a numerical code and most researchers resort to different degrees of approximation. Advancing wet-dry fronts are treated with the method of Brufau et al. (2002), which uses a numerical flux that can be applied to zero-depth cells and that maintains the C-property[1]. The key concept is that the fluxes at the advancing front must be determined from the wet side of the front: the velocity at the cell boundaries separating wet and dry states is determined from the wet side, and the interface flux only uses the information coming from the wet side. This procedure allows including wetting and drying fronts in the ordinary cell flux computations without requiring the artificial wetting of dry cells. Drying fronts pose the additional problem that, during a drying time step, negative water depths may be reached. Mass conservation requires that the time step should be restricted to the value that corresponds to the time that takes the cell to dry out, i.e., to reach h_i = 0. SToRM performs additional checks and adjustments to ensure that mass is conserved at every time step without imposing these constraints to the time step size. These checks and adjustments are presented with greater detail in Simões (2011).

[1] A numerical scheme that preserves exactly initial solutions of a steady state lake at rest is said to verify the C-property.

The shoreline treatment is different from the two preceding cases. A shoreline is defined when all the surrounding dry triangles of a partially or fully wet control volume have a mean bed elevation higher than the stage at the centroid of the triangle. Under this circumstance the shoreline is defined at the control volume edges and is also subjected to a special treatment. Partially wet triangles have corrections applied to their wetted area and water depth. The treatment is different whether drying or wetting is occurring. The interested reader is referred to Simões (2011), where detailed descriptions and validations of the methods are presented.

PARALLEL IMPLEMENTATION

SToRM was developed using the programming language Fortran 90/95 using the traditional instruction-driven SISD (Single Instruction, Single Data) computing model, where a single processor executes one instruction stream that operates on data stored in the same memory as the instructions. The algorithms and techniques used were essentially sequential in nature. The programming style, however, was modular and the use of a code profiler (Intel® Parallel Studio XE 2013 was used) permitted to clearly identify regions of the program that consumed the most central processing unit (CPU) run times and, from those, the sections of the code that were the best candidates for parallelization. These sections were then targeted for treatment, with two development criteria: (1) the parallel code must give identical results to its sequential version, and (2) there must be a reduction in computing run time over the original code.

The hardware tools available for the development of this project consisted of a desktop computer with dual Intel® Xenon® E5-2630 v2 CPUs running at 2.60 GHz, 16 GB of RAM, and using the Microsoft® Windows® 8.1 64-bit operating system. Each of the CPUs contains 6 cores and 12 threads, making a total of 24 threads available to the user. The graphics capabilities were provided by a NVIDIA® Quadro® K600 graphics processing unit (GPU) with 1 GB of memory and 192 CUDA[2] cores. The GPU supports several graphics and compute APIs (Application Program Interfaces), such as OpenGL 4.4, DirectX 11, CUDA, and OpenCL. The software tools used consisted in the group of programming applications available in the Intel® Parallel Studio XE 2013 software package (see https://softare.intel.com for the latest version available).

Parallelism can be achieved in a number of ways, but this project was restricted by the hardware described above and by keeping the code development efforts limited to relatively short times. Furthermore, there was the desire to use standard, high-level programming tools to achieve maximum portability to different hardware platforms and operating systems. Given the possibility of using the programmable graphics hardware as a general-purpose computing machine, both the GPU and the CPU can be used to reach these goals.

GPUs provide an attractive platform for parallel application development because most modern computers include programmable GPUs that have a floating point computational power that typically is more than one order of magnitude higher than comparable CPUs. Additionally, because GPUs have a more scalable architecture, their power is expected to grow considerably faster than the computational power of CPUs. Hagen et al. (2005) have developed a GPU-based numerical model of the SWEs with explicit time marching schemes. They achieved a speedup of more than one order of magnitude over using the CPU alone, and showed that the GPU can be used as an inexpensive alternative to high-performance computers. Interestingly, the number 2 system in the Top500 supercomputers (TOP500 Supercomputing Sites, available at http://www.top500.org/, accessed January 2015) in November 2014, which was the latest published list at the writing of this article, uses NVIDIA GPUs to accelerate computation. Unfortunately, GPUs are based on the SIMD (Single Instruction, Multiple Data) computing model, which is significantly different from the SISD model used in SToRM. In the SIMD model, the processor is first configured with the instructions that will be executed, and then the data stream is processed. In other words, SToRM was developed based on an instruction driven model, while GPU programming requires a stream processing model. These differences require substantial changes to the fundamental algorithms already developed and implemented in SToRM and place an onerous burden in code redevelopment and debugging.

There are other more attractive approaches to parallelism that maintain the same SISD programming paradigm and that constitute established standards and, therefore, are portable across a large spectrum of machines. Two established

[2] CUDA stands for Compute Unified Device Architecture. It is a parallel computing architecture developed by NVIDIA.

standards supported in the Intel® Parallel Studio XE 2013 application development environment are Intel® MPI (Message Passing Interface) and OpenMP (Open Multi-Processing). MPI is a distributed memory multi-processor system in which each processor has its own private memory. The processors are interconnected and can communicate among themselves, therefore the efficiency of communication is very important for good performance. An important realization of such a system is given by computer clusters that may contain hundreds or thousands of individual computational nodes. At the time of this writing, the number 1 system in the Top500 supercomputers list is a cluster of 3,120,000 Intel® Xeon® E5-2692 CPUs, with a peak computing of near 55,000 TeraFLOPS (floating-point operations per second). Sanders et al. (2010) have presented a parallel flow model for flood inundation computations on unstructured grids. They used several different sized clusters and achieved high rates of efficiency in all. Their approach, however, depends on load balancing to a high degree, i.e., on the manner in which the computational grid is partitioned among the multiple nodes of the cluster. The key to achieve a good partitioning is to subdivide the grid into subdomains with equal computation workload while sharing the least amount of data. Alas, partitioning is a computationally expensive task and is typically done only once and at the start of the computer run. Flooding, however, is an intrinsically transient phenomenon, therefore a dynamic load balancing—where all cluster nodes have to process the same number of wet and dry cells during the flooding event—is required to maintain an optimum balance. A very efficient algorithm is needed in order to minimize the computational overhead associated with recomputing the load balance and retransmitting the appropriate data to all the cluster nodes during the flooding process. Developing such an algorithm is very difficult and time consuming, and was outside of the scope of the current project.

The MPI paradigm described above is an example of coarse-grain parallelism, where parallelism in a program is achieved by decomposing the target domain into a set of subdomains that are distributed over the different processors of the machine. OpenMP, on the other hand, is an example of fine-grain parallelism, in which parallelism in a program is achieved by distributing the work of the DO-loops among the different processors, such that each processor computes only a portion of the loop iterations. Given that the most computationally-intensive segments of the code in SToRM are done in DO-loops, OpenMP was chosen as the most suitable choice of technique to achieve the desired goals.

OpenMP is an API for writing multithreaded (MT) applications that consists of a set of compiler directives, library routines, and environment variables. It greatly simplifies the development of MT applications in Fortran, C, and C++. It assumes the hardware provides a shared memory workspace with equal-time access for each process (thread), and that the OS treats every process the same way: it is a SMP, or Symmetrical Multiprocessor architecture. OpenMP, however, also provides a way to directly access the cache associated with each thread, allowing the user to take advantage of this faster type of memory when developing parallel code. This type of system architecture is very similar to the hardware configuration of modern Intel® CPUs, which can be a significant advantage for the OpenMP user.

The approach followed to add parallelism to the computer code SToRM was to use the code profiling tools in Intel® Parallel Studio XE 2013 to identify the segments of the code that consumed the most computer resources (i.e., those which were responsible for the largest portions of the total computer run times) and target them for parallelization using OpenMP. Figure 1 shows a schematic flow chart of the tasks in SToRM and provides a synoptic view of the regions that were parallelized.

Some sections of the code were straightforward to parallelize using OpenMP. These included variable interpolations and computations of the numerical gradients, operations which essentially are dot products and have no data dependencies. Computing the source/sink terms and friction terms was also an easy task, but some algorithmic changes had to be made in order to use thread cache more effectively. Dealing with the computation of the fluxes at cell edges involved the most work. SToRM uses an edge-based data structure which potentially leads to codes with reduced CPU and memory access overhead when compared to codes that use a more traditional element-based structure. However, in multithreaded programs that share the same variables simultaneously, race conditions may appear[3]. Thread synchronization must be used to avoid race conditions. Thread synchronization facilitates organized and disciplined access to shared data at the expense of overall code performance, therefore it must be used with caution and algorithms must be well designed to minimize the synchronization that must be done.

[3] Race conditions are situations where one thread updates a variable needed by another thread before the second thread has a chance to use it.

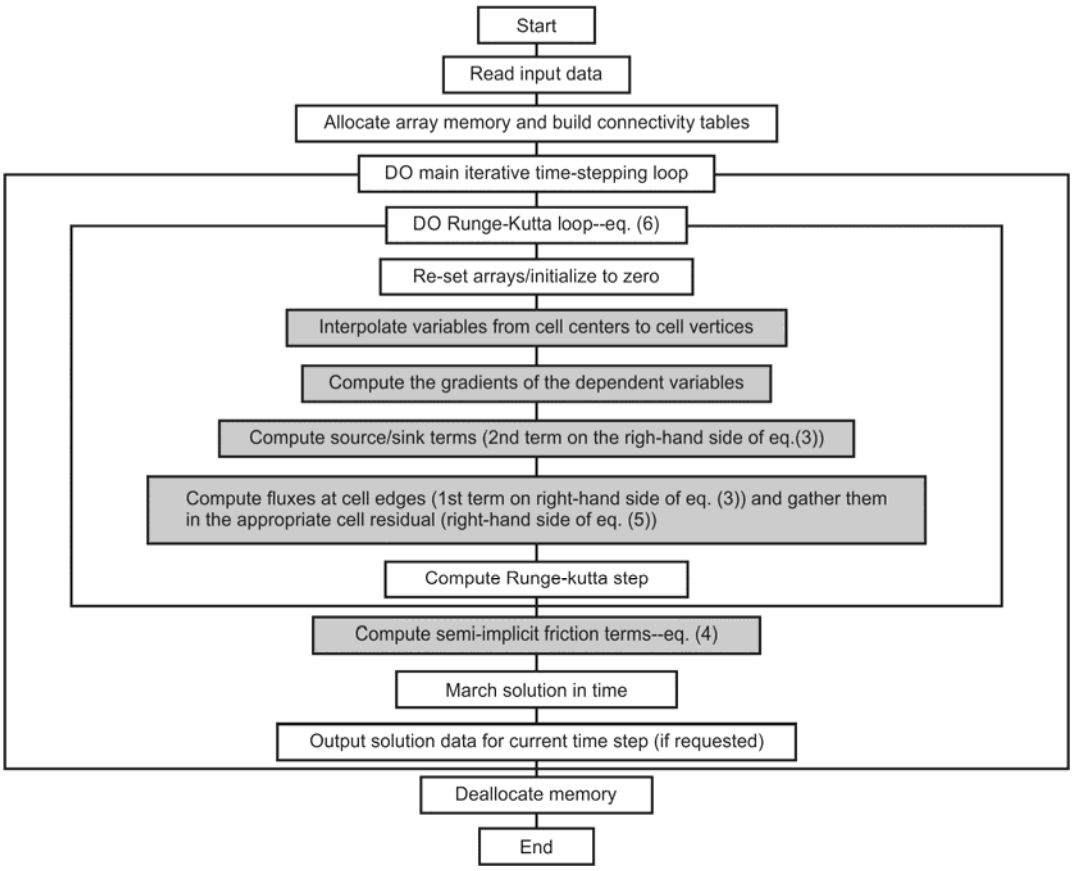

Figure 1 Flow chart of SToRM. Areas in gray represent parallel code. Operation flow is from top to bottom.

In SToRM, different types of edges are classified and distributed to different, independent computational loops (dry edges, fully wet edges, partially wet edges, solid boundary edges, inflow and outflow edges, advancing front edges, receding front edges, and bank shoreline edges). The main solution cycles over the edges and the residuals are summed by scattering (anti-symmetrically) the fluxes to the control volumes sharing the edge. The use of different cycles for different types of edges allows elimination of data dependencies and results in highly optimized code in vector-parallel computers.

At the writing of this paper, certain parts of the code remain to be parallelized. These concern sections that are more complex algorithmically, or that are treated directly by the Fortran language. An example of the latter case is initialization of arrays to zero: in Fortran, a multidimensional array is initialized to zero by the simple construct "`AnArray = 0`", where `AnArray` is an arbitrary user-defined array. The details of how this type of memory initialization is done are privy to the compiler and hidden from the user, but an analysis of the code efficiency has shown that this command does not seem to parallelize under the known compiler directives available to the user. Further investigation is needed to address these issues. Sections dealing with data input and solution output have not been parallelized.

GRAPHICAL USER INTERFACE

Integration of a numerical model within a graphical framework allows bridging the gap between model development and model use, and encourages model dissemination and application. SToRM has been integrated in iRIC (International River Interface Cooperative), a graphical user interface (GUI) framework developed specifically for environmental flow modeling (http://i-ric.org/en/). The iRIC framework provides operational facilities that are model independent, such as data input and output (multiple formats are supported), automatic grid generation (provided by the two-dimensional grid generator and Delaunay triangulation package of Shewchuk, 2002), interactive visualization

and editing of model input and output, ability to work with ancillary data sets for model calibration, and device-independent plotting.

A schematic view of how the SToRM model is integrated in the iRIC graphical framework is given in Figure 2. The graphical user interface is used to receive user input and to plot data, communicating with SToRM through a device-independent file using a format that has become a standard in many applications of computational fluid dynamics (CGNS, see http://cgns.sourceforge.net/). SToRM runtime information can also be displayed in a console window. The parameter definitions needed to customize the GUI to the specific requirements of a particular numerical model are coded in a flat file in XML format (http://www.w3.org/XML/). This file defines custom entry screens that allow the user to enter not only general numerical quantities (such as input file names, time step size, and number of time steps, for example), but also unique parameters required by SToRM, such as the threshold δ_s to detect discontinuities across element edges. The GUI can read data in a multitude of formats commonly used in hydraulics and other digital elevation modeling applications. Entire SToRM set-ups, including computational grids, boundary condition data, parameter definitions, and complete model simulation solutions obtained at multiple simulation times, can be saved in single data files for later use, and for transmission and archival.

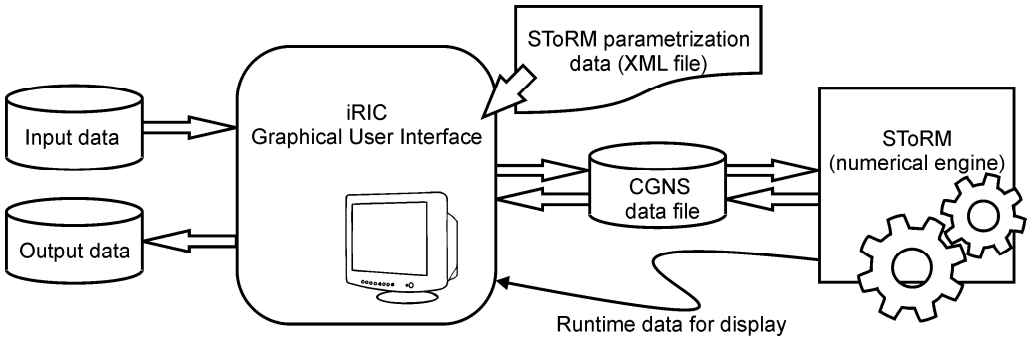

Figure 2 Schematic outline of the integration of SToRM in the iRIC modeling framework.

SToRM is implemented within the iRIC GUI and can be freely downloaded from the official iRIC Project Web Site cited above. The calculations presented in this work were obtained using version 2.3 of the iRIC distribution package.

APPLICATION: ESTIMATING PEAK FLOODING FLOWS

In the week of September 9–15 of 2013, a slow-moving cold front clashed with warm monsoonal air over Colorado, causing unusually heavy rain that resulted in catastrophic flooding along a large extent of Colorado's Front Range. Flooding conditions occurred along streams from Fort Collins in the north, to Colorado Springs in the south over an area that extended for approximately 320 km (200 miles). Nearly 19,000 homes were damaged, with over 1,500 destroyed, and more than 11,000 people had to be evacuated, with eight dead and two more missing and presumed dead. It is estimated that at least 30 state highway bridges were destroyed and an additional 20 seriously damaged, with many miles of roads and freight and passenger rail lines significantly damaged or altogether washed out. Estimates of economic losses have surpassed $2 billion USD (Novey, 2013).

Due to the high discharges and water depths that occurred in many of the affected streams, some of the US Geological Survey gaging stations were submerged or completely destroyed, precluding direct measurement of river stage at those locations. Such was the case at the confluence of the St. Vrain Creek and Boulder Creek near the city of Longmont, northwest of Denver, CO. The recurrence interval of this flood for the Boulder Creek watershed ranged mostly between 4% (25-year) and 2% (50-year) annual chance event (CH2M HILL, 2014), and between 1% (100-year) and 0.2% (500-year) annual chance event for the St. Vrain Watershed (JACOBS, 2014). As a result of high flows, the USGS Gaging Station 06725450 (http://waterdata.usgs.gov/co/nwis/uv/?site_no=06725450), located at St. Vrain Creek at Highway 119 (HWY 119) below Longmont, was destroyed and failed to record the stage at the peak of the flood. No high water marks were collected at this location during the later forensic work related to this flood, therefore preventing the realization of an indirect measurement of the peak flow. A replacement gaging station (06730525) St. Vrain Creek below Boulder Creek at HWY 119 near Longmont (http://waterdata.usgs.gov/co/nwis/uv/?site_no=06730525), was installed near the same location as the destroyed gage (Mark Smith, USGS, Personal

Comm., March 2014). This section describes the application of SToRM to estimate the peak discharge passing at the gaging station and over HWY 119, which had a section over 1.7 km (1 mile) under water.

The data sets available for this work consist of topographic data and flood delineation data. The topography was taken from USDA Geospatial Data Gateway (http://datagateway.nrcs.usda.gov/), which is from pre-flood (2008) USGS national elevation data (NED) at 1/9 arc-second resolution, i.e., with a spatial resolution of 3 meters. There was no post-flood LiDAR data for the site at the time of this study. The topographic data were used to generate a DTM for use by SToRM. Flood delineation data were obtained from remote sensing and were available as breaklines containing the discretized delineation of the flood extents in the area of interest (Chris Cole, USGS, Personal Comm., April 23, 2014). The model was set up to represent an area of 5 km (3.1 miles, east to west) by 4.5 km (2.8 miles, north to south) centered at the USGS Gaging Station 06730525, placing the model's inflow boundaries about 2.5 km (1.6 miles) upstream from the gaging station, and the outflow boundary 2.5 km (1.6 miles) downstream from it, as illustrated in Figure 3. This design places these boundaries away from the area of interest, therefore insulating it from imprecisions due to approximate representation of the water surface elevation at the downstream end, and of synthesized velocity distributions at the upstream boundaries. The outflow boundary was set at St. Vrain Creek at Interstate 25, because it is known that Interstate 25 was not flooded, and knowing that the flow was contained within the bridge opening permitted setting the boundary condition (i.e., water-surface elevation under the bridge) close to that of the actual flood, which is near the invert of the bridge.

Figure 3 Aerial photograph of the modeled region. The limits of the computational grid are given by the yellow polygon shown. Note the inflowing tributaries at the south (Boulder Creek) and southwest (St. Vrain Creek) and the outflow boundary at the northeast (St. Vrain Creek). The circle marks the location of the USGS Gaging Station. (Photo source: USDA Geospatial Data Gateway.)

Surface roughness was approximated by judging the type of land use based on the analysis of aerial photography. There are many land uses in the modeled region, including residential, commercial, agricultural, gravel mining, and open space. Different roughness values were used to represent each, assigned from previous experience using SToRM in similar land surface textures. Using aerial imagery, the computational domain was divided in areas of agricultural land use (Manning's $n = 0.045$), residential ($n = 0.055$), wooded areas in the riparian corridor ($n = 0.065$), ponds and reservoirs ($n = 0.015$), and all other surfaces ($n = 0.035$).

To determine the value of the flow discharge at St. Vrain and Boulder Creeks, which is the objective of this study, a series of runs of SToRM were carried out, each using an estimate of the flow rates for Boulder and St. Vrain Creeks. In practice, a series of discharge guesses that under- and over-predict the answer were used to perform model runs. The results of the model runs were compared to the known flood delineation contours and saved. A series of successive trials gradually honed the answer to the pair of discharges that provided the best possible agreement between the model predictions and the observations.

All model runs were carried out using the same spatial discretization. SToRM uses a spatial discretization based on triangles and the user interface iRIC provides an automatic grid generator that takes into account user input. User input is used to define grid shape and cell size, and is especially important in ensuring that topographic features of hydraulic relevance are discretized with the appropriate accuracy for model representation. Several discretizations using different grid resolutions were tried and the coarsest grid that provided the best computational performance without degrading the quality of the computed flood extents contained 57,055 points (113,140 triangles), representing a grid of triangles with a maximum area of 173.2 m^2 (1864 ft^2) each. The grid was selectively refined in certain regions, such as near the gaging station, and break lines were used to capture a number of significant terrain features.

Each run was started from an initial state in which there was little or no flooding taking place: the water was mostly confined within channel banks and the discharge was low, with an initial discharge of about 8–10 m^3/s (282.5–353 ft^3/s) for each creek. The model run progressed in an unsteady manner, where the inflows at St. Vrain and Boulder Creek were ramped to the estimated values and the computational domain was allowed to flood as if a flooding event was taking place. Similarly, the many ponds present in the computational domain (clearly visible in Figure 3) were started from a dry state and allowed to fill during the ramping of the hydrograph. Once the hydrograph attained the desired high inflow discharges, the run was sustained until steady state conditions were reached. This process does not represent the rate of flooding accurately, because the inflow hydrographs used do not represent the actual flooding event well, but it allows for the model to compute the actual flood extents without the need for any preconceived ideas about what the flood stages should be. In this study, the combination of values that provided the best agreement consisted of a discharge of 600 m^3/s (~21,000 ft^3/s) for St. Vrain Creek and a discharge of 250 m^3/s (~9,000 ft^3/s) for Boulder Creek, resulting in an estimated 850 m^3/s (~30,000 ft^3/s) passing through USGS Gaging Station 06730525 at HWY 119. The final results comparing model simulation and known flood delineation contours are shown in Figure 4.

Naturally, the predicted values of the previous paragraph are dependent on the accuracy of the data used: (1) the DTM data used by the model were sourced from USGS NED with a RMSE of 0.05–0.2 m in elevation (0.154–0.656 ft), and was 5 ½ years old at the time the flooding occurred; and (2) the flood delineation contours are subject to uncertainties in areas of visual complexity and the source images must be obtained at peak flow, which may be an unknown by itself. Finally, the comparison between model predictions and field measurements was done by visual inspection, which introduces undesired operator ambiguity and underlines the need for the development of mathematical criteria that produce objective goodness-of-fit measures and that can be implemented in an automated computational procedure.

The computational approach described above is very demanding in computer resources, because of the number of triangles in the spatial discretization and because of the small time step used (Δt = 0.01 s in equation (6)), which required many time steps for full flooding to occur. Additionally, many computer runs of the same case, albeit with different boundary conditions, had to be carried out, prolonging even further the time needed to reach the final solution. Therefore, this application of SToRM constitutes the ideal problem for testing and applying the numerical optimization techniques described in the previous sections.

To evaluate the efficiency of the parallel algorithms in SToRM, multiple runs of the same case—i.e., of the flooding simulation set-up described in the previous paragraphs—were carried out, first without parallelism to set the base run time T_1, then with multiple threads to determine the code speedup performance, T_1/T_N (where T_N is the run time taken when using N threads). The timing function provided by OpenMP, `OMP_get_wtime()`, was used to determine the value of T_N, but only the parallel regions of the code were timed. T_1 was determined by using only one thread (`OMP_set_num_threads(1)` in OpenMP syntax). The results of using a varied number of threads are shown in Figure 5 (default scheduling, the line with square markers). A run using a single thread took approximately 21 hours of CPU time in the desktop system described in a previous section.

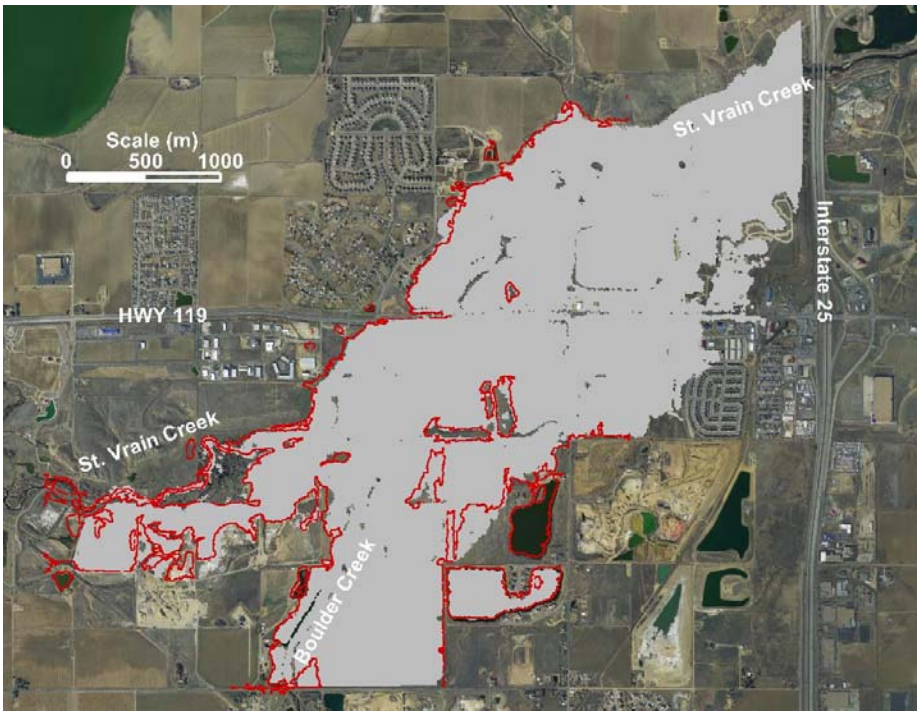

Figure 4 Comparison between observed flood delineation (red line) and predicted flooded area (gray area) on the same background image of Figure 3. Note that the observed flood delineation contour does not extend all the way to the eastern part of the computational domain due to the absence of data.

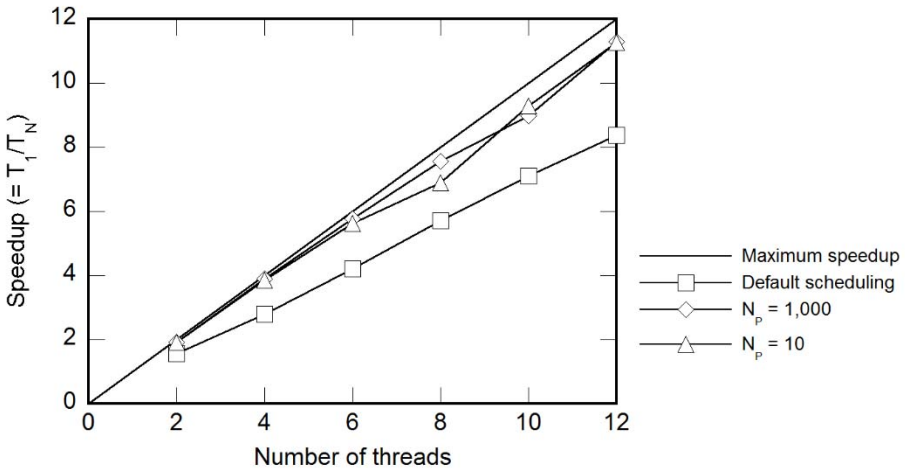

Figure 5 Speedup gain by SToRM's parallel implementation.

The initial results were satisfactory and possessed good scalability[4], but showed a somewhat lower than expected speedup, as seen in the "Default scheduling" data of Figure 5. Scheduling sets the way the iterations of a DO-loop are distributed among the several threads. OpenMP's default scheduling divides each DO-loop in N equal blocks (N = number of threads), each block with an identical number of DO-loop iterations, and assigns one to each thread. During the initial stages of flooding, however, there are many regions of the computational grid that are dry. These regions are included in all the computational DO-loops of the code, but are cycled over without using CPU time because the

[4] Scalability refers to the ability of a parallel system to increase performance when extra processors are added to it.

governing equations are not solved in dry areas. By distributing the cycles of the DO-loops equally among threads, there are some threads that may have very little to do (those with many dry areas), while others have to do much more work because they end up with larger portions of the wetted domain. As a result, the former threads finish their calculations first and must remain idle while waiting for the occupied threads to finish their computations. All the threads must finish their work before the flow of operations is able to proceed along the remainder of the code to the next DO-loop. This idle thread time may result in performance degradation, which may be minimal if the computational region is mostly wet, but that may be substantial when large dry areas exist. This is the reason for the less-than-ideal performance gain observed for the default scheduling in Figure 5.

To overcome the above limitations, a more dynamic type of scheduling scheme was tried, where work may be distributed unevenly among threads to minimize the idle thread time. This is accomplished by dividing the DO-loop iterations into blocks of smaller size, each containing N_P iterations: a DO-loop with 1,000 iterations, for example, would be divided into 5 smaller blocks with 200 iterations each if $N_p = 200$; the same DO-loop would be divided into 100 blocks of 10 iterations each if $N_P = 10$. The blocks are continuously fed to the threads, one block at a time. When a thread finishes its piece of work it gets a new block. This means that, if a thread gets a block of the DO-loop with an unusually high number of dry cells and finishes its work very quickly, it is immediately fed another block of work without having to wait for other threads to complete theirs. This dynamic type of scheduling, hopefully, balances the work out more evenly among the available threads, but comes with a limiting factor: the cost of larger overhead at runtime. This overhead is the added computational time taken by the system. It results from the additional work that must be done to divide the DO-loops and continuously assign the blocks to the processors: more blocks are more onerous to manage than fewer blocks and, consequently, this superior management effort consumes more computational resources. If the blocks are very small, increasing the size of the blocks (i.e., larger N_P) might, therefore, benefit overall code speedup by reducing overhead, but can also cause imbalance if one is not careful—the exact same imbalance that one is trying to avoid by using dynamic scheduling.

Scheduling is problem dependent and is a function of the workload. Workload may vary differently for each case and even for different simulations of the same case. Several block sizes were tried and, for the simulations carried out for the present study, a good value of N_P was found to be N_P =1,000. The results of the speedup obtained with N_P = 1,000 and with N_P = 10 are shown in Figure 5. It can be seen that using dynamic scheduling resulted in a substantial performance gain over the initial results using the default (static) scheduling. Using N_P = 10 did not provide significant differences in speedup gain over using N_P = 1,000. Taking into account that the present run was carried out in a computational grid with 57,055 points and 170,194 edges[5] (recall that SToRM uses an edge-based data structure, therefore many of the most computationally intensive DO-loops are carried over the edges), a rule of thumb for this size problems in desktop computers may be to use a value of N_P that is three orders of magnitude smaller than the number of edges in the computational grid.

CONCLUSION

A depth-averaged, two-dimensional model (SToRM) that solves the SWEs in unstructured triangular grids within the framework of the Godunov-type, cell-centered finite volume method, was briefly presented. The model was developed with the purpose of calculating unsteady flow over complex topography with wetting and drying moving fronts, such as those occurring in catastrophic flooding, and was applied to the estimation of the peak flow discharge passing at the USGS Gaging Station 06725450, near the city of Longmont, northwest of Denver, CO, during the historic flood event of September 2013.

Application of SToRM to problems that extend over large geographic areas, resulting in increasing memory and computational requirements, have created a need for an improvement in code efficiency. This was addressed by using OpenMP to parallelize some of the most computationally-intensive segments of the original code. These initial efforts have resulted in achieving substantial performance gains over the original implementation of SToRM, which was based on sequential algorithms written in Fortran 90/95.

[5] The number of edges in an unstructured grid can be found by using a modification of Euler's formula: $n_T + 1 = n_E - n_V + 2$, where n_T is the number of triangles, n_E is the number of edges, and n_V is the number of vertices (points) in the grid.

The dynamic nature of flooding problems helped identifying bottlenecks in speedup performance gains of parallel algorithms due to the potential presence of large dry regions in the computational domain. These dry areas may become inundated and dry again during the course of a simulation and cannot be ignored, posing a challenge to the computational load balancing and to the optimal use of any multiprocessing computing environment. This difficulty was addressed in SToRM and solved efficiently with the use of dynamic scheduling. A scheduling parameter N_P was proposed, with a suggested value in the order of one thousandth of the number of edges of the computational grid used in the computer simulation runs. This value is, however, problem dependent and user care must be used when selecting it.

Estimation of the peak discharge for the St. Vrain gaging site was accomplished by comparing the computed flood delineation contours with those obtained from remote sensed images. It was found that a close match was obtained when using a discharge of 600 m^3/s (~21,000 ft^3/s) for St. Vrain Creek and of 250 m^3/s (~9,000 ft^3/s) for Boulder Creek.

HYDRAULIC MODELING OF TRUCKEE CANAL ALLUVIAL FANS USING SRH-2D

Rebecca Kallio, Hydraulic Engineer, US Bureau of Reclamation, Denver, CO, rkallio@usbr.gov, Joseph Wright, Hydraulic Engineer, US Bureau of Reclamation, Denver, CO, jmwright@usbr.gov, Victoria Sankovich-Bhals, Meteorologist, US Bureau of Reclamation, vsankovich@usbr.gov

Abstract: Alluvial fans are gently sloping, fan-shaped landforms created over time by the deposition of sediment. Their gentle slope near mountainous regions attracts development in these flood-prone areas. The flow paths of flood events can change with each event, placing development at risk (National Research Council (NRC), 1996). Because of the uncertainty of flow paths and flood extent, many studies have been performed on alluvial fans in the arid west. Most of these studies focus on the flood elevations inside the alluvial fan and mitigation against such events. This study, however, is not focused on the flood elevations inside the alluvial fan; rather it is focused on the effect the alluvial fan has on the flood wave passing through and into a canal.

The Truckee Canal is located in western Nevada, approximately 35 miles east of Reno, Nevada, and adjacent to the City of Fernley. The areas adjacent to the canal are seven alluvial fans emanating from foothills to the west and southwest. The alluvial fans have complex networks of distributary channels that are constantly changing with each flood event as new sediment gets deposited. Infiltration and channel form within alluvial fans drastically varies longitudinally and laterally. These characteristics make flow modeling complex and requires two-dimensional flow modeling.

A two-dimensional hydraulic model SRH-2D (Lai Y., 2008) was used to model the 10-, 25-, 50-, and 100-year unsteady flow through the seven alluvial fans in the Truckee canal basin. SHR-2D has an unstructured hybrid mixed element mesh, which is based on the arbitrarily shared element method for geometric representation (Lai Y. , 2000). Mesh generation flexibility allows complex alluvial network of incised channels to be modeled in greater detail. SRH-2D applies gridded infiltration to model the losses within the alluvial fans. SRH-2D adopts very robust and stable numerical schemes with a seamless wetting-drying algorithm. Finally, SRH-2D uses a finite volume approach where mass balance accounting was performed to determine the validity of model results.

The model results indicated that basins with spares developed attenuate peak discharge and volume; however, the net effect of flow attenuation is lower than expected for developed alluvial fans. Development within the alluvial fans, however seemingly small, can affect the flow attenuation. The historic channels have been either preserved as they pass through developments, or new channels have been formed by road cuts. The result of this development has concentrated the flows so that the flood hydrograph passes through the alluvial fan before it has time to infiltrate into the soils.

INTRODUCTION

A team evaluating the flooding risk of the Truckee canal wanted to determine the hydrologic loadings for the 10-, 25-, 50-, and 100-year events. The loadings were achieved by coupling a one-dimensional rainfall-runoff modeled with a two-dimensional hydraulic model to simulate lateral inflow along the Truckee canal. A two dimensional hydraulic model was necessary to capture the flow dynamics of alluvial fans that have complex channel geometries and varying infiltration.

Project Location and Basin Description: The Truckee Canal is located in western Nevada, approximately 35 miles east of Reno, Nevada, and adjacent to the City of Fernley (Figure 1). The areas adjacent to the canal are seven alluvial fans emanating from foothills to the west and southwest. The alluvial fans have complex networks of distributary channels that are constantly changing with each flood event as new sediment gets deposited. Infiltration and channel form within alluvial fans drastically varies longitudinally and laterally. These characteristics make flow modeling complex and requires 2-D flow modeling.

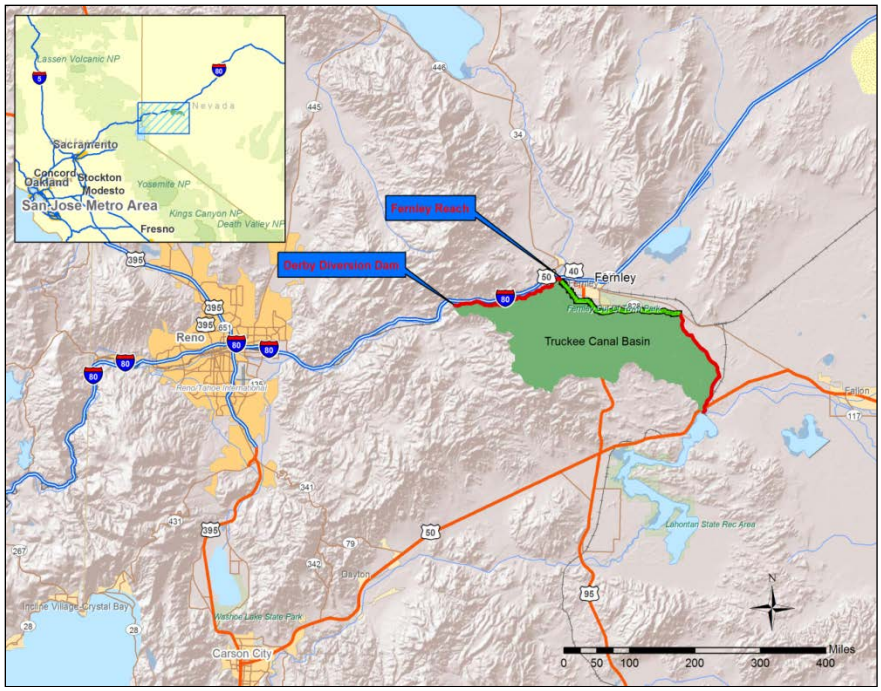

Figure 1 Vicinity map showing the location of the Truckee Canal drainage basin.

The basin area contributing to the Truckee Canal is mostly foothills draining from the south to the north. The Fernley area receives 5.91 inches of annual precipitation. Only the areas to the south of the canal contribute to the flood flows. The overall contributing area along the Truckee canal is approximately 100 mi^2. The alluvial fans are adjacent to the canal emanating from foothills to the west and southwest. The alluvial fans have complex network of distributary channels who's flow paths are in constant flux from sediment deposition. Alluvial fans have mid slopes around 0.016 ft/ft. Small washes inset into Holocene alluvial fans ranging from early to late Holocene in area. A broad distributary network of small incised channels can be found in the alluvial fan consisting of younger Holocene deposits. Alluvial fan channel beds at higher elevations contain predominately gravels and fine moving towards the fan mouth.

Model Selection: The one-dimensional hydrologic model HEC-1, Hydrological Engineering Center 1 (HEC-1) (U.S. Army Corps of Engineers, 1990) was used to model the tributary basins that provide the inflow hydrographs into the alluvial fans. HEC-1 simulates basin surface response to precipitation through a series of interconnect hydrologic and hydraulic components. USACE has superseded HEC-1 with Hydrologic Modeling System (HMS); however, this study chose HEC-1 because of the ability to automate the model and process multiple model runs. Additionally, the HEC-1 model can easily transform Reclamation dimensionless unit hydrographs (Cudworth, 1989). The Reclamation unit hydrograph converts dimensionless hydrographs into a unit hydrograph by three steps. First the basin area is calculated and the lag time is determined. Second, incremental rainfall is converted into incremental runoff while incorporating for losses due to soil infiltration. Third, incremental runoff is transformed into a flood hydrograph. The HEC-1 model simplifies the basin's response to rainfall by lumping parameters. HEC-1 model accurately captures the rainfall response for well-defined basins with incised channels such as those found in the Truckee Canal drainage basin.

The two-dimensional hydraulic model Sediment and River Hydraulics- 2D (SRH-2D) was selected to model the hydraulics within the alluvial fan. SRH2D is a two-dimensional (2D) fixed-bed depth averaged hydraulic model specifically focused on the flow hydraulics of river systems. SRH-2D adopts a zonal approach for coupled modeling of channels and floodplains; a river system is broken down into modeling zones (delineated based on natural features such as topography, vegetation, and bed roughness), each with unique parameters such as flow resistance. One of the major features of SRH-2D is the adoption of an unstructured hybrid mixed element mesh, which is based on the arbitrarily shared element method of Lai (Lai, 2000) for geometric representation. This meshing strategy is flexible enough to facilitate the implementation of the zonal modeling concept; it allows for greater modeling detail in areas of interest, and ultimately leads to increased modeling efficiency through a compromise between solution

accuracy and computing demand. The SRH-2D model is a Reclamation-developed model. The flexibility of the mesh generation allowed the complex alluvial network of incised channels to be modeled in greater detail. Because SRH-2D was developed at Reclamation, custom modifications were easily made to the source code to allow for losses in the alluvial fans.

DATA COLLECTION

Meteorology and Precipitation:

Precipitation Frequency Analysis: Precipitation magnitudes with an associated frequency of occurrence are used as input into the rainfall-runoff model to estimate flood frequency. To compute the precipitation frequency curve for the Truckee Canal watershed, the L-moments regional statistical analysis method was used (Hosking & Wallis, 1997). In regional analyses, it is assumed that additional information in space can account for lack of information in time. In other words, precipitation regional analyses allow for the user to substitute rain gauge observations from within a statistically (and climatically) homogeneous region for precipitation observations at a specific site (i.e., a rain gauge along the Truckee Canal). From this substitution, the user will obtain hundreds to thousands of observations as opposed to the approximate hundred observations (at best) available at-site.

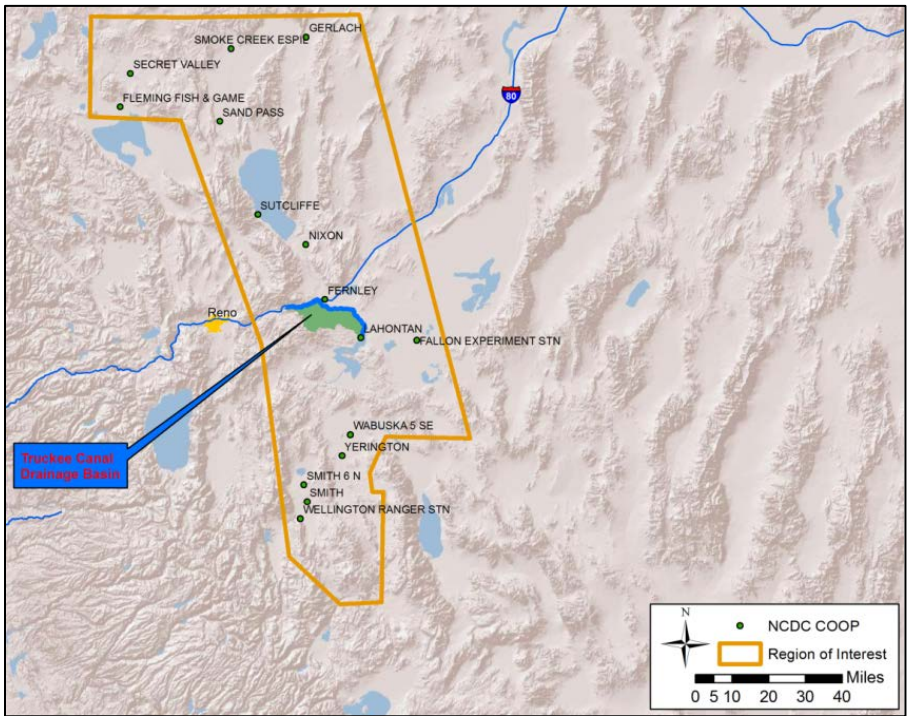

Figure 2 Fifteen NCDC COOP rain gauges with in the Truckee Canal drainage.

Climatically and Statistically Homogeneous Region: 15 NCDC COOP gauges were deemed climatically and statistically homogeneous and were used in the precipitation frequency analysis (Figure 2). These observations amounted to approximately 547 years of station data. The 24-hour annual maxima precipitation observations exhibit low variability of the L-moment ratios (i.e. L-Cv, L-skewness, and L-kurtosis; Table 1). Heterogeneity measures H1 and H2 were computed to assess the variability of station values of L-Cv and L-skewness, respectively. Measures of H1 and H2 (H1=-2.61 and H2=-0.97) confirmed that the chosen region was acceptably homogeneous.

Regional Growth Curve: For the Truckee Canal watershed, the Generalized Logistic (GLO) distribution, a unique form of the Kappa distribution, best describes the regional distribution of the 24-hour annual maxima precipitation dataset. The GLO distribution most closely represents the spread within the cloud of L-skewness and L-kurtosis pairs for the 15 gauges. The regional L-skewness and L-kurtosis estimates further suggest that the GLO distribution is the best-fit three-parameter probability distribution based on L-moment goodness-of-fit tests.

Table 1 L-moments for the 15 gauges in the homogeneous region, where L1 is the location (mean) and t3 is the skewness.

At-Site Precipitation-Frequency Relationship: The regional growth curve is next scaled by the mean of the 24-hour basin-average point (10 mi^2) precipitation (hereafter, referred to as the basin-average mean) to obtain a 24-hour basin-average point precipitation-frequency curve. This curve is representative of point precipitation with a common annual exceedance probability occurring throughout the watershed. The 24-hour basin-average mean for the contributing area of the Truckee Canal watershed is 0.96 inches.

The following equation is used to scale the regional growth curve by the basin-average mean to produce a site-specific precipitation-frequency relationship (Hosking and Wallis, 1997):

$$Q_i(F) = \hat{\mu}_i q(F) \quad (1)$$

Where Q_i is the at-site precipitation-frequency relationship, $\hat{\mu}_i$ is the at-site mean, and q(F) is the regional growth curve.

24-hour Basin-Average Precipitation Frequency: A fixed areal reduction factor (ARF) is applied throughout the frequency range to the 24-hour basin-average 10 mi^2 precipitation frequency relationship to obtain the basin-average precipitation frequency curve. Fixed ARFs were derived in NOAA Atlas 2 for Nevada for multiple area sizes and durations (Miller, Frederick, & Tracey, 1973). For the area size of the contributing portion of the Truckee Canal watershed (approximately 100 mi^2) at 24-hours, the scaling factor is 93.5%. Table 2 presents the precipitation estimates corresponding to these basin-average frequency curves at select return periods.

Table 2 Basin-average precipitation frequency estimates at select return periods.

10	1.536
25	1.913
50	2.245
100	2.628

Terrain: Watershed Sciences, Inc. (WS) collected Light Detection and Ranging (LiDAR) data for the alluvial areas on March 9, 2012. The data were combined with previously acquired LiDAR data in 2008 to ensure complete capture of the alluvial basins. The resulting Digital Terrain Model (DTM) achieved a resolution of 0.72 points per ft^2 with a vertical accuracy of 0.08 feet (Woolpert, Inc., 2012).

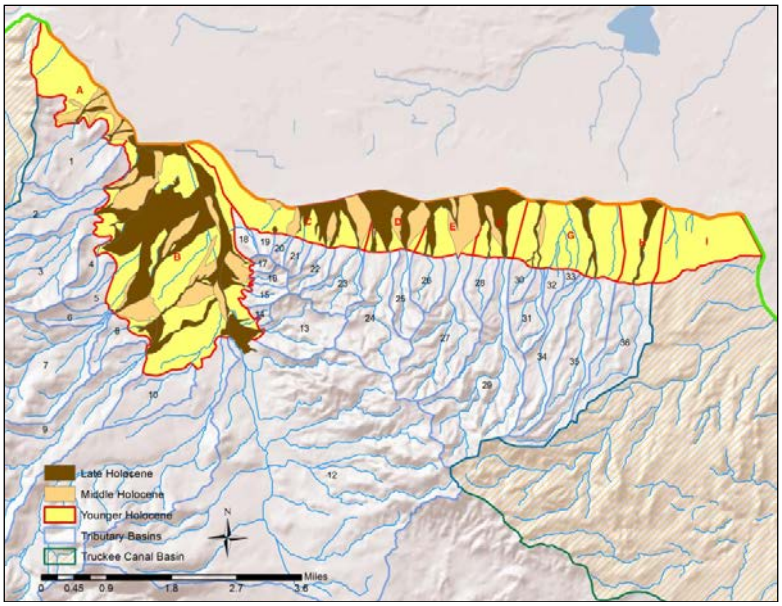

Figure 3 Geology of alluvial fans within the Truckee Canal drainage basin

Alluvial Fan Geology: The bedrock and surficial geology for the Truckee Canal drainage basin has been mapped at a 1:24,000 scale (Faulds & Ramelli, 2009; Faulds, J. E.; Ramelli, A. R.; Herny, C. D., 2008; Faulds, J. E.; Ramelli, A. R., 2005). The alluvial fan basins are comprised of three materials: Lake Lahontan deposits (younger Holocene), middle Holocene alluvial deposits, and old Holocene deposits. The Lake Lahontan deposits consist of gravel beach deposits, gravel deposits, silt deposits, tufa deposits, and silicified sands. In some locations the alluvial deposits may overlay the Lake Lahontan deposits. Locations of these deposits are shown in Figure 3. Because the alluvial deposits are the youngest material on the basin, it was assumed that these represent the locations of flow paths within the basins. When comparing the LiDAR data with the geologic map, the location of alluvial deposits were the same as locations of incised channels. The incised channel locations were also confirmed with a site visit. The channel areas of each sub-basin correlated to the alluvial deposits, and the out-of-bank floodplain areas correlated to Lake Lahontan deposits.

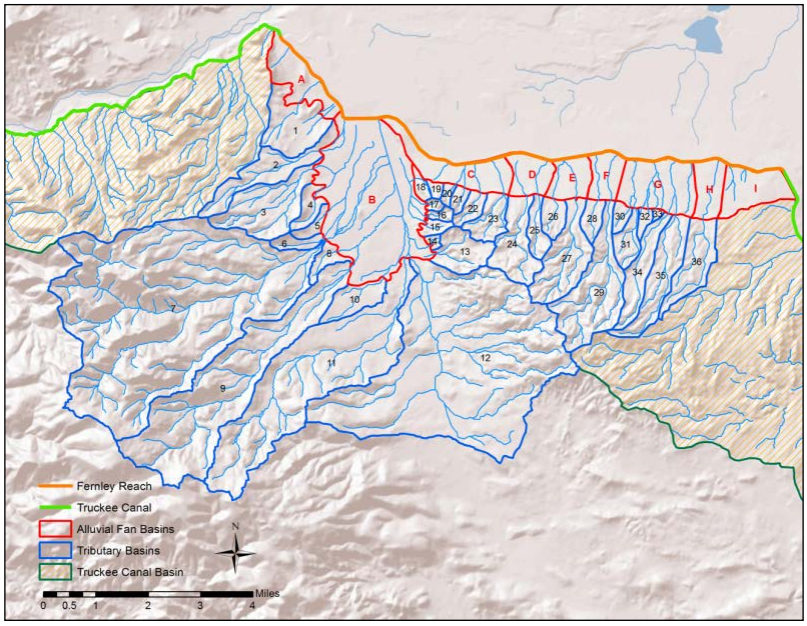

Figure 4 Tributary basins in the Truckee Canal drainage basin.

HEC-1 MODEL INPUTS

Sub-basin Delineation and Characteristics: The individual basins for the apexes of the alluvial fans along the Fernley Reach were determined initially using the national hydrology database (USGS, 2012) and further refined using 30m USGS DEM data (USGS, 2012). This method identified 36 tributary basins and is presented in Figure 3. The lag time was estimated for each sub-basin using methods outlined by the Reclamation Flood Hydrology Manual (Cudworth, 1989) and was calculated using the following equation.

$$Lag\ Time\ = C_t \left(\frac{L \times L_{ca}}{\sqrt{S}}\right)^{0.33} \quad (2)$$

Where L is the watercourse length (feet); L_{ca} is the length along the watercourse to a point opposite of the centroid of the basin (feet); S is the basin slope (feet per mile); and C_t is a constant. The length and slope parameters were estimated using ArcGIS (Environmental Systems Research Insitute (ESRI), 2011)). The value used for the constant, C_t, value of 2.6, corresponding to a Manning's roughness of about 0.1 (Chow, 1959).

Tributary Basin Loss Rates: The computation of loss rates requires consideration of many factors such as historic data, soils information, vegetation, and season. Near the end of a big storm, after the depressions have been filled and the soils within the watershed have been saturated, the difference between rainfall and runoff closely represents the minimum infiltration rate. For this study, the initial loss was assumed to be 0.5 in.

Hydrologic soil groups for each tributary basin were identified from NRCS county-level SSURGO database (Soil Survey Staff, Natural Resources Conservation Service). National Engineering Handbook Part 630 Chapter 7 (NEH) (Natural Resources Concervation Service, 2007) provides range of loss rates for each hydrologic soil group. Table 2 provides the NEH recommend soil loss rates and provides the loss rates selected in this study. The majority of tributary basins were comprised of more than one soil group type; therefore, losses rate of basins were calculated through area weighted method.

Table 3 Estimated soil loss rates for each hydrologic soil group.

Hydrologic Soil Group	Loss Rate (in/hr)		
	Low	High	Used in study
A	0.39	0.3	0.45
B	0.24	0.15	0.3
C	0.11	0.05	0.15
D	0.05	0.00	0.05

The majority of soils in the tributary basins in the Fernley reach are T*ype C* (moderately high potential runoff when thoroughly wet) and *Type D* (high runoff potential when thoroughly wet). Areas of *Type B* (moderately low runoff potential when thoroughly wet) can be found along some of the incised channel areas in basins 7 through 12 and more so in basins 18 through 33. Basins 1 through 6 are reported by NRCS to have exclusively *Type A* (low runoff potential when thoroughly wet), which appears to be a mistake in the NRCS soils reporting. The southern boundary for the *Type A* soils appears to follow a political boundary. Furthermore, the state-level NRCS STATSGO database notes this area as being generally *Type D* (NRCS, 2012).

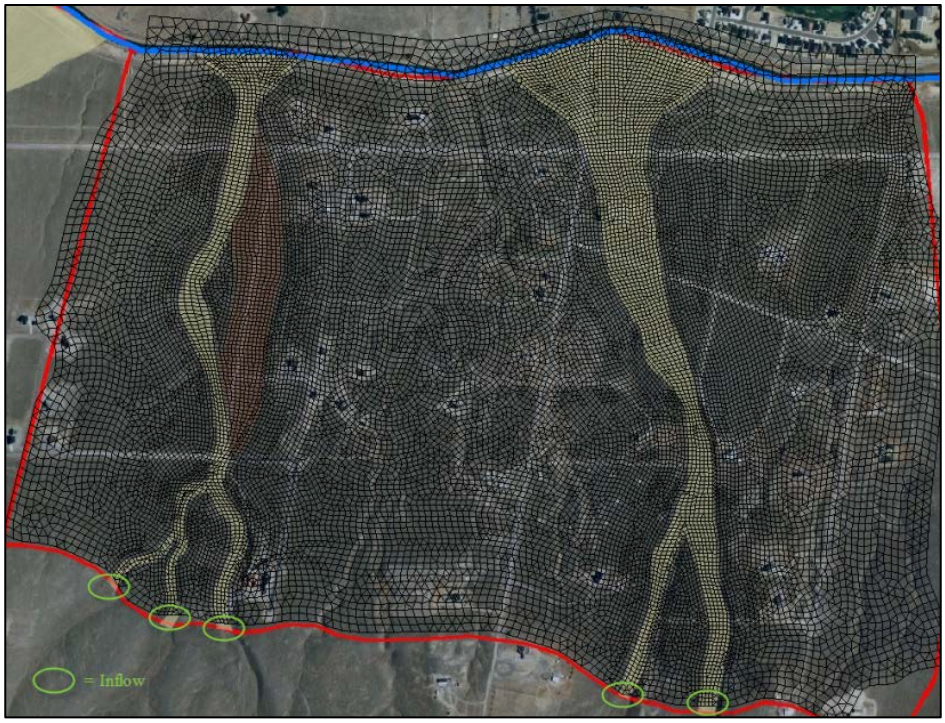

Figure 5 A typical mesh used for the alluvial fan basins. Quadrilaterals were used for younger alluvial channel materials whereas triangles were used from the older area. Alluvial fan basin G is depicted.

SRH-2D MODEL

Each alluvial fan sub-basin was modeled independently of one another. This occurred since terrain data was so robust and demanded large computational resources.

Mesh: Meshes were developed for each alluvial fan sub-basin using Surface Water Modeling Solution (SMS) version 10.1 (Aquaveo, Inc., 2012). The geologic map was imported into SMS to differentiate between in channel locations and out of channel locations. These boundaries were traced to form feature objects. For each feature object, the geologic material type was entered. For each identified identify a Manning's n roughness coefficient. The alluvial channel had no vegetation, so a manning's n of 0.045 was used. Outside of the channel areas were highly vegetated with greasewood and sagebrush; therefore, a Manning's n of 0.1 was used (Chow, 1959). The mesh types where selected for each feature object. The alluvial channels were assigned a quadrilateral mesh type, and the Lake Lahontan deposits were assigned a triangular mesh type. Quadrilateral meshes are used when flow is oriented in a general direction like river channels. Figure 5 illustrates a typical mesh used for this study. Table 4 summarizes the SRH-2D meshes used for alluvial fan basins B through H.

Table 4 SRH2D Alluvial fan mesh summary.

Alluvial Fan Basin	Number of quadrilateral elements	Area (ft^2)		Number of triangular elements	Area (ft^2)	
		Low	High		Low	High
B	19254	1089	24881	6580	613	8373
C	46645	290	19072	9114	110	5155
D	12791	560	1903	2374	191	5334
E	38783	139	263	9942	19	12547

G	17195	905	8810	7541	1097	2864
H	7932	527	708	3235	237	60406

Infiltration: SRH-2D was modified for this study to account for soil losses in the alluvial areas. SRH2D subtracts a given water depth at the end of each time step using a constant loss rate. The majority of alluvial basins contain

hydrologic soil group *Type B* which has a loss rate between 0.15- to 0.45 in/hr. A loss rate of 0.27 in/hr was applied throughout the alluvial areas. A limitation of the SRH2D model is its inability to model rainfall. This means that rain fall over top of the alluvial fans could not be numerically modeled. The majority of contributing flow into the Truckee Canal Fernley Reach comes from the tributary basins; therefore, rainfall occurring over the alluvial areas was not considered to significantly affect the flood inflows. However, it was assumed that all rainfall would be absorbed in the initial losses which would account for the rainfall on the alluvial fans.

Hydrographs: Hydrographs developed from the HEC-1 model were used as inflow into the SRH2D models apex of the alluvial fans. The unsteady inflow condition was placed at the apex of each alluvial fan.

Boundary Conditions: There were no measurements of flow at the outlet of the alluvial fans to develop a rating curve for the boundary conditions. Therefore critical exits were selected as the downstream boundary conditions for the 7 alluvial fan models. This allowed the simulation of the flow across the alluvial fan with unknown water depth conditions on the downstream end. This was accomplished by artificially creating a 2:1 sloped edge along the downstream boundary. To prevent the effect of model instabilities that occur near critical flow boundaries, the boundary was placed approximately 400 ft from the canal bank.

RESULTS

HEC-1 Results: The peak discharge results of the 1-dimensional modeling for the 36 tributary basins along the Fernley Reach are presented in Table 4. The runoff response remains low for events ranging to the 100-yr events for these basins. Because of the low runoff, these basins were omitted in the 2-dimensional model due to their likelihood to create numerical instabilities from low water depths. Tributary basins 7, 9, 11 and 12 are the largest contributors along the Fernley Reach, accounting for about 50 percent of the volume for the extreme events. Alluvial fan basin I does not respond to the 100-yr or more common rainfall events because the loss rate (0.27 in/hr) is greater than the largest 100-yr incremental rainfall amount modeled for this study.

Table 5 Summary of 24-hour peak discharges from the tributary basins along the Truckee Canal Basin, Fernley Reach.

Tributary Basin	Area (mi^2)	24hr Peak Discharge (ft^3/s)

SRH-2D Results: Table 5, Table 6, Table 7, and Table 8 summarize the hydrograph peak discharges and volumes from the alluvial fans along the Fernley Reach for the 10-, 25-, 50-, and 100-yr return periods, respectively. A mass balance was computed for each model simulation. The percent error, summarized in Tables 5 through 8 was calculated by:

$$Percent\ Error = \frac{V_i - (V_o + V_{lost} + V_{surface})}{V_i} \times 100 \quad (3)$$

The overall error calculated by volume for SRH-2D was below 2 percent for all return periods. The percent error in the mass balance is one measure of the model error. The total percent mass balance error is the summation of the volume differences divided by the total inflow volume. All of the outflows listed in Tables 5 through 8 are lateral inflows along the Fernley Reach. Alluvial basin A (pour point 7) was not modeled because of the assumed 100-yr flood mitigation from the developed sub-division, which would result in no canal inflows. Alluvial basin I was not modeled in SRH-2D because it has no upstream contributing flows; therefore, it was modeled in HEC-1 similar to the tributary basins.

DISCUSSION

Alluvial fan flows can lose large amounts of water due to the flow spreading out and infiltrating into the ground over the mouth of the alluvial fan. This flow mechanism occurs in all of the alluvial fans to some extent; however, the net effect of flow attenuation is lower than expected for undeveloped alluvial fans. Development within the alluvial they pass through developments, or new channels have been formed by road cuts. The result of this development has concentrated the flows so that the flood hydrograph passes through the alluvial fan before it has time to infiltrate into the soils.

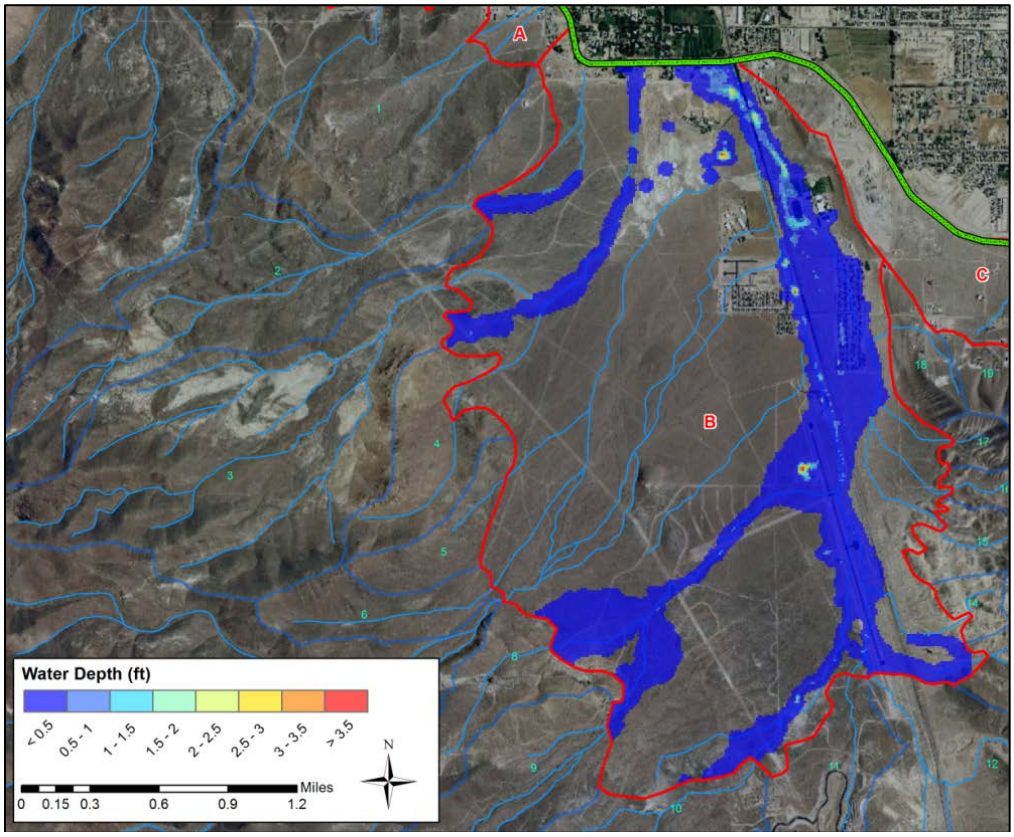

Figure 6 Alluvial basin B water depth got 100-year event at time t=10 hours.

Alluvial basin B is by far the largest flood contributor along the Fernley Reach and also the Truckee Canal. A total of 38.74 mi^2 contributes to 12 significant apexes identified along the apex boundary of alluvial basin B. Highway 95 bisects the basin from north to south providing a conduit for concentrated flow. This becomes apparent in viewing

the 100-yr event at hour 10, the peak of the water depths within the basin (Figure 6**.**). Aerial photographs of the basin also indicate dirt roads are within the historic incised channels to the west of Highway 95. Other development within the basin includes an airport and 2 subdivisions. Although seemingly insignificant in size, they contribute to the concentrated flows. These developments may provide an explanation why large floods have not been noticed in the past, because the recent developments have only recently increased the probability of larger magnitude floods into the Fernley Reach.

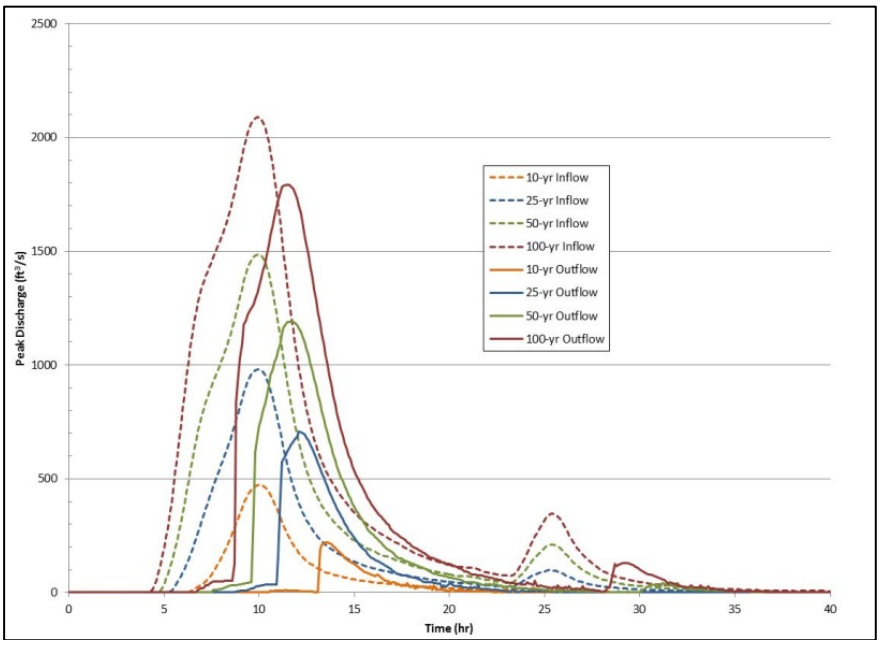

Figure 7 Flood Hydrographs attenuation for 10-, 25-, 50-, and 100-year events in alluvial basin B.

Despite the concentrated flow, a significant amount of the flood hydrograph is lost to water infiltrating into the soil. Figure 6 illustrates that some floods do not flow into the canal at all. Figure 7 illustrates the reduction of the peak inflow into alluvial basin B and the outflow into the right bank of the Fernley Reach. The peak discharge for alluvial basin B is reduced by 14% and 21% for the 100-yr and 50-yr flood events, respectively.

Alluvial basins C through H also show flood hydrograph attenuation, although not as much as expected in undeveloped alluvial channels. The more frequent events, however, did show an increasing amount of attenuation and losses. This is most likely due to less flow concentration within the alluvial fan area resulting in higher losses.

The ponded areas along the right bank in the Fernley Reach are representative of the ground topography in 2008. Material removed from the canal for cleaning since 2008 has changed the topography along the banks. The additional material would affect the amount of ponded water upstream of the canal and could cause additional losses into the soil to occur.

Minor numerical instabilities were noticed in the 2-dimensional model for the lower flow alluvial basins C through H. These instabilities were due to problems associated with SRH-2D when switching between wet and dry elements. Such instabilities are considered to be insignificant and did not affect the overall performance of the model.

CONCLUSION

It had been hypothesized that peak flooding flows within the Truckee canal basin were attenuated due to the adjacent alluvial fans. Classic one-dimensional hydrologic modeling is unable to capture the infiltration losses experience in alluvial fans since the surfaces are dynamic. To better understand the hydrology of the basin, a one-dimensional hydrologic model was coupled with a two-dimensional hydrologic model to simulate the 10-, 25-, 50-, and 100-year flows. This model was un-calibrated since there was no available data to calibrate toward. The model

uncertainty was determined through a mass balance analyses. It was found that only a 2% error in mass balance between the flows entering and leaving the two-dimensional model.

EVALUATING PHYSICAL MODELS OF DAM REMOVAL AGAINST RESULTS FROM CONDIT, MARMOT, AND ELWHA FOR PROCESS DRIVEN SEDIMENT TRANSPORT AND CHANNEL BED RESPONSE

Joanna Crowe Curran, Ph.D., Senior Geomorphologist / River Engineer, Northwest Hydraulic Consultants, 13600 Christensen Road, Suite 350, Seattle, WA 98188, jcurran@nhcweb.com

As dam removals have become more frequent in recent decades, the interest in and research on the downstream impacts of releasing large amounts of formerly impounded sediment on the downstream channel morphology have been investigated. A series of recently completed flume experiments evaluated the downstream effects of dam removal sequencing, impounded sediment grain size distribution, and channel flow rate on sediment transport rates and channel morphology during and following dam removal. Recent dam removals have provided data from field scale experiments in sediment transport and downstream morphologic adjustments following dam removal from situations with a variety of independent driving variables. These provide the data necessary to evaluate the physical modeling results.

Through physical modeling, 5 different dam deconstruction sequences were tested against 2 flow rates and 3 sediment mixtures to evaluate the 30 different combinations of channel and dam type. The dam deconstruction sequencing scenarios simulated were chosen to replicate current dam removal practices and included: removal in horizontal layers from the top down; removal in vertical sections with the first section removed from the middle of the dam; removal in vertical sections where the first section removed is adjacent to the channel edge; notched removal where the sides of the dam remain in place, and complete dam removal in a single step. Each removal scenario was repeated using flow rates designed to simulate low (Froude number =0.2) and high flow (Froude number = 0.6) conditions. Sediment transport was monitored throughout each stage of each dam removal and the bed surface was scanned using a laser displacement scanner after each removal stage. Digital Elevation Models (DEMs) of each bed surface were created from the bed surface laser scans and by differencing these DEMS, the spatial distribution of preferential deposition and erosion downstream of the dam removal was identified and quantified. A bed load monitoring system (BLMS) collected real-time data on the movement of the sediment through the flume channel during the experiments. BLMS data enabled re-creation of the sediment transport rates following each stage of a dam removal. Together these data provided a means of evaluating the impact of each removal type on the rate and volume of sediment movement as well as the short and long term impacts on the bed surface around the dam removal site and downstream.

This talk will present a comparison of results from flume runs against those from recent dam removals. The Marmot Dam removal from the Sandy River, OR is compared to a flume run where the dam was removed in one step, flow was moderate, and the sediment was a gravel and sand mixture. The Condit Dam removal from the White Salmon River, WA is compared to a flume run where the dam was removed in one step, flow was high, and the sediment was a mixture dominated by sand and silt, but with a small gravel fraction. Dam removals from the Elwha River, WA are compared to a flume run where the dam was removed in a sequence of horizontal stages and the sediment was a mixture dominated by sand and silt, but with a small gravel fraction. The comparisons between laboratory and field were evaluated for the representativeness of the flume

results and the information gained from both flume and field measurements. Additional information gained from the lab included measurements of real time estimates of deposition and erosion over the downstream channel reach while the field supplied information on broad scale planform channel changes. Similarities between flume and field results indicate a potential for improving predictive abilities related to sediment transport rates through and changes to the downstream channel over a range of channel and dam removal scenarios.

Research results seek to identify relationships between dam deconstruction sequencing, channel and impounded sediment sizes, and flow rate during removal so that the impact of sediment release with dam removal on the downstream channel morphology can be predicted. Many aging dams are not removed due to the economic expense of dredging impounded sediment prior to deconstruction and fears of ecosystem damage if the sediment is released. By quantifying sediment movement associated with different dam deconstruction sequencing, the effect of dam removal on the downstream channel morphology can be better predicted and impounded sediment can be released and transported downstream in a way that benefits, rather than harms, the downstream ecosystem and protects downstream infrastructure. The experimental results can aid in planning a dam removal to address specific goals related to impounded sediment movement and impact to the downstream channel.

MOUNT ST. HELENS UPDATE: RECENT TRENDS, UNDERSTANDINGS AND PROJECTS TO MANAGE DEBRIS AVALANCHE SEDIMENTS

Chris Nygaard, PE, Portland District US Army Corps of Engineers, Portland, Oregon, christopher.j.nygaard@usace.army.mil; Paul Sclafani, PE, Portland District US Army Corps of Engineers, Portland, Oregon, paul.sclafani@usace.army.mil

Abstract: Since the eruption of Mount St. Helens (MSH) in 1980, the US Army Corps of Engineers has been actively managing debris avalanche sediment in the Toutle River and lower Cowlitz Rivers in southwest Washington State. The Sediment Retention Structure (SRS), a 125 foot tall sediment trap constructed in 1987, is the primary long-term sediment management action. The SRS was designed to trap sediment high in the watershed and prevent problematic deposition in the lower reaches where floodplain development has occurred. The SRS has been effective at trapping sediment since construction and continues trap on the order of 30% of inflowing sediment 27 years after construction.

Since 2006 however, sediment has begun passing the SRS in sufficient quantities such that deposition in the leveed and populated downstream reaches has become a concern. USACE has responded to this change in trends by initiating multiple technical and planning studies as well as management actions. The primary purpose of the studies was to establish a sediment management plan through the current planning period that would be cost effective and responsive to the current economic and environmental landscape. The sediment management actions were designed to reduce flood risk to affected communities in the lower basin. This presentation will provide an update of recent trends, studies, actions and environmental concerns.

Forecasts for large scale and uncertain trends such as sediment load from the MSH debris avalanche are necessarily simplified to express the overall average volumes or rates of decay. Observed data is rarely so well behaved. In the case of MSH sediment load up to two orders of magnitude of annual variation are observed. Downstream deposition is complicated by the non-linear relationship between flow, load and erosion. While overall load from the mountain is lower than predicted in 1985, peak sediment events have deposited large amounts of material which persist for multiple years without physical removal.

Two new studies predicting sediment load from MSH have been received by USACE; a 2012 study by USDA prepared by Simon and Klimetz and a 2014 University of Nottingham Ph.D. thesis by T. Meadows. Using different methodologies for predicting future loads, the two studies come to significantly different conclusions. Simon argues for significant and persistent near term decay in load while Meadows argues for decreased overall load with mild decay into the next century. With continued uncertainty about the future sediment load trends, let alone peak sediment, USACE has prioritized flexibility in its management approach.

In addition to the planning effort that re-evaluated the long term sediment management plan, USACE has responded to increased deposition in the lower Cowlitz River with several actions: 2008 Castle Rock Levee Improvements, 2010 Pilot Grade Building Structures and the 2012 SRS Crest Raise. Purpose, effectiveness, and morphological response to each action will be discussed. Features of the project designed to comply with Endangered Species Act (ESA)

listings will be described. Additional sediment related ESA concerns within the management area will be introduced.

FORECASTING LONG-TERM SEDIMENT YIELD FROM THE UPPER NORTH FORK TOUTLE RIVER, MOUNT ST HELENS

EXTENDED ABSTRACT

Tim Meadows, Senior Hydromorphologist, SEPA, Edinburgh, UK, tim.meadows@sepa.org.uk; Colin Thorne, Professor, University of Nottingham, UK; Nick Mount, Associate Professor, University of Nottingham, UK; Tom Coulthard, Professor, University of Hull, UK.

INTRODUCTION

The disturbance of otherwise stable fluvial systems by heavy sediment loading is a common phenomenon, particularly in mountainous areas (Pitlick, 1993; Rathburn *et al*., 2013), and may result from both natural and anthropogenic processes (Gran and Montgomery, 2005). Post-disturbance sediment yields are often significantly elevated above background levels as a result of increased availability of source material and hydrological changes that result in higher peak floods. Some of the highest specific sediment yields have been recorded in mountain rivers disturbed by explosive volcanic eruptions, with transport rates that exceed the 99th percentile of historic sediment yields reported in undisturbed catchments (Korup, 2012). However, longer-term trends in sediment yields following disturbance are poorly understood, principally due to a lack of documentation, but also because recovery trajectories of disturbed fluvial systems are influenced by a broad range of general and local controls (Manville and Wilson, 2004; Pierson and Major, 2014).

Where long-term recovery trends from explosive eruptions have been monitored, the results often indicate that sediment yields can remain elevated for decades, centuries or even millennia (e.g. James, 1989; Manville and Wilson, 2004; Gran and Montgomery, 2005; Korup, 2005; Koi *et al*., 2008; Manville *et al*., 2009; Pierson *et al*., 2011; Pierson and Major, 2014). Given the potentially damaging socio-economic consequences of persistently high sediment yields, generating projections of long-term sediment yield from disturbed fluvial systems is essential for the development of sustainable sediment management options. However, conventional tools available to fluvial geomorphologists and river engineers, such as reductionist numerical models and empirical analyses, are not ideally suited to the task, making this challenge difficult to address. Recent advances in numerical modelling techniques, however, offer new opportunities to develop quantitative, physically-based predictions of fluvial system recovery following landscape disturbance.

Specifically, reduced complexity, landscape evolution models, which are explicitly designed to operate at low computational cost over long temporal- and large spatial-scales, have the potential to play a significant role in efforts to understand, explain and predict the long-term response of fluvial systems to disturbance. Landscape evolution models attempt to simulate the three-dimensional development of landscapes through time (Kirkby, 1971; Ahnert, 1976), and hence permit the effect of multiple geomorphic processes that contribute to the redistribution of sediment within a catchment to be integrated together over complex topographic surfaces and extended periods of time (Pazzaglia, 2003; Martin and Church, 2004). Such models therefore aim to represent the principal erosion processes operating within a catchment, including those affecting hillslopes and those operating in stream channels. In some cases, bedrock weathering and flexural isostatic uplift in response to denudation are also included.

THE 1980 ERUPTION OF MOUNT ST HELENS

The hydrogeomorphic effects of the catastrophic 1980 eruption of Mount St Helens, Washington State, USA, remain the most thoroughly studied record of long-term landscape impact following a voluminous explosive eruption (e.g. Pearson, 1984; Meyer and Dodge, 1987; Meyer and Martinson, 1989; Simon and Thorne, 1996; Simon, 1999; Major *et al*., 2000; Major, 2004; Major and Mark, 2006; Zheng *et al*., 2014). The Toutle-Cowlitz River system (Figure 1) experienced particularly dramatic landscape disturbance during this event, principally through the emplacement of by a 2.5 km^3 debris avalanche, which buried the upper 60 km^2 of the North Fork Toutle River catchment to an average depth of 45 m and obliterated the pre-eruption drainage network (Lipman and Mullineaux, 1981).

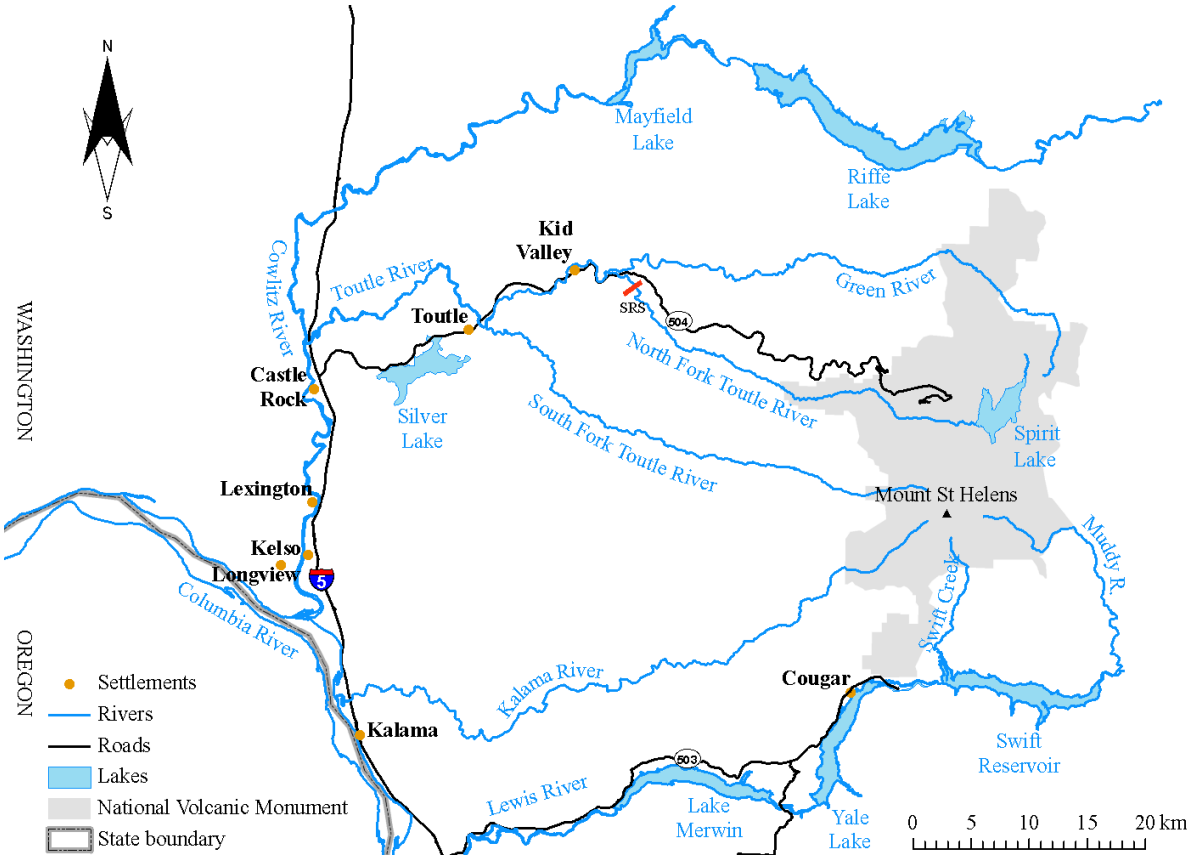

Figure 1 Map of Toutle-Cowlitz River system.

Subsequent channel response on the debris avalanche, dominated by incision and widening, has delivered significant quantities of sediment to downstream reaches of the Cowlitz River, where resultant deposition has reduced channel capacity and increased flood risk unacceptably. Over the 30+ years since the eruption, significant efforts have been made to protect vulnerable communities and to understand trends and mechanisms of sediment yield from the affected catchments. However, despite more than three decades of intensive monitoring at Mount St Helens, the recovery trajectory remains contested and future trends are clouded by uncertainty. Moreover, existing infrastructure designed to reduce downstream sediment-related flood risk may be unable to store sufficient sediment to continue to meet flood risk reduction standards over the long term. Options for future sediment management are therefore currently being assessed (USACE, 2010, 2012) but divergence in predictions of

long-term sediment yield reported in previous studies make option appraisal and decision-making difficult.

CAESAR-LISFLOOD LANDSCAPE EVOLUTION MODEL: BACKGROUND AND APPLICATON

This paper describes the use of a numerical, landscape evolution model (CAESAR-Lisflood (C-L)) to generate long-term forecasts of sediment yield from the upper North Fork Toutle River catchment. The computational efficiency of C-L enables multiple physically-based simulations to be run over long time periods (>100 years) and at the scale of whole river basins. In comparison to other contemporary reduced complexity, landscape evolution models, C-L includes the most sophisticated representation of flow hydraulics (using the LISFLOOD-FP equations of Bates *et al*. (2010), the most detailed model of fluvial erosion and deposition (including multiple grain sizes, lateral erosion and suspended sediment) and the most comprehensive representation of catchment hydrology. Importantly, the model allows for dynamic terrain adjustments and has been shown to demonstrate the complex, non-linear behaviour typical of disturbed fluvial systems (e.g. Coulthard *et al*., 1998; Coulthard and Van De Wiel, 2007) that plays an important role in long-term landscape development.

C-L model parameters were calibrated during a period of model hindcasting in which the fitness-for-purpose of the model was also assessed. During this process, values for key parameters that could not be specified on the basis of empirical data, *a priori* knowledge or pre-existing, recommended values were varied across well-constrained and feasible ranges. Model outputs were then compared to observations using four physically-meaningful evaluation criteria, specifically: total catchment sediment yield; sub-catchment sediment yield; change in cross-sectional area; and change in thalweg elevation. This multi-scale approach facilitated both volumes and mechanisms of modelled sediment yield to be evaluated, which allowed for a comprehensive assessment of model performance to be undertaken. Within the range of variations in model outputs, two model configurations were identified as providing good fits to the observed data for all four of the evaluation criteria, while also accounting for uncertainty associated with the definition of the model parameter that controls the lateral mobility of river channels.

The two selected model configurations were implemented in ensembles with runoff forecasts developed as part of the Columbia Basin Climate Change Scenarios Project (CBCCSP) undertaken by the Climate Impacts Group (CIG) at the University of Washington (Hamlet *et al*., 2010). The runoff forecasts selected from the CBCCSP represented three different global climate model (GCM) simulations and two scenarios for greenhouse gas (GHG) emissions and, therefore, encapsulated the majority of variability associated with uncertainty in predicting the future hydrological regime of the catchment. A total of 36, 91-year forecasting runs were undertaken, along with two, more speculative, 182-year simulations that produced extended forecasts for the 22nd century.

RESULTS

The forecast sediment yields fall into a band with a width of +/-20% of the mean that lies between previous estimates derived principally from the extrapolation of post-eruption trends (Biedenharn Group, 2010; Simon and Klimetz, 2012) (Figure 2). It must be noted that neither the WEST nor Biedenharn Group studies provided estimates of sediment yield beyond the year 2035. However, for comparison with the predictions based on C-L modelling, their

estimates were extrapolated from 2036 to 2100 and plotted in Figure 2. The range of sediment yields forecast by C-L is very well constrained despite conscious efforts throughout the study to maximise the difference between selected model configurations and future hydrological scenarios.

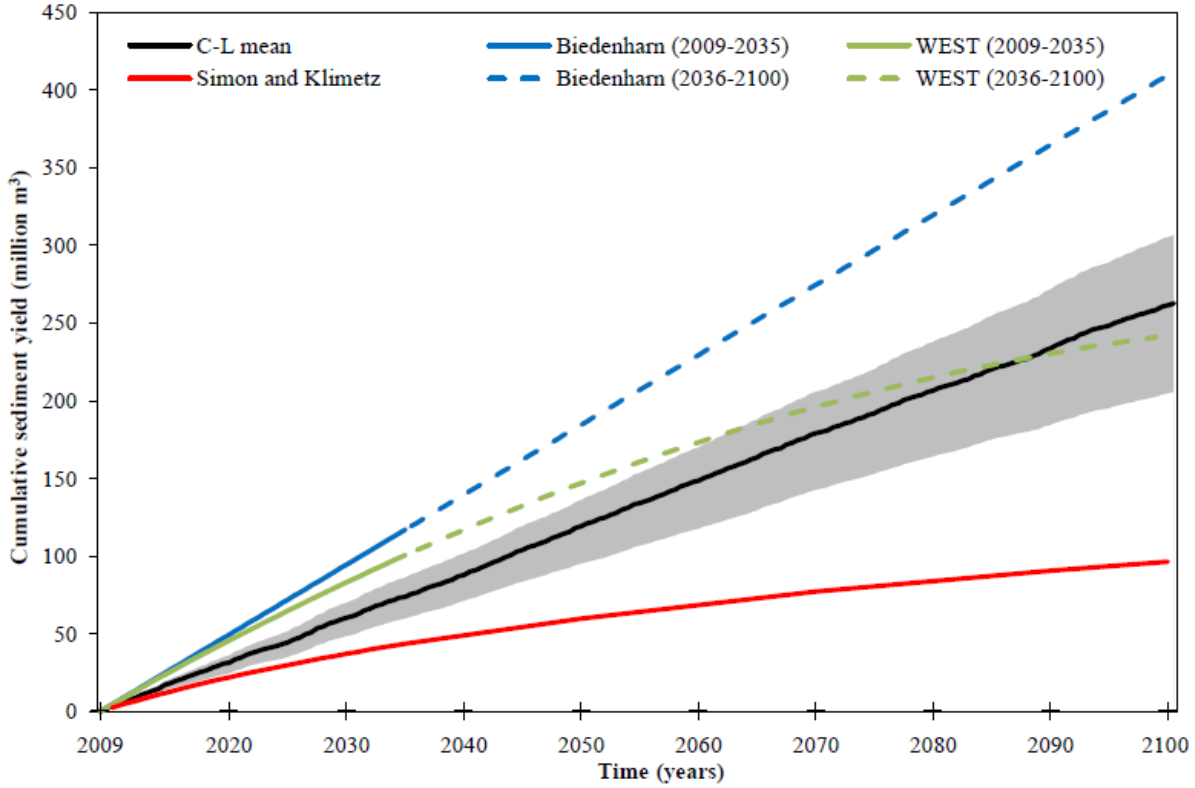

Figure 2 Projections of cumulative catchment sediment yield from the upper North Fork Toutle River from 2009 to 2100. The upper and lower bounds of the shaded area are the maximum and minimum of the C-L forecasts.

Importantly, forecast trends in future annual sediment yields are predominantly linear, and decline in future yields is limited even in forecasts produced by runs in which the parameter defining the lateral mobility of the channel is lower. As a result, the extended forecasts suggest that elevated rates of sediment production may persist into the 22nd century. The predominantly linear trend in cumulative sediment yield modelled by C-L suggests that negative exponential decay functions based on a rate law (Graf, 1977) are inappropriate for predicting sediment yields from the upper North Fork Toutle River catchment. Although the rate law can be used to describe changes in bed elevation and adjustments to the channel long profile, C-L model results reveal that it is *lateral erosion* caused by fluvial undercutting and slumping of high, steep banks, that drives long-term trends in sediment yield, rather than bed scour.

CONCLUSIONS

The C-L forecasts presented in this paper suggest that it may not be possible to maintain flood risk reduction benefits to vulnerable communities on the lower Cowlitz River solely by trapping sediment upstream of a sediment retention structure (SRS) on the North Fork Toutle

River. For example, it has been estimated that the two methods of improving the trap efficiency of the SRS proposed by the USACE (a 13 m dam raise or incremental raises of the spillway combined with grade-building structures) would be effective only until the 2040s if C-L forecasts are realised. This prospect implies that alternative strategies capable of managing sediment-related flood risk in the Toutle-Cowlitz River system into the next century in ways that are economically, environmentally and ecologically sustainable should be investigated. It may be necessary, for instance, to relocate and/or raise vulnerable communities such as Castle Rock, where risks to life and property posed by flooding are particularly high due to its position close to the mouth of the Toutle River and location on the floodplain at the inside of a tight meander bend.

The research reported in this paper also demonstrates the utility of reduced complexity, landscape evolution modelling for long-term forecasting of catchment-scale sediment yield. Although modelling based on cellular automata has often been criticised by proponents of reductionist, 'physics-based' models, in the context of the upper North Fork Toutle River it has been shown to be a powerful tool that can and should be used to explore landscape evolution and response to disturbance. It also has the potential to help inform long-term, catchment-scale planning and sustainable management of environmental hazards associated with, for example, elevated sediment yields. Moreover, the comparison between the results obtained using C-L and those derived from other modelling approaches, such as empirical extrapolation, provides important insights into the relative strengths and weaknesses of these different techniques.

ACKNOWLEDGEMENTS

The research reported herein was performed while the first author was a doctoral student at the University of Nottingham, supervised by the second and third authors and advised by the fourth. The research was funded by a studentship from the School of Geography. It could not have been undertaken without the support of the US Geological Survey, Cascades Volcano Observatory and the Portland District, US Army Corps of Engineers. In this regard, the authors would particularly like to thank Jon Major, Kurt Spicer and Adam Mosbrucker (USGS) and Chris Nygaard and Paul Sclafani (USACE). The research also benefited from input from Dr Andrew Simon, whose advice is gratefully acknowledged.

MOUNT ST. HELENS LONG TERM SEDIMENT MANAGEMENT ALTERNATIVE ANALYSIS

Paul Sclafani, Hydraulic Engineer, U.S. Army Corps of Engineers, Portland Oregon, paul.sclafani@usace.army.mil; Chris Nygaard, U.S. Army Corps of Engineers, Portland, Oregon, Christopher.j.nygaard@usace.army.mil

Abstract: Thirty-three years after the eruption of Mount St. Helens, erosion from the debris avalanche into the Toutle River continues to produce a problematic quantity of sediment for downriver communities. For the past five years the U.S. Army Corps of Engineers has been revisiting the long term sediment management strategy originally developed in 1985 to determine if there are better ways to meet flood protection goals while minimizing both harm to the environment and project costs.

Long term sediment records collected by the USGS Volcanic Observatory coupled with LiDAR and field surveys were used to create a sediment budget for the Toutle River basin. A complete sediment budget was developed from 1980 to 2007. Annual sediment loads for the period from 1999 to 2007 were stochastically sampled to create a predicted sediment record for the project life, extending out to 2035. Within these sampling years the annual sediment load from the Mount St. Helens debris avalanche ranges from 0.6 to 26 million tons. This natural variability of sediment erosion from the debris avalanche provides a reasonable representation of possible future loads to be expected in the basin. Once created, this forecasted sediment load was used as input to the modeling scheme chosen for the project.

A modeling scheme was selected to numerically represent the complexity of the Toutle River basin from the debris avalanche to the mouth of the Cowlitz River. The basin can be considered as a combination of sources and sinks placed in series. The debris avalanche represents the most significant source, the erosion of which is represented by the sediment budget. The highly braided network of streams downstream of the debris avalanche was modeled using Mike 21-C; HEC-RAS was used to develop the rating curve through the sediment retention structure (SRS). Sediment/bed interaction within the Toutle River downstream of the SRS was largely ignored as it was considered a transport reach that terminates at the Toutle River's confluence with the Cowlitz River. A mobile-bed HEC-RAS model was utilized in the lower 20 miles of the Cowlitz River to evaluate the long term sediment transport potential in this reach. Output from the upstream Mike-21C model was used for the upstream sediment load input into HEC-RAS. The water surface profiles from the RAS models were used in conjunction with HEC-FDA to compute the Level of Protection (LOP) provided by the levees located on the Lower Cowlitz Rivers. Flow- frequency and levee-fragility curves were developed to support this LOP computation.

Uncertainty/variability was incorporated into this analysis through the available period of flow records, uncertainty in levee performance, variability in bedform, and incoming the sediment load. Model uncertainty was also incorporated into the FDA model through sensitivity of key hydraulic parameters such as the roughness and contraction/expansion coefficients.

The resulting LOP estimates for each levee represent the frequency of an event that reflects a 90 percent probability of levee failure.

With the modeling scheme developed and the predicted sediment loads created for the project out years, a trend in LOP for the levees was computed for the project life. Specific authorizing language dictates that the Corps maintains LOP at a specified level. It was demonstrated that, for the "do-nothing" alternative, the LOP violates the authorization within five years. Based on this trend, a study was initiated to evaluate alternatives that would result in fulfilling the congressional authorization. Initial phases of this analysis identified the 16 measures as potential measures for evaluation. Using two rounds of screening, each measure was evaluated as to the degree to which it:

- Reduces flood risk on the Cowlitz River;
- Is low-cost based on preliminary cost estimates;
- Minimizes impacts to the environment;
- Is reliable;
- Is adaptable to changing conditions; and
- Is acceptable to the public.

After the two rounds of screening, six measures were forwarded for continued scrutiny. Of these, two were considered primary measures in that they have the potential to be employed as stand-alone measures. The rest were secondary measures that may be used to enhance the performance of the primary measures.

This short list was carried forward for further analysis during development of the long term sediment management plan, and each measure was thoroughly evaluated. The remaining four measures were grouped to form three action alternatives carried forward for further evaluation:

- Cowlitz River dredging only;
- SRS dam raise only; and
- Phased-construction (SRS spillway crest raise and GBS with as-needed dredging).

Within the model construct developed for the "do-nothing" alternative, each of the final alternatives was modeled and evaluated. Each alternative has been determined to meet the overall sediment management needs and are deemed relatively efficient, effective, complete, and they will allow for the management of the significant uncertainty in future sediment deposition.

In the evaluation of the final alternatives, it became clear that each alternative provided a specific benefit and contained unique drawbacks. For example, the dredging-only option, which involves dredging the lower 20 miles of the Cowlitz River, is highly adaptable to changing conditions, however placement of dredge material is problematic in terms of logistics and considering environmental concerns. The SRS-raise option has a high degree of certainty of trapping sediment, however, it is not adaptable to changing conditions and requires high up-front costs. The phased-construction approach combines the adaptability of the dredging only plan and the effectiveness of the SRS raise. The phased construction plan is currently the preferred alternative.

The preferred alternative attempts to incorporate the high level of uncertainty in the basin through an adaptive management plan that only implements actions when the monitoring efforts show a need. The three components of the plan include gaining additional sediment capacity by raising the spillway crest and adding structures within the sediment plain to promote the depositional grade. The final component is emergency dredging in the Lower Cowlitz River to maintain the ability to react to unexpected extreme sediment loads. Inherent in an adaptable plan is a monitoring effort that quantifies sediment deposition in the Sediment plain and in the Lower Cowlitz.

In the case of the Toutle Basin, identification of the need is tied to the annual evaluation of the LOP. Evaluation of the LOP requires that sediment load measurements, survey data, and field observations be collected annually. A decision matrix has been put together that identifies the appropriate annual monitoring activities, decision criteria to implement a sediment control measure, and decision criteria for what type of sediment control measure is necessary. Specifics of these decision criteria will be part of the annual operation plan for the phased construction approach.

TWO-DIMENSIONAL NUMERICAL MODELLING OF HYPERCONCENTRATED FLOWS

Jianchun Huang, Ph.D., P.E., Hydraulic Engineer, Bureau of Reclamation, Denver, CO, yhuang@usbr.gov; Yong Lai, Ph.D., Hydraulic Engineer, Bureau of Reclamation, Denver CO, ylai@usbr.gov; and Kuowei Wu, Water Resources Planning Institute, Water Resources Agency, Wu-Fong, Taichung, Taiwan, kuowei@wrap.gov.tw

Abstract: SRH-2D, a two-dimensional sediment transport model developed at the U.S. Bureau of Reclamation, is extended to simulate hyperconcentrated flows by considering the effect of sediment concentration on the the sediment fall velocity, sediment capacity and sediment erosion and deposition. The governing equations for shallow water equations are modified to be suitable for two dimensional unsteady hyperconcentrated flow modeling. Density variance and sediment exchanges between flow and bed are incorporated. The revised model is tested and verified using two cases: an idealized transient flow and sediment process due to a dam-break flow over a horizontal bed and a more complex dam-break flow with a sudden width enlargement. The model results show that the numerical model can predict the water surface elevation with reasonable accuracy. The results also show that the extra terms related to the density gradient and the terms related to the exchange between the flow and the erodible bed are important for hyperconcentrated flow. They increase the water front speed and wave height during a dam break.

INTRODUCTION

Hyperconcentrated flow can occur in high-discharge flows of water and sediment. The definition of hyperconcentrated flow varies among different researchers. Pierson (2005) defines hyperconcentrated flows to be between two extremes. At the low extreme, water transports sediment in such quantities that the sediment has negligible effect on flow behavior and the fluid remains Newtonian. At the other extreme, high-discharge debris flows and mudflows transport much more sediment than water can carry. For such cases sediment concentrations are often in excess of 60% by volume and 80% by weight. For debris and mud flows sediment plays a very important role in flow behaviors and mechanics (Wan and Wang, 1994; Coussot and Piau, 1994). Some researchers refer the debris flows and mudflows also as hyperconcentrated flow (NRC, 1982; O'Brien and Julien, 1985; and Julien and Paris, 2010).

One dimensional (1D) numerical modelling has often been used to simulate hyperconcentrated sediment-laden flows. For example, Zhang et al. (2001) presented a 1D unsteady numerical model for hyperconcentrated sediment-laden flows and applied it to the Lower Yellow River with a length of 394km. A semi-empirical equation of sediment transport capacity was used. Cao et al. (2004 and 2006) presented a 1D numerical model for a hyperconcentrted sediment laden flow. They used a second-order TVD method in conjunction with the HLLC Riemann solver and the SUPERBEE limiter. The extra terms related to the mixture density were included in the momentum equation, but not in the mass conservation equation. The exchange between the flow and the erodible bed was included in the mass and momentum equations. Wu and Wang (2007) presented a 1D hyperconcentrated model for dam-break flow over movable beds. The mass and momentum equations included the contribution of the sediment erosion and deposition. Guo et al. (2008) presented a hyper-concentrated sediment transport model for the lower Yellow River. The model considered the effect of high concentration on the flow density and sediment settling velocity. The variation of the mixture density and the exchange between the flow and the erodible bed were not included in the mass and momentum equations. Mouri et al. (2011) simulated an extreme flood and sediment flux in a mountain stream with a 1D numerical model. The mass and momentum equations considered no contribution of the sediment erosion and deposition. Abderrezzak and Paquier (2011) investigated sediment transport capacity formulas in dam-break flows. He et al. (2012) simulated unsteady hyperconcentrated sediment-laden flow in the Yellow River, China. They incorporated the extra terms related to the density of turbid flow into mass and momentum conservation equations, but not the contribution of sediment exchange between the flow and the bed.

Kim and Lee (2012) presented a 1D and 2D finite volume method for a hyperconcentrated sediment laden flow in a Cartesian coordinate system. They pointed out that the contribution of density should not be ignored in a hyperconcentrated sediment laden flow. Shallow water equations (SWE) with variable density were solved and the

sediment erosion and deposition terms were taken account in the depth-averaged continuity and momentum equations.

In this paper, we develop a 2D hyper-concentrated flow and sediment model based on the existing SRH-2D model and previous 1D model studies. .

DESCRIPTION OF THE NUMERICAL MODELS

The governing equations for 2D, unsteady, hyperconcentrated sediment-laden flow were revised from shallow water equation to include the density variance and sediment exchanges between flow and bed. The governing equations include mass and momentum conservation equations for the water-sediment mixture, the mass conservation equations for each sediment class carried in the flow, and the bed morphological change equation.

$$\frac{\partial(h)}{\partial t}+\frac{\partial(hU)}{\partial x}+\frac{\partial(hV)}{\partial y}=\frac{(E-D)}{1-P} \tag{1}$$

$$\frac{\partial(hU)}{\partial t}+\frac{\partial(hU^2)}{\partial x}+\frac{\partial(hUV)}{\partial y}=-gh\frac{\partial z_s}{\partial x}-\frac{\tau_{bx}}{\rho}-\frac{\rho_s-\rho_m}{2\rho_s}gh^2\frac{\partial S_v}{\partial x}-\frac{\rho_b-\rho_m}{\rho_m}\frac{(E-D)U}{1-P} \tag{2}$$

$$\frac{\partial(hV)}{\partial t}+\frac{\partial(hUV)}{\partial x}+\frac{\partial(hV^2)}{\partial y}=-gh\frac{\partial z_s}{\partial y}-\frac{\tau_{by}}{\rho}-\frac{\rho_s-\rho_m}{2\rho_s}gh^2\frac{\partial S_v}{\partial y}-\frac{\rho_b-\rho_m}{\rho_m}\frac{(E-D)V}{1-P} \tag{3}$$

$$\frac{\partial(hS_k)}{\partial t}+\frac{\partial(hUS_k)}{\partial x}+\frac{\partial(hVS_k)}{\partial y}=E_k-D_k \tag{4}$$

$$(1-p)\frac{\partial z}{\partial t}=\sum_k(D_k-E_k) \tag{5}$$

where t = time (s); x and y=horizontal Cartesian coordinates (m); h = water depth (m); U and V = depth-averaged velocity components (m/s) in x and y directions, respectively; g = gravitational acceleration; z_s is water surface elevation (m); z is bed elevation (m); $\rho_m = \rho_0(1-S_v)+\rho_s S_v$=density of the water-sediment mixture (kg/m^3); $\rho_b = \rho_0 p+\rho_s(1-p)$=density of the saturated bed (kg/m^3); ρ_0 and ρ_s= densities of water and sediment (kg/m^3); respectively; S_v=$\sum S_k$= total volumetric sediment concentration; S_k = volumetric sediment concentration of size class k; p = bed sediment porosity; E and D = total sediment entrainment and deposition fluxes (m/s) across the bottom boundary of flow, representing the sediment exchange between the water column and the bed. E_k and D_k = sediment entrainment and deposition fluxes of size class k; and bed friction is calculated using the Manning's roughness equation as follows:

$$\begin{pmatrix}\tau_{bx}\\ \tau_{by}\end{pmatrix}=\rho C_f\begin{pmatrix}U\\ V\end{pmatrix}\sqrt{U^2+V^2};\qquad C_f=\frac{gn^2}{h^{\frac{1}{3}}} \tag{6}$$

where n is the Manning's roughness coefficient.

There are two ways to calculate sediment erosion and deposition for superconcentrated flows.

Cao et al. (2004 and 2006) presented sediment erosion and deposition for superconcentrated flows as,

$$D=\alpha c\omega_0(1-\alpha c)^m \tag{7}$$

$$E=\begin{cases}\varphi(\theta-\theta_c)uh^{-1}d^{-0.2} & \text{if } \theta\geq\theta_c\\ 0 & \text{else}\end{cases} \tag{8}$$

where D, E=sediment deposition and entrainment fluxes across the bottom boundary of flow (m/s), representing the sediment exchange between the water column and bed; ω_0= settling velocity in clear water (m/s), α is specified empirically by $\alpha = \min[2, \frac{1-p}{c}]$; m = exponent=2.0; h = flow depth (m); d = sediment particle diameter (m) of size class k; p = bed sediment porosity (-) =0.4; $R = \sqrt{sgd}d/\nu$; $s = \frac{\rho_s}{\rho_0} - 1$; ν = kinematic viscosity of water = 1.2E-6 m^2/s; and θ = Shields parameter=$U_*^2/(sgd)$; θ_c = critical Shields parameter for initiation of sediment movement = 0.045; and U_*=shear velocity (m/s);c is depth-averaged volumetric sediment concentration; and φ=0.015[m$^{1.2}$].

Another method is to estimate the sediment deposition and erosion the same way as in other low concentration sediment transport numerical models. The sediment transport capacity for hyperconcentrated flow is presented in the previous section. Sediment erosion and deposition for the kth-sized sediment group were calculated based on sediment transport capacity $S_{*,k}$ and volumetric sediment concentration S_k, respectively.

$$D = \alpha\omega_{s,k}S_k \tag{9}$$

$$E = \alpha\omega_{s,k}S_{*,k} \tag{10}$$

where α=recovery coefficient which ranges from 0.001 in the case of continuous deposition to 1.0 for severe erosion; $\omega_{s,k}$= settling velocity for kth-sized sediment group (m/s). Compared with Eqs. () and (), it is found that the recovery coefficient α is the ratio between the bottom and average concentrations.

Many equations have been proposed to calculate the sediment transport capacity (Zhang and Zhang, 1992; Guo et al., 1995; Yang et al., 1996; Ni et al., 2004; He et al., 2012, and Taiwan Water Resources Agency, 2012). Due to space limit, only two sediment transport capacity equations are presented here which are used in the second test case.

Wu and Long (1993) presented suspended sediment transport capacity, written as

$$S_{*k} = k\left[\frac{\rho_m}{\rho_s - \rho_m}\frac{u^3}{gh\omega_m}\right]^{\mathrm{M}}\Delta P_{*k} \tag{11}$$

where S_{*k}= suspended sediment concentration of class k (kg/m^3); k and M are two empirical parameters, k = 0.452kg/m^3 and M = 0.762; h and u = averaged depth (m) and velocity (m/s) in a cross section, respectively; ω_m = group settling velocity = $\left(\sum_{k=1}^{N_s}\Delta P_{*k}\omega_{sk}^M\right)^{1/M}$; ω_{sk} = settling velocity of sediment size k; ΔP_{*k} = percentage of suspended sediment transport capacity for the k-th class = $(\Delta P_{bk}/\omega_{sk})^\phi / \sum_{k=1}^{N_s}(\Delta P_{bk}/\omega_{sk})^\phi$; ΔP_{bk} =bed material size fraction for the k-th class; ϕ is an empirical coefficient = 0.8; ρ_s and ρ_m are sediment and flow sediment mixture densities (kg/m^3), respectively; g = gravitational acceleration.

A formula proposed by Dou et al. (1999) can be used to determine the bed-load transport capacity, which is written as

$$q_{\mathrm{b}k} = \frac{K_b}{C_0^2}\frac{\rho_s\rho_m}{\rho_s - \rho_m}(u - u_{ck})\frac{u^3}{g\omega_m}\Delta P_{bk} \tag{12}$$

where $q_{\mathrm{b}k}$ = bed-load transport capacity per unit width for the k th grain size fraction (kg/ms); K_b = empirical coefficient (=0.1 calibrated by experiment); C_0 = dimensionless Chezy coefficient = $C\sqrt{g}$ in which $C = h^{1/6}/n$ and n = Manning's coefficient; and u_{ck} = incipient velocity (m/s) of the k-th bed-load fraction; calculated by

$$u_{ck} = \left(\frac{h}{d_k}\right)^{0.14}\sqrt{17.6\frac{\rho_s - \rho_0}{\rho_0}d + 6.05\times10^{-7}\times\frac{10+h}{d_k^{0.72}}} \tag{13}$$

where h = water depth (m); d_k = grain diameter (m) of class k; ρ_s and ρ_o are sediment and clear water densities (kg/m^3), respectively.

The 2D flow and sediment transport model, SRH-2D, is updated to include the extra terms related to the density gradient and the exchange between the flow and the erodible bed in the mass and momentum equations (Eqs. through). In the mass conservation equation (Eq.), the RHS represents the mass exchange between the flow and the erodible bed, which might be potentially signification in a hyperconcentrated flow which large erosion or deposition. The 3rd terms in the RHS of Eqs. (and) represent the effect of density variations, which makes the current hyperbolic system differ from the traditional shallow water equation in which the sediment concentration has no impact on the flow. The 4th terms in the RHS of Eqs. () and () represent the momentum transfer due to sediment exchange between the water and the erodible bed.

MODEL TESTS AND VERIFICATIONS

Simulation of a Dam-break Flow in a Mobile Channel: The numerical model is used to simulate an idealized transient process due to a dam-break flow over a horizontal bed. The channel length is set to be 50km, and the dam is initially located at the middle of the channel (x=25 km). The initial water depths upstream and downstream of the dam are h1=40 m and h2=2 m, respectively. Uniform sediment of size d=4 mm is used and the Manning's roughness of n=0.03 is presumed.

To simulate the 1D problem, three cells are used in the transversal direction and symmetric boundary condition is used for the two side boundaries. The simulation is focused on the transient process due to dam-break, rather than process driven by unsteady hydrographs, thus the wall boundary condition is adopted for the upstream and downstream boundaries. A spatial step of $\Delta x = 10$ m and a time step of 0.1 s are used. Initial sediment concentration was unknown in the original paper by Cao et al. (2004), and zero initial sediment concentration is chosen here.

Figure 1 shows a comparison of the free surface and bed profiles simulate by SRH-2D with and without those extra terms associated with hyperconcentrated flows and in Cao et al. (2004). The following are observed.

Bed erosion occurs during dam break near the location of dam. Bed erosion is a combined effect of sediment eroded from the bed and deposited on the bed. SRH-2D obtained similar bed erosion with Cao et al. (2004). The location of the maximum erosion originally occurs at the dam, and then moves upstream.

Ignoring the extra terms related to the density gradient and the terms related to the exchange between the flow and the erodible bed increases the bed erosion during a dam break problem. It can be understood that the extra term from the sediment eroded from the bed would slow down the momentum of the flow, thus reduce the capability of the flow to erode bed. However, this observation is only valid in a horizontal channel without slope. The increased sediment density could increase the channel's capacity to erode bed in a sloped channel.

The extra terms related to the density gradient and the terms related to the exchange between the flow and the erodible bed in hyperconcentrated flow increase the wave front speed and height.

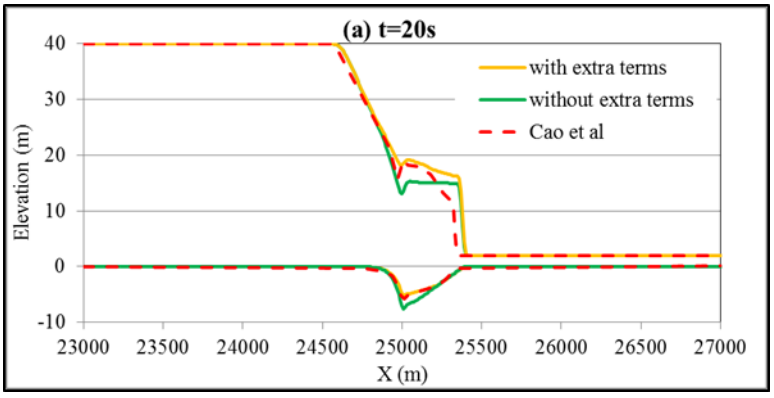

Figure 1 Evolution of water surface and bed profiles

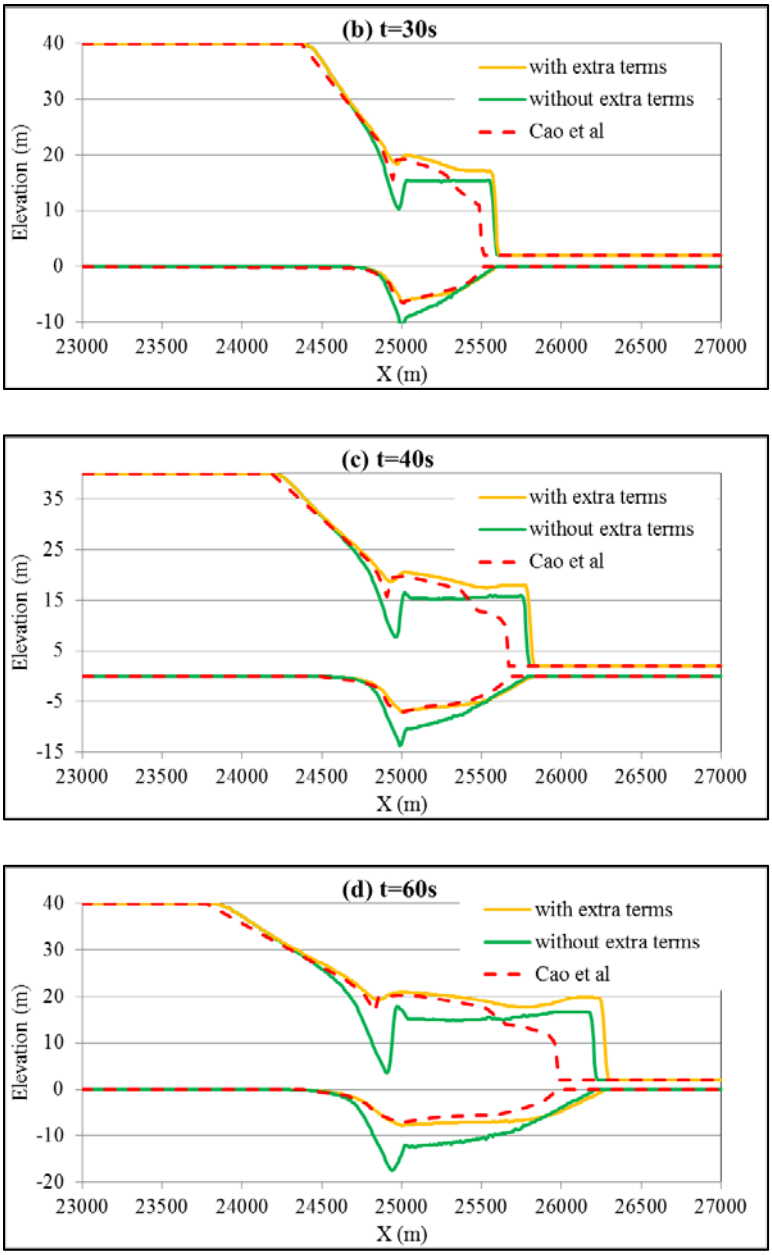

Figure 1 Continued

Simulation of a Dam-break Flow in a Mobile Channel with a Sudden Enlargement: Dam break experiments over mobile beds were performed at the Civil Engineering laboratory of the Université Catholique de Louvain, Belgium (Zech et al., 2008; Spinewine and Zech, 2007; and Palumbo et al., 2008) and was simulated by Xia et al. (2010).

The experiment was conducted in a 6m long flume with a non-symmetrical sudden enlargement from 0.25 m to 0.5 m width located 1 m downstream for the gate at x=3 m. The dam break was simulated by a rapid downwards movement of a thin gate at the middle of the flume to reach initial test conditions that approach as much as possible the idealization of an instantaneous dam collapse while minimizing perturbations to the sediment and water during gate removal. The sediment used was uniform coarse sand ranging from 1.2 to 2.4 mm with d_{50}=1.82 mm and a density of 2680 kg/m^3. Before bed profiling, the sand was compacted in place to reach a reproducible solid packing of concentration 53% (47% porosity). The initial conditions included 0.1 m sand thickness over the whole flume

and an initial clear water depth of 0.25 m upstream of the gate and dry bed downstream of the bed. A Manning's coefficient of 0.026 was used for the simulation.

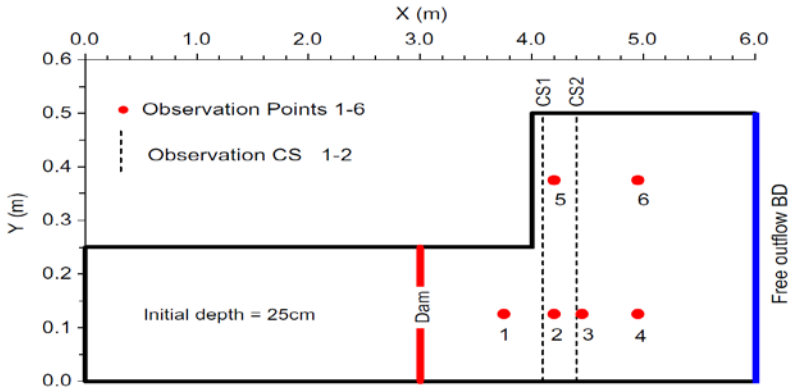

Figure 2 Sketch of a dam-break flow experiment over a mobile bed (Source: Xia et al., 2010)

Figure 3 shows measure and simulated water surface elevation time series, Xia et al. (2010) simulated, and SRH-2D simulated at locations P1 (3.7, 0.125), P2 (4.2,0.125), P3 (4.45,0.125), P4 (5.0, 0.125), P5 (4.2, 0.375), and P6 (5.0, 0.375). It can be seen that the current numerical model predicts the water surface elevation well in both the magnitude and timing.

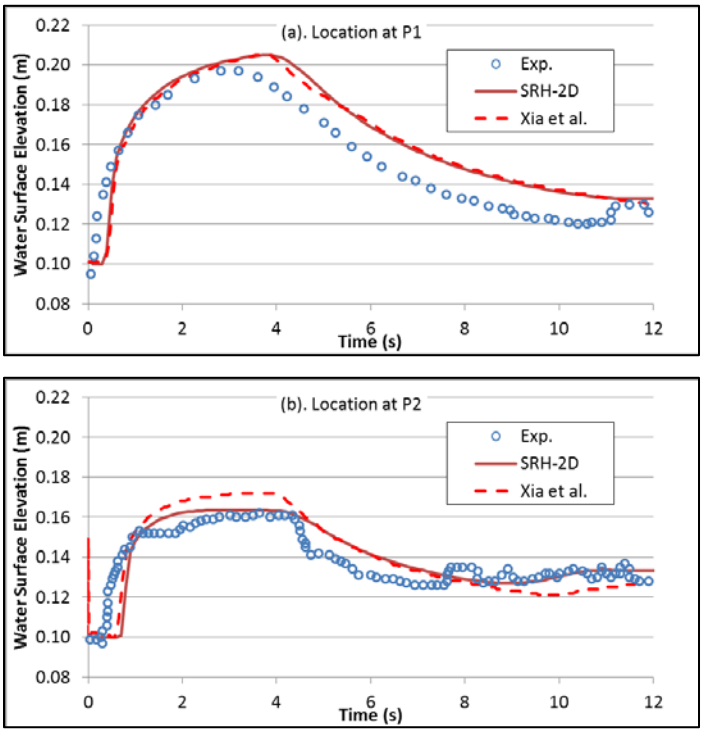

Figure 3 Comparisons between the observed, Xia et al. (2010) calculated, and current SRH-2D calculated water surface elevations

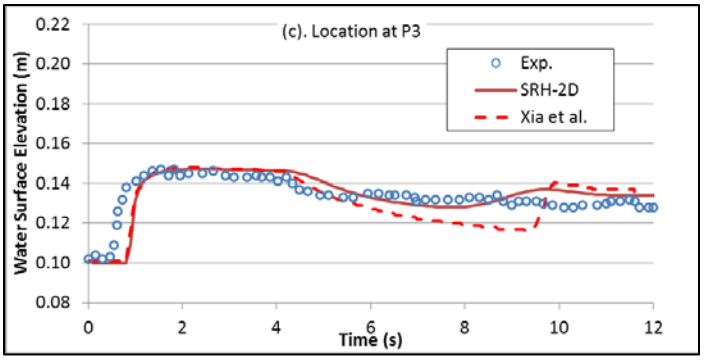

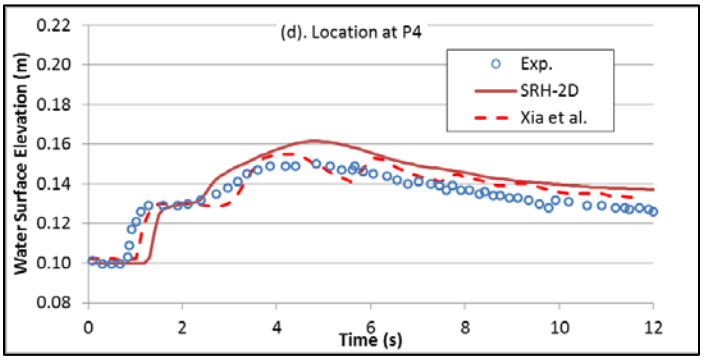

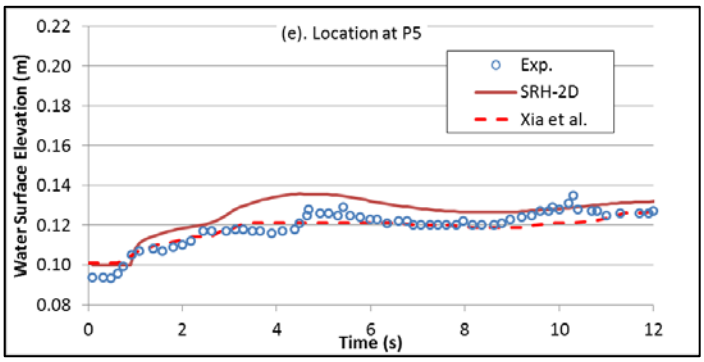

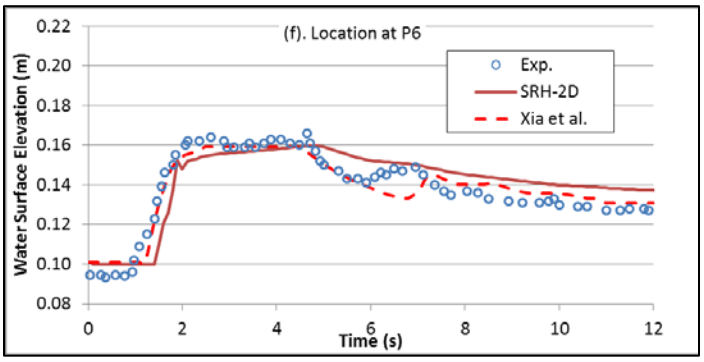

Figure 3 Continued

Figure 4 shows the comparisons of the bed profiles observed in laboratory, simulated by Xia et al. (2010), and simulated by SRH-2D. The SRH-2D simulation includes the discussed extra terms related to hyperconcentrated

flow. The sediment erosion and deposition were simulated using the sediment transport capacity functions of Wu and Long (1993) for suspended load and Dou et al. (1999) for bed load. At CS1 (x=4.1 m), the maximum bed scouring depth was predicted well, however, the model under-predicted the deposition on the left side of the channel after expansion. At CS2 (x=4.4), the model over-predicted the channel erosion and under-predicted channel deposition. A circulation zone is created by the channel expansion, and the deposition rate is closely related to the size of the circulation zone and the turbulence within it.

The test case was also simulated using the erosion and deposition equations for hyperconcentrated flow of Cao et al. (2004 and 2006, and Eqs. and) and the sediment transport capacity function of Engelund and Hansen (1966). Cao et al.'s equations over-predicted channel erosion by one order of magnitude and Engelund and Hansen's equation under-predicted the erosion by one order of magnitude. Both of these equations are intended for rivers, but the Engelund and Hansen formula was not developed for hyperconcentrated flows.

The following conclusion can be drawn from this testcase:

- The numerical model predicts the water surface elevation with high accuracy in a suddenly expanded channel.
- The numerical model reproduces the channel erosion well, however with less accuracy compared with the simulation of water surface elevation. The numerical model under-predicts the sediment deposition in the circulation zone.
- The sediment erosion and deposition rate can be calculated directly from corresponding equations or indirectly from sediment transport capacities. The correct simulation of the channel bed depends on the correct selection of these equations and model calibration.

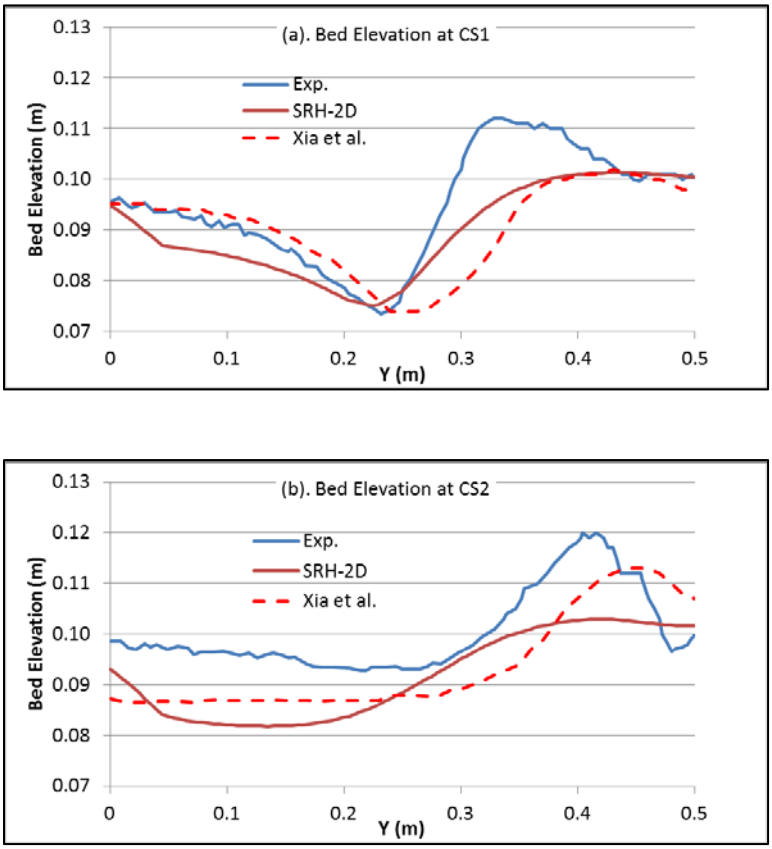

Figure 4 Comparisons between the observed, Xia et al. (2010) calculated, and current SRH-2D calculated water surface elevations

Summary

The current SRH-2D model developed at Bureau of Reclamation is extended to include the effect of sediment concentration on sediment fall velocity, sediment erosion and deposition, density variance in the momentum equation, and the exchange of flow and bed in the mass and momentum equations. The numerical model is tested and validated using two cases : an idealized transient flow and sediment process due to a dam-break flow over a horizontal bed and a more complex dam-break flow with a sudden enlargement. It is shown that the modifications are necessary for hyper-concentrated flow simulation. Also, the new model is validated and is found to predict the observed water surface elevation fairly well.

The study also finds that hyperconcentrated sediment-laden flow alters the flow density and the particle fall velocity. Currently equations for sediment erosion and deposition rates for a hyperconcentrated flow are based on laboratory data or are site specific. They should be examined before they can be applied to actual field conditions.

The extra terms related to the density gradient and the terms related to the exchange between the flow and the erodible bed in hyperconcentrated flow increase the water front speed and wave height during a dam break.

Abstract: Passive acoustic techniques for the measurement of Sediment-Generated Noise (SGN) in gravel-bed rivers present a promising alternative to traditional bedload measurement techniques. Where traditional methods are often prohibitively costly, particularly in labor requirements, and produce point-scale measurements in time and space under highly heterogeneous conditions, acoustic techniques offer the potential to inexpensively monitor gravel movement quasi-continuously over larger spatial scales. While acoustic methods show great potential, significant work is required to provide a general relationship between acoustic signals and physical bedload sampling under field conditions. We addressed this problem by deploying hydrophones for monitoring SGN in the Lucky Hills subwatershed of the USDA-ARS Walnut Gulch Experimental Watershed for the 2014 runoff season (July-September). Bedload was collected using a pit sampler attached to a supercritical Santa Rita-style measuring flume at the catchment outlet. Results of the comparison of physical measurements with SGN monitoring are shown for three runoff events. The field results are compared with expectations derived from theory and laboratory experiments to suggest improvements and new directions for future SGN investigations.

INTRODUCTION

Conventional measurements of bed load are difficult, time consuming, often of unknown accuracy, and expensive. Consequently, data on the rate of bed load transport of most streams is lacking. There is an ongoing need for low-cost instrumentation that can be deployed to work autonomously in remote locations. One promising technology that has been used as a surrogate for bedload in the past is recording sound made by particles transported by flow, which will be referred to as Sediment Generated Noise (SGN), and converting the acoustic energy into a transport rate (Gray et al. 2010). The equipment needed for the recording is relatively inexpensive and is amenable to customization into a self-contained unit. Previous work has examined sound propagation in shallow natural environments (Forrest et al. 1993; Forrest 1994) and the potential for SGN monitoring in large rivers (Barton 2006). A key need for the advancement of SGN work is a broader database of acoustic signal in different hydraulic settings and the development of data analysis techniques. For this information to be useful, the acoustic data needs supporting independent sediment load measurements that can be used in the

interpretation of the acoustic data. Our work was supported by the Federal Interagency Sedimentation Project and represents an effort to improve the techniques used to convert SGN to rates of bed load transport. Here, we describe a field test in a natural channel within the Walnut Gulch Experimental Watershed, near Tombstone, Arizona. The results include a detailed analysis of the frequency content of the acoustic signal and correlation of load with specific acoustic bandwidths.

METHODOLOGY

Data were collected in the Lucky Hills watershed, a 9.1 acre subwatershed of the United States Department of Agriculture (USDA), Agriculture Research Service (ARS) Walnut Gulch Experimental Watershed near Tombstone, Arizona. Average annual precipitation for the watershed over the period 1961-2013 was 356 mm yr^{-1} with approximately two-thirds of annual precipitation occurring during the summer monsoon season (July-September). Soils in the watershed are primarily sandy loam with a large fraction of coarse material composed of fragmented rock. Figure 1 shows the particle size distribution of bed material taken near the outlet of the Lucky Hills watershed. Further characterization of the study area is available in Ritchie et al. 2005.

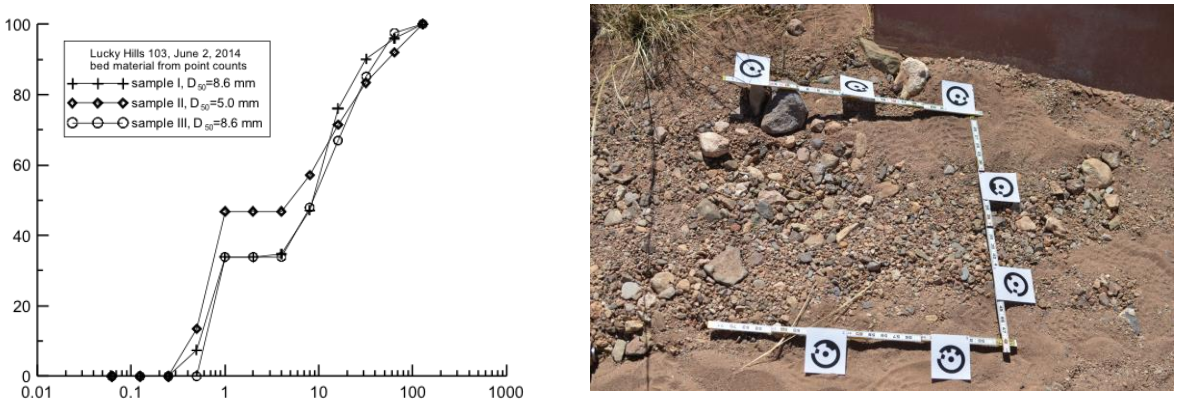

Figure 1 Left: Particle size distribution (mm) from three samples taken along the Lucky Hills watershed main channel. Large fractions of sandy loam and coarse angular material resulted in a bimodal size distribution. Right: Photo of typical coarse sediment deposits along the ephemeral channel.

Two hydrophones were deployed in the watershed immediately upstream of the Santa Rita style measuring flume at the watershed outlet (Figure 2). Due to the low flow depths anticipated during runoff events, the hydrophone housing was installed within 2 cm of the bed oriented in a downstream direction. Each hydrophone was deployed in a PVC housing affording moderate directionality in the measured acoustic signal. Hydrophones and amplifiers from Teledyne Reson were used to record sound at a rate of 25 kHz, using a computer with a multi-channel data acquisition card. The hydrophones were manually activated at the onset of precipitation prior to the appearance of runoff and sampled through the entire hydrograph.

Figure 2 Left: The Santa Rita style flume at the outlet of Lucky Hills subwatershed. This view faces upstream from the outfall (where the pit sampler was later placed) toward the hydrophone mount (post seen in the upstream channel). Right: Photo of the PVC housing of the downstream hydrophone (mounting post visible in center of left photo).

Coarse sediment was collected at the outflow of the measuring flume using a 75cm deep rectangular pit sampler. The walls of the sampler were constructed with 3 mm perforated sheet steel to allow water and finer particles to pass through during a runoff event. After each event the bulk load was removed from the pit trap, dried, and sieved into four size classes using ½", 16 mm, 32 mm, and 64 mm sieves. The size range for coarse sediment collection was chosen based in part on both the particle size characteristics of the site and on expected acoustic emissions from particles based on earlier studies. The particle size distributions derived from channel sediments shown in Figure 1 show a bimodal distribution with very little mass occurring in the 1-10 mm range. Thorne (1985, 1986) found that peak emission frequency and equivalent spherical diameters of natural marine sediments approximately followed the relationship

$$f_{peak} = 209/D^{0.88} \quad (1)$$

where the frequency, *f*, is given in Hz and diameter, *D*, in meters. Accordingly the expected peak emission frequency for a 10 mm particle should be approximately 12 kHz which is very near the resolving limit of our 25 kHz sample rate.

RESULTS

Seven runoff events were monitored between August 1 and September 8, 2014 (Figure 3). The total coarse sediment load (>12mm) for each event ranged from 0.13 kg to 444 kg, peak stage from 1.5 cm to 26 cm, and runoff duration from 28 minutes to 5.25 hours (Table 1). The size distribution of the coarse sediment load for each event is summarized in Figure 4 and Table 1. In each of the larger events, the intermediate coarse fractions (16-64 mm) represented the majority of the sampled mass.

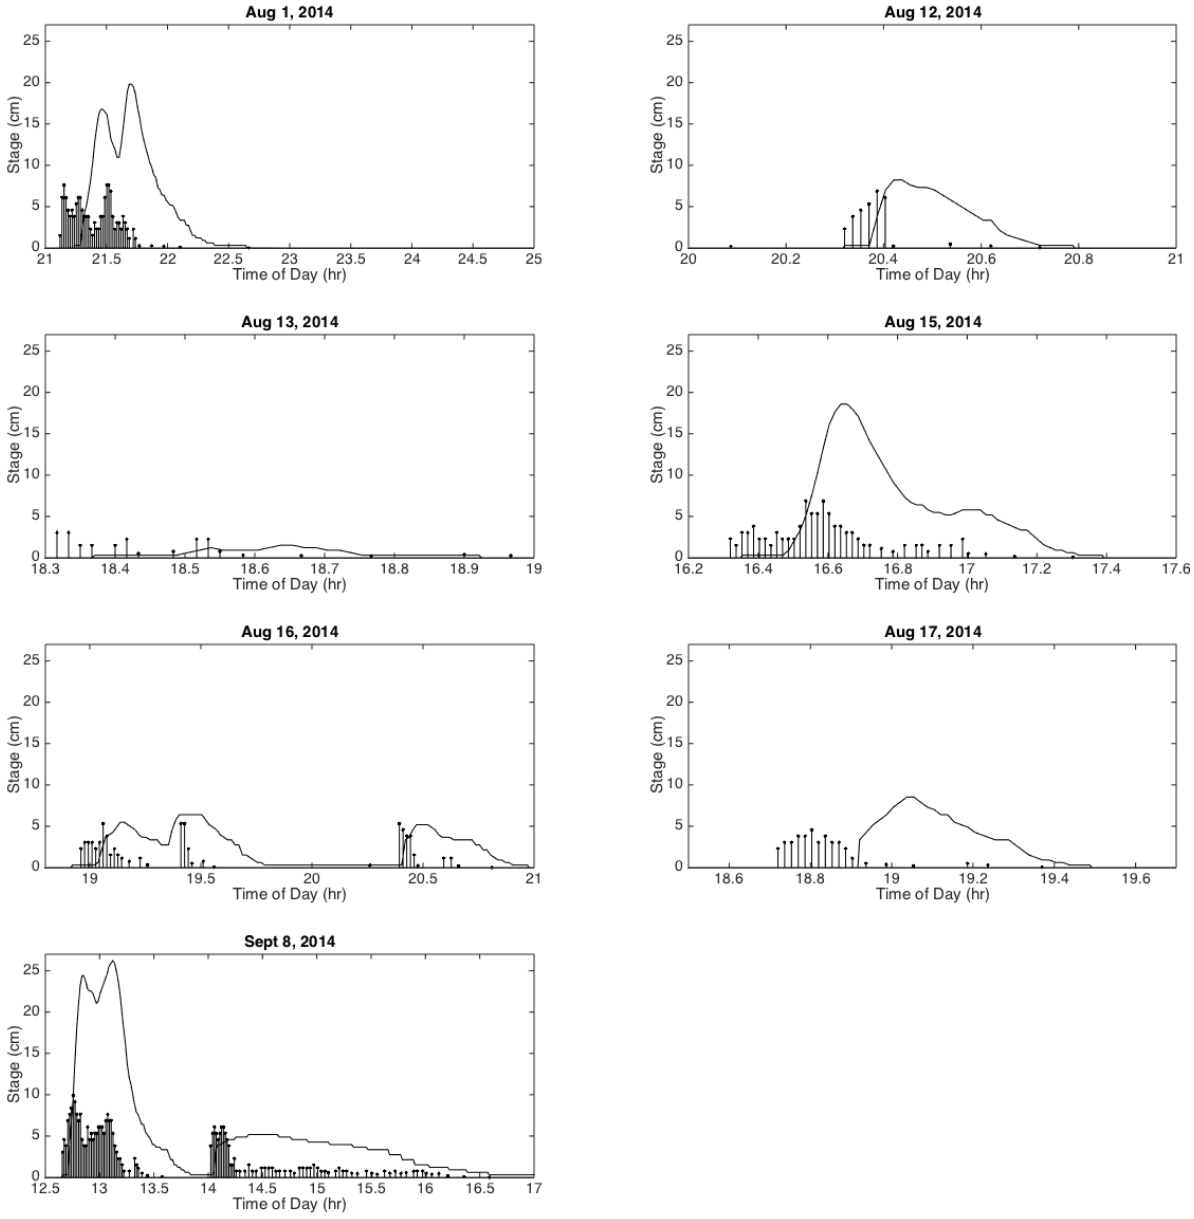

Figure 3 Hydrographs of the seven runoff events from Lucky Hills subwatershed monitored in August-September 2014. The stem plots overlaid show the occurrence of precipitation (heights shown are 1/10 of rain rate in mm/hr) at Rain Gage 83 near the center of the watershed.

Figure 5 shows a sample hydrograph from the flow event on August 15. The acoustic data for these events is also shown, represented by the integrated acoustic signal (volts) over one minute bins. There is an initial peak in the acoustic data associated with flow-induced noise around the instrument housing as the hydrophones were submerged (at ~8cm stage) followed by a period of elevated acoustic activity during the peak of the hydrograph until the stage again falls below the submergence level of the instrument. Three of the events (August 1, August 15, and September 8) reached depths significantly above 8cm which provided the target acoustic data with the hydrophone fully submerged.

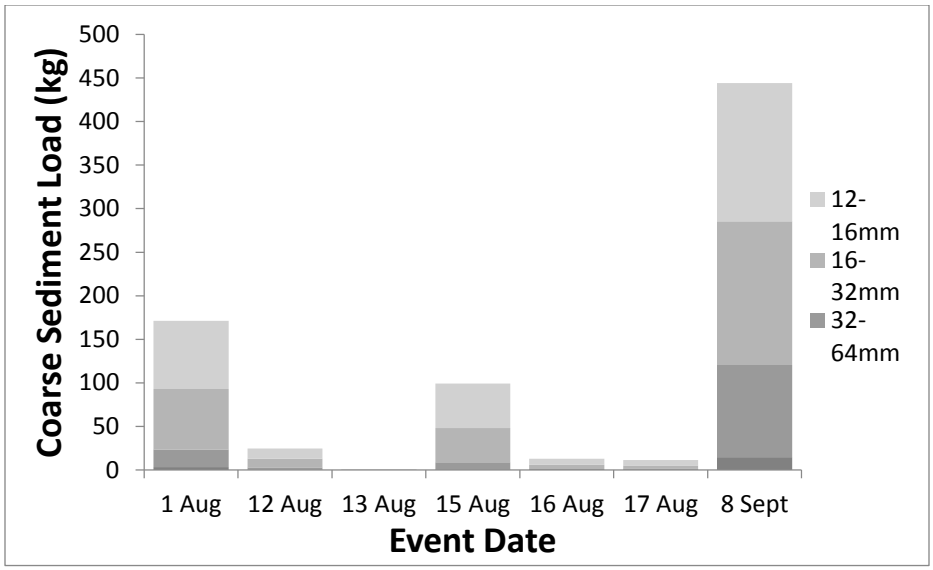

Figure 4 Coarse sediment load by size fraction for the seven runoff events monitored in 2014 in the Lucky Hills subwatershed. Coarse sediment was collected in a pit trap below the outlet flume and sieved for size fractions.

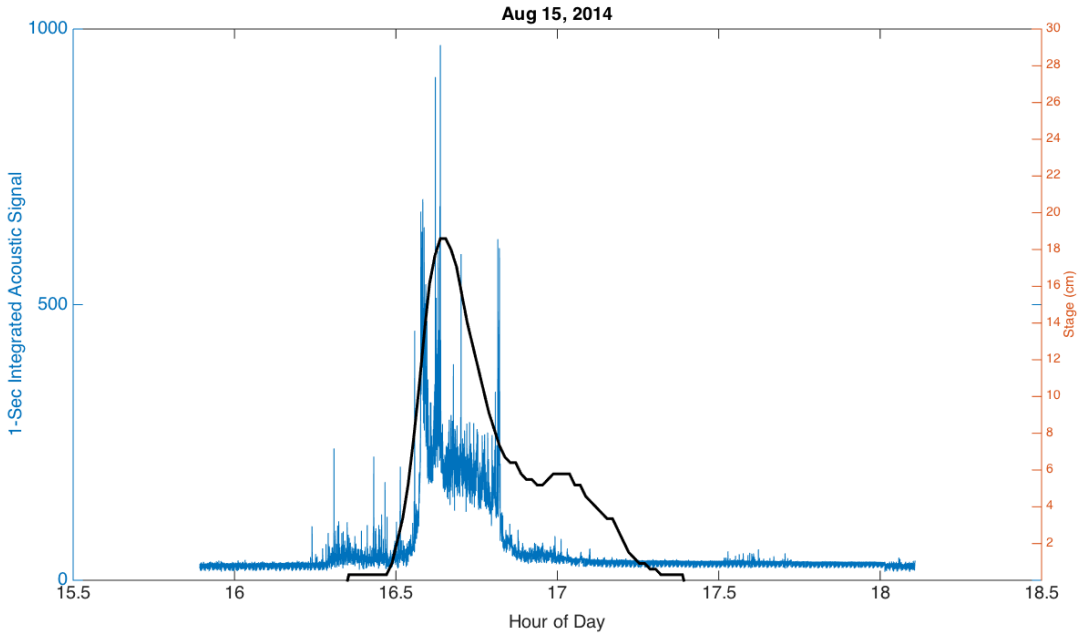

Figure 5 Hydrograph (black) and concurrent rectified acoustic signal (25kHz sampled voltage summed over one-second bins) for the August 15, 2014 runoff event. Note the rain noise prior to the rise in the hydrograph, and spikes in acoustic signal around stages of 8-10cm as the instrument was submerged and later reemerged associated with flow noise generated by the instrument housing.

The acoustic signal recorded over the course of the hydrograph is a composite of: (1) rain drop noise striking the instrument before it was submerged and the water surface after submergence; (2) elevated flow noise near the time of submergence when the water surface was at the hydrophone; (3) flow noise around the instrument housing while the instrument was submerged; and (4) acoustic emissions from particle collisions. Bjorno (1994) studied the acoustic spectra of rain splash on a free water surface and found that the acoustic energy peaked near 15 kHz with a minimum near 5 kHz. Flow noise around the instrument housing was recognizable by ear during and after submergence and displayed characteristic frequencies in the 0-2 kHz band. With these observations suggesting a window of opportunity where noise generated by particle impact would not be mixed with sound from other sources, we focused analysis on frequencies in the range 3 kHz – 11 kHz. Figure 6 shows the correlation over the three largest events between the coarse sediment load and the integrated acoustic signal in each of eight 1-kHz frequency bands beginning at 3 kHz. Each data point in Figure 6 is the correlation over three events between sediment load and SGN amplitude for a frequency band. In all cases the correlations are high, but the larger size fractions show both higher correlations and more structure as a function of frequency band with a peak near 5-6 kHz. Employing Thorne's relationship for peak emission frequency (equation 1), this would correspond to a particle size of approximately 24 mm which is notably near the median of the coarse fraction in Figure 1. The lack of frequency dependence in the correlation in the 12-16 mm particle size class suggests that the signal was made up of a combination of particle impact other flow-generated noise. It is logical that SGN and 12-16 mm load are still well-correlated, but the greater energy generated by the impacts of larger particles provide a better picture of how transport changed with passage of the hydrograph. Finally, while three events make a sparse data set, the overall high correlations in Figure 6 as well as the linear relationship shown in Figure 7 show a very promising relationship between coarse sediment load and integrated acoustic signal in the 5-6 kHz band for the three events.

Table 1 Coarse sediment load and runoff statistics for the seven monitored events.

Event	**Runoff**		**Coarse Sediment Load** (kg)				
Date	Duration (hr)	Peak Stage (cm)	>64mm	32-64mm	16-32mm	12-16mm	Total
Aug 1	1.4	19.8	3.31	20.27	69.45	78.07	171.1

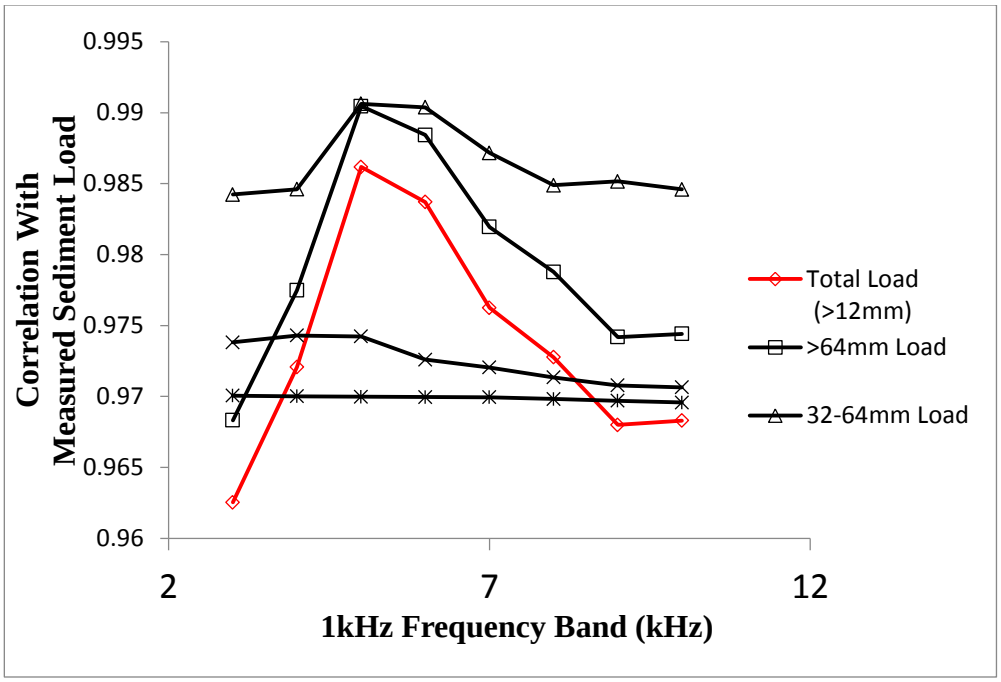

Figure 6 Correlation between coarse sediment load data and integrated acoustic signal for three runoff events (Aug 1, Aug 15, Sept 8). The power spectra of the acoustic data were integrated in 1 kHz bands from 3 kHz to 10 kHz to examine correlation with each size class of total sediment load. Correlation for the coarsest fractions is strongest in the 5-6 kHz frequency range.

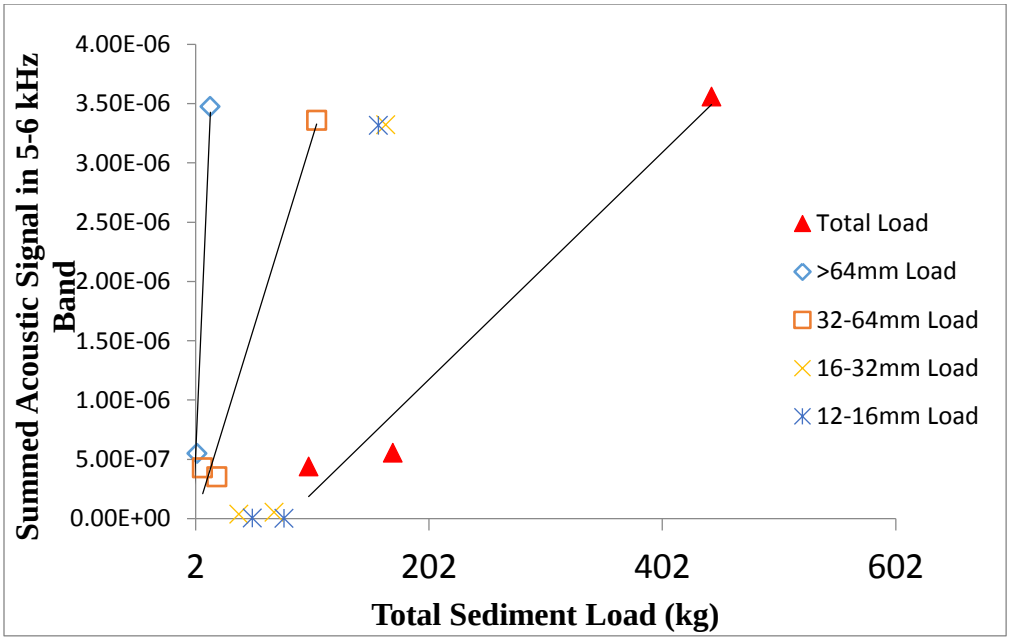

Figure 7 Relationship between integrated acoustic signal in the 5-6 kHz band versus coarse sediment load for the three largest runoff events.

CONCLUSION

We deployed hydrophones in a flashy ephemeral watershed in southeast Arizona to evaluate the potential for using passive acoustic measurements to monitor coarse sediment transport in streams. This location provided discrete flow events during which the entire coarse sediment load of the stream could be captured for analysis and characterization. While shallow flows reduced the number of events that completely submerged the hydrophone, the results of the three large flow events shown in Figures 6-7 are a high quality acoustic data set with known sediment loads. In particular, the frequency range 3 kHz-11 kHz provides a useful window that is below the peak frequencies of rain splash but above the dominant frequencies of flow noise. Correlation between total sediment load and integrated acoustic signal was high for all size classes across the frequency range of interest with a peak for the large size classes in the 5-6 kHz band.

This study has implications for future efforts to use SGN as a surrogate for bedload in flashy streams.

- Development of hydrodynamic housings for hydrophone deployment would further reduce flow noise around the instrument and simplify data analysis.
- Further study of the frequency content of acoustic phenomena such as raindrop impact may help in the separation of SGN from sound generated from other sources.
- It may be possible to use the low frequency data from the hydrophone system as an indication of flow strength, increasing the usefulness of data collected in remote deployments.

Abstract: Passive acoustic technology has the potential to allow continuous measurement of bedload moving through streams by recording Sediment-Generated Noise (SGN) from interactions between coarse bedload particles. The technology is relatively economical and is amenable to automated operation. While the magnitude of recorded sound has been shown to be well-correlated with bedload transport, substantial work is still needed before the technique is ready for broad deployment. A key need is a quantitative understanding of the measurement volume from which sounds are received so that field sites may be properly instrumented and data properly analyzed to estimate bed material flux. The propagation of sound in an acoustic waveguide, limited propagation of lower frequencies in shallow streams, and the effect of bed roughness on sound propagation are examples of specific areas in need of experimental research. Towards this end, a series of experiments was initiated, in collaboration with the University of Mississippi National Center for Physical Acoustics, in a flume at the National Sedimentation Laboratory in Oxford, Mississippi. The results of sound propagation testing in an empty tank, over a gravel bed, over a bed of cobbles and gravel, and over a cobble bed will be presented, along with a relationship for determining transmission loss for the different bed types.

INTRODUCTION

During efforts to develop methods for quantifying bedload transport using Sediment-Generated Noise (SGN), very little information on sound propagation in shallow water with rough boundaries was found. Most acoustic propagation research has been in marine environments (e.g., Thorne 1985 and 1986), where there is nearly infinite lateral extent and where shallow refers to depths of tens of meters. The characteristics of sound propagation over boundaries composed of gravel, cobbles, or boulders has not been documented. Without this knowledge, it is not possible to arrive at a reasonable estimate of the measurement volume of a hydrophone submerged in a stream. The development of more general calibrations for SGN conversion, which do not depend on the specific characteristics of the stream reach used for calibration, has been stymied by the lack of a technique for obtaining an estimate of the distance or volume from which SGN can be detected. There are several reasons why an estimate of the measurement volume is important in SGN measurement: (1) as a step towards development of a general approach to converting SGN data into bedload flux; (2) to determine how much of a stream is being monitored (needed for proper

scaling of bedload estimates); (3) for planning number of instruments to place in channel; and (4) for quantification of uncertainty and data quality.

Even though high amplitude sounds originating from a long range can produce the same amplitude at a receiver as low amplitude sounds originating from a short range, sound propagation characteristics and instrument parameters may be used to establish a maximum range from which sounds can be received. There are limits to the amplitude of sound generated by particle collision, and these will be a related to the bed material size distribution. By starting with an estimate of maximum likely amplitudes, a sound propagation model, and instrument parameters, an estimate of the measurement footprint can be made. Some of the parameters that will affect the size of the measurement volume include: characteristics of the sound field, bed material size distribution, water depth, bed roughness, hydrophone parameters, and recording system.

Sound pressure levels (SPL) are generally reported in the decibel (dB) scale: $SPL=20 \log(P_e/P_{ref})$ where P_e is the measured amplitude of the sound wave and P_{ref} is the reference amplitude (Urick, 1975). The decay of acoustic amplitude with range (R), caused by the spreading of sound waves in an unbounded medium (spherical spreading), is: $TL=20 \log(R)$, where TL is transmission loss. Spreading in a medium with two parallel reflecting boundaries (cylindrical spreading) is: $TL=10 \log(R)$ (Urick, 1975). For a stream bed that is covered with sand, gravel, and cobbles, it is not clear how TL should be calculated, especially since the environment often has complex and variable cross-sectional geometry. The work described here addresses the need for establishing the correct TL model for sound in a rectangular channel with one rough boundary.

METHODOLOGY

Data were collected in a rectangular cross-section with three realistic roughnesses: gravel (D_{50}≈35 mm), cobbles (D_{50}≈150 mm) and a mixture of the two, made by filling the pores of the cobble bed with gravel. The Root Mean Square (RMS) roughness of each bed was measured using a commercially available laser scanner (Figure 1). The flume section was 8.5 m long by 1.2 m wide and was lined with 3 layers of redwood lattice. For the frequencies of interest, roughly 1-10 kHz, the redwood did not provide anechoic conditions; however, the signal amplitude over distance had drastically fewer large amplitude excursions, caused by modal interference, than were observed with bare flume walls and bed. Four hydrophones were spaced at 1, 2, 4, and 8 m from the origin (Figure 2). The hydrophone positions were not changed; the sound source was moved 4 meters from the origin in 25 cm increments to provide smaller range increments. Sounds were recorded at three different depths (≈25, 30, and 35 cm), but the effect of depth for the frequencies and depths of these experiments was small.

A.

B.

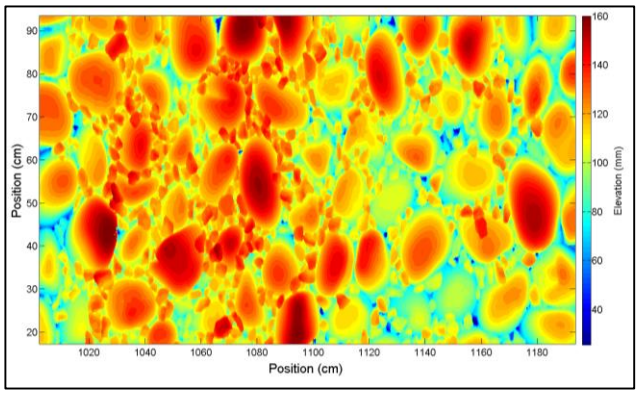

Figure 1 (A) Line laser scanner used to define RMS roughness values. (B) Laser scan data from mixed gravel/cobble roughness.

Figure 2 Hydrophones deployed over the cobble bed.

Hydrophones and amplifiers from Teledyne Reson were used to record sound at a rate of 50 kHz, using a computer with a multi-channel data acquisition card. A mechanical sound source was constructed, using a pneumatic cylinder that could be remotely activated (Figure 3). The sound produced by the impact of the steel puck on the aluminum barrier was an impulse followed by a brief ring down, resulting in a short signal without a clearly defined frequency spectrum. The signal was well-suited to the needs of this work, since it minimized the effect of water-depth related attenuation of low frequencies.

Figure 3 Mechanical sound source

RESULTS

Figure 4 shows that the transmission loss did not follow either the cylindrical or spherical models; however, there are clear patterns of transmission loss with range and increasing bed roughness. The rms roughness height of the bed materials is: gravel ≈ 13 mm, cobbles ≈ 31 mm, cobbles+gravel ≈ 18 mm, and redwood lattice ≈ 8 mm. Based on the acoustic amplitude and bed roughness measurements, transmission loss equations can be found from Figure 5. For example, transmission loss in the gravel case is estimated by substituting its rms roughness (13 mm) into $Y=0.22X+17$, yielding TL ≈20 log (R). As can been seen in Figure 5, TL increases rapidly with increasing roughness, and the intermediate case of cobbles+gravel shows a transmission loss between the cobble and gravel cases. The increase in TL with increasing roughness can be attributed to sound scattering, which reduced the amplitude of the signal propagating to the hydrophones. Another contributing effect is multiple contacts with the sides and bottom of the flume and the water surface. Each contact resulted in a loss of amplitude, although the scattering effects of bottom contacts likely resulted in the greatest losses.

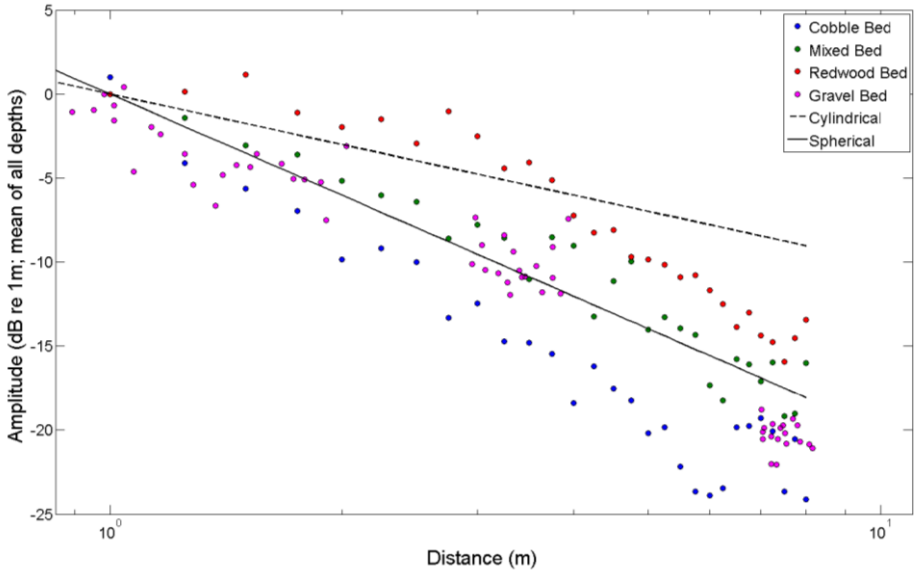

Figure 4 Results from propagation experiments.

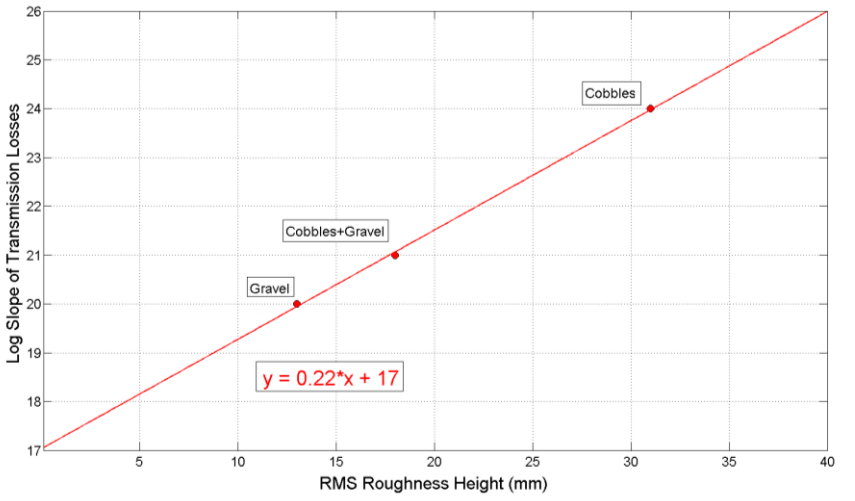

Figure 5 Transmission loss multipliers for a range of bottom roughness. The equation can be used to estimate the transmission loss based on measured RMS bottom roughness.

CONCLUSION

The results shown in Figures 4 & 5 represent an important step towards a more comprehensive picture of sound propagation in a shallow-water waveguide with rough boundaries. The propagation of sound generated by mechanical impact was measured over gravel, cobbles+gravel, and cobble beds, yielding a relationship that can be used to estimate the transmission loss for each

of the beds. Future work on this topic should include a field component, since the rectangular cross-section of the flume does not represent the geometry found in most stream channels. Field experiments will make use of the same mechanical sound source and instrumentation that was used in the laboratory. In addition, at least two of the hydrophones will be located at a small fixed distance from one another, allowing for the coherence of the sound field to be evaluated. This is another key step towards a general understanding of the sound field in a wave-guide with rough boundaries and will be affected by both the roughness of the bed and the wedge shape on the sides of the channel.

ABSTRACT

Various methods of employing passive acoustics to monitor bedload transport have been explored in both the lab and field. Expanding upon this research, a hydrophone-based passive acoustic bedload-monitoring system was designed, tested and deployed by researchers at the University of Mississippi and the National Sedimentation Laboratory in Oxford, MS. Several field studies have been conducted at various sites: the Elwha River in Port Angeles, WA; the Trinity River in Weaverville, CA; Bear Creek in Denver, CO; and the Walnut Gulch Watershed in Tombstone, AZ. At each field study, acoustic data was collected alongside physical measurements of bedload transport. Preliminary results correlating sediment transport with the measured sediment generated noise will be presented. In addition, the design and fabrication of an improved prototype system is underway. The new system is designed to be more easily deployed and operable by non-experts. This will greatly expand the range of available testing environments. Results from this effort will be presented alongside any available calibration data taken with the new system.

EXTENDED ABSTRACT

The prospect of using passive acoustic methods to monitor bedload transport has been investigated in various facets. The acoustic properties of impacting gravel particles were investigated (Thorne 1985) in a laboratory setting. Preliminary work was done on the Trinity River (Barton et al. 2010) which showed that using hydrophones to detect gravel movement showed promise. To continue this research, a passive acoustic system comprising of equipment already owned by researchers at the National Center for Physical Acoustics was assembled and tested. The system was tested at four different field sites shown in Figure 1: the Trinity River in Weaverville, Ca; the Elwha River in Port Angeles, CA; the Walnut Gulch Watershed near Tombstone, AZ at the Lucky Hills sub-watershed; and Bear Creek in Denver, CO.

Figure 1 Top Left: Photograph of the first iteration of the passive acoustic bed load monitoring system, deployed at Douglas City on the Trinity River, CA. Top Right: Installation of three hydrophones at the Elwha River, WA. Bottom Left: Installation of two hydrophones at the Lucky Hills subwatershed near Tombstone, AZ. Bottom Right: Installation at the Bear Creek, near Denver, CO

Figure 2 shows positive correlation between acoustic root-mean-square (rms) and bedload discharge at the Trinity River. The discharge was determined from concurrent physical samples taken by Graham Matthews and Associates. Although there were physical samples taken at the Elwha River, they were designed to calibrate the impact plates also being tested at the time. The physical samples were repeated at individual locations, and were thus unusable as a 'total discharge' measurement. Therefore, an attempt was made to correlate the acoustic data with the data collected from the impact plates spanning the river. Figure 3 shows that the overall trends between acoustic rms and bedload discharge are positively correlated. The data from Walnut Gulch in still in analysis as of this writing. All of these tests indicate the usefulness of acoustic surrogates. For this reason, the researchers at the NCPA began a project to redesign the system to make it much more portable, robust and user-friendly.

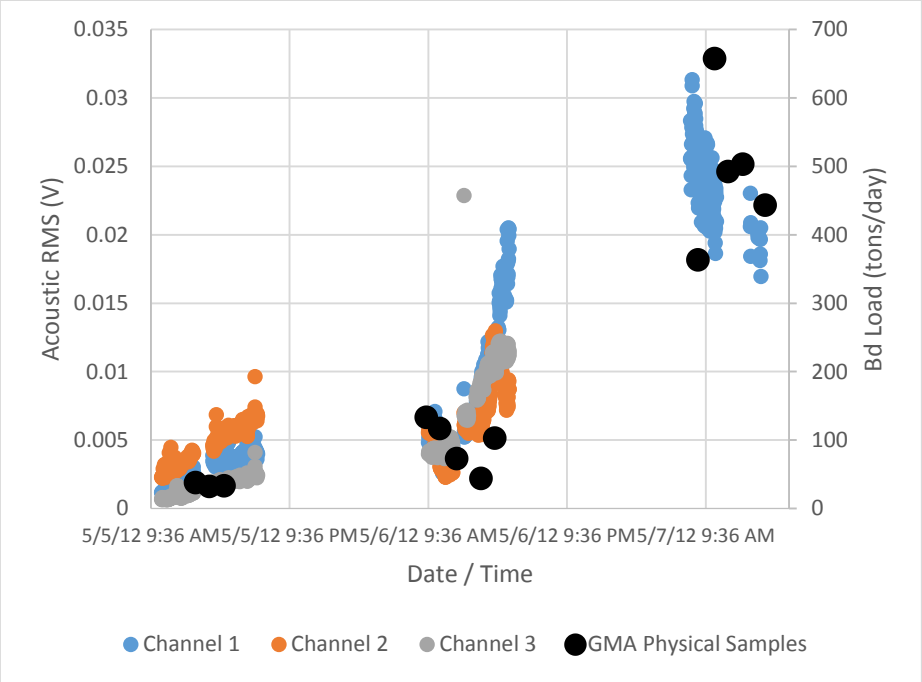

Figure 2 Acoustic data shown with physical measurements of bed load at the Douglas City site on the Trinity River, CA. Graham Matthews and Associates collected the physical bed load measurements

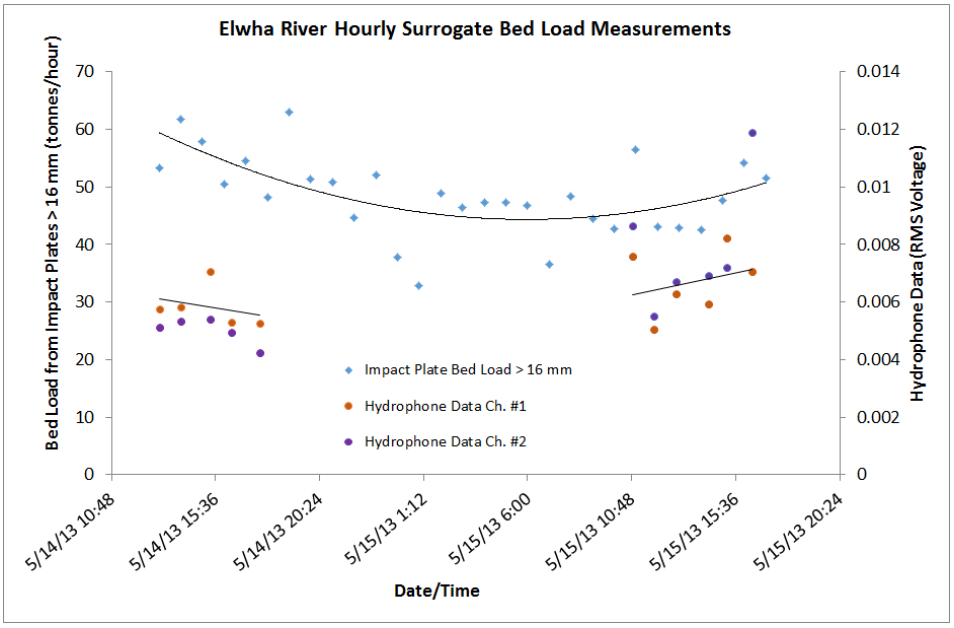

Figure 3 Comparison of bed load transport measured with the Elwha bed load impact plate system using a preliminary calibration and data from two hydrophones deployed approximately 70 meters upstream. Data shown are hourly averages of both systems

The system as it was deployed in the aforementioned field studies was comprised entirely of laboratory-grade equipment. As such, many of the components were delicate and unwieldy. Every aspect of the data collection process was investigated for improvements. The improvement process began with researching and testing alternate hydrophone options. The RESON TC-4013 hydrophones used in the field studies are delicate and far more sensitive than is necessary for the project. After testing three alternatives, the HTI 96-MIN Exportable hydrophone was chosen. This hydrophone is suitably sensitive at the audio range, and has a built-in amplifier. This eliminates the need for the external amplifiers required by the RESON hydrophones. In addition, the HTI hydrophones are sturdy and robust. A casing and mounting system for this hydrophone are currently in design. The casing will be designed to reduce flow noise around the hydrophone as much as possible, and it will also provide protection from debris. Other areas of the system including data recording, power requirements, and duration of operation are still under investigation as of this writing.

CONTINUOUS BED LOAD MEASUREMENT WITH IMPACT PLATES ON THE ELWHA RIVER, WASHINGTON

Robert C. Hilldale, Hydraulic Engineer, Sedimentation and River Hydraulics Group, Bureau of Reclamation, Denver, CO, rhilldale@usbr.gov

Abstract: A bed load impact plate system has been installed on the Elwha River for the purpose of continuously measuring coarse bed load during and after the removal of two large dams. The surrogate bed load measurement system consists of 72 instrumented stainless steel plates spanning approximately 38 meters across the channel and is currently capable of quantifying coarse bed load ≥16 mm. Each plate is instrumented with either a geophone (46 plates) or an accelerometer (26 plates). To date, a preliminary calibration of the geophone impact plates has been obtained using 16 data points, achieving an r^2 value of 0.796. Each data point is a temporal average of 8 - 10 physical bed load measurements correlated to the impulses measured with the geophones. The most recent calibration data and calibration procedures are presented herein. Observations of temporal and spatial variability in coarse bed load transport during and after dam removal are discussed.

INTRODUCTION

The use of indirect or surrogate technologies for quantifying fluvial sediment transport is a rapidly expanding field, providing the ability to continuously monitor sediment transport with high resolution. In an effort to provide continuous, high resolution measurement of coarse bed load transport on the Elwha River during and after the removal of Elwha and Glines Canyon Dams, a system of instrumented, stainless steel, bed load impact plates was installed in 2008 and 2009 at river kilometer 5 (measured upstream from the mouth, Figure 1). The Elwha impact plate system was patterned after the Swiss geophone impact plate system (Bänziger and Burch 1990; Rickenmann and McArdell 2007) installed at several locations throughout Switzerland, Austria, and Israel (Rickenmann et al. 2014). The Elwha impact plate system differs from the Swiss system by installing accelerometers on 26 of the 72 instrumented steel plates, with 46 plates instrumented with a geophone. Additionally, the dimensions of the Elwha impact plates vary slightly from the Swiss system. A thorough review of surrogate methods for quantifying bed load transport is given in Gray et al. (2010), Rickenmann et al. (2012), and Tsakiris et al. (2014). This manuscript will discuss the installation, preliminary calibration, and observations of bed load transport with respect to spatial and temporal variability. Observations of continuously measured bed load transport on the Elwha are presented and discussed.

The decision to construct a series of impact plates was based on the following: (1) maturity of the Swiss impact plate system (Rickenmann et al. 2012, 2014); (2) the ability to continuously collect bed-load data without operating personnel; (3) robust construction and demonstrated longevity (>10 years); (4) limited maintenance requirements for the physical system; (5) ability to measure bed load with a 0.5-m resolution across the stream; and (6) nonintrusive and compatible with an ecologically sensitive river (Hilldale et al. 2014). The primary drawback of the Elwha impact plate system is its inability to register a response to particles < 16 mm on the geophone plates and particles < 8 mm on the accelerometer plates. The impact plate system on the Elwha River was installed in conjunction with a previously planned concrete weir for the purpose of surface water diversion.

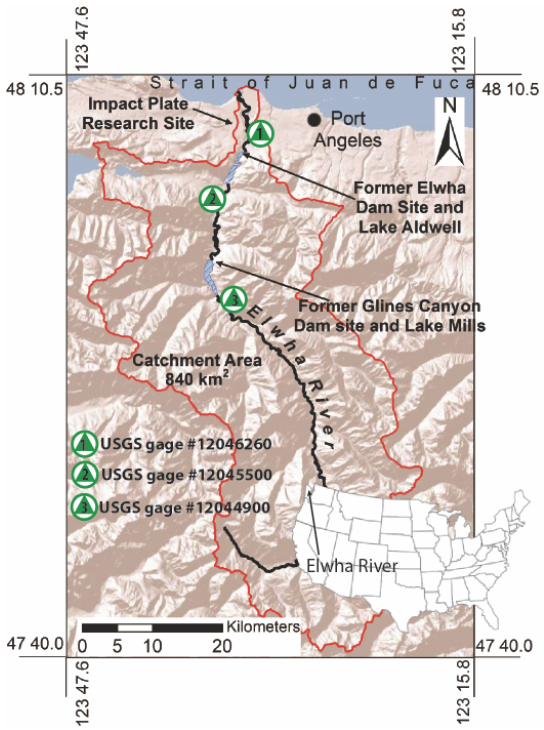

Figure 1 Location map of the Elwha River, Washington

The Elwha River: The Elwha River flows north from the Olympic Mountain range of Washington State, USA and terminates at the Strait of Juan de Fuca (Figure 1), which connects Puget Sound with the Pacific Ocean. The catchment is largely within the protected lands of Olympic National Park, consisting mostly of forested land, much of it pristine wilderness. The Elwha River is supplied with varying contributions of snowmelt, rainfall, and groundwater discharge and has a maritime climate with relatively wet, mild winters and dry, cool summers (Curran et al. 2009). Annual precipitation in the basin ranges from 560 cm in the upper basin (elevation 1,350 m) to 140 cm near the mouth (elevation 0 m) (Munn et al. 1998). The U.S. Geological Survey has operated the McDonald Bridge gage (USGS streamflow-gaging station #12045500) since 1918. The mean annual discharge is 42.8 m^3/s (Magirl et al. 2014). The 2-year, 10-year, and 100-year recurrence interval floods are 400 m^3/s, 752 m^3/s, and 1,240 m^3/s, respectively (Duda et al. 2011).

Elwha and Glines Canyon Dams: The removal of Elwha and Glines Canyon Dams on the Elwha River in Washington State is the largest dam removal project in U.S. history to date (Duda et al 2011). A total of 21 million m^3 of sediment was stored behind both dams; including an estimated 2.5 million m^3 of gravel and cobble sized sediment. Elwha Dam (32 m high, located at river kilometer 7.9) constructed in 1913, and Glines Canyon Dam (64 m high, located at river kilometer 21.6) constructed in 1927 (Figure 1) began concurrent removal beginning in September 2011. The removal of Elwha Dam was completed in May 2012, and the final portion of Glines Canyon Dam was removed in September 2014. Detailed information on the Elwha River's response to dam removal during the first two years can be found in East et al. (2014) and Magirl et al. (2014).

The Elwha Impact Plate System: The Elwha impact plate system was installed in two phases. During the first phase plates 1-12 were installed on river right. Plate numbers 1, 3, 5, 7, 9, 11 and 12 are instrumented with geophones and plates 2, 4, 6, 8, and 10 are instrumented with accelerometers. Wiring was installed in 2008 for the entire system and the wiring to be used for plates 13-72 was stored in a temporary wooden channel constructed in place of the impact plate housing to be built the following year (Figure 2). In 2009 the remaining impact plates and instrumentation were installed (Figure 2B). Plate numbers 13 – 72 are instrumented with a repeating pattern of one accelerometer plate and two geophone plates for the remainder of the cross section (e.g. plate # 13 = accelerometer,

plate # 14 and #15 = geophones, plate # 16 = accelerometer…). All wiring was routed through two conduits to the computer cabinet on the right bank and was labeled for later installation of the streamside computer monitoring system in 2011. Details on the computer hardware and software can be found in Hilldale et al. (2014).

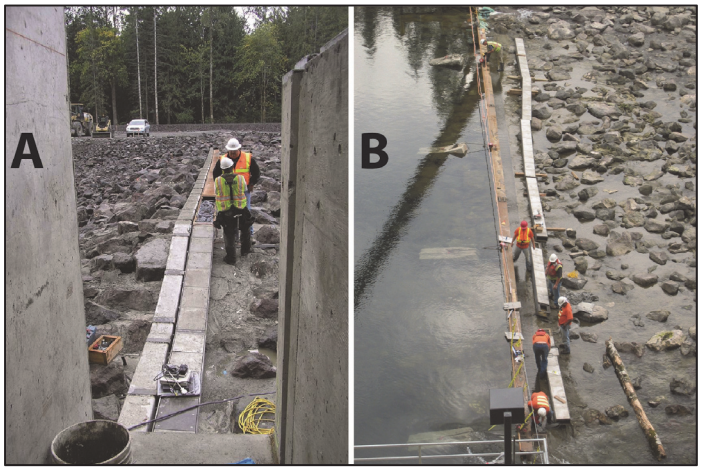

Figure 2 (A) 2008 installation of impact plates and sensors (#1 – #12) on river right, and wiring for the entire system. (B) 2009 installation of remaining impact plates (#13 – #72).

The stainless steel impact plates are 15.9 mm thick, 349 mm in the longitudinal (flow) direction, and 517 mm in the lateral dimension. The plates are mounted with their short sides adjacent to each other on a steel housing that is mounted to the downstream side of a channel spanning concrete weir. Figure 3 shows the configuration of the weir, which is at the crest of an engineered riffle with a slope of 0.015 m/m. Wiring for each instrument is routed to the stream bank through conduit contained within the housing. A low flow notch has been constructed to force low discharges against the intake structure (Figure 4). Additional details about the impact plate system can be found in Hilldale et al. 2014).

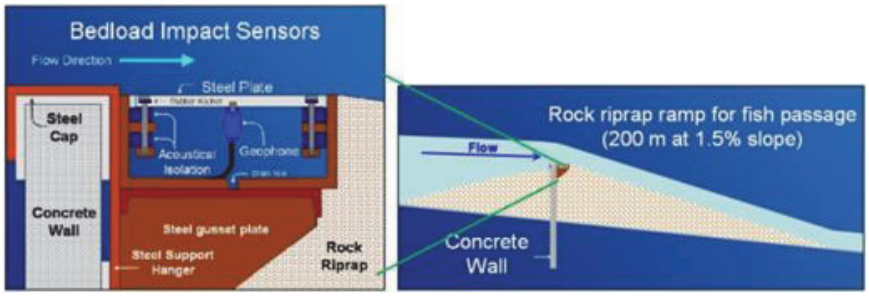

Figure 3 Drawing of the longitudinal view of the Elwha impact plate system.

A geophone induces a small voltage when a particle with sufficient mass and velocity causes the plate to deform. The voltage is sent to one of three monitoring computers, where the induced voltage is compared to the predetermined threshold value, 0.1 volts. If the voltage surpasses the threshold value, the computer program registers an impulse. The system samples at 20 kHz, accumulating impulses from individual plates for 1 minute. The software then stops collection for 19 seconds to provide limited post processing and write the data to an ASCII file for each plate.

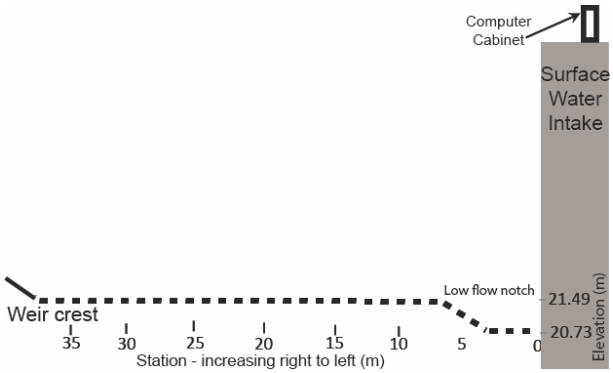

Figure 4 Cross section drawing (looking downstream) of the measurement weir.

SYSTEM TESTING AND CALIBRATION

In situ testing prior to dam removal indicated that the geophone impact plates are able to detect particles > 16 mm, and the accelerometer plates are capable of detecting particles > 8 mm. Physical bed load measurements for calibration of the geophone plates have been underway since November 2012, shortly after a major release of delta sediment the previous month from Lake Mills during the removal of Glines Canyon Dam. All references to system calibration in this manuscript refer only to those plates instrumented with a geophone. Calibration of the accelerometer plates requires further signal processing prior to in situ calibration. Flume testing is currently underway to determine an appropriate correlation between the accelerometer signals and measured bed load.

Field measurements of bed load for the purpose of system calibration were made using a TR-2 bed load sampler (Hubble et al 1985) with a 2 mm mesh bag. The TR-2 was deployed using a crane and winch mounted to a 6.4 m long cataraft that was tethered to a tag line across the channel (Figure 5). Five separate bed load sampling trips were made in November 2012, March 2013, May 2013, June 2013, and April 2014.

Figure 5 Photographs of the TR-2 (left) and the cataraft (right) used to measure bed load on the Elwha River

In November 2012 bed load transport consisted almost entirely of particles finer than 2 mm resulting in no meaningful bed load measurement due to clogging of the 2 mm mesh bag. By March 2013 bed load had coarsened significantly (Figure 6) and obtaining a correlation between measured bed load and registered impulses on the impact plates was possible. However, scatter in the individual surrogate measurements and the physical measurements using very short sample times (1 minute for the impact plate data, < 10 seconds for the physical samples) was significant enough to warrant a different approach to calibration.

A new methodology used for calibrating the geophone impact plates was employed beginning with May 2013 bed load measurements and uses both temporal and spatial averaging. The spatial average covers a 2 meter lateral distance (1 meter on either side of the TR-2), which will include two or three plates depending on the sampler location relative to the spatial arrangement of the geophone and accelerometer plates. It is assumed that bed load transport across this distance is uniform, which is consistent with USGS bed load measurement protocol outlined in Edwards and Glysson (1999). The temporal averaging uses a 30 minute sample time to obtain a reliable mean, where the TR-2 is deployed at the same station for 30 minutes, typically resulting in 8 - 10 physical measurements. The period of 30 minutes was chosen based on a temporal analysis of several arbitrarily chosen geophone plates, where the cumulative mean and standard deviation of impulses per minute arrived at a steady value in less than 30 minutes under steady flow conditions. This finding is consistent with those from a field study by Kang (1982) and a flume study by Kuhnle and Southard (1988). All measured bed load values are temporally averaged and correlated with a temporal and spatial average of the surrogate measurement from corresponding geophone impact plates. This correlation provides the necessary information with which to perform a field calibration of the impact plate system. Additional details regarding the sampling protocol can be found in Hilldale et al. 2014).

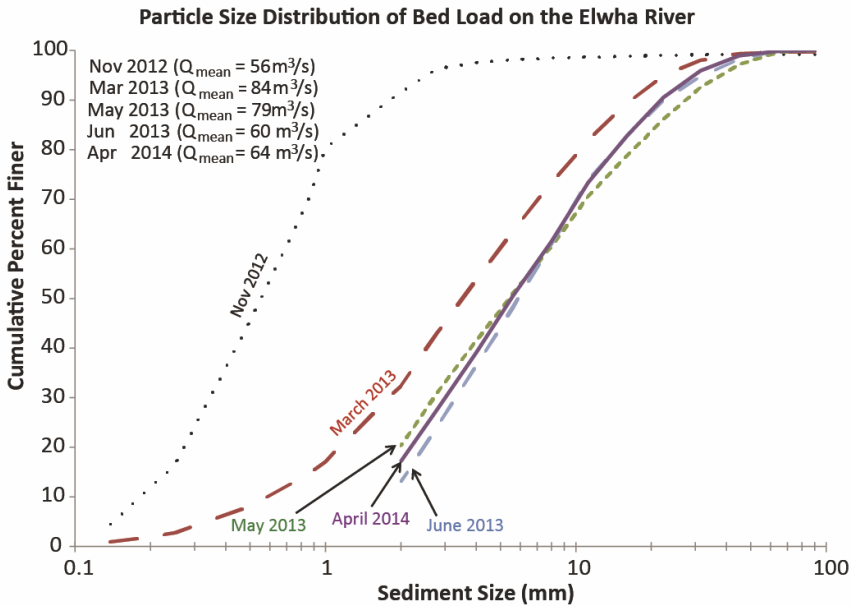

Figure 6 Grain size distribution of bed load collected with the TR-2 during system calibration.

Calibration of the Swiss geophone impact plate system using physical measurements of bed load has been shown to be best represented with a linear regression (Rickenmann et al. 2014). Based on the similarity of the impact plate systems and for comparative purposes, a linear regression has been used for the Elwha impact plate system shown in Equation 1 (Rickenmann et al. 2012):

$$IMP = k_b M \tag{1}$$

Where *IMP* represents the number of registered impulses by the geophone plate(s), *M* is the mass of sediment, and k_b is the calibration coefficient. The most recent calibration of the Elwha geophone impact plates is shown in Figure 7, indicating that k_b = 1.562x + 9.51 with a coefficient of determination (r^2) of 0.796. This calibration factor is considered to be preliminary and may change somewhat with additional data. The k_b value reported here benefits from nine additional calibration points compared to that reported by Hilldale et al. (2014). It should be noted that bed load measurements in June 2013 were not able to be used for calibration due to the malfunction of the computer monitoring system.

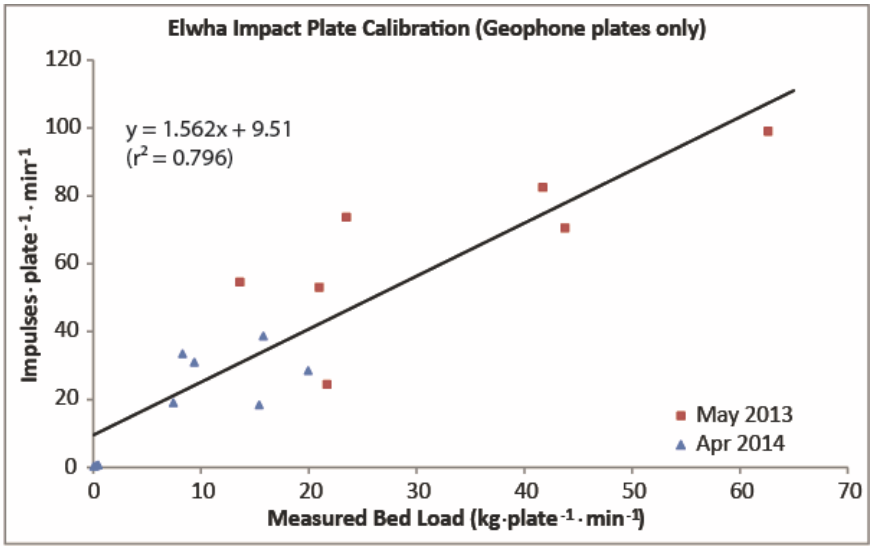

Figure 7 Plot of geophone calibration data for the Elwha impact plate system.

BED LOAD MEASUREMENT DURING DAM REMOVAL

Perhaps the most important data obtained from the impact plate system is the measurement of bed load over time. Past research has shown that correlations of bed load transport (Q_s) and discharge (Q) are poor (Habersack 2008) using a power law relationship:

$$BL = aQ^b \tag{2}$$

where BL = bed load in units of mass, Q = discharge in m^3 s^{-1}, a, and b are coefficients. Data from the Elwha bed load impact sensors also indicate that discharge is a poor predictor of bed load transport throughout the year. Figure 8 indicates a wide variability of both the coefficient (a) and exponent (b), varying throughout the year. Exponents nearly span an order of magnitude in this small sample set.

Given the unsatisfying accuracies of quantifying bed load using stage-discharge relationships or transport equations (Bunte 1990, Reid et al. 1985, Habersack et al. 2008, Kuhnle 1992), measurement of bed load presents itself as the better alternative. However, classic means of bed load measurement using pressure difference samplers present other challenges, namely poor temporal resolution, uncertainty related to involuntary particle entrainment (Bunte et al. 2008) and flow disturbance (Habersack et al. 2012). These measurements are difficult and costly to make, and potentially dangerous, on medium to large rivers during peak flows. Additionally, deployment of personnel and equipment to measure bed load during flood events is often logistically prohibitive. The use of surrogate methods for bed load measurement provides a means to eliminate many, if not all, of the challenges regarding physical measurement of bed load (aside from in-situ calibration). Surrogate bed load measurement stands to improve upon the resolution and timeliness of bed load measurement, the accuracy of which being highly dependent upon the in-situ calibration.

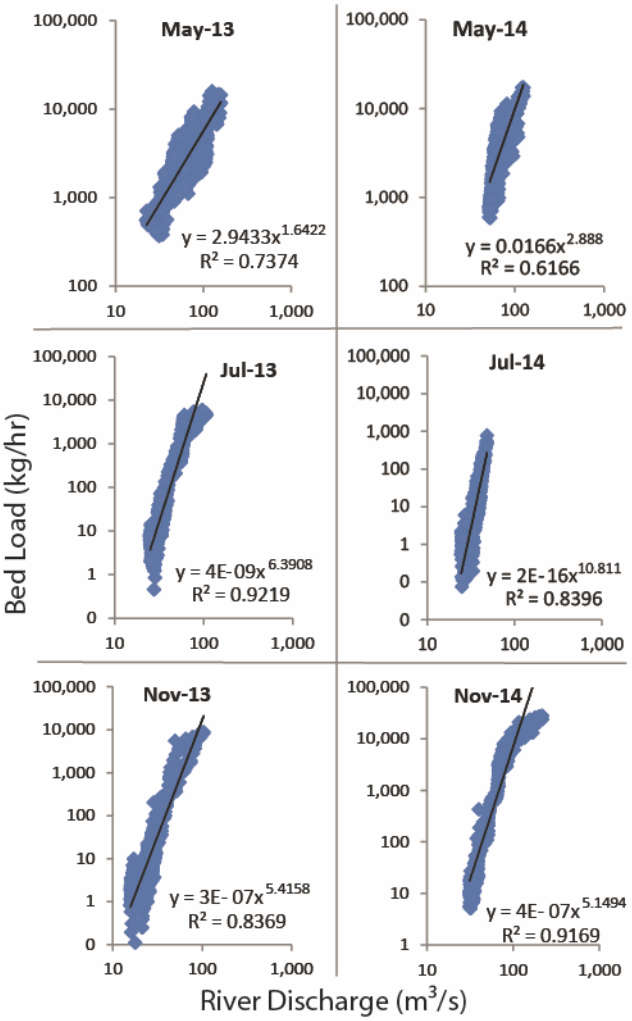

Figure 8 Plots of bed load versus discharge for selected months. November 2014 data reflects only the latter half of the month due to a brief malfunction of the data collection system.

Bed load transport > 16 mm on the Elwha River was quantified over the first two years (September 2011 through September 2013) of the incremental removal of Elwha and Glines Canyon dams using the impact plate system and a preliminary calibration of the geophone impact plates (Figure 9, Magirl et al. 2014). Geophone threshold values during most of year-one were set in such a way as to preclude the application of a bed load-to-surrogate relation. Using the standard deviation of the relative error for the preliminary calibration data (Hilldale 2014), uncertainty of the surrogate measured bed load > 16 mm is ± 52% (Magirl et al. 2014).

Because there is interest in the total bed load transported during dam removal, bed load from 2–16 mm was estimated using the ratio of coarse-grained (> 16 mm) to finer-grained (2–16 mm) material from the measured bed load samples (Figure 6) and by linearly interpolating between sample periods. The sediment-size distributions from sampled data were used to determine monthly proportions of the two size ranges, providing monthly bed load transport estimates (Figure 9). Uncertainty for bed load between 2 and 16 mm is estimated to be ± 80% (Magirl et al. 2014). For the purpose of this discussion bed load is considered to consist of particles > 2 mm. Readers are referred to Magirl et al. (2014) for additional information regarding sediment loads on the Elwha River during the first two years of dam removal.

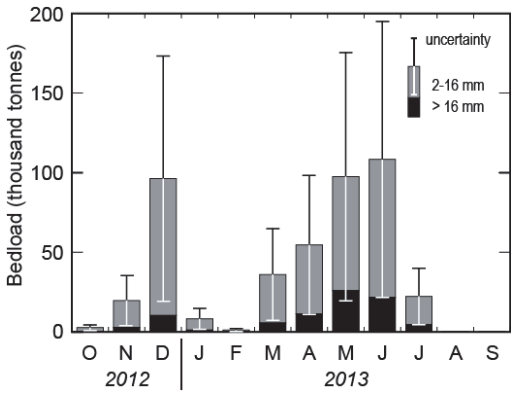

Figure 9 Monthly bed load plot for particles > 16 mm and particles between 2 and 16 mm (from Magirl et al. 2014).

BED LOAD TRANSPORT FLUCTUATIONS

Temporal and spatial variation of bed load transport has been documented in both flume (Kuhnle and Southard 1988) and field studies (Kang 1982, Reid et al. 1985, Bunte 1990, Habersack et al. 2001, Habersack et al. 2008, Habersack et al. 2012). Observations of coarse bed load transport on the Elwha present marked temporal and spatial fluctuations over more than three years of observation.

Lateral Variability: Monthly bed load data from November 2012, 2013, and 2014 (Figure 10) indicates significant variability in bed load transport (> 16 mm) across the channel. In November 2012 and November 2014 the greatest proportion of bed load transport is at river right against the surface water intake. During November 2013 bed load transport is primarily focused at stations 9.6 m to 11.7 m (Figure 10). A consistent drop in sediment transport exists at station 6.6 m, where the weir transitions from the low flow notch at river right to the flat portion across the remainder of the channel (see Figure 4). Additionally, coarse bed load transport is consistently very low or non-existent beyond station 32.5 m.

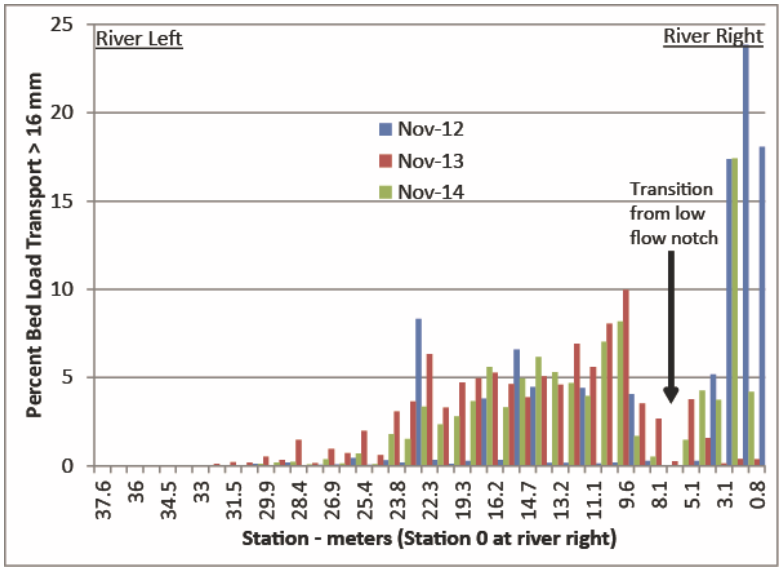

Figure 10 Graph showing the proportion of bed load transported across the channel using impact data from each geophone in the Elwha impact plate system. The transition from the low flow notch to the flat portion of the weir is shown in figure 4.

Temporal Variability: Short term and long term fluctuations of coarse bed load transport can be examined in detail using 1 minute continuous bed load data. Observations shown in Figure 11 are at a single plate (#18, station 10.1 m) over a selected day of steady flow on May 28, 2013 and May 3, 2014. Plate #18 was chosen because it is within an active portion of the cross section, and the month of May was chosen because it coincides with spring runoff, a period of typically high bed load transport. Upon examination, the periodicity of peak transport typically occurs between 15 and 35minutes, with a mean fluctuation of approximately 26 and 29 minutes in May 2013 and 2014, respectively.

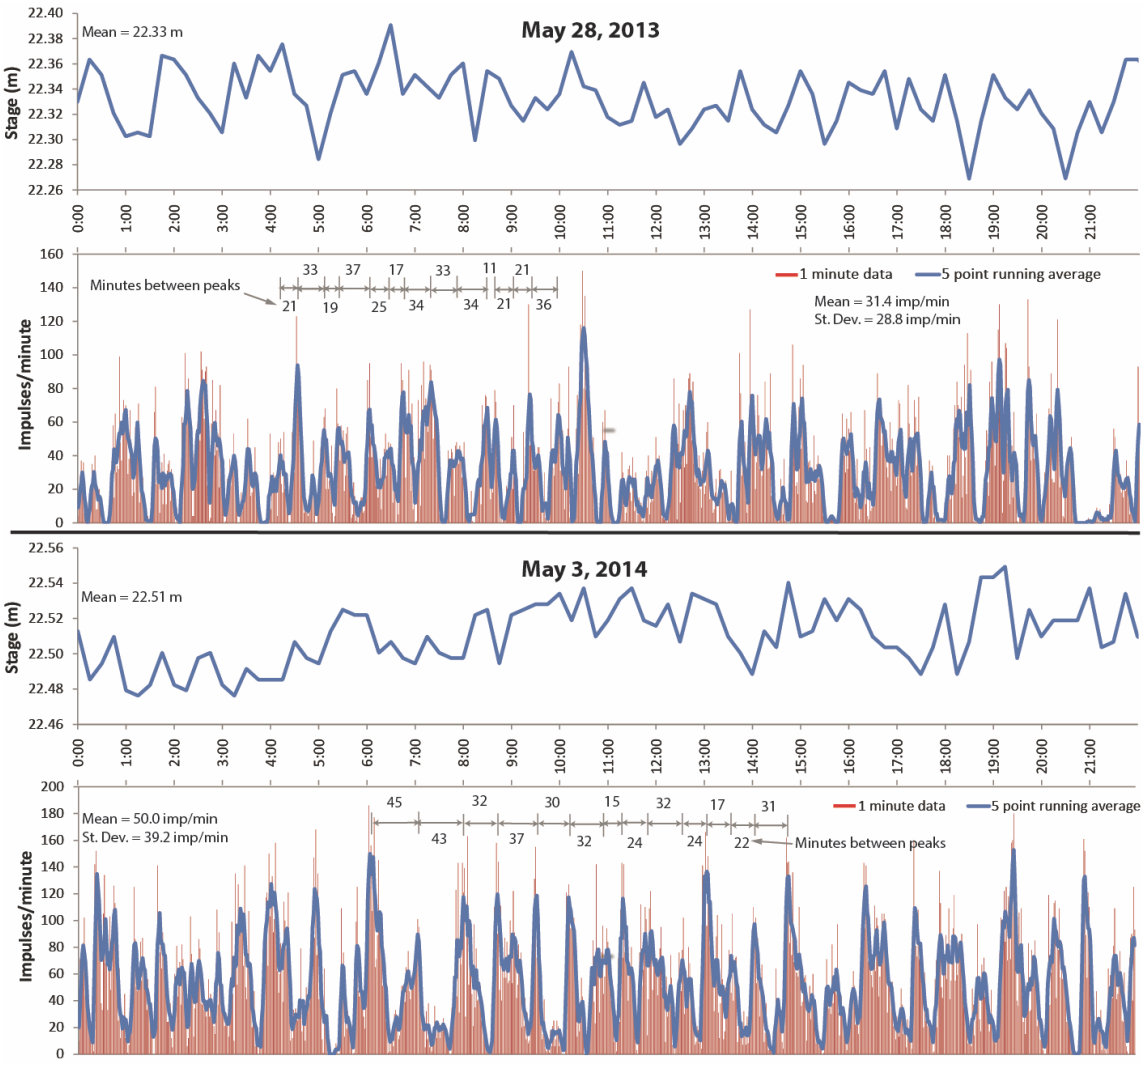

Figure 11 Plot of 1-minute bed load data during steady flow periods, May 28, 2013 and May 3, 2014.

DISCUSSION

The temporal variability in bed load measured with the Elwha impact plate system shows similarities to that measured by Habersack et al. (2008, 2012) on the River Drau, which is a perennial river similarly sized to the Elwha. Bed load measurements by Habersack et al. (2012) were accomplished with; a large Helley-Smith sampler, a bedload trap, and geophone impact plates. Habersack (2012) collected several bed load measurements at a single station using the large Helley-Smith sampler, while high temporal resolution was obtained using the bedload traps and geophone impact plates. All three methods indicate a periodicity of bed load peaks ranging from 15 – 35 minutes, very similar to that found on the Elwha River (Figure 11). Short term temporal variations in bed load have

been attributed to the stochastic nature of sediment supply and the passage of dunes or migrating sheets of bed load (Habersack et al. 2008).

Flume experiments by Kuhnle and Southard (1988) also indicated measurable bed load periodicity. The researchers attributed the short term (4 – 16 minutes) fluctuations to long, low amplitude bed load sheets, while the cause for longer term fluctuations (~ 25 minutes) was not conclusively determined. However, Kuhnle and Southard (1988) indicated that a possible cause for the longer term periodicity was related to the formation and subsequent destruction of large clasts, or gravel clusters, on the bed.

Although Figure 11 seems to indicate a quasi-periodicity similar to that found by other researchers (Kuhnle and Southard 1988, Habersack et al 2012), a Fourier analysis of the Elwha impact plate data indicates no dominant frequency for peaks of bed load transport. Kuhnle and Southard (1988) report a similar finding for particles > 16 mm. Results from their flume experiments indicate a significant difference in temporal variability for the largest size class in transport, 16-32 mm, when compared to smaller particles. Kuhnle and Southard's (1988) largest size class (16-32 mm) corresponds to what is measured on the Elwha River with the impact plate system, where 16 mm is the minimum detectable size.

Because the bed load measurements made with the Elwha bed load impact plate system were made during and shortly after dam removal, it is presumed that the Elwha River is oversupplied with sediment, resulting in a transport limited system. Measurements of bed load transport on the Elwha River during this time period indicate an ample supply of sand, disproportionately large soon after the release of large volumes of sediment from Lake Mills in October 2013. Visual observations were made of a point bar repetitively migrating up and downstream 150 m over the course of several hours, also indicative of an oversupply of sediment.

Based on previous studies (e.g. Reid et al. 1985, Kuhnle and Southard 1988, Habersack et al. 2008, Kuhnle 1992 Strom et al 2004) and data provided by the Elwha bed load impact system, temporal fluctuations of coarse bed load transport can be attributed to gravel bed forms and the stochastic nature of bedload transport, especially for the largest particles in motion. Gravel bed forms are generally limited to gravel sheets and clusters. It has been determined (Proffitt and Sutherland 1983, Dietrich et al. 1989, Hassan and Church 2000, Papanicolaou et al. 2003, and Strom et al. 2004) that gravel cluster bed forms develop under low sediment availability, which is certainly not the condition under which the Elwha bed load observations have been made thus far. This points to the presence of bed load sheets (or a kinematic wave claimed by Reid and Frostick 1986) as the primary explanation of the temporal fluctuations and apparent periodicity observed on the Elwha River. Many researchers indicate a strikingly consistent temporal fluctuation of bed load transport in the range of 15 – 35 minutes, similar to the findings of the Elwha bed load impact system. These fluctuations, or pulses, occur both in natural streams (Kang 1982, Reid and Frostick 1986, Habersack et al. 2012) and flumes (Kuhnle and Southard 1988, Strom et al 2004) under a variety of hydraulic conditions and sediment supply.

The spatial variability at the measurement cross section on the Elwha River (Figure 10) can be attributed to three major factors. 1) The geometry of the measurement weir affects flow patterns in and near the low flow notch influencing bed load transport. 2) Approximately 160 meters upstream of the measurement weir the Elwha River makes a 90 degree turn to the left, forcing flow to river right against bedrock. This forms a point bar at the bend which, at times of very high sediment supply, has extended downstream to the measurement weir on river left. 3) The presence of a wing wall on river right (17-23 m upstream of the measurement weir) focuses high velocity in the center-right portion of the cross section (approximately stations 9 – 12 m). However, these geometrical features do not explain why the highest proportion of bed load transport has changed location throughout the observation period. The temporal fluctuation of the highest concentration of bed load transport is the result of changing bed geometry upstream of the measurement weir during and after dam removal, which can be attributed to the oversupply of sediment. During bed load measurements with a TR-2 in November 2012, shortly after the large release of sediment from Lake Mills, bed elevation was measured at a single station documenting two dune cycles with a period of 12

and 15 minutes and an amplitude of 0.2 m. For three consecutive days in March 2013, depth measurements taken during discharge measurements indicated the position of the thalweg at stations 16.4, 14.4, and 7.4 meters on March 13, 14, and 15, respectively. With such shifting bed conditions it is expected that the location of the highest concentration of bed load transport will be very dynamic.

Power law relationships of coarse bed load to river discharge (Figure 8) indicate a broad range of coefficient *a* and exponent *b* (Eq. 2). Arriving at definitive conclusions regarding the relationship between river discharge and bed load transport on the Elwha River may be premature due to the changing conditions of sediment supply during and after dam removal, but there appears to be a seasonal consistency thus far, with spring snow melt run-off providing the lowest exponent (*b*) in the power law relationship (Eq. 2). The nature of the hydrograph and antecedent conditions likely plays a role in the intra-annual variability of the coefficient and exponent of the power law relationship. Continuous bed load data from the Elwha impact plate system will provide valuable insight into various bed load transport predictors.

CONCLUSIONS AND OUTLOOK

The Elwha impact plate system is in a state of preliminary calibration of the geophone plates, while the accelerometer plates are currently being tested in the flume. The calibration of the geophone impact plates will improve with additional bed load measurements and calibration data. However, it remains to be seen if the calibration will change significantly with the coarsening grain size distribution and decrease in sediment supply as the Elwha River works toward equilibrium transport conditions. Turowski and Rickenmann (2009) have shown that a cover effect plays a role in the calibration of an impact plate system, where increased sand loads dampen the impact of gravel particles on a plate. This occurrence will be evaluated as the calibration moves forward.

The method of system calibration described in this paper, using spatial and temporal averaging with multiple physical measurements over a 30-miute period, provides a reliable mean bed load transport rate with which to calibrate the impact plate system. It is acknowledged that pressure difference samplers are intrusive (Habersack et al. 2012) and sampling efficiency varies widely depending on the sampler characteristics (Johnson et al. 1977, Beschta 1981, O'Leary and Beschta 1981, Bunte et al. 2008). Every effort was made to insure, to the extent possible, that involuntary entrainment did not take occur upon placement on the bed and that the TR-2 did not scoop sediment upon retrieval during bed load measurements collected for calibration of the Elwha impact plate system. Sampler characteristics and deployment methodology remained constant throughout bed load measurements for system calibration. Given the limitations of physical bed load measurement at the measurement weir, using a pressure difference sampler (e.g. TR-2) deployed from a tethered raft is the only feasible option. Based on the findings of this study and by Kuhnle and Southard (1988), a 30-minute temporal average at a single station appears sufficient to capture the temporal variability in bed load transport, greatly improving the accuracy of the measurement and therefore improving the calibration of the Elwha impact plate system. It is acknowledged that Bunte et al. (2004) concluded that it may take up to 1 hour to sample the largest particles in transport using Dietrich and Whiting's (1989) proposed method for estimating minimum sampling time. Because physical bed load measurements are being collected for several hours for system calibration, it is presumed that the largest particles in transport are being measured and included in the calibration.

Reid and Frostick (1986) claimed that "the predictive modeling of bed load transport in alluvial rivers has made faltering progress over the past 50 years". This statement was made some 30 years ago and the performance of bed load formulas remains poor (Habersack et al. 2008). Certainly, the inability to obtain quality bed load measurements with sufficient temporal and spatial density can be blamed for the lack of progress, as well as the fact that bed load transport is a complex process. Kleinhans and van Rijn (2002) note that the hiding and exposure function in bed load transport equations is the primary uncertainty for predicting fractional bed load transport, which is consistent with temporal variability demonstrated here. Similarly, Kuhnle (1992) concludes that the formation and destruction of bed forms and the presence of bed load sheets are responsible for short term temporal variability in bed load

transport. The uncoupled relationship of bed load transport with stage, giving rise to event based and in some cases annual hysteresis is another cause of unsteadiness in bed load flux. The details mentioned here are poorly understood, but given the recent advancements in and implementation of continuous bed load measurement, our understanding of bed load transport stands to improve in the coming decades.

The Elwha impact plate system shows great promise for future evaluation of bed load transport in a moderately sized, perennial, gravel bed river. It will be possible to examine the intricacies of coarse bed load transport with high resolution data from a Eularian perspective. Equally as important will be the knowledge gained from continuous bed load measurement over a period of many years during and after the removal of two large dams. Furthermore, continuous measurement of bed load can be combined with continuous suspended load measurements on the Elwha River through collaboration with the USGS (Magirl et al. 2014), who are continuously measuring suspended sediment concentration using turbidity and acoustic backscatter at the measurement weir containing the bed load impact plates.

ACKNOWLEDGEMENTS

This project has been funded by the Bureau of Reclamation's Science and Technology research program, project numbers 0115, 9562, and 6499. Dr. James Chambers, Wayne Carpenter, and Bradley Goodwiller of The National Center for Physical Acoustics at the University of Mississippi have provided (and continue to provide) outstanding assistance with signal processing along with set-up, installation, and maintenance of the computer monitoring system. Many thanks to Smokey Pittman and the crew at Graham Matthews and Associates for their professionalism and unparalleled expertise in sediment measurement during calibration efforts.

USGS TRAINING OF SEDIMENT DATA COLLECTION TECHNIQUES

By Gary P. Johnson[1], John R. Gray[2], Kurt Spicer[3], and Mark Landers[4]

Sediment Data Collection Techniques is a USGS sponsored training course, held annually in the early spring in the Pacific Northwest area near Mount St. Helens. About half of the course is classroom instruction, and the other half is devoted to "hands-on" field experience using a variety of samplers and techniques on bridges and wading in west-central Washington streams including those draining the Mount St. Helens region. This training course is intended to provide instruction in:

- Basic fluvial-sediment concepts
- Sediment sampler characteristics
- Field techniques (including Safety concepts) for sampling
- Laboratory analyses of sediment samples
- Overview of computation of sediment-discharge records
- Selected methods for estimating sediment properties from surrogate technologies
- Overview of a records computation protocol using continuous turbidity
- Physical bedload samplers, and
- Quality-assurance procedures

A course website containing all presentations and a plethora of other information germane to sediment-data collection and analysis techniques is provided before the training session. Students have the option of downloading each presentation or printing hard-copies to bring to the class. The website also provides the agenda, maps, lodging details, and other links of interest.

The course is designed for:

- Those actively engaged in/or supervising individuals engaged in sediment or water-quality data-collection activities, or who plan to become involved in these activities.
- Those interested in sediment-surrogate technologies for suspended-sediment-, bed-material-, and bedload-data collection.
- Those who are or will be actively involved in the collection of data for Surface-Water Toxic Waste, NAWQA or NASQAN Programs, coal hydrology studies, geomorphic assessments that require fluvial-sediment data, science-supported activities for stream restoration, and other monitoring or research endeavors involving fluvial sediment.

MAXIMIZING THE RELIABILITY AND COST-EFFECTIVENESS OF YOUR SUSPENDED-SEDIMENT DATA

J.R. Gray, Scientist Emeritus, U.S. Geological Survey, Reston, Virginia, graysedimentology@gmail.com, and Denis O'Halloran, Hydrologic Technician, U.S. Geological Survey, Sacramento, California, dohall@usgs.gov

Abstract An annual record of daily suspended-sediment discharges produced for a U.S. Geological Survey (USGS) streamgage requires suspended-sediment data that are representative of the flow past a river cross section. Depth-integrated isokinetic sampling by a hydrographer at appropriately selected, multiple cross-stream interval centroids by either or both of the Equal-Discharge-Increment (EWI) or Equal-Width-Increment (EDI) methods provide physical samples for subsequent laboratory analyses and use in computation of the daily sediment record. The expertise and attentiveness of the hydrographer, coupled with the sampling scheme used, can have a considerable and consequential influence on the reliability and cost-effectiveness of the derived sediment record.

An evaluation of largely controllable technical and cost factors supports the preferential use of the EDI method, with separate concentration analyses on each sample, for at least one of the two required depth-integrated cross-section sample sets. This conclusion stems from two primary considerations: The value of visually comparing the contents of individual samples to identify and discard bad samples, thus preempting their submission for laboratory analysis; and identifying concentration trends in the cross-section that, in concert with the information from the second sample set, represents a second opportunity to ferret out bad data.

The cost of individual concentration analyses for a single EDI set of six samples is about double that for a six-sample EWI composite-concentration analysis. However, the additional cost of the individually analyzed EDI sample set over that for an EWI composite-concentration analysis – about 1.3 percent – pales in comparison to the annual funding requirements for producing a daily sediment record.

Preventing erroneous sample data from degrading the quality of the sediment record – and permanent storage in the USGS National Water Information System – is desirable for the sake of the accuracy of the records produced, database integrity, and return on investment. The combined cost of composite analyses on two cross-section sample sets as a percentage of total station costs is not substantially less than that for one sample-set composite analysis plus one EDI sample set analyzed to produce concentration values for each sample. Coupled with enhanced data reliability, the added cost of the latter approach is readily justifiable as a cost-effective "sediment-data quality-assurance policy."

INTRODUCTION

Production of an annual record of daily suspended-sediment discharges by the U.S. Geological Survey (USGS) is a time- and resource-intensive undertaking that requires considerable experience and expertise. Requirements for a demonstrably reliable and accurate sediment record include:

- Collection of suitable suspended-sediment samples using appropriate sampling equipment and methods,
- Analyses of the samples by a certified fluvial-sediment laboratory,
- Derivation of a suspended-sediment concentration (SSC) time-series dataset for each day, with continuity between days, for merging with the concomitant water-discharge time series to compute mean daily suspended-sediment discharges and mean time-weighted SSCs, after the
- Judicious application of correction coefficients relating data collected at a relatively high frequency, such as by an observer (Johnson, 1997), autosampler, or surrogate technology (Gray and Gartner, 2009), to mean SSC values for the river derived from periodic and/or episodic sample sets collected by a hydrographer.

The overall quality of these records is, at best, difficult to quantify. A number of factors and potential sources of error can increase the variance of, or introduce bias in a computed record. These include:

- Failure to adequately account for the temporal and spatial variability inherent in the sediment-transport process (Topping et al., 2011),
- Potential inaccuracies or outright errors introduced by sampler selection, performance, and/or deployment; and sample processing, shipment, and/or storage at the sediment laboratory prior to analysis,
- Potential, albeit rare, sediment laboratory-related errors, and
- The incorrect application of, or failure to apply, the aforementioned correction coefficients.

Production of a reliable daily sediment record at a USGS streamgage presupposes that none of the several links in the sediment data-collection and -analysis chain will fail. This evaluation focuses on one of those links: Selection and use of the cross-section sampling method(s) used by the hydrographer, and the laboratory methods requested to process and analyze the sample sets. The evaluation's objective is to identify demonstrably reliable and cost-effective approaches available to the hydrographer for obtaining the field-calibration data for computing daily suspended-sediment records and permanent storage in the USGS National Water Information System (NWIS). The expertise and attentiveness of the field hydrographer coupled with the selected sampling scheme can have a considerable and consequential influence on the reliability and cost-effectiveness of the derived sediment record.

COLLECTION AND COMPUTATION OF SUSPENDED-SEDIMENT-DISCHARGE RECORDS

Numerous methods are available for the computation or estimation of suspended-sediment discharges in open-channel flows (Gray and Simões, 2008). The USGS sanctions two such methods for storage of daily values of suspended-sediment discharge, time-weighted suspended-sediment concentration (SSC), and water discharge in the NWIS:

1. A method that interpolates and, when necessary, extrapolates from SSC data derived from periodic or intermittent physical samples to develop a continuous SSC time series. The SSC time series is merged with a concomitant water-discharge time-series dataset to produce the daily sediment records (Porterfield, 1972; Koltun et al., 2006); and
2. Continuously monitored turbidity as an SSC surrogate (Rasmussen et al., 2009).

Other suspended-sediment surrogate technologies including those based on hydroacoustic, densimetric, and laser technologies have been or are being evaluated (Gray and Gartner, 2009). Some are incorporated in operational programs (Rasmussen et al., 2008; Voichick and Topping, 2014).

Regardless of the monitoring technique or technology selected for operation of a daily sediment station, the reliable measurement and computation of fluvial-sediment loads fundamentally depends on collection and analyses of representative water-sediment samples that integrate variations in the velocities and sediments suspended in the stream cross section. Historically, analytical results from these cross-section discharge-integrated samples were the sole SSC data used to develop the temporal SSC trace (for the most part limited to the Nation's larger rivers), or to adjust SSCs derived from samples collected on a relatively frequent basis by an observer or autosampler to be representative of the mean SSC value in the cross section (Porterfield, 1972; Johnson, 1997; Koltun et al., 2006). More recently, samples representative of the flow past the cross section are being used to calibrate an SSC surrogate time-series (Rasmussen, et al., 2009; Gray and Gartner, 2009; Voichick and Topping, 2014).

Edwards and Glysson (1999), Nolan et al. (2005), Gray et al. (2008), and Gray and Landers (2014) describe methods approved by the Federal Interagency Sedimentation Project (FISP) and USGS for collecting suspended-sediment samples for subsequent laboratory analyses. For physical sampling in all but the shallowest or most sluggish flows (generally, with cross-section depths less than about 0.3 meter and/or mean flow velocities less than about 0.5 meters/second), two USGS-approved methods for deploying an isokinetic sampler in a single vertical are available: point-integration and depth-integration. Contemporary use of the point-integration method is rare because it is relatively costly and time-intensive, and depth-integrating bag samplers developed since the mid-1990s for use in rivers with depths exceeding about 4.5 meters are available (FISP, 2015; Gray and Landers, 2015). Ergo, the point-integration sampling technique is ignored hereafter. Non-isokinetic sampling techniques are also ignored. However, the potential relevance of these sampling techniques may be inferred by the reader in the ensuing discourse.

Approved USGS sampling techniques rely on the use of an appropriate isokinetic sampler developed by the FISP (2015). A list of FISP isokinetic samplers, their physical characteristics and deployment limitations is available from Davis (2005), Gray et al. (2008), and Gray and Landers (2014; 2015). When a mean value for SSC (or SSC and particle-size distributions, PSDs) representative of the flow-weighted cross section is sought, such as for subsequent use in computation of a daily suspended-sediment record, FISP isokinetic samplers are deployed using either the Equal-Width Increment (EWI) and/or Equal-Discharge Increment (EDI) methods (Edwards and Glysson, 1999; Nolan et al., 2005; Gray et al., 2008; and Gray and Landers, 2014). The data-quality and economic ramifications related to the selection and use of either or both of these sampling methods constitute the focus of the ensuing discourse.

Description and Requirements for Use of the EWI and EDI Methods

Characteristics Common to the EWI and EDI Methods: Both the EWI and EDI methods entail collecting depth-integrated samples in a river cross section. The cross section is computationally segregated into intervals. An isokinetic sampler appropriate for the ambient depth and flow velocities in the cross section is lowered at a constant rate in a water column (vertical) located at the centroid of each interval. After the briefest contact with the bed, the sampler is retrieved at a constant rate. This is repeated at each vertical, changing sample containers as appropriate.

In larger rivers, some hydrographers retrieve the sampler at the 0.90 or 0.95 depth (i.e., without contacting the bed) to minimize the risk of snagging a submerged object, or to preclude the inadvertent collection of bed material by gouging the sampler nozzle into the relatively soft lee face of a dune or infirm bed (Gray and Landers, 2014). This approach can result in an abnormally large unsampled zone between the bed and the nadir of the deployed sampler. If a vertical SSC gradient exists, this partial-depth sampling approach may produce biased samples, usually toward underrepresentation of SSC. Hence the quest for safer sampling and avoidance of sample contamination is potentially countered by the collection of biased data.

During the course of a sampling transect, each sample container (a glass or plastic bottle, or collapsible bag) either must be replaced before overfilling, or the contents decanted to a compositing vessel for subsequent subsampling, such as with a USGS churn splitter, or by pouring through a sub-sampling device, such as a USGS cone splitter (Capel and Larsen, 1996). Subsampling, while more or less a routine step for collecting chemical-quality data, is discouraged for suspended-sediment data collection. This stems from recognition of potential subsampling vagaries that include both a potential for an increase in data variance, and introduction of bias.

At least two sets of cross-section samples are collected per site visit (Nolan et al., 2005; Topping et al., 2011; FISP, 2013; Gray and Landers, 2014). Samples are analyzed to enable comparisons of mean SSCs and PSDs derived for each sample set.

Sampler-transit rates exceeding 0.4 multiplied by the mean stream velocity ("four-tenths rule") are impermissible. Maximum transit rates for some samplers are less than the four-tenths rule (Edwards and Glysson, 1999).

Overfilling the sample container invalidates a sample. Overfilled samples must be discarded and the sampler re-deployed in the interval(s) that contributed to the overfilled sample.

Each sample should be examined closely for comparisons of the relative estimated SSCs in the sample set (after visually compensating for unequal sample volumes). Of particular interest is the quantity and size of sand-size particles that quickly settle to the bottom of the container. With rare exception, analyses of samples adulterated during the sampling process yield spuriously large SSCs, and inordinately coarse PSDs.

The photograph in figure 1 shows two near-equal volume samples collected from the same vertical on December 11, 2014, as part of a 2-set EDI measurement on the Toutle River at Tower Road near Silver Lake, Washington (USGS station 14242580). The photograph was taken less than a minute after the samples were swirled. Disparities in the quantity, and possibly also the coarseness of the accumulated sediments, are readily apparent. Collecting, examining, and, if needed, analyzing additional samples from this vertical may have been warranted.

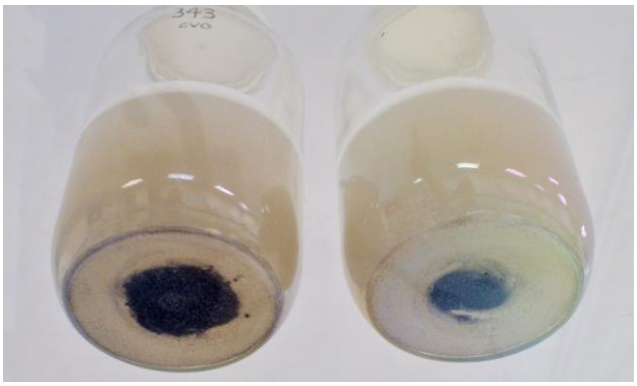

Figure 1 Photograph of two near-equal volume samples collected from the same vertical in the Toutle River at Tower Road near Silver Lake, Washington, on December 11, 2014, showing different accumulations of sediment.

The importance of examining each sample upon collection, or at least before departing the site, is hard to overstate. Ignoring this crucial step may result in retaining a sample that provides biased data due to operator error or inadvertent sample adulteration. Unreliable data generated by a hydrographer, as opposed to an observer or by automated means, are particularly counterproductive for at least four reasons:

1. The data are illegitimately ascribed the highest degree of confidence due to the employment status and presumed expertise of the collector(s), and well-documented validity of the sample-collection methods,
2. Hydrographers are correctly admonished to be generally disinclined to discard analytical results of samples, and of hydrographer-collected samples in particular,
3. The results are counterproductive from record-computation, time, and cost-effectiveness perspectives, and
4. If the spurious data represent an influential part of the streamflow hydrograph, they also may deleteriously influence the accuracy of records computed for other periods.

If the hydrographer fails to recognize a potentially bad sample on-site and does not resample the vertical(s), and/or otherwise fails to sleuth the problem – or if a bad sample received by a laboratory is analyzed but the data are neither flagged nor discarded as part of the routine dataset evaluation – the unreliable data will unknowingly compromise the quality of the computed suspended-sediment discharge record. This represents not only a failure to provide the reliable daily-value sediment record expected in return for the allocated funds, but also may compromise the effectiveness of management decisions based on the erroneous record.

Characteristics Specific to the EWI and EDI Methods

Equal-Width-Increment Method: An EWI measurement entails division of a river cross-section into equal-width intervals. Typically 10-20 verticals are sampled. The hydrographer deploys an appropriate isokinetic sampler in the centroid of the width of each interval. The sampler transit rate must be constant and equal in both the downward and upward directions – and in all sampling intervals – to ensure collection of a representative sample.

Because of its uniform transit rate, use of the EWI method allows retention of samples collected from multiple verticals into a sample container. Although sample containers can be changed after each EWI vertical is sampled, it is seldom done. This is due to the added data-collection effort; extra laboratory expense; and the availability of a generally less-costly but demonstrably superior means for obtaining data describing the cross-section SSC and PSD variability as described in the next sections.

Use of the EWI method requires knowledge of the river width at the sampling cross section. Additionally, before collecting an EWI sample set, a careful hydrographer will identify a vertical at which the product of width and mean velocity likely is at a maxima. Selection of a proper combination of a transit rate and nozzle diameter will preclude overfilling the sample container at this vertical. Absent this precautionary measure, a previously empty container may overfill while sampling in a single vertical, compelling the hydrographer to discard that and all other samples collected as part of the in-progress EWI transect. The next attempt at EWI sample collection either must include a more rapid transit rate and/or use of a smaller-diameter nozzle.

The magnitude of the water discharge is required for subsequent suspended-sediment discharge computations. However, knowledge of the lateral distribution of water discharge is not a prerequisite for EWI sample collection.

An analysis of a laboratory-produced EWI composite sample yields a single mean SSC value, and, if requested, one PSD. The same is true for an appropriately derived aliquot of a composite sample produced by a sample-splitting device, if such subsampling is necessary (Capel and Larsen, 1996).

Equal-Discharge-Increment Method: An EDI measurement entails the computational segregation of a river cross-section into intervals of equal discharge. Usually 4-10 verticals are sampled. The hydrographer deploys an appropriate isokinetic sampler in the centroid of each interval of water discharge at a constant downward rate and retrieves it at a constant rate. However, unlike the EWI transit rate which must be uniform in both vertical directions, the downward and upward EDI transit rates for an EDI vertical – and the rates used at each vertical – need not be equal. The contents of an overfilled sample container simply are discarded and that vertical resampled, usually with a briefer time-of-immersion. The vertical can be sampled multiple times to obtain the desired sample volume without changing the sample container.

Use of the EDI method requires knowledge of the distribution of water discharge in the cross section. This can be derived from an antecedent discharge measurement made with a mechanical current meter or acoustic Doppler current profiler (USGS, 2015). Alternately, if the channel is relatively stable, a discharge-width relation based on previous discharge measurements can be developed. This relation delineates the stage-dependent location of each

sampling centroid based on percentages of the total water discharge on each side of a vertical. Figure 2 shows a relation developed for EDI sampling at the Cowlitz River at Castle Rock, Washington (USGS station 14243000).

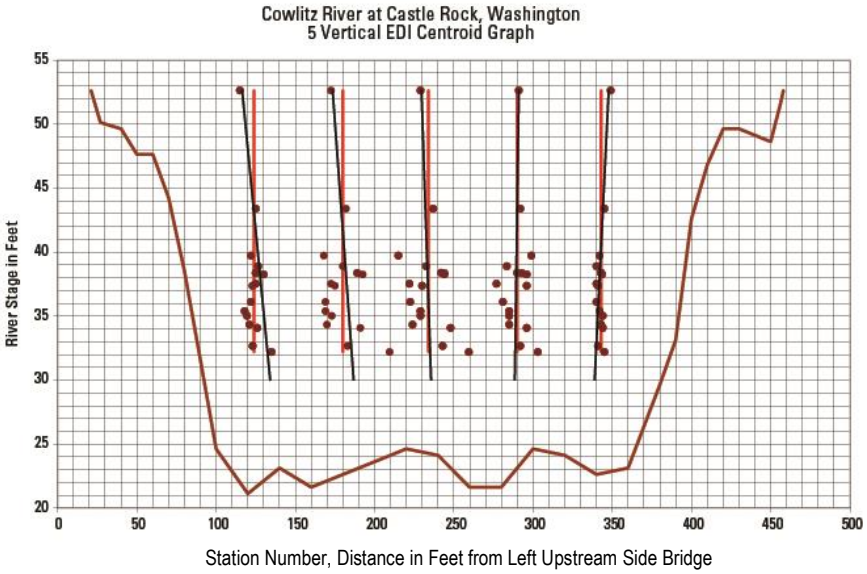

Figure 2 Graph depicting a water discharge centroid location versus stage relation developed from discharge measurements for the Cowlitz River at Castle Rock, Washington. The graph was developed to select verticals for collection of 5-vertical EDI sample sets at this site. Regression lines are black. Vertical red lines were hand-derived.

As each EDI sample is independent and discharge-weighted, the samples can be analyzed individually. Alternately, if all EDI sample volumes are more or less equal (in practice, each sample volume should be within about five percent of the mean sample-set volume), an EDI composite analysis can be performed. Individual-sample analyses as part of at least one EDI cross-section sample set are recommended, as described in the ensuing sections.

If an EDI composite analysis is sought, the extra attention and effort required to obtain a set of near-equal-volume samples is hard to justify compared to use of the EWI sampling method. The same cross-section-averaged data, more or less, are produced by either technique. Hence, the challenge to produce a set of near-equal-volume samples for an EDI composite analysis can be avoided theoretically without change in data quality by using the EWI method.

TECHNICAL CONSIDERATIONS FOR USE OF THE EWI AND EDI METHODS

Use of an appropriate sampler deployed by either the EWI or EDI method – with proper on-site and subsequent quality-control steps – will provide representative data for sediments and other constituents in suspension. However, inevitably, some adulterated samples that go unrecognized are received and analyzed by sediment laboratories. These can include bad samples in hydrographer sample sets as well as those collected by observers or autosamplers. Even valid samples can be adulterated as part of the sample handling, shipping, and storage continuum. The authors, who have reviewed scores of daily USGS sediment records from dozens of USGS Water Science Centers, have ample reason to believe that this problem occurs at a frequency worthy of concern.

Without proper screening, analytical results from composite analyses adulterated by a bad sample(s) collected at one or more verticals will be factored into the ensuing computation of the mean SSC value. With rare exception, the resulting composite SSC value is biased toward higher values. The degree of the bias can be a function of a number of factors, but can range up to an order-of-magnitude or so.

Such an outcome is more prevalent in lower-SSC streamflows where even a few grains of bed material inadvertently introduced to a sample can substantially influence the derived SSC value. Acceptance and use of spuriously variant mean-SSC values (and concomitant PSDs) result in the proportional derivation of erroneous instantaneous sediment-discharge data in addition to any subsequently derived statistics that are based on the bad data.

The hydrographer's challenge is to understand the potential for this problem and to implement procedures to preempt its occurrence. In addition to examining each sample upon collection for the presence of an inordinate

amount and/or coarseness of sand, use of the EDI method and individual-sample SSC analyses provide results that, with rare exception, enable the hydrographer to identify and discard bad SSC values.

A benefit of having each sample from an EDI cross section analyzed for SSC is exemplified by results of concurrent EDI and EWI sample sets collected on March 24, 2014, as part of field-based instruction for the USGS training course, "Sediment Data-Collection Techniques" (Johnson et al., 2015). The sample sets were collected from the bridge at the aforementioned Cowlitz River streamgage by students under the close supervision of course instructors with some three centuries of cumulative experience in sedimentology (Gary P. Johnson, USGS, written communication, 2015). SSC plots that include percentages of sand-size material are shown for the EWI (figure 3) and EDI (figure 4) cross-section sample sets. For instructional purposes, SSC and sand-fine split analyses were performed on individual EWI samples. Likewise, sand-fine splits in addition to the usual SSC analyses were performed on each EDI sample. Normally a laboratory-derived composite sample would have resulted in production of a single SSC value for the 12-bottle EWI sample set. Instead, the mean EWI SSC value was computed as the cumulative mass of sediment divided by the sum of the sample volumes. A mean EDI SSC value was calculated by the routine method of summing the individual SSC values and dividing by the number of EDI samples – five.

The mean SSC value of 262 mg/L from the EWI 12-sample set exceeds the 71 mg/L value for the concurrently collected EDI 5-sample set by a factor of 3.7. This is an inordinately large mean-SSC differential, and one that should invite skepticism from a competent record analyst.

Examination of the EWI SSC data indicates the presence of at least one outlier. The SSC value for station 140 is about double the SSC average for the other stations excluding that for station 330. The percent fines at station 140 is the maximum for this sample set, ergo, the percentage of sand-size material is at a minimum. Although the reference to "cracked bottle" gives the analyst more ammunition to question the validity of the station 140 SSC value, for present purposes this value was retained and attention directed to the more-egregious station 330 outlier.

The SSC value of 2,947 mg/L at station 330 is some 90 times larger than the average SSC of the other 11 EWI samples. The 2-percent fines value for this outlier is at odds with the average value of 43-percent fines determined from the four cross section sample sets, which ranged from about 30-80 percent fines. With little if any doubt, the inconsistent and inordinately influential station 330 SSC and PSD data are bad. Although it is possible that the sampler was incorrectly deployed – perhaps left on the bed for more than an instant before being retrieved – it is more likely that the sampler nozzle gouged the soft lee face of a sand dune at the nadir of the sampler's deployment, inadvertently adding bed material to the suspended-sediment sample.

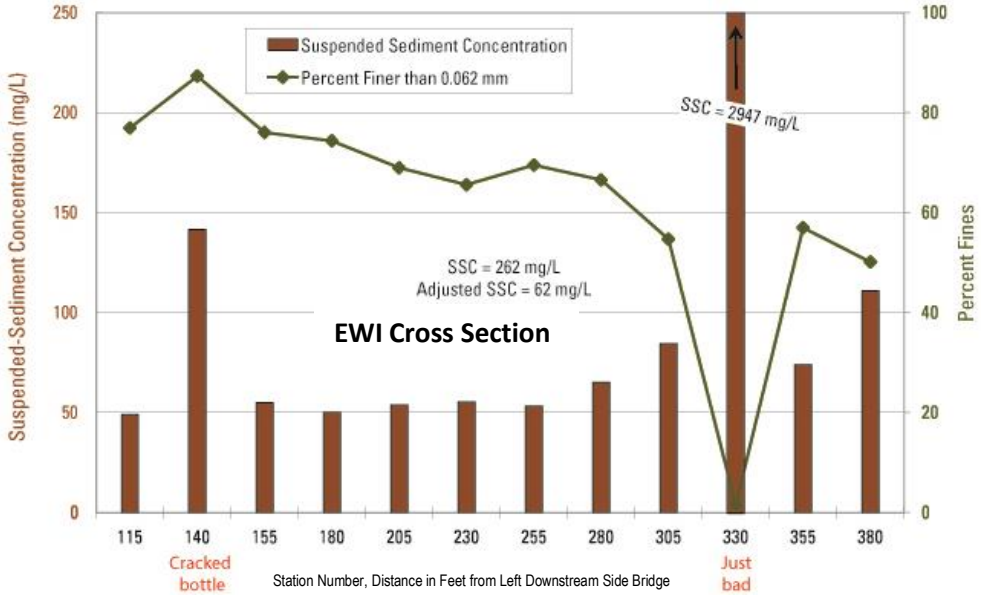

Figure 3 Graph showing SSCs and percent of material finer than 0.062 millimeters for samples collected using a US DH-76 suspended-sediment sampler and the EWI method (the EDI sample set depicted in figure 4 was collected concurrently at the USGS Cowlitz River at Castle Rock, Washington, streamgage on March 24, 2014, as part of the USGS training course, "Sediment Data-Collection Techniques"). References to "Cracked bottle" and "Just bad" were noted by the sample collectors. Sand-fine split and individual-sample SSC analyses were performed on the EWI sample set for instructional purposes.

If an inexperienced and/or inattentive hydrographer failed to notice the comparatively large mass of sand in the station 330 EWI sample and submitted it as part of the EWI sample set for a composite analysis, the resulting spuriously large SSC value of 262 mg/L and inordinately small percentage of fine material would become part of the station record as a relatively muted but still substantial composite-sample outlier. If the record analyst failed to identify and discard this composite-sample outlier in the ensuing analysis, suspended-sediment discharges computed for any part of the record influenced by this composite outlier will be inflated, perhaps by a factor of about 3.7. It is worth noting that USGS record analysts are instructed to be reluctant to discard hydrographer-collected data based on the premise, "if our own data cannot be trusted, what data can be trusted?"

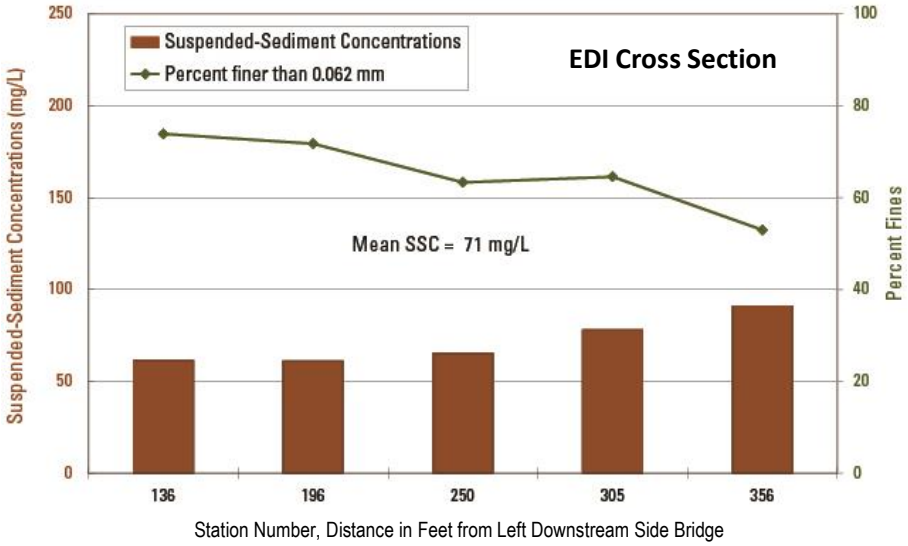

Figure 4 Graph showing SSCs and percent finer than 0.062 millimeters values for samples collected using a US DH-95 suspended-sediment sampler and the EDI method (the EWI sample set depicted in figure 3 was collected concurrently at the USGS Cowlitz River at Castle Rock, Washington, streamgage on March 24, 2014, as part of the USGS training course, "Sediment Data-Collection Techniques").

If, on the other hand, the EWI station 330 sample was inspected, suspected, disrespected, and duly discarded in the field after one or more unbiased duplicate samples were collected, the correct composite SSC value would be derived, assuming that the true station 330 SSC value was consistent with those for adjacent sections. Alternately, if the record analyst, upon receipt of these data, rightly deduced that the concurrent EDI SSC and sand-fine split values were internally reasonable and consistent, as were all individual EWI sample results other than the station 330 outlier (and perhaps also that for station 140), the EWI outlier(s) could and should be discarded.

If a composite analysis had been performed on the EWI sample set (figure 3), the perceptive record analyst would deduce that "something's wrong" with the EWI composite SSC and percent finer than sand values. After carefully evaluating all relevant information, the analyst should feel compelled to discard those data. In this case, only the values from the EDI sample set would be reported and used in record computations. This, of course, would achieve the desired technical outcome – production and use of reliable data – even if the time, effort, and funds associated with collection and analysis of the EWI sample set ultimately were wasted.

An EDI sample set can also include one or more samples with spuriously large SSC(s). However – unless, or perhaps even if an egregiously careless job was done at the sampling site – it is typically and imminently clear from results of separately analyzed EDI samples if an SSC value is unreliable. In this case, unlike in the preceding discourse that centered on the EWI composite outlier, all is not lost. An outlier in the EDI sample set simply can be mathematically eliminated from the mean-SSC computation. Alternately, an experienced analyst may discern a lateral SSC trend in the EDI data and, presupposing a high degree of confidence, estimate a replacement SSC. In this case, the estimated value is used only in the computation of the mean EDI SSC, but not stored as a discrete value.

The thrust of the previous discourse can be summarized as follows: For suspended-sediment studies, the EDI method provides both more, and more readily verifiable information than the EWI method. A composite EWI SSC value that contains the water-sediment contribution from one or more undetected anomalous sample(s) cannot be corrected. It is a bad value – the production of which cost time and money – upon being analyzed and forevermore.

On the other hand, the EDI method provides more detailed cross-section information and thus enables a more informed evaluation of the dataset. This in turn enables the analyst to revise the mean SSC value if bad data are identified and discarded.

Thus, routine use of the EDI method with individual SSC analyses as part of suspended-sediment data collection can be considered to be a "sediment-data quality-assurance policy" of sorts. However, as with the benefits accrued from ownership of a health or life insurance policy, use of the EDI method with individual sample analyses comes at a cost. This observation led to the following economic analysis performed to answer the following questions: "What is the magnitude of additional costs of the EDI method with individual sample analyses compared to those for the EWI or EDI composite method," and "Does the additional cost of the EDI method justify its use from data-quality and knowledge-gain perspectives?"

ECONOMIC CONSIDERATIONS FOR USE OF THE EWI AND EDI METHODS

With rare exception, program managers seeking cost savings select the least-expensive data-collection and -analysis scheme for operation of a daily sediment station or sediment-monitoring network. The degree to which cost reductions might affect data quality is difficult to determine, and may not be adequately considered when selecting a data-collection scheme. The ensuing analysis was performed to ascertain if the costs associated with the routine use of the EDI method with SSC analyses performed on individual samples – as part of at least one of the two cross-section sample sets collected per site visit – are reasonable as compared to those for the more prevalent dual EWI samples set (or for a single EWI sample set, contrary to USGS policy for collection of suspended-sediment data). The evaluation inevitably mixes subjective and objective factors that include but are not limited to the following considerations, each of which should be addressed in the design and operation of a daily sediment station:

- Factors associated with data production,
- The data-quantity and -quality expectations of the funding organization(s),
- The value of demonstrably good data, and
- The arguably insidious nature of unidentified bad data that degrade the quality of the sediment record, waste relatively and typically limited resources, and may result in incorrect management decisions.

A practical economic analysis was performed primarily to define and compare sediment-laboratory processing costs associated with use of the EDI method; the EWI methods; and as a combination of the two. The evaluation focused on analytical costs of hydrographer cross-section sample sets. Other sediment-related costs, such as for analyses of partial-section samples collected manually or by an autosampler, are largely independent of the hydrographer-collected samples. Likewise, the sampling scheme selected has little if any effect on the capital, travel, and labor costs associated with sediment-station operations.

Ergo, the economic analysis focused on data-analysis costs of cross-section sample sets collected as part of hydrographer station visits. The economic analysis performed was cognizant and appreciative of the perpetual competition between the quest to maximize data quality and the oft-limited resources for production of the record.

A survey of production sediment laboratories located in six USGS Science Centers, all using methods described by Guy (1961), and Knott et al., (1992; 1993), was conducted in 2014 to ascertain the costs to perform the following selected analyses:

- Suspended-sediment concentrations (SSC) analyses only,
- SSC and sand-fine break (S/F; percent finer than 0.062 millimeters in median diameter) analysis, and
- SSC and full size (FS; percentages from 0.002–2.0 millimeters in median diameter).

Table 1 lists the average analytical costs for three types of sediment-laboratory analyses. They are based on cost information from USGS production laboratories in Water Science Centers located in California, Iowa, Missouri, Kentucky-Indiana, New Mexico, and the Cascades Volcano Observatory, Washington.

Table 1 Average costs for laboratory analyses, from information provided by six USGS Science Centers in 2014.

Sediment Laboratory Analysis Type	Average Cost Per Analysis
Suspended-Sediment Concentration (SSC)	$17.00
SSC and Sand/Fine (SSC + S/F)	$40.00
SSC and Full Size (SSC + FS)	$170.00
Each Additional Container, Composite Analysis	$8.30

A second 2014 survey was conducted to determine the range of costs charged by the USGS for operating a daily sediment station (considered herein to exclude the concurrent collection of streamflow data) in tandem with a continuous-record streamgage for streamflow data (hereafter referred to as a "sediment streamgage"). The cost data in table 2 were provided by all but one first-survey respondent are included in the second survey. The Wyoming-Montana Water Science Center cost data were used in lieu of a second-survey response from Kentucky-Indiana.

Table 2 Average annual costs to operate a USGS Daily Suspended-Sediment Station (without streamflow data) and a Sediment Streamgage (with streamflow data), based on data provided by six USGS Science Centers in 2014.

Type of Data Produced by a USGS Gaging Station	Average Annual Cost
Daily-Record Sediment Station (sediment data only)	$32,700
Daily-Record Streamflow Station (streamflow data only)	$17,500
Daily-Record Sediment and Streamflow ("Sediment Streamgage")	$50,200

Operation of a sediment streamgage results in production of three sets of daily values that are computed, reviewed, permanently stored, and available to the public: Suspended-sediment discharge; mean time-weighted SSC; and water discharge; along with selected ancillary data. Table 2 lists the average annual costs for operating a sediment streamgage, and the costs of collection of the sediment records versus those for the combined sediment and the streamflow records. Because production of a daily sediment record requires continuous streamflow data, essentially all USGS sediment stations are operated as sediment streamgages that collect continuous streamflow records selected regardless of the funding source(s).

Cost comparisons for selected EDI and EWI sampling-event options are listed in Table 3. These options include costs for collecting one of the two required cross-section sample sets per site visit (referred to as a "sampling event"); collecting either four, six, or nine bottles in each cross-section set (a range that encompasses the number of bottles routinely collected as part of a sample set); and requesting the desired laboratory analyses (Table 1). In all sample-analysis options proposed other than the minimalist dual-EWI sampling method, individual samples collected as part of an EDI sample set are analyzed to identify SSC values for each vertical sampled.

Particle-size analyses–either sand-fine splits or full-size analyses–can be performed as part of either an EWI or EDI composite sample set. Size analyses performed on an unbiased, composite sample set have the advantages of being based on a demonstrably representative sample while providing a sufficient mass of sediment for a full-size analysis.

Although individual size analyses on samples from an EDI sample set would add information useful for better understanding transport characteristics per sediment-size fraction in the cross section, and for the ensuing sediment-record analysis, the relatively substantial added cost would be prohibitive. Additionally, the mass of sediment in individual EDI samples may be insufficient for a full size analysis. The authors are unaware of routine size analyses being performed on most or all suspended-sediment samples submitted to any USGS Water Mission Area sediment laboratory. At least one other USGS sediment laboratory routinely uses optically based analyses to produce concurrent sand-gradation and SSC data on each suspended-sediment sample. Routine production of particle-size data from each sample is highly desirable from the perspectives of the data analyst and data user, albeit substantially more expensive than if only SSC data are produced. These and perhaps other data produced by technologically advanced means may be sanctioned for storage and public release given compliance with USGS (2004) policy, to wit: "All data stored in publicly accessible USGS databases (the NWIS, and other publicly accessible files) must be collected and analyzed using approved collection and analytical protocols."

The combination of options listed in Table 3, factoring in sampling and analytical costs, are but some of the many sample-analysis options available. The authors consider these to represent realistic options for many sediment-monitoring planning purposes. They also might be used as a starting point in the quest to optimize the available resources with the data, and data-quality needs for collection of a daily sediment record – a quest that should include contingency plans for adequately characterizing the suspended-sediment SSCs and PSD of floods that may occur during the monitoring period.

A protocol for an annual sediment-station sampling program that presupposes ten sampling events (hydrographer site visits to collect a suite of physical samples for subsequent laboratory analyses plus a measurement of water discharge if required) was selected as a comparison of annual stations costs using the EDI, EWI, and a hybrid combination of the two methods (FISP, 2013). The hybrid composite sample set is collected using either the EWI or

EDI method (table 4). Options for three types of laboratory analyses–SSC, sand-fine split, and a full-size–were included. The actual number of sampling events in a given year might vary due to a number of factors including the frequency, timing, and magnitude of medium and higher flows at the station.

Table 3 USGS laboratory analysis cost comparisons for selected EWI and EDI single cross-section sampling event options. Laboratory costs are average values for each analytical type as shown in table 1.

Options for analyses of individual EDI subsamples, and for composite EWI or EDI analyses

EWI # of Sample Containers/X-S for Composite Analyses	SSC only Composite Analysis*	SSC + Sand/Fine Composite Analysis	SSC +Full Size Composite Analysis
4	$42	$65	$195
6	$58	$83	$212
9	$84	$106	$236

EDI # of Sample Containers/X-S for Individual Analyses	SSC Individual Analyses	SSC + Sand/Fine Composite analysis	SSC + Full Size Composite Analysis
4	$68	$65	$195
6	$102	$83	$212
9	$153	$106	$236

*The cost of an EDI composite SSC analysis is equal to that for an EWI composite analysis regardless of the number of samples collected and analyzed.

The program covers a year of sampling over a presumed range of flows: three low-flow site visits where only SSC analyses are requested (in part because a dearth in sediment mass in samples collected during lower flows often precludes accurate size analyses), and seven low-to-high flow site visits where SSC and particle-size analyses (sand-fine or full-size analyses) are sought.

Table 4 uses data from tables 1 and 3 to compare costs of sole use of the EDI method, sole use of the EWI method, or in a hybrid combination of the two. They describe cost scenarios for consistent submitting for analysis four, or six, or nine samples per cross-section, with two sample sets obtained per site visit, and ten hydrographer visits per year. Numerous permutations of these analytical options could be developed; regardless, the authors contend that no operational sampling scheme used by a credible hydrographer– given the analytical costs and frequency of site visits–would result in substantially reduced annual analytical costs than the minimum of $1,261 for dual EWI cross sections with four samples collected per cross section, and composite analyses performed on both sample sets.

The analytical cost for the minimalist dual-EWI sample set is the least costly method evaluated for a given number of samples collected per cross section, ranging from 21-33 percent (for samples sets of four and nine samples, respectively) less expensive than a dual-sample set that includes one EDI individually analyzed sample set. However, as previously noted, sole use of the EWI method tends to increase the risk of inadvertently acquiring unreliable data. For example, if analyses of one or both composite sample sets included bed material gouged from any of the 10-20 EWI verticals typically sampled in a single cross section, the composite value will not be representative of the stream conditions. The two marginally more costly methods, on the other hand, each provide at least one cross-section sample set analyzed individually for SSCs–a substantial advantage over the dual-EWI sample-set approach.

Table 4 Cost comparison for the EDI, EWI, and hybrid methods with an annual protocol of ten sampling events and four, six, or nine samples collected as part of each of two cross sections. All individual EDI samples are analyzed solely for SSC. All EWI and EDI composite sample sets are analyzed for SSCs and in some cases also for PSDs.

Sampling-Event Approach with Two Cross Sections/Event	**Number of Sampling Events, Types of Laboratory Analyses, and Costs**				
Sampling Event Cost Scenarios X-S is Cross Section	**3 Low-Flow EDI Individual SSC Analyses**	**1 Low-Flow SSC and Sand-Fine Split Composite**	**4 Medium-Flow SSC and Sand-Fine Split Composites**	**2 High-Flow SSC and 2 Full-Size Analysis Composites**	**Sum of Costs, Ten Sampling Events**
Four Containers/X-S					
Approach I: EDI Individual + Composite	$330	$133	$532	$526	$1,521
Approach II: Two EWI Composites	$252	$107	$428	$474	$1,261
Approach III: Hybrid of EDI Individual SSC + EWI or EDI Composite for Size Analysis	$330	$133	$532	$526	$1,521
Six Containers/X-S					
Approach I: EDI Individual + Composite	$480	$185	$740	$628	$2,033
Approach II: Two EWI Composites	$348	$141	$564	$540	$1,593
Approach III: Hybrid of EDI Individual SSC + EWI or EDI Composite for Size Analysis	$480	$185	$740	$628	$2,033
Nine Containers/X-S					
Approach I: EDI Individual + Composite	$711	$259	$1,036	$778	$2,784
Approach II: Two EWI Composites	$504	$190	$760	$638	$2,092
Approach III: Hybrid of EDI Individual SSC + EWI or EDI Composite for Size Analysis	$711	$259	$1,036	$778	$2,784

Table 5 summarizes annual absolute and relative costs for sediment-station operation for each of three sampling approaches: The cost-identical dual-EDI and hybrid approaches (approaches I and II), and the minimalist dual-EWI approach (III).

Table 5 Annual absolute and percent costs for the hydrographer-collected 6-sample set option shown in table 4 in comparison with total costs of a daily sediment station and a sediment streamgage (sediment and streamgage).

Station Type	**Average Annual Cost (see Table 2)**	**Approach I (Dual EDI) or Approach II (Hybrid) Cost (see Table 4)**	**Approach III Dual EWI Composites Cost**	**Added Annual Station Costs as Percent: Either Dual EDI (I) or Hybrid (II) minus Dual EWI Composites (III)**
I: Daily Sediment Station	$32,700	$2,033 6.2%	$1,593 4.9%	1.3%
II: Sediment Streamgage	$50,200	$2,033 4.0%	$1,593 2.8%	1.2%

The dual-EDI sampling approach is functionally and economically identical to the FISP (2013) hybrid approach; the only difference is submittal of an EDI sample set instead of one collected by the EWI method for a composite analysis. Their marginally higher cost is more than balanced by the dual benefits of individual EDI SSC values and with the cost savings associated with a single analysis on the composite sample set. If the composite analysis results are deemed unreliable compared to individual EDI sample-set results, discarding the EWI results is unfortunate, but all is not lost; the mathematically averaged EDI SSC results – after a careful evaluation – provide a mean SSC value for subsequent record computations. Additionally, the time spent in record analysis ultimately is reduced.

Following are observations gleaned from table 5, which relied on information from the previous four tables:

- One should expect the need to allocate about 5-7 percent of the annual daily sediment station cost toward laboratory analyses of sample sets collected by hydrographers. For the sediment streamgage, that range might fall to about 3-4 percent.
- To attain an a minimally acceptable level of confidence in hydrographer-produced data, one should be reticent to allocate much less than about six percent of the annual cost of a daily sediment station for laboratory analyses, or about four percent of sediment streamgage costs.
- The allocation of an additional 1-2 percent of funding to the total operating costs of a sediment streamgage enables use of the reliable hybrid or dual-EDI methods (table 5, approaches I and II) in lieu of the comparatively risky (from a data-quality perspective) sole use of the dual-EWI method (approach III).
- This cost evaluation does not include de facto increases in the percentage of analytical costs versus total-station costs if any bad data collected by the hydrographer must be discarded.
- Conversely, the added monetary value of enhanced data quality due to the exclusion of bad data may be substantial albeit unquantified and perhaps unquantifiable. Regardless, these de facto cost benefits are quite real and should be recognized as such when considering the cost of the sediment record.

SUMMARY AND CONCLUSIONS

The technical and economic consequences of sole use of a dual-EWI as opposed to a dual-EDI, or a hybrid of the two methods – based on practical considerations related to data quality versus the resources to collect and analyze the samples for computation of an annual sediment record – have been described in the previous sections and can be summarized thusly: The expertise and attentiveness of the field hydrographer coupled with the selected sampling scheme can have a considerable and consequential influence on the reliability and cost-effectiveness of the derived sediment record.

Factors germane to this conclusion follow:

1. **HYDROGRAPHER, EXAMINE THY SAMPLES**: At the risk of being pedantic, it is difficult to overstate that the single most important activity available to the hydrographer is to minimize the potential for collecting bad data at a site by routinely examining the volume and quantity of accumulated sediments of each sample upon or soon after collection. Samples with anomalous quantities and/or sizes are the first and foremost tip-off that something may be amiss. The wise and conscientious hydrographer will not depart the site without resampling the vertical(s) that contributed to the potentially anomalous water-sediment mixture. The hydrographer must ascertain if the visual observations are likely to reflect the sedimentary conditions at the sampled verticals, or if results of the sample analyses are likely to contribute to the desk-bound analyst's headaches when trying to deduce what might have gone awry at the sampling site.
2. **BAD DATA HAPPEN**: Some data that unequivocally are at odds with the preponderance of those used to produce a sediment record appear in the large majority these datasets. Although some of these outliers defy logical explanation, a careful review of field notes, laboratory reports, and other information usually infer with a high degree of confidence that the outliers originated as bad samples. The authors have ample reason to believe that this problem occurs at a frequency worthy of concern to those producing or using the data.
3. **BAD DATA ARE...BAD**: Without proper screening, analytical results from composite analyses adulterated by bad subsamples from one or more verticals will be factored into the computation of the mean SSC value. With rare exception, the resulting composite SSC value is biased toward higher values.
4. **ADDED COST FOR "BEST JOB" IS REASONABLE**: The annual station-operation costs for an increased number of analyses of hydrographer-collected samples listed in (one EDI sample set with individual-sample SSC analyses plus a second sample set composite analysis; table 5, approaches I or II; see FISP, 2013) exceed the minimalist dual-composite approach (approach III) by a paltry1-2 percent.

5. **AND YOU GET A BIGGER BANG-FOR-BUCK**: The hybrid or dual-EDI sample-set options have the added benefit of minimizing the risk of unknowingly including bad data in the permanent record. This is a consequence of the availability of spatially detailed SSC data from the individually analyzed EDI sample set that is both internally (within-set) comparable, and externally comparable to the results from the companion cross-section sample set. Additionally, the time spent in record analysis ultimately is reduced.
6. **A COST-EFFECTIVE QUALITY-ASSURANCE POLICY FOR YOUR SEDIMENT DATA**: To summarize the preceding observations: An EDI sample set with SSC analyses performed on each sample provides useful information on the cross-sectional SSC distribution. Also desirable, albeit rarely produced and generally cost-prohibitive, are size analyses on individual EDI samples. These data provide a "sediment-data quality-assurance policy" of sorts that enables the hydrographer to identify and discard unreliable EDI single-vertical SSC values, and/or to ascertain if the concurrent composite SSC value is consistent and reasonable with that for the EDI SSC value. This, in turn, either substantially increases the likelihood that hydrographer-collected data are demonstrably reliable, or enables the hydrographer to discard unreliable data. Conversely, this benefit is lost when using the dual-EWI composite approach.
7. **ERGO, AN ENDORSEMENT:** The authors unequivocally endorse the FISP (2013) hybrid option – or using that approach but substituting the EWI composite analysis with a composite EDI analysis – for the cost-effective and comparatively reliable derivation of hydrographer-collected SSC and PSD data. This endorsement is particularly germane to sediment-record computations for periods of medium-and-higher flows that are most influential in suspended-sediment transport.

ACKNOWLEDGEMENTS

The quality of this manuscript was improved substantially by reviews provided by Larry Freeman (retired), Kurt Spicer, Louis Cannarozzi, and Jim Kolva of the USGS; and Marie Garsjo (retired) and Jerry Bernard (retired), Natural Resources Conservation Service. The economic analysis relied on and benefited from information provided by the USGS Cascades Volcano Observatory Science Center, and the California, Iowa, Missouri, Kentucky-Indiana, New Mexico, Washington, and Wyoming-Montana USGS Water Science Centers. The artistic prowess of the USGS's Annette Goode in the production or alteration of the schematics in this manuscript was greatly appreciated.

COLLECTING A BETTER WATER-QUALITY SAMPLE: REDUCING VERTICAL STRATIFICATION BIAS IN OPEN AND CLOSED CHANNELS

Abstract

Collection of water-quality samples that accurately characterize average particle concentrations and distributions in channels can be complicated by large sources of variability. The U.S. Geological Survey (USGS) developed a fully automated Depth-Integrated Sample Arm (DISA) as a way to reduce bias and improve accuracy in water-quality concentration data. The DISA was designed to integrate with existing autosampler configurations commonly used for the collection of water-quality samples in vertical profile thereby providing a better representation of average suspended sediment and sediment-associated pollutant concentrations and distributions than traditional fixed-point samplers. In controlled laboratory experiments, known concentrations of suspended sediment ranging from 596 to 1,189 mg/L were injected into a 3 foot diameter closed channel (circular pipe) with regulated flows ranging from 1.4 to 27.8 ft^3/s. Median suspended sediment concentrations in water-quality samples collected using the DISA were within 7 percent of the known, injected value compared to 96 percent for traditional fixed-point samplers. Field evaluation of this technology in open channel fluvial systems showed median differences between paired DISA and fixed-point samples to be within 3 percent. The range of particle size measured in the open channel was generally that of clay and silt. Differences between the concentration and distribution measured between the two sampler configurations could potentially be much larger in open channels that transport larger particles, such as sand.

INTRODUCTION

Collection of representative water-quality samples in fluvial systems can be complicated by large sources of variability, both temporal and spatial. For example, Horowitz (1995) found both horizontal and vertical concentrations of suspended sediment in a stream or river tend to increase with increasing distance from stream banks and depth. These increases were associated with greater concentrations of sand-size particles. This is especially notable with very fine to coarse sand-sized particles, in that suspended concentrations may be considerably higher within 3 feet of the channel bed (Guy, 1970). The stratification of solids in a flowing water column may result in biased concentration data collected from open channels.

Watershed managers depend on assessment and monitoring of water quality and flow data to help target pollutant reductions, identify the most important sources of pollutants, and evaluate the benefits of select stormwater management practices. One of the most common uses of water-quality data is to calibrate and verify urban pollutant models. Sediment concentrations and particle size distributions are especially important to assure the models provide useful results because studies have shown concentrations of urban pollutants generally increase with decreasing particle size, yet the majority of mass lies in coarse particles (Evans et al., 1999; Sansalone and Buchberger, 1997; Characklis and Wiesner, 1997; Waschbusch et al., 1999; Li et al., 2005). Once tested, models can be one of the only cost effective approaches to developing watershed plans in urban areas when confronted with the high cost of monitoring all potential sources of runoff and the stormwater management practices used to treat it. For example, the Wisconsin Department

of Natural Resources (WDNR) has promulgated a series of stormwater performance standards that will require qualifying cities to reduce the annual total suspended solids (TSS) load in urban runoff by 20 percent (Wisconsin Administrative Code NR 151, 2002). Models are used by both the WDNR and permitted entities to help determine if the goal is achieved. Another example is the development of total maximum daily loads (TMDL) for impaired waters under section 303(d) of the Clean Water Act (U.S Environmental Protection Agency, 2011). Urban areas around the country are subject to development of TMDLs that require the calculation of the maximum amount of a pollutant a waterbody can receive. Without accurate flow and pollutant concentration data to calibrate and verify models used to determine TMDLs, they could generate erroneous results that could significantly reduce the effectiveness of watershed planning. Millions of dollars are spent annually by environmental managers, engineering consultants, and others to mitigate, control, and prevent sediment and sediment-associated pollution in our nation's waterways. Accurate concentration data are vital to their decision-making process.

To help reduce uncertainty, the use of surrogate technology has been explored as a means to estimate time-varying sediment concentration (Wood and Teasdale, 2013). While this approach has been successful, it is generally focused on sediment and does not address the wide range of pollutants commonly imposed on the regulated community. To obtain reliable and representative data, Bent and others (2000) suggest the automatic sampler intake should be placed near the point at which the concentration approximates the mean sediment concentration for the channel cross-section over a full range of flows. This concept for intake placement has great merit, but the mean cross-section concentration is constantly changing as flow conditions vary (Edwards and Glysson, 1999). It is unlikely that specific guidelines for locating a sample intake for flow conditions at one water level would produce the same intake location relative to the flow conditions at a different water level. To resolve this, the USGS recommends use of equal-width-increment (EWI) samples to develop a cross-sectional coefficient to be applied to fixed-point sample concentrations (Edwards and Glysson, 1999). However, collecting depth- and width-integrated samples over a range of conditions may not be possible for a number of reasons, such as brief duration of runoff, limited access, hazardous conditions, and rapidly varying flows, especially in urban streams (Harmel et al., 2010). These techniques are also impractical for most closed systems used to convey urban stormwater. Furthermore, traditional fixed-point samplers can artificially bias sediment concentration in a water sample, especially in flashy or ephemeral streams where the zone between bed and suspended load may vary depending on water depth. Ideally, the location of the sample intake should be adjusted to reflect changing water depths.

To address this concern, the USGS – Wisconsin Water Science Center has developed a fully automated Depth-Integrated Sample Arm (DISA). The DISA was designed to integrate with existing autosampler configurations for collection of water-quality samples in vertical profile thereby providing a better representation of average sediment and sediment-associated pollutant concentrations and distributions than traditional fixed intake samplers.

The primary objective of this study was to determine whether the DISA can collect water-quality samples from both open and closed channels over varying hydraulic conditions that are more representative of the average conditions in a water column, in terms of suspended-sediment concentration (SSC) and particle size distribution (PSD), than a traditional fixed-point sampler.

METHODS

The general field of application of the DISA was originally developed in 2008 for closed conduits used to convey stormwater runoff in urban environments, such as storm sewers. As such, its design was optimized for collection of a water sample in vertical profile from the center of a circular pipe or culvert. Operation of the DISA made use of a linear actuator with position sensing capabilities to drive a rotary sample arm assembly attached to the ceiling of a closed conduit. The actuator was controlled via datalogger to move forward or retract to one or more desired positions in the water column. Once in

position, the DISA intake remained in place until the autosampler completed its normal purge/withdraw cycle. A detailed description of the device can be found in Selbig and Bannerman (2011).

Evaluation of the DISA in a closed conduit was done in 2011 at Colorado State University's hydraulics laboratory (figure 1). The DISA was programmed to collect water-quality samples at four points spaced vertically from a flowing water column of known discharge. For example, if the depth of water to be sampled was 1 foot, the DISA was programmed to take the first sub-sample at 0 percent depth (bottom of pipe), 25 percent depth (0.25 foot above the pipe floor), 50 percent depth (0.50 foot above the pipe floor), and 75 percent depth (0.75 foot above the pipe floor). Although the depth of water varied during laboratory tests, the percentages remained the same. A pre-mixed manufactured sand with particle diameters ranging from 53 to 425 μm was injected at calibrated rates to create known concentrations ranging from 596 to 1,189 mg/L. Calibrated flows rates ranged from 1.4 to 27.8 ft^3/s. Full details of the experimental design can be found in Selbig et al. (2012).

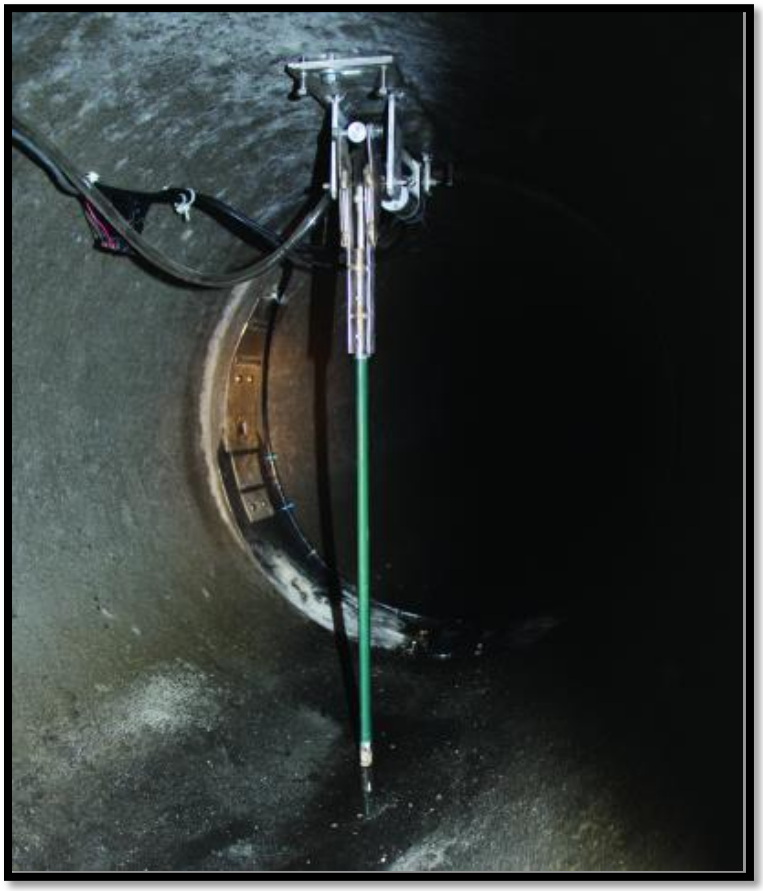

Figure 1 Image of the DISA in a closed conduit (storm sewer) with the sample arm extended in the vertical position. When at rest, the arm lies in the horizontal position near the pipe ceiling with the end of the intake pointing in the direction of flow. The sample arm (identified as green in this photo) can be sized to fit various conduit diameters. Photo by USGS.

In 2013, the DISA was modified and updated for use in open channels. Instead of being mounted to the ceiling of a closed conduit, the updated DISA is fully submersible and is anchored to the channel bed. The updated DISA includes a linear actuator with a variable rate of travel. In other words, when coupled with the static pumping rate of an autosampler, the DISA can move slower in shallow water and faster as the depth increases in order to keep the volume of water captured in each sample container consistent. Any

debris that may have accumulated on the sample arm assembly while acquiring a sample is cleared away by water discharging past as it retracts into the horizontal position

The first field-level evaluation of the DISA was done at Underwood Creek, an urban stream in Milwaukee, Wisconsin. The sampler was installed near the USGS streamgage on Underwood Creek in a section of restored channel that had its concrete lining removed in 2009. The channel was approximately 8 feet wide with a baseflow depth of approximately 2 feet and a streambed that consisted of sand, gravel and cobble. Inspection of the drainage basin revealed several large wet detention ponds intercepting stormwater runoff prior to drainage into the Underwood Creek. The DISA was attached to an aluminum frame that was anchored to the streambed using 0.75-inch steel rod. A fiberglass fairing was fabricated to shield the DISA from any debris as well as prevent the device from becoming buried in silt or organic detritus (figure 2). The sample intake was oriented in the downstream direction and was attached to an autosampler on the bank (figure 2). A second sample line was installed adjacent to the DISA similar to what would be used for a fixed-point intake associated with an autosampler (Edwards and Glysson,1999). The intake of the second sampler was located at a fixed depth of approximately 0.7 foot above the streambed. Each sampler was programmed to take a 1 liter sample for every 0.3 foot increase and 0.5 foot decrease in water level on the rise and recession limb of the hydrograph, respectively. Upon completion of each sub-sample, the DISA would return to a horizontal position near the streambed which cleared away any accumulated debris. Comparison of SSC and PSD were made between samples collected by the DISA and the fixed-point sampler. Additionally, EWI samples were periodically taken coincident with the DISA and fixed-point samples to represent a discharge-weighted concentration of the channel cross section. The coincident sampling was done in July and August, 2013 that included 3 stormwater runoff events where flows ranged from 7 to 817 ft^3/s

RESULTS AND DISCUSSION

Closed Conduits

In the 2011 laboratory experiments for closed conduits, the DISA was shown to improve the accuracy of sediment concentration and distribution by reducing stratification bias inherent in stormwater runoff in urban storm sewers. The results described herein are a digest of a paper previously published in the *Journal of Environmental Monitoring* and have been adapted from Selbig et al. (2012) with permission from The Royal Society of Chemistry.

For each trial flow rate, all four sub-samples collected by the DISA were combined to represent a single, average SSC. The resulting concentration was then compared to the injected concentration for assessment of sampling accuracy. A similar comparison was made for the fixed-point sampler. Although both samplers tend to overestimate SSCs in the water, the DISA had better agreement with injected concentration. Mean and median SSCs measured by the DISA came within 13 and 7 percent of the injected value, respectively, compared to 166 and 96 percent for the fixed-point sampler (table 1). An analysis of paired samples using the Wilcoxon signed-rank test confirmed that fixed-point concentrations were statistically greater than the DISA concentrations at the 5 percent significance level. The summary statistics detailed in table 1 suggest that as more of the water column is captured in a sample, a more accurate representation of the actual concentration will result. Increasing the number of collection points spaced vertically through the water column can also reduce variability through better averaging of the dynamic exchange of solids between stratified zones. The DISA demonstrates reduced variability as indicated by a lower coefficient of variation in table 1.

Table 1 Summary statistics of the percent of actual SSCs measured from the DISA (7 samples with sub-samples at 0, 25, 50, and 75 percent of water depth) and fixed-point (10 samples) samplers. A value of 100 represents perfect equality. A value greater than 100 indicates overestimation. Adapted from Selbig et al. (2012) with permission from The Royal Society of Chemistry.

Statistic	FIXED	DISA
Minimum	37	92
Maximum	795	135
Median	196	107
Mean	266	113
Standard Deviation	238	15
Coefficient of Variation	0.9	0.1

Slight changes in the distribution of particles in a sample could result in modest changes in the overall SSC of a sample. Larger particles would carry more mass resulting in a larger mass concentration. Therefore, larger sediment concentrations measured in the fixed-point samples are likely due to the over-sampling of coarse particles that tend to accumulate near the bottom of the water column. This solids stratification concept was illustrated in one laboratory test after comparing the average concentration, by particle size, between the DISA and fixed-point samplers to the actual, injected value (figure 3). Both DISA and fixed-point particle concentrations showed relatively close agreement to the actual value for particle diameters less than 106 μm; however, differences become greater as particle diameters increase. In this particular laboratory test, the fixed-point sampler overestimated actual concentrations by 33

percent for particles less than 53 μm to 185 percent for particles between 212-300 μm (figure 3). The DISA was better able to represent the full range of particles, limiting the oversampling of particles between 212-300 μm to just 47 percent greater than the actual value (figure 3).

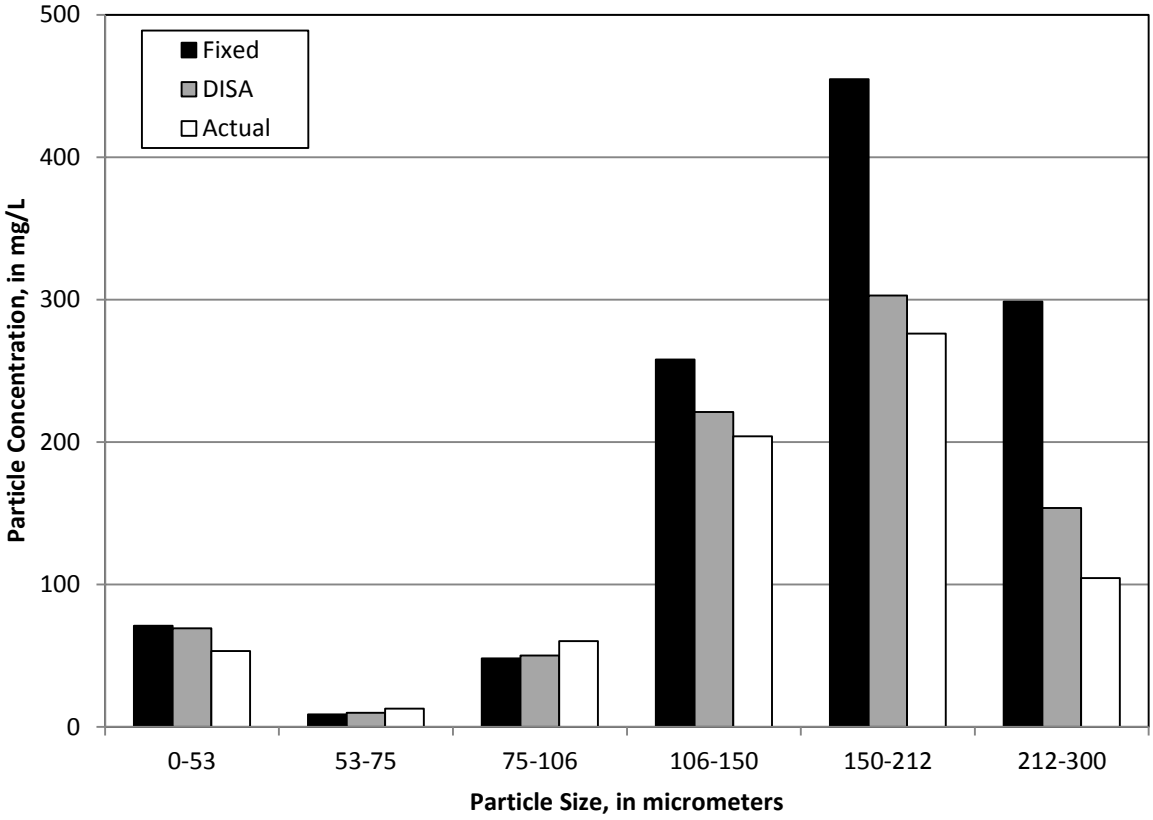

Figure 3 Comparison of the concentration of particles, by size, measured in the DISA and fixed-point samplers to the actual, injected concentration for one laboratory test in a closed conduit, 2011. Reproduced from Selbig et al. (2012) with permission from The Royal Society of Chemistry.

Open Channels

Based on the proven efficiency of the DISA in a closed conduit, it was assumed that when installed in the open channel of Underwood Creek, the DISA would yield a SSC and PSD more representative of the average condition than a fixed-point sampler. Overall, there was close agreement in SSCs between the DISA and fixed-point sampler over a range of flow conditions (figure 4). Examination of SSCs in both DISA and fixed-point datasets revealed a highly skewed distribution. Therefore, the median is a more appropriate representation of the population center than the mean (Ott and Longnecker, 2001). The median difference in SSC between paired samples was 3 percent greater in the DISA than the fixed-point sampler. While this difference is small it is statistically significant. Hypothesis testing by use of the Wilcoxon signed-rank test (Helsel and Hirsch, 1992) showed the DISA to be statistically greater than the fixed-point ($p > 0.05$). This is likely the result of only a few samples where differences in SSC between the two sample collection methods were large.

Of the 32 samples collected, only 6 showed any significant departure from a line of equality. These 6 samples (identified as red in figure 4) were all collected during the same July 21, 2013 storm event near

the peak of the hydrograph. Of the two EWI samples collected during this event, SSCs in the corresponding DISA samples were 79 and 95 percent larger and the fixed-point 43 and 57 percent lower (figure 5). It is unclear why both samplers differed from the concurrent EWI samples or why SSCs in the DISA sampler were much larger than those in the fixed-point while the vast majority of other samples collected during this and other events show close agreement. One explanation could be the proximity of the DISA intake to the channel bed. Since the DISA begins its sample collection approximately 2 inches above the streambed, sediment transporting as bedload could have been collected by the DISA and thus elevate resulting SSCs, especially for this particular event. This zone of sediment transport would have been precluded from both the EWI (minimum of 4 inches above the bed when using a DH-81) and fixed-point samplers (set at 8 inches above the bed). However, if the DISA were, in fact, sampling a portion of bedload, the majority of resulting SSCs should have been larger than those in corresponding fixed-point samples for all sampled events. Another explanation may be a large amount of organic debris found entangled around the fixed-point sampler during the July 21 event (figure 6). This may have resulted in lower SSCs by preventing exposure to the full range of suspended particles in the water column. The DISA, by design, is self-cleaning and therefore did not experience a similar problem. In either case, a simple adjustment to the DISA can prevent future sampling of bedload whereas preventing debris from accumulating on a fixed-point sampler is more challenging. The majority of data (with exception of the 6 samples from the July 21 event) suggest concentrations of sediment in both the DISA and fixed-point samplers were similar in an open channel setting, but generally greater than those measured by the EWI samples (figures 4 and 5).

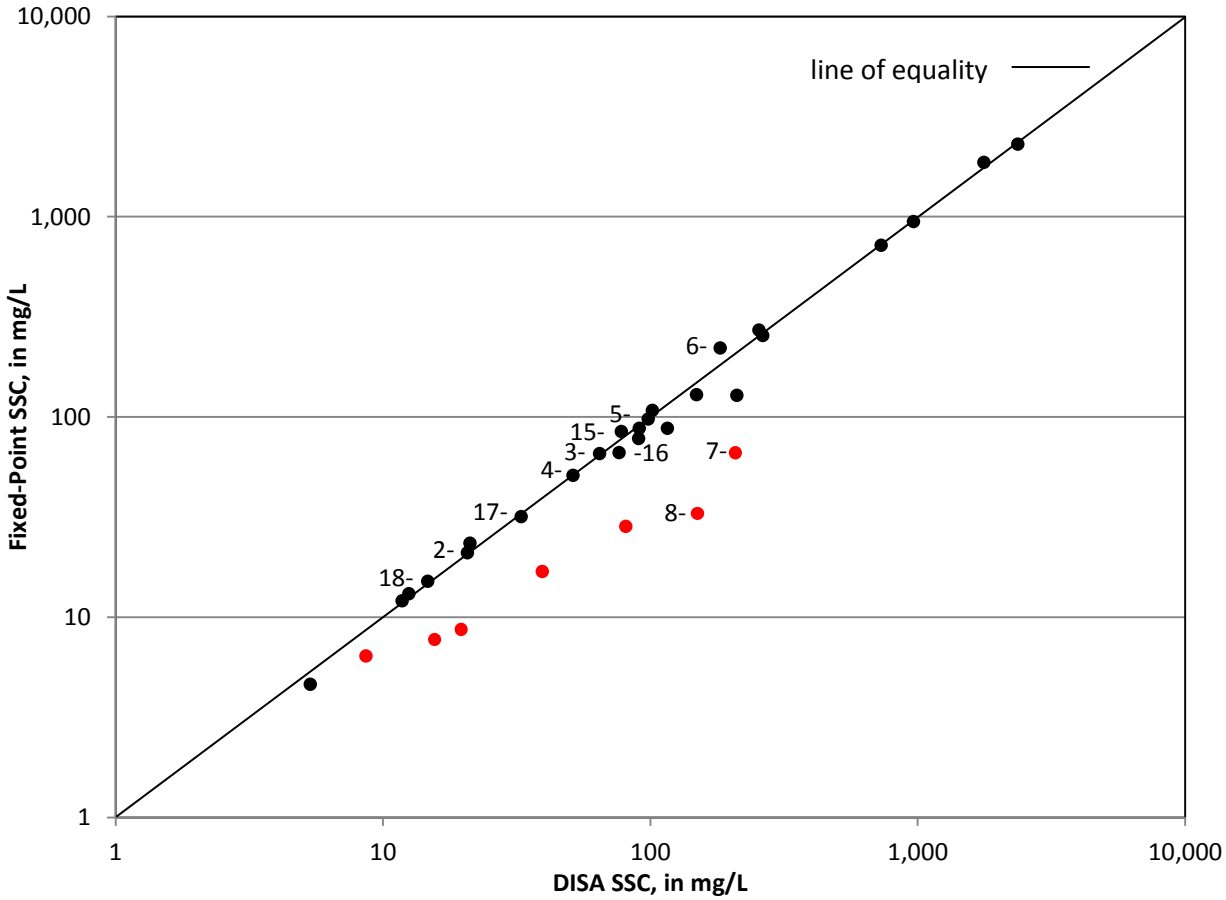

Figure 4 Concentration of suspended sediment in paired samples using the DISA and fixed-point collection methods. Red dots represent samples with the greatest departure from the line of equality, all of

which were collected during a single storm event. Labels refer to the corresponding EWI sample number detailed in figure 5.

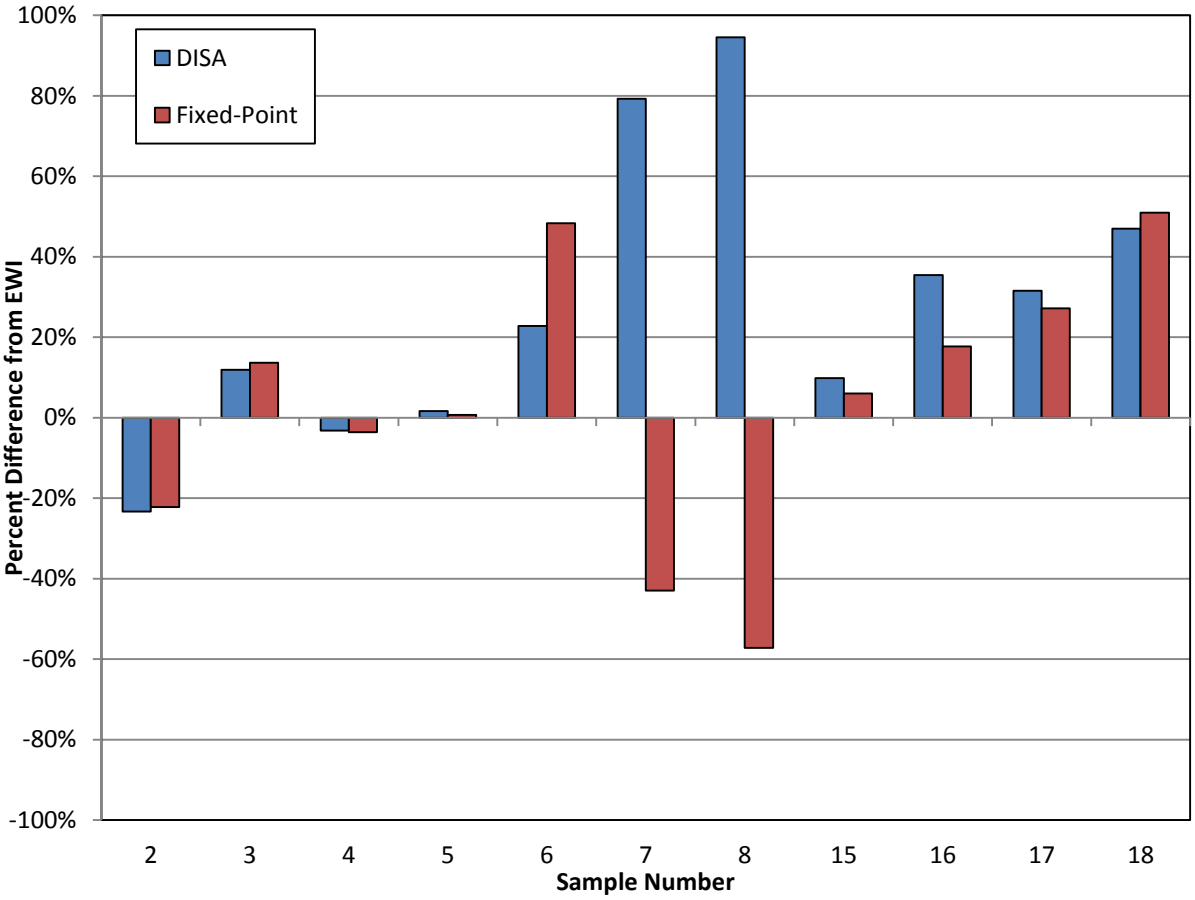

Figure 5 Percent difference in suspended sediment concentration measured in the DISA and fixed-point samplers to those measured in the EWI sampler.

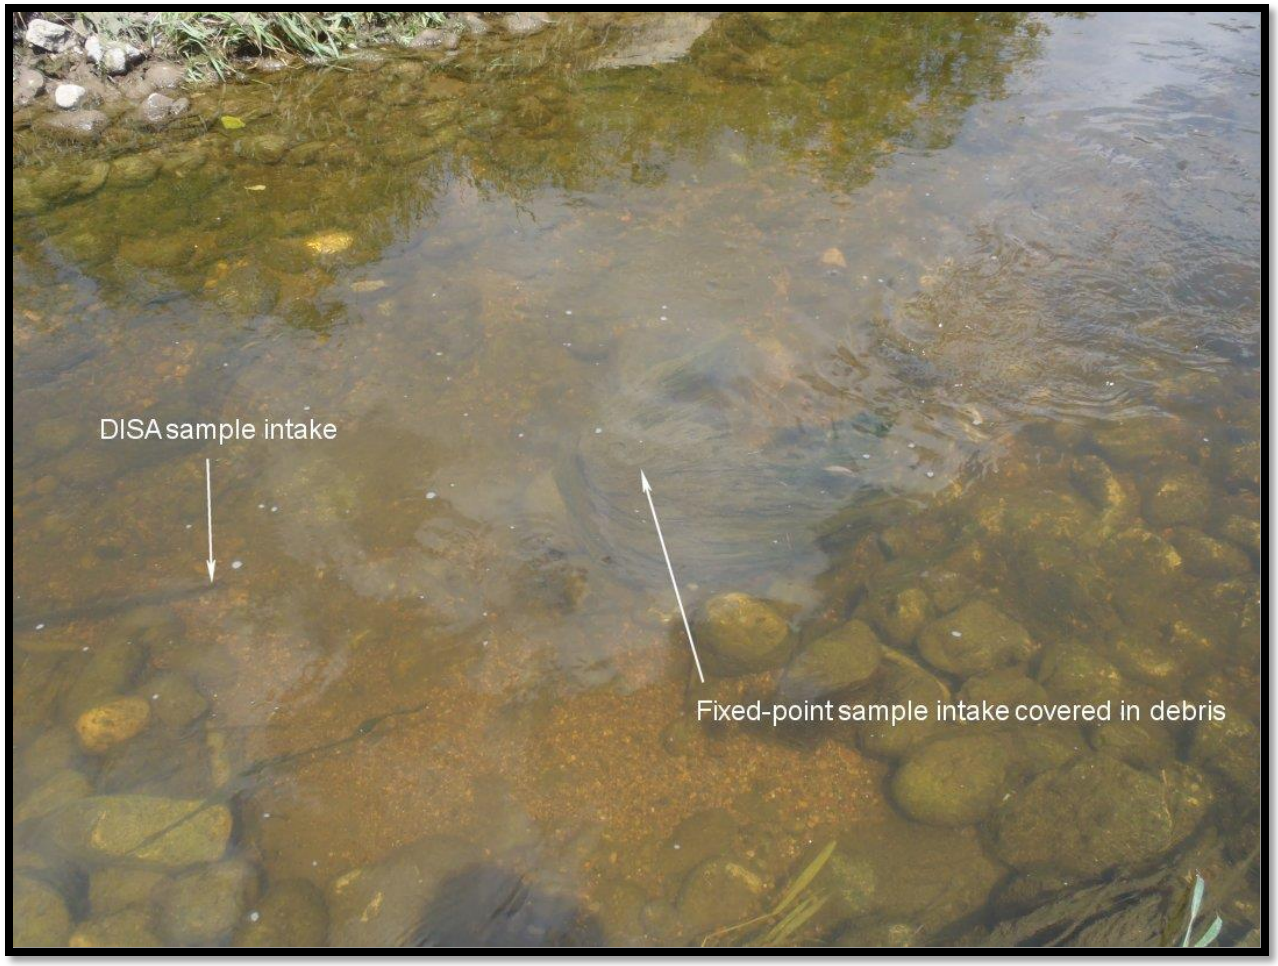

Figure 6 A large amount of organic debris covering the fixed-point sampler may have caused resulting SSCs to be much lower than corresponding DISA samples. Photo by USGS.

The DISA is designed to collect a vertical composite of the entire water column, rather than a single, fixed point thereby reducing any stratification bias caused by the presence of sand (>63 μm). A larger fraction of sand moving through a water column would likely increase heterogeneity which could increase the variability of resulting concentration data dependent on where a sample was acquired. If the water column were well mixed, differences between the DISA and fixed-point sampler would be minimal, as was the case in this study. Inspection of the PSD in DISA, fixed-point, and EWI samples showed median particle diameters (d_{50}) to be primarily that of clay and silt (<63 μm) (figure 7). Smaller particles are more easily mixed throughout the water column rendering placement of the sampler intake of less importance. Figure 7 also illustrates a general departure from equality between the d_{50} measured by the fixed-point and DISA samplers. Both sampler types show similar median particle diameters up to approximately 40μm at which point the d_{50} in the fixed-point and EWI samplers tend to remain the same while the DISA continues to increase. It is unclear whether this pattern would continue with increasing particle diameters. Additional testing in a controlled laboratory setting would help test the DISA's ability to accurately sample a wide range of particle concentrations and distributions.

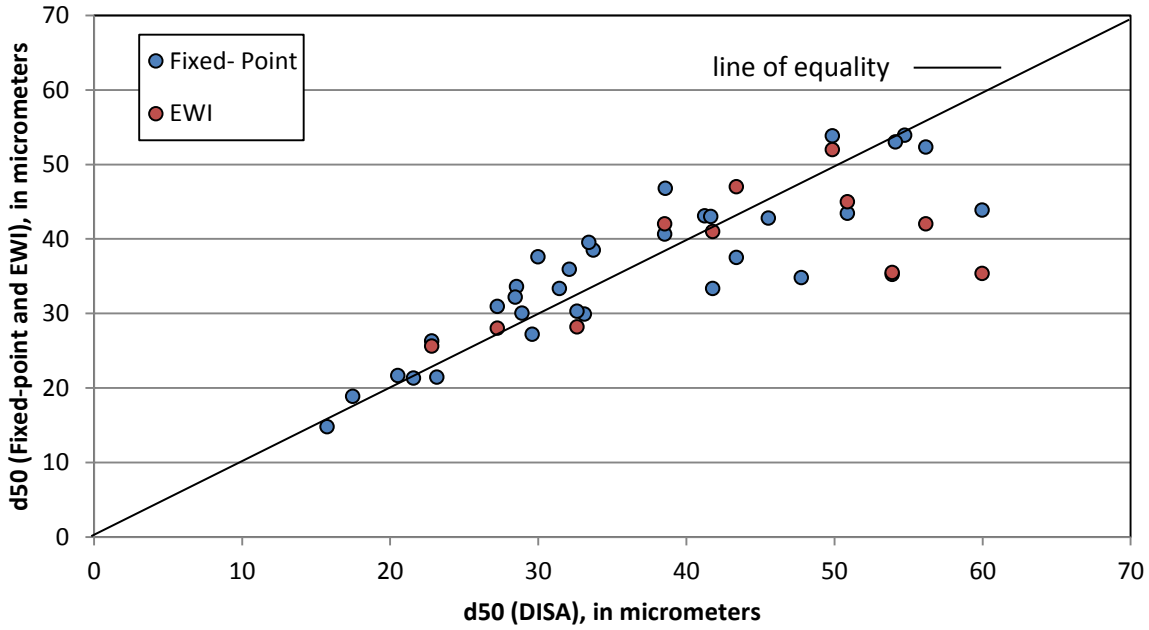

Figure 7 Median particle diameters in paired samples collected by the DISA, fixed-point and EWI samplers.

CONCLUSION

Stratification of particles in a flowing water column can be a source of bias and variability in sediment concentrations and distributions. In closed conduits, such as storm sewers, use of the DISA has shown that integrating samples from the entire water column, rather than from a single, fixed point, can result in a more accurate representation of sediment concentration and distribution, especially as the stratification of solids becomes more apparent with an increased presence of sand. When tested in an open channel, the DISA showed no marked improvement to the accuracy of sediment concentration or distribution compared to fixed-point and EWI sample collection methods. The small amount of sand measured in the water column at the open channel field site rendered placement of the sample intake of less importance. Differences between the median particle size and SSCs measured between the two sampler configurations could potentially be much greater in a fluvial setting with coarser sediment transport. An assessment of channel characteristics prior to sample collection can help determine if water-quality concentration data could benefit from the DISA sample collection method.

The DISA can improve water-quality datasets by reducing bias and variability in concentration and distribution of solids caused by stratification. In turn, environmental managers have greater confidence as they develop plans and policies to improve the quality of our Nation's waters.

INTRODUCTION

Answers for many critical water-related issues require solid-phase water-quality data that are representative, accurate, and consistent. Collection of suspended sediment samples for subsequent analyses of solid-phase constituents that represent water-column sediment concentrations requires use of appropriate isokinetic samplers and sampling techniques (Davis, 2005a). Recent review of field and laboratory data indicates that the Federal Interagency Sedimentation Project (FISP) collapsible bag-type sediment samplers may not function isokinetically under certain low velocity and/or low temperature conditions. Updated guidance and operational limits for FISP bag-type samplers were issued in FISP Memorandum 2013.01 (2013). This paper describes new information and guidance for operation of FISP bag-type samplers and ongoing efforts to further characterize the factors that influence bag-type sampler efficiency.

Suspended sediment concentration (SSC) and sediment-associated water-quality constituent concentrations can be highly variable in stream cross sections, particularly when sand-size particles ($\geq$ 0.0625 millimeters (mm)) are suspended in appreciable quantities. Consequently, samples representative of the flow throughout the cross section must be collected using depth- and width-integrated methods and isokinetic samplers (Edwards and Glysson, 1999; Nolan et al., 2005; Gray et al., 2008). Isokinetic sampling means that water enters the nozzle of a sampler without accelerating or decelerating relative to streamflow velocity (ambient velocity) at the locus of the sampler nozzle opening. The measure of isokinetic sampling is the intake efficiency (IE), which is defined as the ratio of the velocity through the nozzle entrance (Vn) to the ambient stream velocity (V); IE = Vn/V, where Vn and V are averaged over the sample collection time and depth for each specific sample. Before a bag sampler is released for field use, the IE is confirmed to be within $0.9<IE<1.1$ at velocities of 3–4 feet per second (ft/s) at laboratory water temperature by flume tests conducted at the U.S. Geological Survey Hydrologic Instrumentation Facility (HIF), Stennis Space Center, Mississippi.

The importance of isokinetic sampler function on sampled SSC is illustrated in Figure 1 (Gray et al., 2008). The study on SSC bias with IE was performed in early FISP research using empirical methods and reported in FISP Report No. 5 (1941). These early FISP findings have been validated in preliminary results from new FISP-sponsored research in 2014-15 using computational fluid dynamic modeling. If flow decelerates as it enters the nozzle (IE < 1, sub-isokinetic), the sample SSC will tend to be biased high; conversely, if flow accelerates as it enters the nozzle, and the sample SSC will be biased low. The bias in SSC for the coarsest grade of sand (0.45mm) shown in Figure 1 is approximately +10% for IE=0.75, at a velocity of 5 ft/s. For a theoretical suspended-sediment sample made up of 25% of each of the size classes shown

in Figure 1 (0.01mm, 0.06mm, 0.15mm, 0.45mm) collected in a stream velocity of 5 ft/s, the overall bias for an IE 0.80, 0.75, and 0.50 is 3.5%, 4.9%, and 13.1%, respectively. The errors associated with SSC measurements due to measurement plus analytical error sources vary with concentration and grain-size distribution as well as site conditions at the time of sample collection. However, based on replicate samples, at concentrations above 20 milligrams per liter, differences of +/- 10% are common (Horowitz 2008, Edwards and Glysson, 1999). Although bias error due to non-isokinetic sampling conditions should always be considered and minimized, overall bias errors of less than 5% are much less than the typical SSC uncertainty. Under some field and deployment conditions it may not be possible to collect a sample with 0.75<IE<1.25; in which case it is particularly important to document the IE so that potential bias in sand SSCs can be considered by users of the reported data. For particles finer than sand size (≥ 0.0625 mm) the bias is less than 10%, even at extreme non-isokinetic conditions (see purple– and blue–dashed lines in figure 1). Thus, it is acceptable to sample under non-isokinetic conditions if the sand percentage of SSC has been shown to be negligible in prior analyses of samples collected at that site under similar conditions. In any case, Vn and V should be recorded and the IE calculated with each environmental sampling effort.

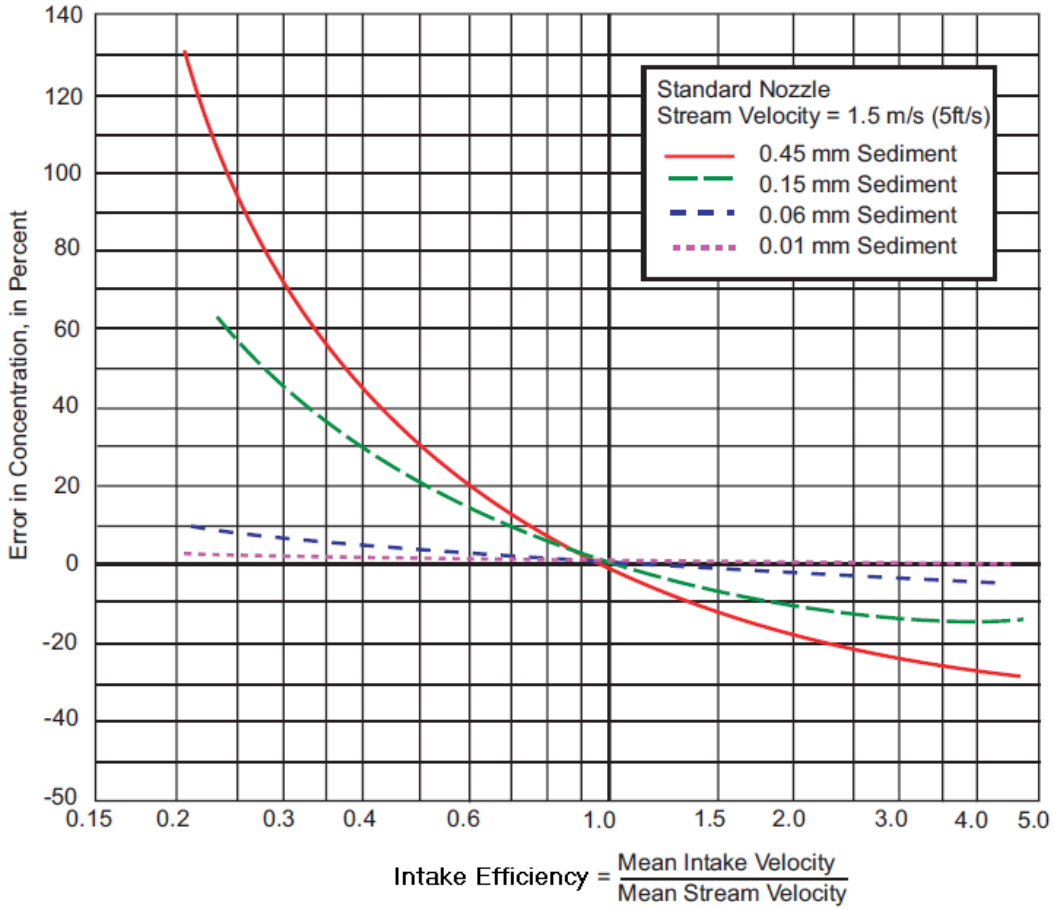

Figure 1 Errors in SSC under variable non-isokinetic sampling conditions for four sediment sizes (0.01mm, 0.06mm, 0.15mm, 0.45mm). Mean velocity of flow in the flume of 5 ft/s was maintained during data collection. Figure from Gray et al. (2008), based on data from FISP Report No. 5 (1941).

Factors that affect the IE of isokinetic samplers include sampler type and nozzle size, ambient stream velocity, water temperature, sampler orientation relative to the flow, and the volume of water collected relative to that of the sample container. IE in bag-type samplers tends to decrease rapidly as stream velocities decrease from about 4 to 2 ft/s, depending on the type of sampler, nozzle size, and stream temperature (Davis, 2001; McGregor 2006; Sabol and Topping, 2013). Because bag-type samplers require ambient velocity in order to fill, the effects of all other IE-related factors tend to increase as velocities approach the minimum recommended operating velocities. Substantial concentrations of sand are not typically in suspension for velocities less than the minimum operational limits of bag-type samplers, and this may mitigate the influence of non-isokinetic sampling on the accuracy of SSCs and sediment-associated water-quality constituent concentrations. Sample volumes should never exceed maximum sample container capacities or IE will decline very rapidly as described by Szalona (1982). Sampling up to full bag capacity did not affect IE in tests conducted in extensive laboratory tests at warm temperatures and in limited field tests in larger rivers (Davis, 2001).

RECENT STUDIES

Recent field studies have indicated problems with intake efficiencies of the US D-96 bag-type sampler. Sabol and Topping (2013) conducted an extensive study of sampling efficiencies of the US D-96 and US D-77 bag-type samplers in the Colorado River within Grand Canyon National Park. The US D-77 bag-type sampler was removed from the list of recommended samplers in 2002 (USGS OWQ Technical Memorandum 2002.09); however the US D-77 bag-type sampler results of Sabol and Topping (2013) are useful in evaluating historical sample data. Selected primary findings of Sabol and Topping (2013, page 64) are:

- Although both the US D-77 and US D-96 bag-type samplers have been proven to sample isokinetically in flumes, typically both sampled sub-isokinetically in field tests on the Colorado River.
- The US D-96 sampler performed closer to isokinetic conditions than the US D-77 bag-type sampler.
- Water temperatures in the field test environment are colder than in FISP laboratory test environment, and affect the sub-isokinetic performance of the samplers; but this is not the dominant effect.
- Intake efficiencies of the US D-77 and US D-96 bag-type samplers are time dependent. IEs decrease over time as sampling duration (and thus sample volume) increases. Intake efficiencies of rigid-container samplers in this environment were found to be constant with time, when recommended procedures were used.
- Analyses of paired, concurrent samples collected in the Colorado River using the US D-96 sampler and two rigid-container samples (tested to be isokinetic) indicate that the US D-96 samples have a positive bias error of +5 to +6 percent in the concentration of particles $\geq$ 0.0625mm, and this observed bias error is consistent with the observed sub-efficiency of the sampler according to the results from FISP Report No. 5 results shown in Figure 1.

Sabol and Topping (2013) hypothesized that the "most likely physical mechanism responsible for the large time-dependent decreases in intake efficiency observed in the Colorado River tests of both the US D-77 bag-type and US D-96-type samplers is the improper venting of the rear of the sampler cavity." They experimented with increasing the sampler venting by modifying the sampler tray from the standard FISP tray length (16.75 inches (in) long) to a shorter tray length (15.5 in long) and found slight but significant improvements in the US D-96 IE when the shorter tray length was used. In late-February 2013, the FISP tested the standard and shortened trays on a new US D-96 sampler and on a US D-96-A1 sampler that had been used in the field study of Sabol and Topping. The D-96-A1 is dimensionally identical to, but weighs 52 pounds less than, the D-96. The tests were conducted in a 6-foot (ft.) wide by 3-ft. deep, 250-ft. long tilting flume at a stream velocity of 3.31 ft/s (+/- 2%) and water temperatures of 20-22 °C (68-72 °F) at the USGS HIF hydraulics laboratory. A 3-liter (L) sample bag was used in the field and lab studies. While the FISP lab study indicates decreasing IE with increasing sample duration and volume, the IE is within the range of 0.9 to 1.15 for the 5/16 and ¼ in. nozzle sizes; and within 0.85 to 1.0 for the 3/16 in. nozzle size (Figure 2). Comparing the shortened versus the standard tray length, there was no notable difference for the 5/16 in. and ¼ in. nozzle sizes and slight improvement was noted with the shorter tray for the 3/16 in. nozzle (Figure 2). Moreover, the 2013 FISP test results agreed very closely with those from the FISP US D-96 sampler development data (Davis, 2001). Thus, the results of Sabol and Topping (2013) appear to be associated with field conditions that are not being replicated in the laboratory flume environment and may or may not be due to sample cavity venting in those conditions.

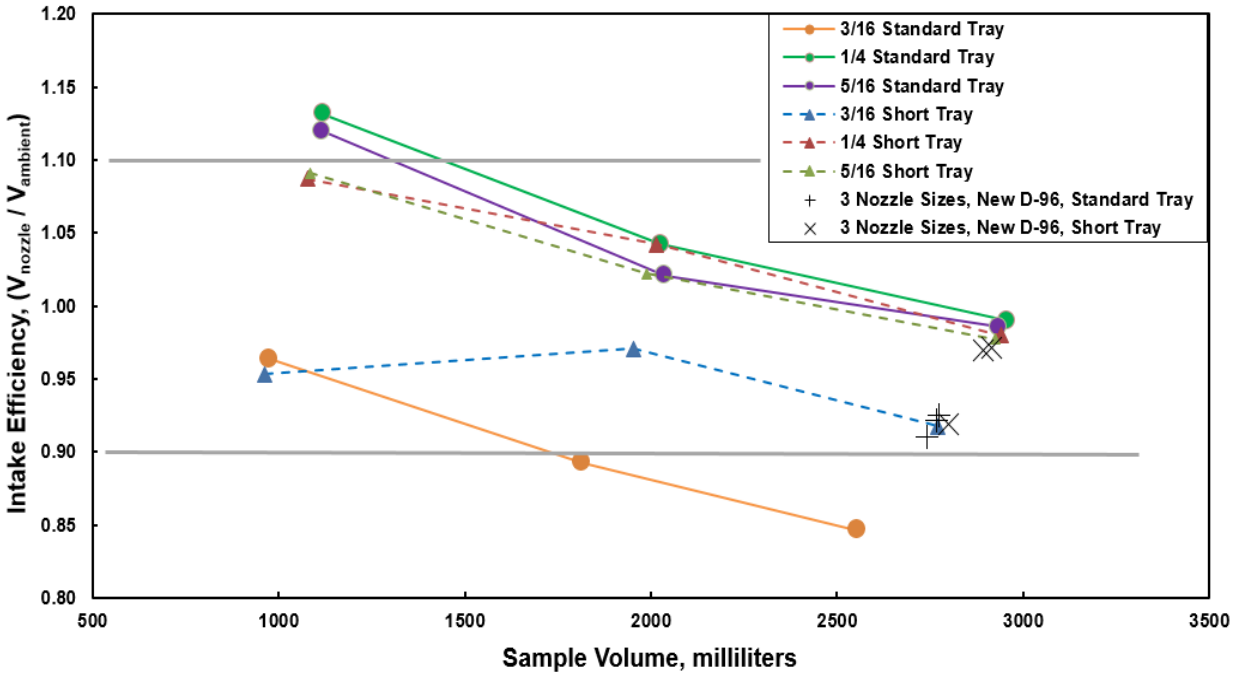

Figure 2 Intake efficiency results for US D-96 bag-type sampler conducted during February, 2013 in the tilting flume located at the USGS Hydrologic Instrumentation Facility. Tests run using standard FISP tray (16.75 in. long) and shortened tray (15.5 in. long) and available nozzle sizes (in inch fractions). For all tests the water velocity is 3.31 ft/s and the temperature is 20-22 C. Each point represents an mean of 5 to 10 measurements.

Additional field studies are being conducted to evaluate the IE of FISP bag-type samplers. An extensive study of depth-integrated sampling methods was conducted by the USGS Mississippi Water Science Center (Heather Welch, Mike Manning, and Claire Rose, personal communication). Over 240 samples, including replicates for each sampling vertical, were collected on the Mississippi River at Vicksburg, MS during 8 field trips from April 2013 to August 2013, at water temperatures ranging from 13 to 28 ^{o}C (55 to 82 ^{o}F). Velocity was measured concurrently with sample collection using an acoustic Doppler current profiler along with high-accuracy marine GPS technology to control boat movement during sampling. Velocities during normal flows in the sampled reach of the Mississippi River can surge by 1-2 ft/s within a range of 3-9 ft/s over the duration of a sample. The ADCP velocity data, concurrent with each sample, were extensively examined to obtain as accurate a concurrent sample velocity as possible. Both ¼ and 3/16 in. nozzle sizes were used. The mean IE from this data set of 240 samples was 0.81 with a standard deviation of 0.12 and IE was not significantly correlated with sample duration or volume, nozzle size, nor with stream velocity.

Field studies were conducted by the USGS, Arizona Water Science Center (Jessica Anderson and Corey Sannes, personal communication) in Water Year 2014 using US D-96-A1 (3 liter bag), and DH-2 (1 liter bag) samplers on the Colorado River at Lees Ferry, AZ. This study evaluated methods to increase the accuracy of the IE test results by limiting possible errors introduced in the field measurements. A Price-AA meter was mounted atop a D-96A1 sampler and velocity was measured concurrently with an ADCP mounted on a boat next to the sampler for the duration that the sampler was under the water surface. Two of the questions posed in the study design were: (1) Does the method by which the velocity is measured affect the intake efficiency results? and (2) Is there a directional bias either by the meter or the sampler when performing a depth-integrated sample? Tests conducted with the US D-96A1 sampler transiting through the vertical (depth-integrated samples) resulted in a mean IE of 0.70 for nine tests using a Price-AA meter; and a mean IE of 0.63 for thirty-two tests performed using an ADCP to measure velocity. Tests conducted holding the sampler at fixed locations at 2- and 10-foot depths with a ¼ in. nozzle resulted in a mean IE of 0.69 for nineteen tests using a Price-AA meter and an IE of 0.78 for nineteen tests using an ADCP to measure velocity. Tests conducted holding the D-96-A1 sampler at fixed locations at 2- and 10-foot depths with a 5/16 in. nozzle resulted in a mean IE of 0.62 for nine tests using a Price-AA meter and an IE of 0.69 for eleven tests using an ADCP to measure velocity. Velocities measured using the Price-AA (presumed to be more representative of ambient velocity at the locus of the sample nozzle) resulted in lower IE values for these tests; but sample durations did not have a significant effect on the IE results. The DH-2 had a mean IE of 0.89 with a 3/16 in. nozzle and a mean IE of 0.88 with a 1/4 in. nozzle. From all of the tests performed at this site, it was determined that the major variables that seem to affect the IE results in the field are the sampler type and nozzle size. More data needs to be collected with both samplers and with each nozzle size to determine if there is directional bias.

IE is determined, in the field or the laboratory, from measurements of ambient stream velocity (ideally at the locus of the sampler nozzle) and nozzle velocity determined from known nozzle intake area and measured sample volume and duration of sample collection. Any component measurement errors translate directly to errors in the computed IE. In the laboratory these factors

are measured with high accuracy. In field studies, the greatest source of measurement error typically is the stream velocity; and this can be more difficult when measuring from a boat. However, velocity measurement errors are not the likely cause of indicated IE in these field studies because they used detailed and careful evaluation of the velocity measurements and other measured factors. It is also noteworthy that field testing in large rivers and towed-sampler IE tests conducted during development FISP bag-type samplers do not indicate sub-isokinetic performance. The reaches of the Colorado River sampled in the above sited studies are much steeper than those in the large river test areas and in the Mississippi River, resulting in greater shear stress, turbulence, and velocity gradients. These are the likely environmental conditions, in addition to colder temperatures, that result in the sub-isokinetic performance of the bag-type samplers tested, as stated by Sabol and Topping (2013). The sub-isokinetic performance in the above noted studies appear to be due to conditions that do not occur in laboratory testing nor in all riverine conditions.

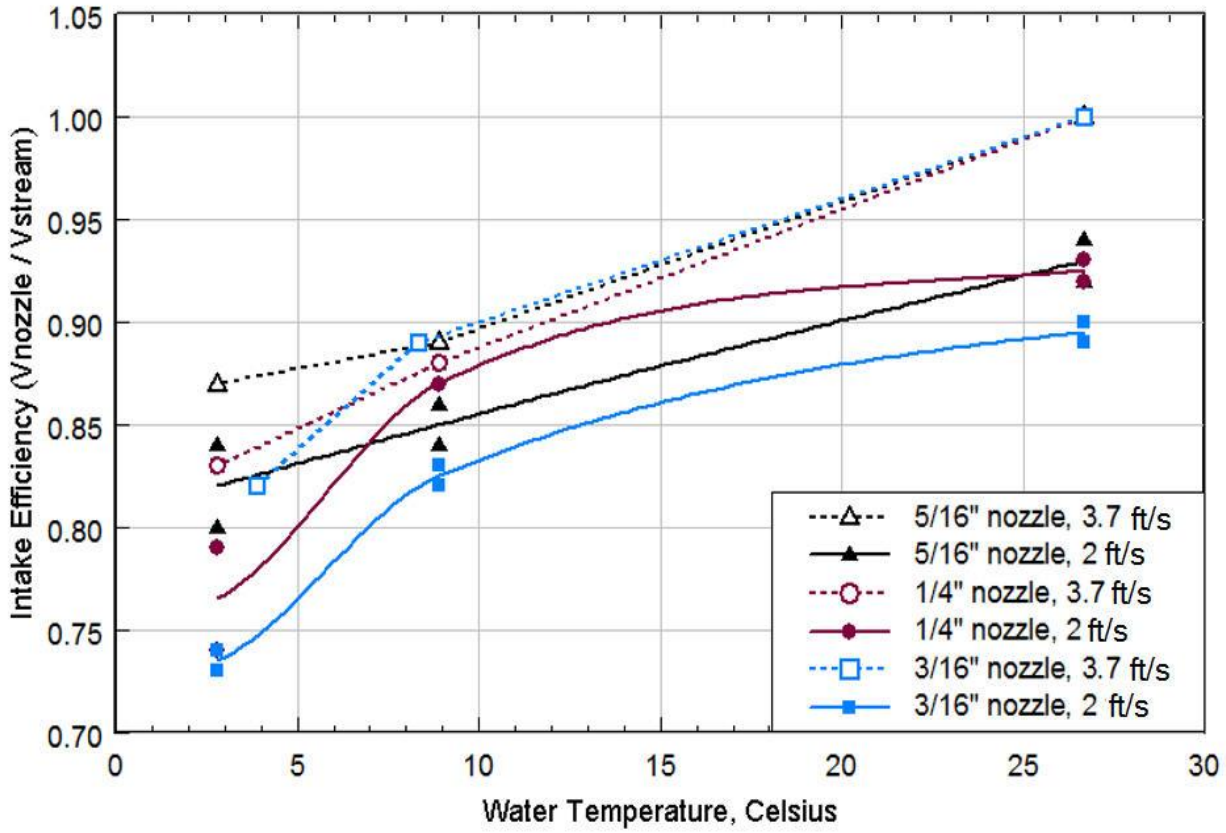

Figure 3 Changes in IE (intake efficiency) with temperature and fitted curves for the FISP US D-96 bag-type sampler at three water temperatures, and nozzle sizes, and two velocities, from data in Davis, 2001.

TEMPERATURE EFFECTS

Decreasing stream temperatures tend to cause decreasing sampler IEs because friction losses increase through the sampler nozzle as fluid viscosity increases. This effect becomes more

pronounced at lower velocities as shown in Figure 3 (from data in Davis, 2001). Tests of FISP samplers are typically conducted at water temperatures between about 24ºC–29ºC (75º–85ºF), in the warmer range of most field sampling conditions. Cold–water tests indicate that the US D-96 functions sub-isokinetically (IE < 0.9) at temperatures less than about 10ºC (50°F) at velocities less than about 3.7 ft/s for all nozzle sizes (Davis, 2001). A theoretical and empirical evaluation of temperature effects also was conducted by Sabol and Topping (2013) for US D-96 bag-type samplers in the Colorado River in Arizona. These data and subsequent review of FISP bag-sampler calibration data prompted revision by FISP of previous temperature-indexed minimum operational velocity limits; the revised limits are shown in Table 1.

RECOMMENDATIONS AND SUMMARY

FISP Memorandum 2013.01 (2013) supplements the FISP reports and operation manuals for the FISP US-series DH-2, D-96, D-96A1, and D-99 bag-type samplers (Davis 2001 and 2005a and b; McGregor, 2006) with the following recommendations to users of FISP bag-type samplers:

- Obtain quality-assurance field measurements of IE before each set of samples is collected during site visits using care to measure the stream velocity at the sample location as concurrently as possible.
- Incorporate the revised, temperature-indexed minimum stream velocities (Table 1) for bag-type samplers into data-collection practices where possible.
- If measured IE clearly indicates sub-isokinetic performance, evaluate potential bias in reported concentrations, based on percent of sand-sized material (≥ 0.0625 mm) in the sample using the chart in Figure 1 and evaluate the significance of this bias to the overall sample concentration accuracy and the purpose of the sampling effort.

The memorandum gives step-by-step instructions for field measurement and computation of IE, and provides a spreadsheet template to facilitate the computations for user-specified nozzle sizes. Revised minimum operational velocities for FISP bag-type samplers where sand-size (≥0.0625 mm) material may be in suspension are shown in Table 1. The new minimum velocity guidance is indexed to water temperature for specific nozzle sizes. The minimum-velocity requirement remains unchanged for temperatures greater than 27ºC (80°F) for all nozzle sizes, and for temperatures greater than 10ºC (50°F) for ¼- and 5/16-in. nozzle sizes. Field tests of IE are particularly important when sampling near these operational limits. Recent studies have demonstrated that the samplers do not operate isokinetically in some riverine environments, even within these limits.

In summary, recent, detailed studies have found that the FISP US D-96 and D-96A1 bag-type samplers operates sub-isokinetically (IE<0.9) in some field conditions. FISP test results in a laboratory tilting flume have not replicated these field results; and have confirmed the original results from sampler development and sampler operational guidance. Moreover, field IE testing does not uniformly indicate sub-isokinetic sampler performance. Colder water temperatures are a known cause of lower IE and revised, temperature-indexed minimum velocity guidance has been issued by the FISP in view of this effect. Colder water temperatures cannot, however, explain the magnitude of observed sub-isokinetic performance in the some of the recent studies; and the actual contributing causes and their relative influence on low IE remains uncertain. It is likely

that the effects of turbulence (at different scales) and transit through relatively high velocity gradients are important factors, as stated by Sabol and Topping (2013). FISP now recommends field IE measurements during each sampling effort and recording of this quality-assurance data with sample analytical data. If any non-isokinetic sample performance is documented, then the potential concentration bias should be evaluated based on the results of FISP Report No. 5 (1941) summarized in Figure 1. While it is essential to recognize and evaluate any source of potential bias in sample results; the bias effect should not be overstated. The significance of any IE-caused bias should be evaluated based on particle size distribution of the sediment, the significance of the bias to specific particle size classes, the overall accuracy of the analyzed sample concentration, and the accuracy needed to address the purposes of the sampling effort.

						1/4	120	3.7	3	3
						5/16	78	3.7	3	3

[1]The maximum recommended velocity for bag-type sampler deployment is based on maximum drift angle of the suspension cable (25–30 degrees). Actual maximum velocity should be determined based on this maximum drift angle and field safety considerations.

[2] The 3/16 in. nozzle is more sensitive to velocity and temperature effects and should only be used when necessary to sample maximum depths.

[3] The maximum theoretical depth is based on a maximum transit rate of 0.4 times the mean flow velocity in the sampled vertical and the sample bag capacity (6 L for the US D-99 sampler).

[4]Test results are not available for temperatures <10ºC (50°F). In colder water it is particularly important to test and record intake efficiency with each sample data set.

CONVECTIVE ACCELERATION EFFECTS FROM TRANSVERSE IN-STREAM STRUCTURE INSTALLATIONS

S. Michael Scurlock, Ph.D, Post-Doctoral Fellow, Colorado State University, Fort Collins, Colorado, scurlock@engr.colostate.edu; Christopher I. Thornton, Ph.D; Associate Professor, Director Engineering Research Center, Colorado State University, thornton@engr.colostate.edu; Steven R. Abt, Ph.D; Senior Research Scientist/Scholar, Colorado State University, sabt@engr.colostate.edu; Drew C. Baird, Ph.D, Hydraulic Engineer, United States Bureau of Reclamation, dbaird@usbr.gov

Abstract: Transverse instream structures are rapidly gaining popularity in stream restoration and bank stability applications, yet are implemented with an incomplete knowledge of induced structure hydraulics. Transverse structures extend laterally from the channel bank into the flow field, serving to redirect conveyance away from the outer bank of the channel for navigation and erosion objectives. Three types of instream structures, the spur dike, vane, and bendway weir, were constructed and evaluated within a physical model representation of a natural channel. High-resolution mean-flow and turbulent velocity data were collected from similar planimetric structure configurations with a focus upon convective acceleration and turbulence at the structure tips. The zone of influence at the structure tip is critical for design considerations due to implications for sediment mobility and structural integrity. This research presents specifics of flow effects at the tips of the three structure classifications, provides comparisons between structure types, and gives implications for design procedures and sediment mobility.

INTRODUCTION

An emphasis on alternative methods for bank stabilization and river restoration in meandering systems has gained momentum in recent years. Transverse in-stream structures have been utilized in channel bend stabilization projects as a means of diverting erosive forces away from the outer bank of a migrating river. Bendway weirs, spur dikes, and bank-attached vanes are specific types of in-stream structures, identical planimetrically, yet different in their cross-sectional geometries and intended hydraulic effects. Planimetric and cross-section schematics of in-stream structures are provided in Figure 1, detailing differences between structure classifications in the cross-sectional view. In a general hydraulic sense, bendway weirs redirect flows over the top of the crests, spur dikes shift flows around the structure tip, and bank-attached vanes combine both crest overtopping and redirection around the tip to the channel center. Typical geometric parameters of interest for instream-structure design are the structure width, W, length, L, spacing, S, elevation difference between the water-surface elevation and structure crest elevation, Δz, planform angle, θ, and crest-slope angle, φ. Guidelines for the construction and installation of instream structures in channel bends as functions of the geometric parameters exist, yet are largely anecdotal.

Bendway weirs were initially developed by the U.S. Army Corps of Engineers to improve navigation in bends of the Mississippi River (Derrick et al., 1994). Structures are typically placed in series along the outside of a channel bend, are angled upstream, and have a submerged crest elevation at design flow. Flows encountering the crest are redirected to the channel center over the structure axis. Three primary sources for documentation and interpretation of bendway-

weir design and construction guidance were identified as McCullah and Gray (2005), Lagasse et al. (2009), and Julien and Duncan (2003). Currently, design guidelines for bendway-weir configurations are anecdotal, and have largely been developed on the basis of expert judgment (Rhoads, 2003).

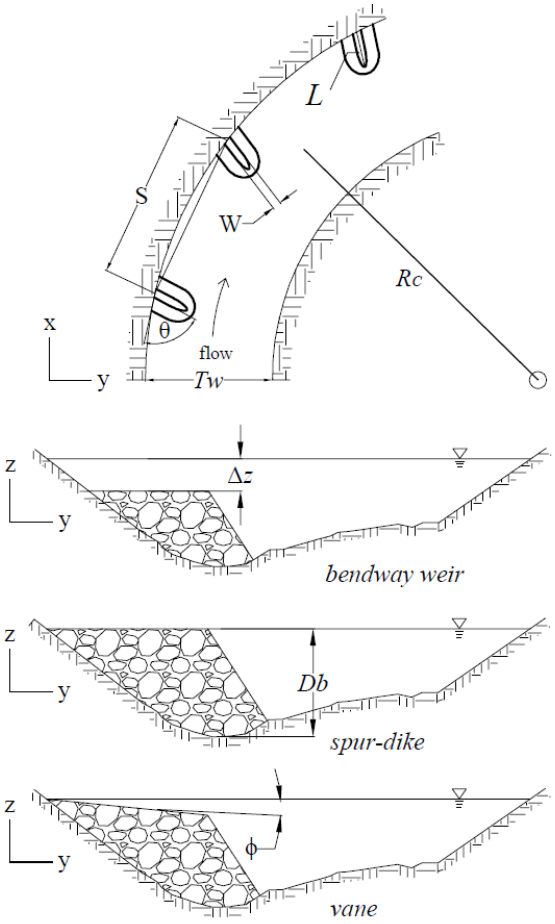

Figure 1 Instream structure geometric parameter definitions

Spur dikes, also referred to as groynes or jetties, extend from the outer bank to the channel center. They are placed in series throughout a channel bend, and are set either perpendicular or angled to the stream flow direction. In contrast to bendway weirs, spur-dike crest elevations are constructed at the design water-surface elevation and no conveyance is meant to overtop the structure crest. Spur-dike hydraulics encourage sedimentation within the structure grouping, or field, and provide outer-bank erosion protection (Radspinner et al., 2010). Current design guidelines for spur dikes are summarized by the Federal Highway Admninistration publications of Brown (1985) and Lagasse et al. (2009).

Bank-attached vanes, also known as barbs, represent a hybrid between the bendway weir and spur dike. Sturctures are constructed with a crest elevation at the design discharge water-surface elevation at the outer bank and extend into the channel at a downward angle. Vanes allow an increasing level of flow to pass over the structure crest moving into the channel center. Similar to the other transverse in-stream structure types, vanes are constructed in series and set either

perpendicular or angled upstream to the flow direction. Unique publications of geometric design criteria, including summarizations from Rosgen (2001), McCullah and Gray (2005), Brown and Johnson (1999), and others, are found in NRCS (2005), Johnson et al. (2001), and Maryland (2000).

Transverse instream structures are designed to deflect outer-bank conveyance to the channel-center, increase flow resistance near the base of the outer bank, and inhibit helical motion and redistribution of momentum near the outer bank (Derrick, 1997). Field data from studies such as Scott et al. (2011), Rhoads (2003), Smith and Wittler (1998), and Wardman and Papanicolaou (2006) for bendway weirs, and Dahle (2009) for vanes, have confirmed that transverse instream-structure configurations are typically effective at redirecting bulk channel conveyance to the central channel. Investigations into specific flow patterns associated with single structures and configuration fields have been conducted utilizing physical and numerical modeling. Hydraulics associated with transverse instream structures have been reported as three-dimensional and complex, yet the literature indicates specific and recurring trends of flow behavior across independent sources.

Abad et al. (2008) coupled surveyed field data with a three-dimensional numerical model to emulate flow characteristics at various flow depths around a bendway-weir configuration installed in an Illinois meander bend. Key insights from the study included areas of convective acceleration and high boundary shear-stress at the tips of the structures, increased velocity and shear stress over the crest of the structure at the bankline, and locally increased bed shear downstream of the crest due to plunging flows. At the lowest flow evaluated in the study, the modeled bendway weirs did not experience overtopping flows, therefore behaving as spur dikes. Acceleration and increased boundary shear stress at the structure tips, over the structure crest at the bankline, and at the overtopping jet and bed interface were noted.

Jia et al. (2002, 2005, 2011) investigated the efficacy of bendway weirs to disrupt the helical secondary current in channel bends and documented flow patterns using numerical and physical modeling on a single structure angled 70º upstream. Acceleration of the flow velocity over the weir crest and around the structure tip, and a recirculation zone directly behind the structure were reported.

McCoy et al. (2007) detailed numerical modeling results of flow encountering submerged, bendway-weir like structures angled perpendicular to the approaching flow. Evaluated structures had abrupt, blunt noses instead of being gradually angled into the channel center. Authors noted significant convective acceleration over the structure crest and around the blunt structure tip. Flow encountering the structure separated at a stagnation velocity zone at the structure face, and was redirected over and around the obstruction. Recirculation zones, or eddys, were observed to form behind the structures and between adjacent structures. Streamlines were not shown to exhibit substantial planimetric circulation in the upper water column and the effects of the structure field diminished within two structure lengths of the downstream crest. Conveyance was observed to shift to the inner channel, away from the increased roughness of the modeled structure series.

Duan (2009) performed laboratory physical modeling on a spur dike installed in a straight, mobile-bed channel under clear-water conditions. Results of the study included documentation of flow separation downstream of the structure, strong planimetric recirculation in the upper water-column which decayed moving deeper into the flow, induced cross-sectional rotation, and high tip velocities. Flow interaction with the spur dike shifted the conveyance and bulk mean kinetic energy to the outside of the tip of the structure and incited circulation and increased turbulent kinetic energy downstream and behind the structure crest.

Jamieson et al. (2013) installed vanes constructed from scaled riprap in a mobile-bed, trapezoidal laboratory channel bend and collected bathymetry and velocity data. Vanes were imbricated in series and constructed according to NRCS (2005) guidelines. Planimetric velocity measurements illustrated an effective conveyance shift from the outer bank at baseline conditions to the channel center with the installed structure configurations. Authors noted scouring downstream of the vane crests which was attributed to the combination of plunging crest flow and local acceleration around the vane tip. When vanes were constructed with the bank key-in point below the water surface, increased outer-bank erosion was noted, similar to bankline flow acceleration noted for bendway weirs (McCoy et al., 2007, Abad et al., 2008). Varying degrees of disruption of the secondary current was noted for the vane configurations and was attributed to the strength of plunging flow over the vane crest.

Studies from the literature indicated a recurring set of hydraulic trends associated with the installation of transverse in-stream structures. The bulk flow conveyance is shifted towards the channel-center, acceleration occurs around the structure tip, and acceleration is observed along the outer bank at the bankline key in for submerged crests. This proceeding focuses upon the quantification of the convective tip acceleration that occurs for bendway weirs, spur dikes, and bank-attached vanes. Comparable physical models of the three structure types were constructed and resulting hydraulics were quantified. Tip velocities were isolated and information pertaining to maximum tip velocities for structure design was obtained.

PHYSICAL MODELING

The Middle Rio Grande River between Cochiti Dam and Elephant Butte Reservoir in New Mexico has been the focus of extensive river restoration work since the upstream Cochiti Dam construction in 1975. The dam effectively disconnected the sediment continuity to the downstream reach, resulting in a geomorphic shift from a historically braided channel to a slightly sinuous, incising system. The United States Bureau of Reclamation, as the responsible agency for management of the river, jointly launched an investigative study on the performance of transverse in-stream structures with Colorado State University. A physical model was constructed at a 1:12 Froude scale representing two surveyed bends from the Middle Rio Grande. A model schematic and topographic representation of the flume is presented in Figure 2 and an image of the completed downstream bend of the model is presented in Figure 3. The downstream bend of this physical model was selected to investigate tip velocity effects between the three structure types, and comparable physical model structure configurations were designed.

Physical models of bendway-weirs, spur dikes, and bank-attached vanes were designed according to slightly different methodologies. However, each configuration was constructed to

have the largest amount of direct comparability between structure types. Spacing, structure width, and orientation angle were identical. Quantified design parameters are summarized in Table 1. The process of bendway-weir design included available guidelines to ensure applicability to the current state of knowledge. Thornton et al. (2011) evaluated four spur-dike configurations in the same physical model as the current study. Methodologies reported by Thornton et al. (2011) describe spur-dike geometric parameter determination by a variation of projected length to match a desired cross-sectional area blocked percentage (A*). Following these methods, the spur-dike configuration was designed to match a desired A* value of 19.4. The lower crest height of the bendway weirs made alterating A* to match that of the spur dikes impractical. The vane configuration kept the same length of the spur dikes and incorporated a 10% sloped crest.

Hydraulic parameters such as the channel top width and design flow depth are integral parts of instream-structure design; however, parameters vary with longitudinal distance along naturally-formed channel bends due to pool and riffle sequencing and erosional processes. It was assumed for the purposes of the instream-structure design that such parameters are bend-averaged at a bankfull, or approximately two-year return interval, scaled prototype discharge of 6,000 ft^3/s (12 ft^3/s model scale). Top-width for the model was found by bend-averaging surveyed waterlines at the bankfull flow condition across the representative channel-bend cross sections. The hydraulic flow depth (D) was determined as the most representative parameter for instream-structure design criteria and was calculated from each cross-sectional T_W and flow area (A) using $D = A/T_W$ and were averaged across the downstream bend. Cross-sectional flow area was calculated from numerical integration of surveyed bathymetric data.

Bendway-weir crest length was specified as the distance from the intersection of the weir crest and the channel bankline to the weir tip, not including the transition slope from the crest to the channel bottom (Lagasse et al., 2009). Also, the weir should be long enough to cross the stream thalweg (Lagasse et al., 2009). Setting the crest length at $T_W/3$ for the downstream bend resulted in structures which adhered to ranges of L from the literature and generally crossed the stream thalweg. For each spur-dike structure, a projected cross-sectional bathymetry and area blocked was determined. Starting with a crest height at the bank waterline and specifying a tie-in slope of 1V:1H, the projected crest length was adjusted such that the total cumulative weir blockage was 19.4% of the baseline cross-sectional flow area. Vanes were designed such that the $L_{W\text{-}PROJ}$ at each structure was the same as the spur-dike configuration. Crest lengths for the spur dike and vane configurations ranged from $T_W/4$ to $T_W/3$. The calculated range of $L_{W\text{-}PROJ}$ for impermeable spur dikes exceeded the maximum design from Lagasse et al. (2009); however, vane crest lengths fell within specified ranges found in the literature.

Crest elevations were determined based upon the intended hydraulic effects of the structures. Spur dikes and vanes have crest elevations which are set at the design flow water-surface elevation at the bankline tie in. Bendway-weir crest height was set at one-third of the bend-averaged bankfull hydraulic flow depth, or two-thirds of the hydraulic flow depth below the water surface.

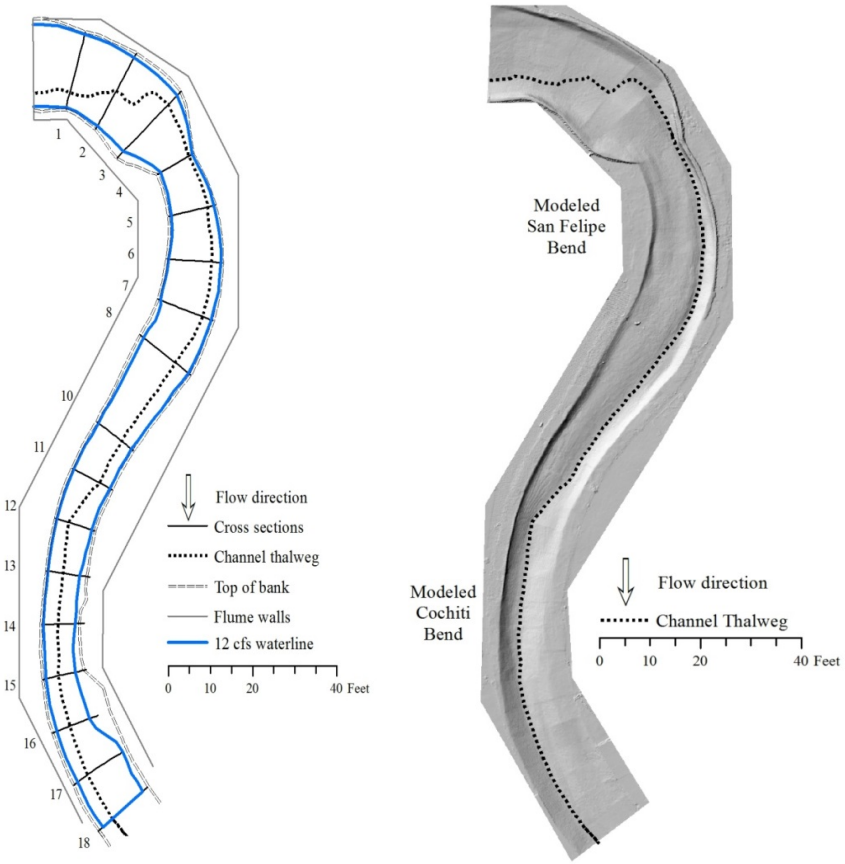

Figure 2 Native topography plan view schematic and constructed surface

Crest orientation angle was established at 60º, measured clockwise from the bankline tangent. The orientation angle coincides with design recommendations for bendway weirs, yet violates spur dike and vane recommendations (Lagasse et al., 2009; NRCS, 2005). Crest widths were constructed from approximately 0.3 ft to 0.5 ft angular rock, corroborating with design guidelines specifying instream structure crest widths of $d_{100} - 3d_{100}$, where d_{100} is the diameter of the largest grain size implemented in construction. Additionally, crest widths were set at a prototype 12 ft, allowing construction equipment to traverse the structure during installation. Each transverse instream structure was constructed from a plywood for centered in the crest and angular rocks were placed to form the required dimensions. The completed structures were impermeable to interstitial flows due to the plywood template. Topographic representations of the structures from LiDAR data, flume schematics, surveyed waterlines, and velocity data-collection locations are presented in Figure 4.

Mean-flow and turbulent velocity characteristics were obtained using two acoustic Doppler velocimeters (ADV). A SonTek® ADV of ±1% measured accuracy, and a Nortek Vectrino® ADV of ±0.5% accuracy were both utilized. ADV data have been collected in laboratory and field applications, and further details may be found in Voulgaris and Trowbridge (1998), Wahl (2000), McLelland and Nicholas (2000), Strom and Papanicolau (2007), and many others. ADV instruments operate at a high frequency (≥ 25 Hz) and allow for the determination of mean and fluctuating velocity components over the course of a sampled time period. A minimum of 1500

velocity data were obtained at each data-collection location. Data were processed using WinADV as detailed by Wahl (2000), and data used for instream-structure analyses typically had percentage-good scores greater than 70%, correlation values greater than 70, and signal-to-noise values greater than 15.

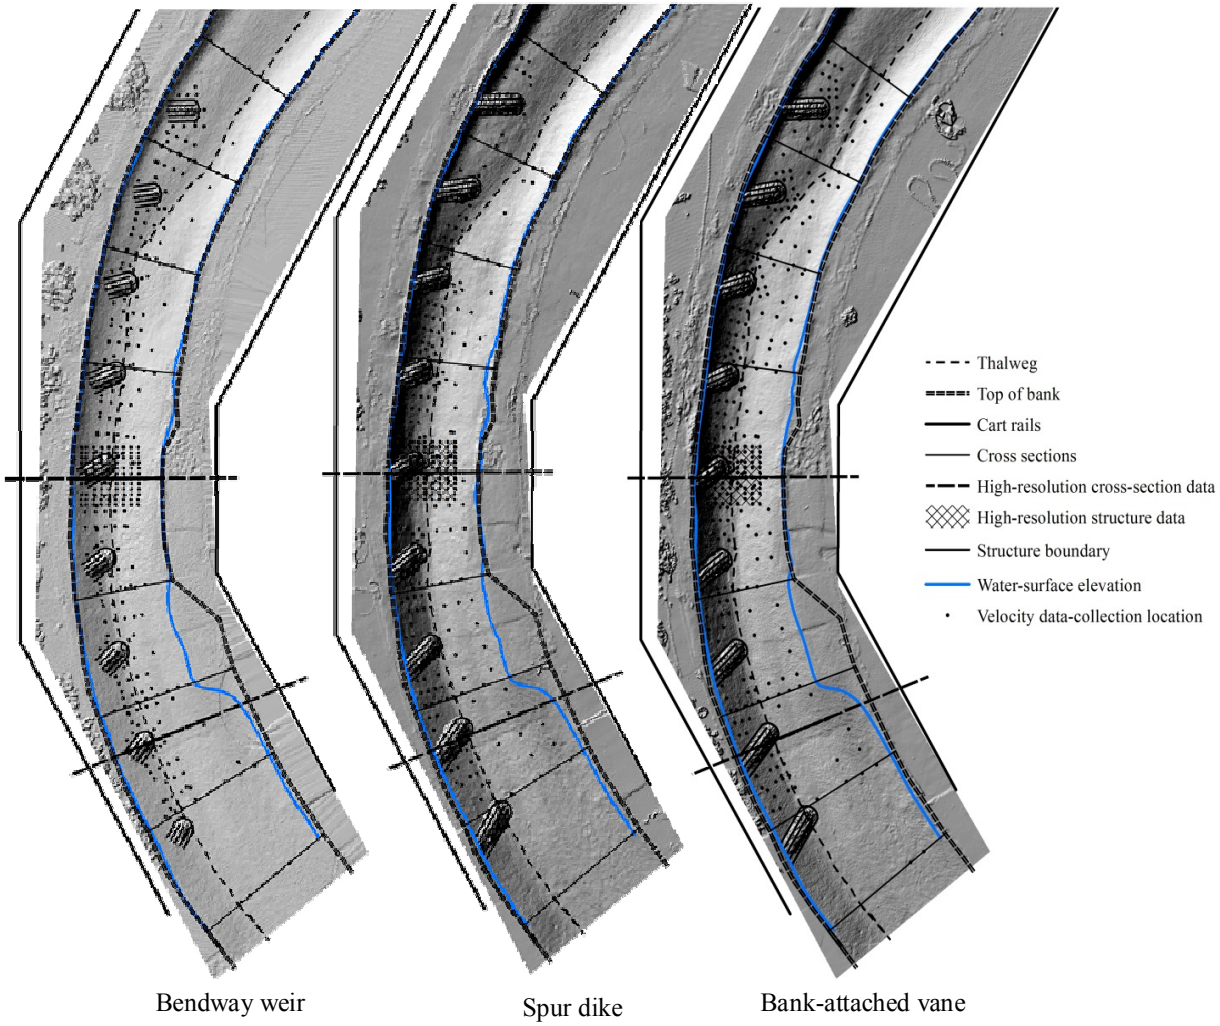

Figure 4 Constructed in-stream structure configurations and data-collection points

IN-STREAM STRUCTURE DATA RESULTS

Velocity data collected at each of the data-collection locations were processed and tabulated. Data at 60% flow depth measured below the water surface elevation were extracted as a surrogate for the depth-averaged flow. Velocities were normalized by the bend-averaged baseline cross-sectional velocity, computed through flow area and volumetric flow rate. The normalization value was found to be 1.702 ft/s at bankfull, normal-depth flow conditions. In general, all evaluated structure configurations exhibited velocities lower than the baseline velocity at the outer bank of the channel, and shifted the conveyance to the channel-center and inner-bank where all configurations showed velocities higher than baseline conditions. Normalized velocity values range from approximately zero to two for all configurations, corresponding to full velocity reduction or velocity doubling from baseline conditions, respectively.

Figure 5 depicts interpolated normalized velocity distributions for the evaluated in-stream structure configurations. Blue shades indicate velocities slower than the normalization condition, or less than unity, and red shades indicate velocities faster than normalization conditions, or greater than unity. For all structures, a strong gradient occurred between reduced and accelerated velocities, illustrated by the rapid transitions in the velocity distributions. The location of the shear gradient was found in the vicinity to the outer bank of the structure tips. Highest velocities were noted at the inner-bank vicinity of the structure tips.

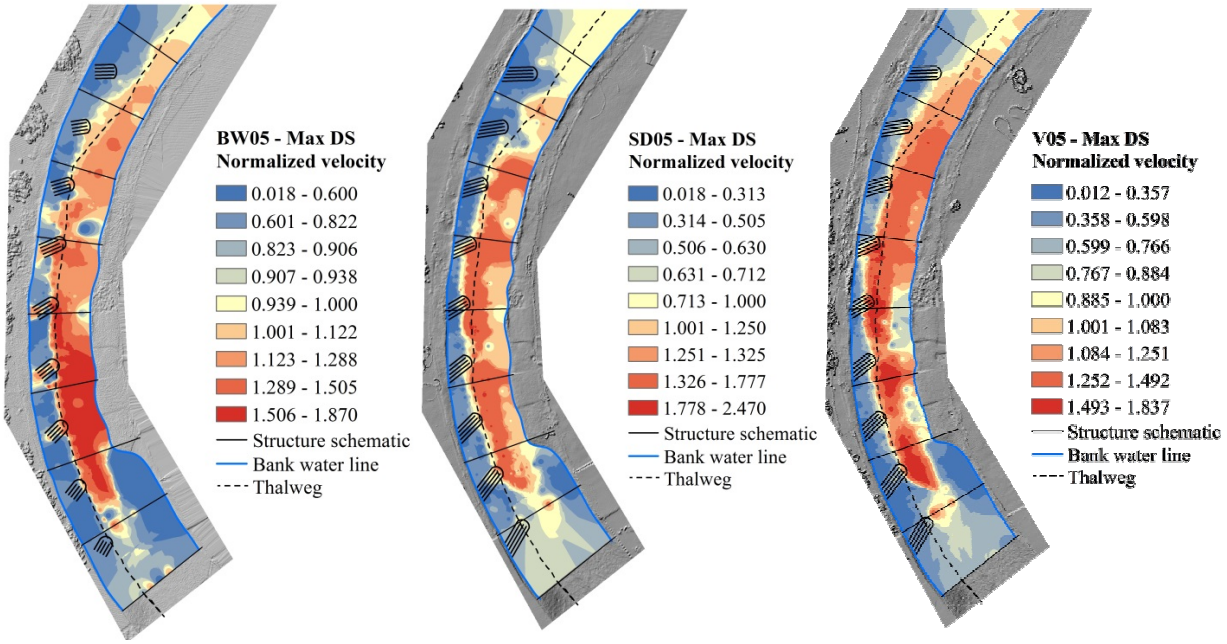

Figure 5 Normalized velocity fields (BW, SD, V = bendway weir, spur dike, vane, respectively)

Flow encountering the in-stream structures was observed to have specific features depending on the structure type. The bendway weir redirected flow over the top of the structure crest to the channel center, yet also split the conveyance to the outer bank. A localized region of higher velocity was noted at the outer-most bank region for the bendway weirs, coinciding with results reported by Lyn and Cunningham (2010) and McCoy et al. (2007). A strong degree of turbulence was noted for the bendway weirs as a function of the vertical induced currents. Velocity vectors recorded around a bendway weir are displayed in Figure 6 where flow redirection, vertical acceleration, and plunging flow are visualized. Spur dikes with no crest overflow exhibited strong planimetric recirculation zones between structures similar to those reported by Yossef and de Vriend (2011). This flow pattern was not observed for bendway weirs and to a much lesser degree in the bank-attached vane configuration. Strong recirculation zones may lead to scalloping of the bank and eventual flanking. The vanes did not exhibit outer-bank split conveyance or strong planimetric recirculation zones. A common hydraulic trait for all structures was the convective acceleration around the tip of the structure crest. Visualized in Figure 6, flow is redirected around a stagnation velocity point at the structure interface, spatially accelerating around the tip of the structure. As noted in Koken and Constantinescu (2014) and Minor et al. (2007), the tip of transverse in-stream structures is the focal point for initiation of sediment mobility. Laboratory results indicated that the tip of the structures experience the

highest velocities in the channel. Crest-tip velocities were isolated from the full dataset and analyzed for each structure type.

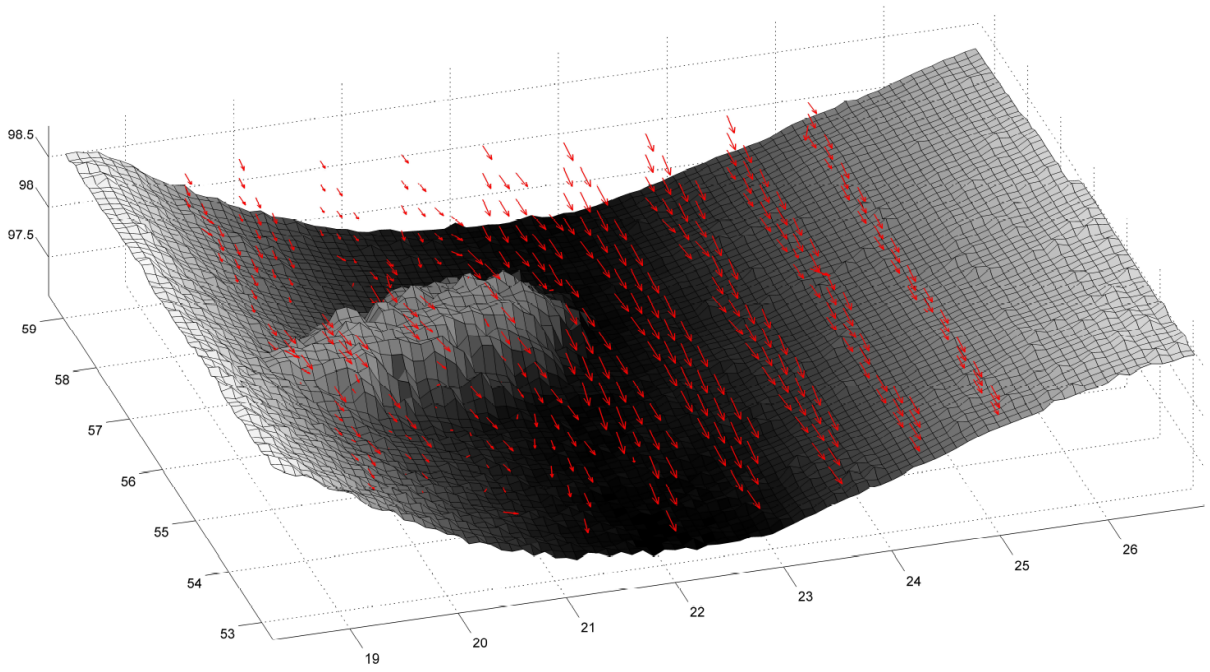

Figure 6 Velocity vectors (red) recorded around a bendway-weir structure (looking upstream)

STRUCTURE CREST TIP VELOCITY ANALYSIS

Increased velocity at the structure tip is directly related to the convective acceleration imposed by the structure boundary. Quantification of the velocity increase is important for structure stability through correct rock sizing and construction methods. Data located at the tip of the structures and in the near vicinity were isolated from the full data-collection location set illustrated in Figure 4. Values were normalized by the bend-averaged baseline flow condition and the maximum value and mean value were extracted from the dataset. Table 2 summarizes the maximum and average velocity and normalized values for each configuration. Maximum normalized velocity (*MVR*) values ranged from approximately 1.6 to 1.7 with the bank-attached vanes producing the smallest values and the spur dikes the largest. On average, normalized velocity values (*AVR*) range from approximately 1.3 to 1.6, with the bendway-weir configuration producing the smallest values and the spur dike the largest.

Table 2 Structure tip velocity summary

Configuration	Max vel. (ft/s)	*MVR*	Avg. vel. (ft/s)	*AVR*
Bendway weir	2.898	1.703	2.238	1.315
Spur dike	2.933	1.724	2.721	1.599
Bank-attached vane	2.692	1.582	2.437	1.432

Results adhere to physical intuition of the flow field. A larger channel obstruction decreases the cross-sectional flow area and increases flow acceleration. Spur dikes were the largest structure, followed by vanes, then bendway weirs which corresponds to the normalized average tip velocity magnitudes. The maximum observed velocity for the spur dike was also the largest recorded during testing. Bendway weirs produced a higher maximum velocity than the bank-attached vanes. The flow field for the bendway-weir configuration was more erratic and turbulent than the other structures. Observed hydraulics and high maximum velocities indicate that the bendway-weir structure type in particular should be evaluated further to fully understand hydraulic mechanisms.

SUMMARY AND CONCLUSIONS

Transverse in-stream structures are being installed to mitigate outer-bank erosion and stabilize migrating river channels. A physical model study of bendway weirs, spur dikes, and bank-attached vanes was undertaken in order to facilitate investigation of specific hydraulics associated with the structures and the differences between them. One configuration of each structure classification was installed according to recommended design guidelines from the literature and the desire for structure comparability. Models were evaluated under bankfull, design flow conditions and comprehensive velocity data were collected throughout the flow field.

Velocity distributions indicated that the tips of the structures were highly susceptible to the strongest hydraulics in the channel. Structure stability requires that rock sizing be appropriately scaled to expected velocities. Tip velocities for the structures were isolated and normalized by the baseline velocity averaged throughout the bend. It was found that on average, spur dikes had the highest tip velocities, followed by bank-attached vanes and bendway weirs. Maximum tip velocity analysis indicated that structure installations increased velocities up to 1.72 times the baseline average velocity. From the results of this study, it is recommended that rock sizing methods based upon flow velocity include a factor of safety of two times the baseline bend-average velocity.

ONE-DIMENSIONAL SEDIMENT MODELING OF LEVEE SETBACK AND FLOODPLAIN GRAVEL PIT CAPTURE ON THE YAKIMA RIVER, WA

Peter C. Brooks, P.E., Senior Engineer, Northwest Hydraulic Consultants, 13600 Christensen Road, Suite 350, Seattle, WA 98188, pbrooks@nhcweb.com; Dave McLean, Ph.D., P.E., Principal, Northwest Hydraulic Consultants, 405 - 495 Dunsmuir Street, Nanaimo, BC V9R 6B9 Canada, dmclean@nhcweb.com; Andrew Nelson, Geomorphologist, Northwest Hydraulic Consultants, 13600 Christensen Road, Suite 350, Seattle, WA 98188, anelson@nhcweb.com; Karen Hodges, Natural Resource Specialist\Project Manager, Water Resources Division, Yakima County Public Services, 128 N. 2nd St., Yakima, WA 98901, karen.hodges@co.yakima.wa.us

EXTENDED ABSTRACT

The Yakima River in eastern Washington State has been confined due to the construction of numerous levees over the past century. Although providing valuable flood protection, levee confinement has interrupted natural morphologic processes resulting in reduced channel complexity and habitat. As part of a plan to reactivate the Yakima River floodplain to reduce flood elevations and velocities as well as increase access to back channel habitat, the Yakima County Flood Control District has undertaken a Section 1135 Environmental Restoration Feasibility Study with the Seattle District U.S. Army Corps of Engineers for a levee setback project on the Yakima River, within the City of Yakima, WA.

However, the area is the site of former gravel mining and three large gravel pits are currently located landward of the existing levee. These pits would be vulnerable to capture through channel avulsion were the levee to be setback. Gravel pit capture poses threats to channel stability by disruption of sediment transport continuity and upstream headcut migration. An existing SRH1D model was used to evaluate possible effects of gravel pit capture on upstream and downstream channel adjustment. Computational analyses were complemented by a geomorphic assessment and review of case studies of previous gravel pit capture episodes on the Yakima River and elsewhere. Findings were used to assess risks to morphologic stability, channel habitat, and surrounding infrastructure, including several Federal flood protection levees still located on the reach.

Eco-Hydraulic Modeling to Support Levee Setback and Floodplain Design

Blair Greimann, Hydraulic Engineer, Bureau of Reclamation, Denver, CO, bgreimann@usbr.gov; Rebecca Kallio, Hydraulic Engineer, Bureau of Reclamation, Denver, CO, rkallio@usbr.gov

EXTENDED ABSTRACT

The San Joaquin River Restoration Project (SJRRP) is located below Friant Dam near Fresno, California. The project is a direct result of a Settlement reached in September 2006 on an 18-year lawsuit to provide sufficient Chinook salmon habitat by the U.S. Departments of the Interior and Commerce, the Natural Resources Defense Council (NRDC), and the Friant Water Users Authority (FWUA). The Settlement received Federal court approval in October 2006. Federal legislation was passed in March 2009 authorizing Federal agencies to implement the Settlement.

The Settlement is based on two goals: (1) Restoration : To restore and maintain fish populations in "good condition" in the main stem of the San Joaquin River below Friant Dam to the confluence of the Merced River, including naturally reproducing and self-sustaining populations of salmon and other fish; (2) Water Management: To reduce or avoid adverse water supply impacts to all of the Friant Division long-term contractors that may result from the Interim Flows and Restoration Flows provided for in the Settlement.

One of the major requirements of sustaining fish populations will be the creation of a sufficient amount of floodplain habitat for juvenile salmon rearing. The river is constrained by levees in many reaches and it is necessary to setback the levees to contain the restoration flows and to create floodplain habitat. Because the setback requires the purchase of valuable agricultural land in the Central Valley of California, the floodplain design should be carefully designed in order to maximize the benefit of this expensive resource.

The existing floodplain habitat for the SJRRP was first quantified using a two-dimensional hydraulic model (SRH-2D, Lai, 2008). The depth and velocity over approximately 100 miles of the San Joaquin River was computed. The reach was divided into several separate models to decrease computational time and make the terrain datasets more manageable. Habitat Suitability Indices (HSI) were applied to depth and velocity output from the model and then cover suitability was estimated using vegetation mapping of the river corridor. The required floodplain area was based upon estimation of the assumed territory size required to meet a sustainable population.

Once the required suitable floodplain was estimated a levee setback was proposed and the designs for the floodplain grading and revegetation were developed to meet the required habitat objective. The hydraulic and sediment transport conditions were simulated using one- and two-dimensional hydraulic and sediment transport models (Huang and Greimann, 2010; Lai, 2008). The floodplain design incorporated the expected channel evolution into the design. The revegetation strategy is based upon results from the one and two-dimensional hydraulic and sediment transport models that were linked to vegetation modules that simulate the interactions

between riparian vegetation, flow and sediment. The models simulate the effect of vegetation on hydraulic roughness, as well as the effect of hydraulics on the establishment and mortality due to desiccation, scour, and inundation.

SEDIMENT TRANSPORT IN STREAM CHANNEL DESIGN

Peter Wilcock, Professor, Water Sciences Department, Utah State University, Logan, Utah, wilcock@usu.edu

ABSTRACT

Stream channel design has been strongly yoked to the concept of equilibrium channel geometry, building on regime theory and hydraulic geometry over the past century. Although plausible at a cursory level, equilibrium methods are unsatisfactory for a variety of reasons. They say nothing about the nature and duration of adjustment. They provide no quantitative basis for incorporating uncertainty. They generally make little or no distinction between channels with similar flow and vastly different sediment supply.

All agree that stream channel dimensions and dynamics depend on the supply of water and sediment. Here, we link water and sediment supply to specified behavior of the channel as a complete strategy for incorporating sediment transport in stream channel design. The approach builds on the classic concepts of threshold and alluvial channels. A threshold channel is one for which the bed material is immobile at a specified discharge. An alluvial channel is one whose transport capacity must be balanced against the rate of sediment supply. It is useful to define a third type of channel that combines the first two – over-capacity threshold – in which transport capacity exceeds supply but design flows do not exceed threshold limits for channel erosion. This type of channel is more common than often realized and is, in fact, unintentionally designed in many cases. Using these three channel types, we develop a basis for evaluating the significance of sediment supply to the performance of a design channel. At small sediment supply rates, channel performance is relatively insensitive to uncertainty in sediment supply and may be designed following threshold channel principles of stream competence. At large sediment supply rates, the potential for storing or evacuating channel-changing quantities of sediment is much larger. Design options include (i) active channel shifting {requiring acquisition of sufficient riparian corridor}, (ii) an over-capacity threshold channel {if sufficient slope is available}, or (iii) an alluvial channel that balances sediment supply and capacity {which may require additional investment for adequate estimates of potentially large rates of sediment transport}.

With specified values of water and sediment supply and a designated channel behavior, basic relations for hydraulics and sediment transport are solved to provide a suite of channel design choices. At this point, characteristic values of, for example, channel width can be drawn from hydraulic geometry relations or local experience in order to select among the range of possible design options. All three design strategies are placed on a common basis to allow effective and complete evaluation of design options under uncertainty. For useful application, it is not sufficient to merely characterize uncertainty. That uncertainty must be incorporated in the analysis and design of stream channels. A computational tool for estimating uncertainty will be presented within a strategy for incorporating sediment transport in channel design.

RESTORING ANDSUSTAINING RIVER ENVIRONMENTS USING AN IN-STREAM TRAINING METHOD

Chi Bui, Hydraulic Engineer, Albuquerque, New Mexico, cbui@usbr.gov

BACKGROUND

Historically, the Rio Grande at San Felipe used to be a braided river with a sand bed channel and a very high sediment load. Through channelization from 1932 to 1960s, the channel was straightened. As Cochiti Reservoir was built and began to impound water for flood and sediment control in 1975 which caused the reduction in flood peaks and sediment load, the channel generally became narrow and incised, and the bed material became coarser (Harvey, 2007; Shah-Fairbank et al., 2010). The reservoir traps approximately 99% of the current sediment supply to the downstream reach (Shah-Fairbank et al., 2010). The primary sediment supply to the downstream reach is from channel erosion and tributary inputs. Consequently the channel bed material size has become coarser over time, transitioning from sand to gravel, and the channel longitudinal profile has been lowered about four feet on average after the construction of the dam. The bed profile of the reach has been reasonably stable since 1992, an indication that the bed could have been armored under the post-dam flow regime. Sediment transport models suggest that significant bed mobilization would not occur at flows less than the 100-year peak of 10,000 cfs (Harvey, 2007). The reach immediately below the dam has incised and river meander bends have developed. In some areas the incision has dropped below the root zone, eroding banklines with mature cottonwood trees, and threatening infrastructure adjacent to the waterway. One specific location on the Rio Grande where this condition has occurred is immediately upstream from Angostura Diversion Dam. This location is about 21 miles downstream of Cochiti Dam. There are two meander bends where bank erosion has become a concern at three locations, RM 210.0, RM 210.1, and RM 210.3 as illustrated in Figure 1, threatening irrigation drains that border each side of the river.

In 2011, a multi-disciplinary project team was formed, including Tetra Tech, the Pueblo of San Felipe, and Bureau of Reclamation (Reclamation) staff, to initiate a process of providing bank protection at these three sites that included an initial site visit, development feasible alternatives to address the river maintenance concern at each site, selection of a preferred alternative at each site based on engineering effectiveness, ecosystem function, ease of compliance, and Pueblo preference. While individual alternative concepts were evaluated for each of the sites, the close proximity of the three sites on two consecutive bends for the downstream sites made the combination into one comprehensive project more palatable to the project team. This combination also facilitated the evaluation of adverse impacts between sites for the final design. The final design was a combination of longitudinal fill stone toe protection (LFSTP) and bendway weirs coupled with removal and/or lowering of bars.

1-DIMENSIONAL HYDRAULIC MODEL

The design of the bendway weirs and LFSTP requires inputs such as velocities, width, depth, energy slope, etc. which can be acquired from a one-dimensional (1-D) HEC-RAS hydraulic model. The outputs of the design are the ranges of bendway weir length, planform angle,

spacing, and height, and the fixed values of the LFSTP crest width and height. Different combinations of bendway weir configurations can slightly change the hydraulic conditions around the weirs that cannot be modeled by a 1-D HEC-RAS model. Therefore, a two-dimensional (2-D) hydraulic model with SRH-2D was used to assist in the process to optimize the final bendway weir configurations.

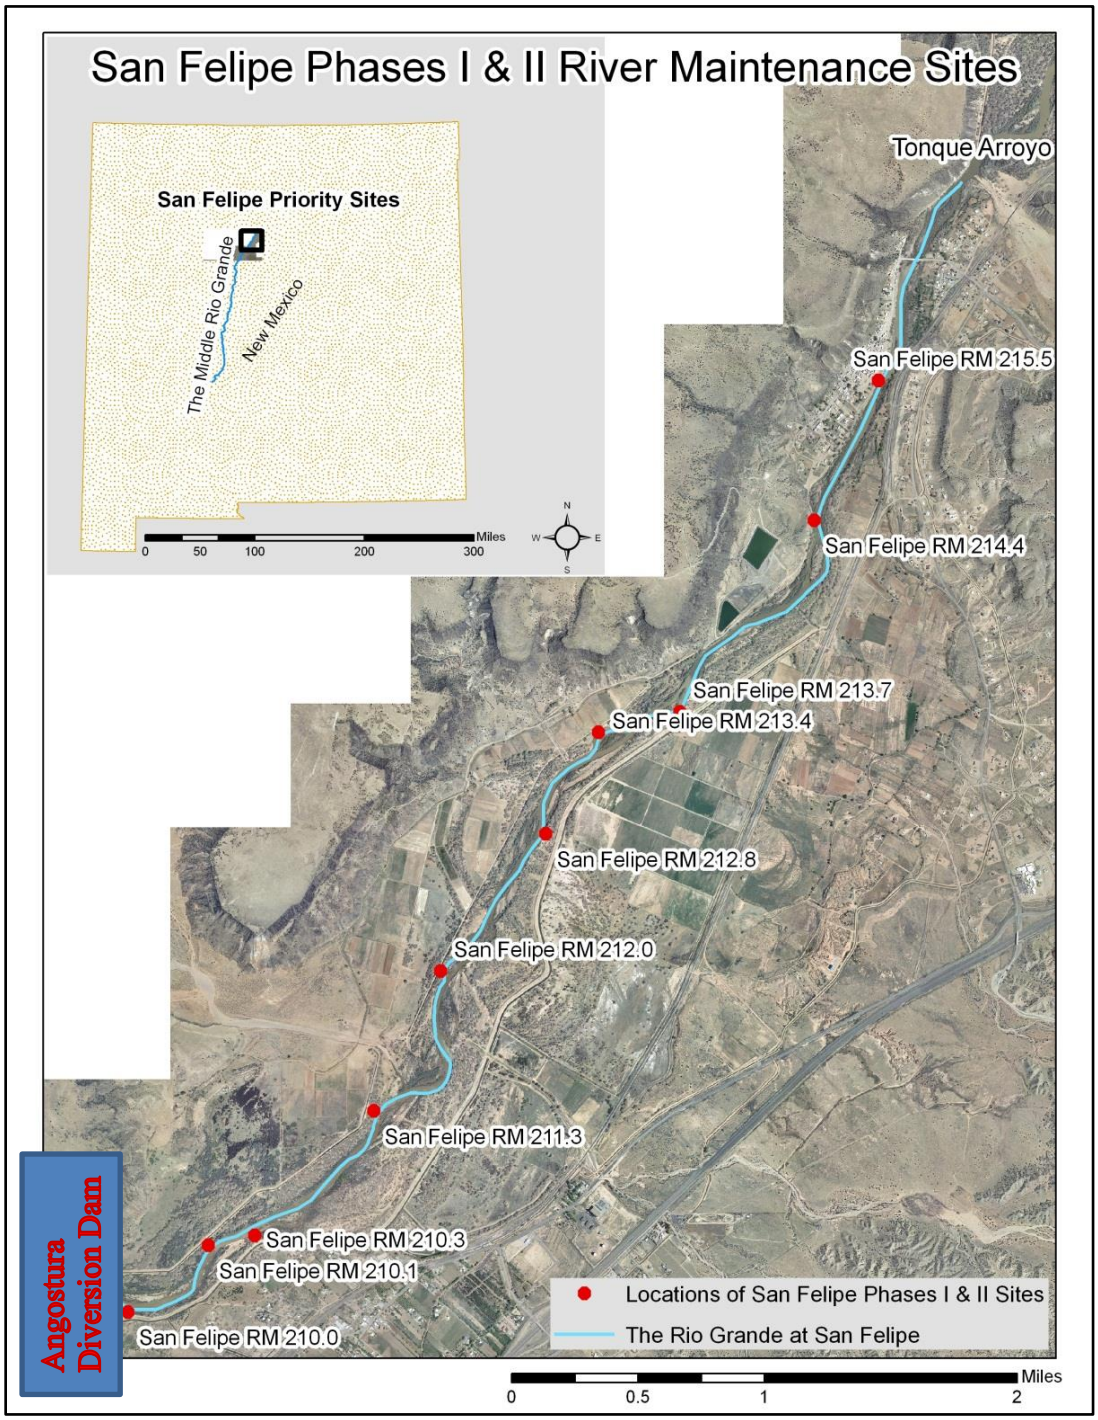

Figure 1 Map of ten priority sites along the Rio Grande at San Felipe.

There was a 1-D HEC-RAS model developed in 2007 using cross sections surveyed in 2007 to model the ten (10) priority sites illustrated in Figure 1. The floodplain elevation of the 2007 model was based on a digital terrain model (DTM) created from the 2002 photogrammetrically derived aggradation-degradation elevation. The downstream end of the model stopped just upstream from the Angostura Diversion Dam. The model was calibrated with Manning's n values gradually decreasing from upstream to downstream because the bed material is coarser upstream and becomes finer as it gets closer to the Angostura Diversion Dam. Photography of subsequent years after the model was compared with the 2007 photography and did not show denser vegetation encroachment into the channel. Therefore, it was assumed that the original Manning's n values were applicable to the updated 1-D HEC-RAS model built in 2012. The boundary of the 2012 HEC-RAS model covered from the priority site at RM 212.0 to just past the Angostura Diversion Dam.

Ineffective flow areas and obstructions were used in the geometry to model bendway weirs, areas in between weirs, and the LFSTP. Since the design of bendway weir spacing was in the range from 70 feet to 80 feet and the spacing of cross sections ranged from 150 feet to 500 feet, interpolated cross sections were required to model 12-foot wide bendway weirs. It is likely that errors inherent from the difference in bed elevation of the interpolated model and the actual river channel are present. The bendway weirs and LFSTP were modeled as obstruction objects. Areas of recirculation flow between weirs were modeled as ineffective flow areas (Sclafani et al., 2012).

In the process of riprap sizing, maximum velocities of the design flow at cross sections were required. However, this parameter cannot be obtained accurately from a 1-D hydraulic model. Instead of using a 2-D model at an early design stage that required a lot of effort, flow distribution was used to run the 1-D model to provide velocities for sub-sections of a channel cross section. These velocities are not the true 2-D velocity field, but they are interpolated velocities based on channel depth values of those sub-sections.

The pre-project 1-D simulation provided the hydraulic parameters for scour calculation, riprap sizing, and the design of the bendway weirs and LFSTP. The post-project 1-D simulation was performed for one design configuration. Then it was decided that it was more efficient to adjust design parameters using AutoCAD Civil 3D and GIS and to analyze results using a 2-D hydraulic model, so different design configuration combinations were tested with a 2-D model.

DESIGN CALCULATIONS

Immediately upstream of the Angostura Diversion Dam, the bend on the right side of the river is referred to as the upstream bend, and the bend on the left side of the river is referred to as the downstream bend in this report. The priority site RM 210.3 is immediately upstream from the upstream bend and on the opposite bank. The upstream bend passes through RM 210.1. RM 210.0 is located at the downstream end of the downstream bend.

Scour Computations: Expected scour depth was estimated as the first step of the analysis. An extensive, but not exhaustive, review of scour equations was conducted to identify a number of methods that would be appropriate for the project site. Long-term scour computation used

Yang's, Shields', Lane's, and Peter-Myer-Mueller's approaches, and competent velocity method. The selected scour equations for general and bend scour can be categorized as mean velocity equations, regime equations, and bend equations. The bend equations are based on the degree of tightness of a bend that is responsible for a transverse bed slope with significantly increased depth near the outer bank. The total scour depths developed under the 100 year-return flow of 10,000 cfs for two (2) bends are summarized in Table 1.

Table 1 Calculations of total scour

Scour Components		Velocity Equations			Regime Equations			Bend Equations		
		Limiting Velocity	Mean Velocity	Zeller[1] (1989)	Neill (1973)	Lacey (1930)	Blench (1969)	Maynord[1] (1996)	Zeller[1] (1989)	Thorne (1997)

[1]Developed for sand bed rivers, assumed conservative for gravel bed

Riprap Sizing: There are many approaches that are used in the professional engineering practice for sizing revetment riprap. NCHRP 568 (Lagasse, 2006) evaluated seven of the most commonly used revetment riprap sizing equations and recommended the EM 1601 equation (USACE, 1994) on the basis of discriminating between stable or failed riprap, bank and bend correction factors, and the reasonableness of safety/stability factors. The EM 1601 calculated D_{50} size can be used as the first approximation of the minimum riprap size needed for the design of the LFSTP at the upstream bend which is 12 inches. This riprap size ensures the longitudinal structure stability for discharges up to 100-year return flow of 10,000 cfs. The proposed correction factor for cross-stream features recommended by de Almeida and Martin-Vide (de Almeida and Martín-Vide, 2009) is about 2, which results in a transverse D_{50} size of 24 inches for both the upstream and the downstream bends to withstand the 100-year return flow of 10,000 cfs.

Design of Longitudinal Fill Stone Toe Protection (LFSTP): LFSTP is continuous riprap revetment with a trapezoidal cross section placed along the toe of a bankline to increase the roughness at the toe of the bank against erosion forces from incoming sustained high flows and to adapt to scour holes near the outer bank developed under sustained high flow conditions (Martin-Vide et al., 2010). Additional critical functional elements of the LFSTP are the keys and

tie-backs buried in the floodplain to prevent high flows from flanking the structure (McCullah and Gray, 2005). The LFSTP crest elevation was designed to be approximately 0.5 ft higher than the point bar at the upstream bend so that the hydraulically rougher stone toe will protect the toe of the outer bank until the hydraulic pressure is released as water overtops the high point of the opposite point bar. The width of the LFSTP was designed to provide rock that would self-launch into scour holes developed under sustained high flows along the toe of the stone structure which consequently protects the right bankline (Martin-Vide et al., 2010). As rock self-launches to the estimated scour depth, the crest width of the LFSTP is reduced to the minimum width of $2*D_{100}$ which is 4 ft (Derrick, 2011) keeping the original crest height unchanged. Since there is uncertainty in how the rock self-launches, a factor of 1.5 was added to the quantity of the self-launching rock that lands in potential scour holes (Derrick, 2011; Maynord et al., 1989). Tie-backs and keys are the LFSTP components that extend from the bankline into the floodplain. Keys are oriented perpendicular to the bankline while tie-backs are located at the upstream and downstream ends of the LFSTP and oriented at an angle from 20^o to 30^o with the bankline (Derrick, 2011). Assessing this area to be relatively, it is necessary to key the stone structure into the stable ground beyond the 1935-1962 channel boundaries, which gives the key length of 100 feet and a tie-back length as 600 feet.

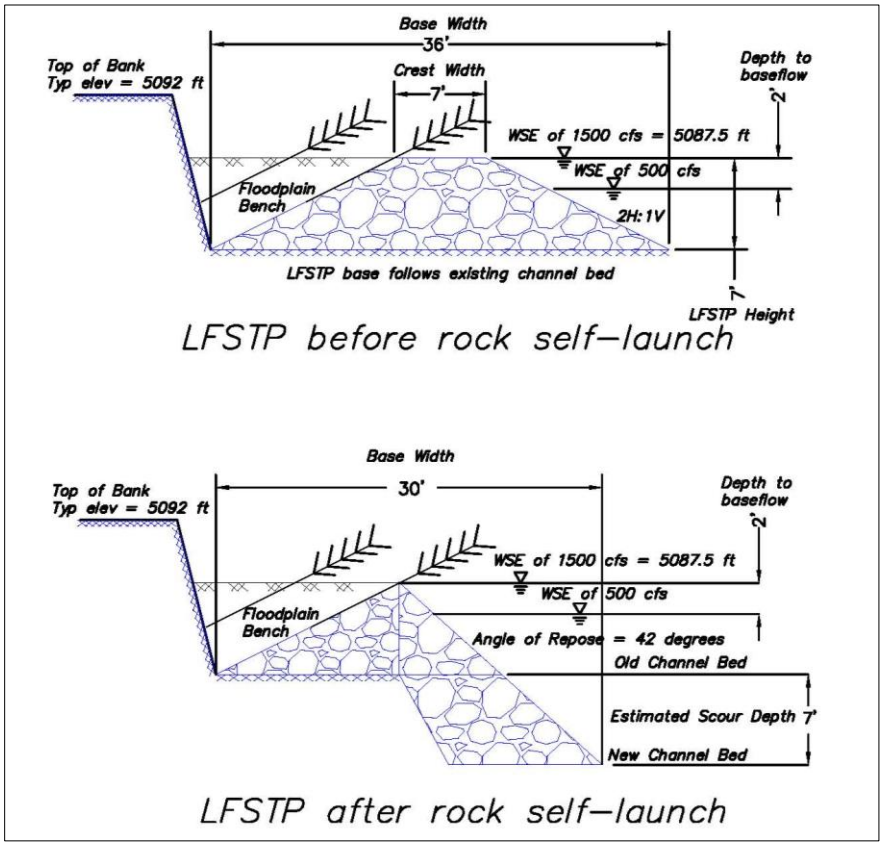

Figure 1 Process of LFSTP riprap launching into scour holes

Design of Bendway Weirs: Bendway weirs are low and upstream angled rock in-stream structures that help to lower velocities along a bankline and redirect the thalweg path away from the bankline (Kinzli and Thornton, 2010). The design references for bendway weirs are HEC-23

(FHWA, 2011), NCHRP 544 Report (McCullah and Gray, 2005), and Reclamation's modeling recommendations for transverse features such as spur dikes and vanes (Scurlock et al., 2012). From literature (FHWA, 2011; McCullah and Gray, 2005) the entire ranges of recommended bendway weir design parameters were derived. These ranges were narrowed down to a reasonable set of weir length, height, spacing, and planform angle. This was done based on literature documentation that cautioned against certain combinations (FHWA, 2011; Jia et al., 2005; Kinzli and Thornton, 2010). The narrowed ranges of the design parameters were combined into 18 combinations for the upstream bend and 37 combinations for the downstream bend. These sensitivity tests were used to determine the sensitivities of design parameters to velocities at the outer bank and at the centerline of the channel. After the sensitivity test, three design combinations were selected for each bend and a 2-dimensional (2-D) model was developed to test the post-weir baseline design parameters scenarios with the three design combinations at each bend. The scenarios modeled with a 2-D model are summarized in Table 2.

Table 2 Design parameters matrix tested with a 2-D model

Weir Parameters	Simulation ID	Weir Length (ft)	Weir Angle (degree)	Weir Spacing (ft)	Crest Elevation (ft)
Upstream Bend	Post-weir Baseline Design Parameters	65	60	85	5085
	MOD 2	65	60	85	5085.5
	MOD 3	60	70	80	5085
	MOD 4	70	70	90	5085
Downstream Bend	Post-weir Baseline Design Parameters	70	60	70	5084
	MOD 2	70	60	70	5084.5
	MOD 3	70	60	70	5083.5
	MOD 4	70	60	70	5083

FINALIZE DESIGN WITH A 2-D MODEL

SRH 2-D was selected as the hydraulic modeling software for this analysis because it was written and has been maintained by Reclamation so that the design team could get prompt technical support from Reclamation's current software developer.

As the 2-D model required very dense terrain data and there were no surveyed channel data points within areas in between the surveyed cross sections, the reach elevation was interpolated with cross sections six feet apart in HEC-RAS and exported to GIS to build the terrain for the 2-D model. As the 2-D model would be used to visually compare velocity distributions of different combinations of weir design parameters, the systematic errors caused by the interpolation of the terrain were thought to be similar for all tested bendway weir parameter combinations at the design discharge (2-year return, 5,600 cfs), which should not affect the overall final design selection. Values of WSE, velocities, shear stresses, etc. from the 2-D model would not be used specifically in the design process but rather to finalize a preferred design. Therefore, when it was assumed that the terrain systematic errors were constant for all combination simulations, the 2-D

model could assist the process to finalize the bendway weir design parameters. All 2-D simulation runs were performed with the assumption of a fixed bed and bank.

The post-weir baseline design parameters in Table 2 were initially considered to be the final parameter selection because they had a good balance between moderately reducing the outer bank maximum velocities and moderately increasing the centerline and inner bank average velocities. Therefore, they served as the post-weir design parameter baselines so that other parameter modifications should be compared to them. MOD 2 slightly changed the baseline condition by increasing all bendway weir height by 0.5 ft to investigate how higher weirs would benefit the project areas. MOD 3 has a different combination of weir design parameters at the upstream bend and a lower weir crest elevation with all other parameters unchanged at the downstream bend. MOD 4 tested another combination of bendway weir design parameters at the upstream bend as well as another lower weir crest elevation at the downstream bend with all other parameters unchanged. As the crests of the bendway weirs at the downstream bend were lowered to 5083 ft for MOD 4, the elevation of the bar near the southern end was excavated to 5082 ft, 1 ft lower than the bendway weir crest elevation at the downstream bend to release some hydraulic pressure from the high velocity field along the water intake structure. For all other modifications and baseline simulations, this bar elevation (5083 ft) was always lower than the bendway weir field at the downstream end. After the first four simulations, it was determined that MOD 3 was the best option for the upstream bend because it created a more distinct thalweg path immediately off the tips of the bendway weirs. Also the post-weir baseline simulation had the best combination for the downstream bend from the sensitivity analysis while other combinations did not show any significant difference in reducing near bank velocities. Besides it was found that lowering the bar at the southern end to 5082 feet would help to release the hydraulic pressure against the water intake structure. Therefore, this bar lowering feature was added to MOD 3 for the upstream bend and to the post-weir design parameter baseline for the downstream bend as the final weir design parameters that are summarized in Table 3.

Table 3: Final bendway weir design parameters

Weir Parameters	Bar Elevation (ft)	Weir Length (ft)	Weir Angle (degrees)	Weir Spacing (ft)	Crest Elevation (ft)
Upstream Bend	5082	60	70	80	5085
Downstream Bend	5082	70	60	70	5084

EXPECTED RESPONSE

The post-design 2-D model results showed that the velocities against the outer bank along the weirs at a bend were significantly reduced while area with higher velocities were moved to the tops of the weirs and toward the opposite point bank as in Figure 4. The model also showed that areas in between weirs had a variety of low to moderate velocities as in Figure 4. The primary hydraulic benefits of this project design are the relocation of the erosive force away from the bankline so that the river can still effectively deliver water and dissipate energy through its bends under high flow conditions within a confined space. The project's geomorphic benefits include the development of variable depth environments as the river scours along weir tips and opposite

point bars and deposits sediment in between weirs as in Figure 5. This provides bank protection, while still maintaining the current channel width and allows some geomorphic adjustments in a confined environment. The environmental benefits are potential establishment of vegetation in deposited areas between weirs and behind the LFSTP, plus a variable velocity and depth environment as in Figure 6 that potentially increases the opportunity for aquatic habitat. Therefore, it is hoped that this in-stream river training method will restore and sustain the ability of the reach to transport water and sediment, protect infrastructure along the waterway, and encourage ecosystem diversity within a confined and altered fluvial environment.

MODELING THE WEST BRANCH PLEASANT RIVER SYSTEM, ADDISON, MAINE FOR RESTORED TIDAL FUNCTION

Ecosystem Restoration Feasibility Study

EXTENDED ABSTRACT

US Army Corps of Engineers
New England District
Rhonda Needham Anderson & Heather Rausch

Table of Contents

1.0 INTRODUCTION.

Ridge Road crosses the mouth of the West Branch of the Pleasant River in Addison Maine (Washington County). The town of Addison is located at the confluence of the Pleasant River and the West Branch of the Pleasant River, approximately 53 miles southeast of Bangor, Maine. The study area extends upstream from the mouth of the West Branch of the Pleasant River for approximately one mile until the river, and its tributaries, intersect Route 1. Up to approximately 470 acres of fresh water wetlands could be tidally restored in the towns of Addison and Columbia, Maine.

The purpose of the West Branch Pleasant River Ecosystem Restoration Feasibility Study is to develop and evaluate tidally restored salt marsh habitat alternatives for the West Branch of the Pleasant River (West Branch); with the goal of recommending a State and Federally preferred plan for development. The Federally preferred plan must also meet Maine Department of Environmental Protection (MEDOT) transportation needs.

The Maine Department of Transportation (MEDOT) requested the U.S. Army Corps of Engineers' (Corps) assistance in restoring the fresh water marsh upstream of Ridge Road to a salt marsh. MEDOT owns, and is responsible for, the tide gates and roadway embankment at Ridge Road that are currently in disrepair and need to be replaced. The tide gates consist of six culverts with one way flapper gates that open toward the sea when the tide is low. This allows the river waters to discharge from the West Branch while seawater is blocked from entering the West Branch marsh. As a consequence, there has been inconsequential tidal influence upstream of Ridge Road since 1940 when an old bridge was replaced with the current road works.

This hydrologic and hydraulic analysis evaluated several alternatives to replace the existing gated structure at Ridge Road as well as culverts located upstream along the West Branch and several tributaries to reintroduce tidal exchange and ultimately restore the salt marsh.

2.0 SITE HYDROLOGY

a. Climate and Principle Flood Sources.

The climate of Addison is coastal, with moderately warm summers and cold winters. The average annual temperature of Addison is 45 degrees Fahrenheit (F) ranging from an average minimum temperature of approximately 12 degrees F in January to an average maximum temperature of approximately 77 degrees F in July. Surrounding bodies of water tend to temper extreme climate conditions. The mean annual precipitation is approximately 41 inches and is fairly uniformly distributed throughout the year.

The town of Addison is subject to coastal flooding caused by nor'easters and hurricanes. Nor'easters are the more frequent type of storm in this area. They can occur any time of the year, but are more prevalent in the winter months. Hurricanes, which are relatively rare, occur in the later summer and early fall months; however, they historically have not produced significant flooding in this area.

b. Tidal Regime.

In the study area, tides are semi-diurnal, with two high and low waters occurring during each lunar day (approximately 24 hours and 50 minutes). The resulting astronomic tide range varies constantly in response to relative positions of the earth, moon, and sun; the moon having the primary tide producing effect. Maximum tide ranges occur when the orbital cycles of these bodies are in phase. A complete sequence of astronomic tide ranges is approximately repeated over an interval of 19 years, known as a tidal epoch. Coastal storms and hurricanes can cause tides to be much higher than astronomically predicted. Although exact information of tidal characteristics are presently lacking at the site, approximate characteristics were developed from historical tide data (1931 to present).

c. Tidal Analysis.

The West Branch Pleasant River confluence with the Pleasant River is approximately one mile upstream from Pleasant Bay, which extends approximately eight miles downstream before discharging into the Gulf of Maine at Dyer Island. Tide elevations, heights and ranges are most accurately recorded locally and at NOAA gage stations.

The nearest NOAA gage station to the West Branch study area is in Millbridge, Maine, on the Narraguagus Bay, which also discharges to Pleasant Bay, approximately 10 miles south of Addison, Maine. Tide elevations increase as the tide travels from the open ocean, through Pleasant Bay, and up the Pleasant River due to the narrowing of the river channel. Since tide elevations published in the USACE Tide Profiles often represent the open ocean, this is not considered an accurate reference for tide elevations at the West Branch.

In order to analyze the impact of tides along the West Branch, tide elevations were established for various tidal occurrences and datums, as shown in Table 1. Since a NOAA tide gage is not available at this study area, recorded tide data collected by David Burdick as part of the 2009 Evaluation of Pre-Restoration Conditions in the West Branch of the Pleasant River, Maine were correlated to the Millbridge, Maine NOAA tide. This allows various tide events, recorded in 6-minutes intervals to be evaluated at the West Branch study area.

During storm conditions, nor'easters and hurricanes cause the tides to increase. Due to the duration of nor'easters, they often last through one or more tide cycles. The combination of sustained onshore winds and high tide causes significant elevation increases. This is known as storm surge. In Addison, the greatest storm surge is caused by winds from the southeast quadrant. The FEMA FIS also includes the wave height analysis. The coastline along the Pleasant River, on the west side of the community has a limited fetch and thus a wave height of only 3-feet and a wave period of 2.8 seconds. The fetch includes the distance waves can be generated without intersecting a land mass. (Reference 1)

TABLE 1
Estimated Tide Elevations at West Branch Pleasant River, Addison, Maine
(Estimated from interpolating NOAA recorded tides at Milbridge, Maine
and tide data recorded at the Addison, Maine pier in 2005[4].)

	Elevation NAVD88 (ft)
FEMA Zone AE Elev	11.3
100-yr Frequency Flood Event	10.8
50-yr Frequency Flood Event	10.5
10-yr Frequency Flood Event	9.8
2-yr Frequency Flood Event	9.4
1-yr Frequency Flood Event	9.0
Maximum Predicted Astronomic High Water	8.5
Mean High Water Spring (MSHW)	7.5
Mean Higher High Water (MHHW)	6.6
Mean High Water (MHW)	6.2
National Atlantic Vertical Datum (NAVD88)	0
Mean Sea Level (MSL)	-0.2
Mean Tide Level (MTL)	-0.4
National Geodetic Vertical Datum (NGVD29)	-0.7
Mean Low Water (MLW)	-6.0
Mean Lower Low Water (MLLW)	-6.3

d. Freshwater Drainage Area.

The West Branch has a total drainage area of 11.0 square miles. The drainage area extends to the foothills of Columbia and Columbia Falls. The topography of Addison ranges from moderately sloped in some area to relatively flat in other areas. Soil cover of the area is generally shallow and rock outcroppings are common. Vegetation consists primarily of softwood forests and hay field meadows.

The West Branch drainage area does not include United States Geological Survey (USGS) continuously recorded streamflow monitoring to provide real-time flow data. Additionally, the 1991 Addison Maine FEMA FIS does not include a streamflow analysis of the West Branch (reference 2). Other USGS streamflow gages

located in Washington County with watershed characteristics similar to the West Branch were investigated for comparison purposes. Although USGS Gage 01021470 Libby Brook near Northfield, Maine (DA 7.79 square miles) and USGS Gage 01021480 Old Stream near Wesley, Maine (DA 29.1 square miles) have potentially similar watershed characteristics, both only include seven years of record which is not enough to develop of streamflow analysis. Additionally, neither of these towns have a flood insurance study with a streamflow analysis for reference. USGS Gage 01022500 Narraguagus River at Cherryfield, Maine (227 square miles) is considered too large for comparison with the West Branch Pleasant River; however, the Cherryfield, Maine flood insurance study does include a streamflow analysis of the West Branch Narraguagus River (79.6 square miles). Although still considerably larger than the West Branch Pleasant River, it was referenced for comparison with the hydrologic analysis conducted for this study.

e. Hydrologic Modeling.

The Corps of Engineers Hydrologic Engineering Center Hydrologic Modeling System (HEC-HMS) was used to simulate the rainfall runoff in the West Branch. Since the West Branch does not have real-time streamflow data to compute 2-yr, 10-yr, and 100-yr flows from actual precipitation events, the U.S. Weather Bureau Technical Paper, No. 40 (TP-40) synthetic precipitation data was utilized to develop these relationships within the HEC-HMS model. The HEC-HMS model utilized similar methodology as the flow analysis conducted by the Natural Resources Conservation Service (NRCS) in their 2003 and 2007 report (reference 3).

The HEC-HMS model is comprised of two components, first the rainfall data necessary to calculate the storm event as provided by TP-40 as presented in Table 3. Secondly, the topography regime represented by the Soil Conservation Service (SCS) dimensionless unit hydrographs, based on the time of concentration, percent impervious, loss rates known as the curve number (CN) and initial abstraction (Ia) that includes all losses prior to runoff as presented in Table 4 (reference 1). Additionally, the West Branch watershed was delineated into three sub-watersheds representing Bells Brook (5.0 square miles), Branch Brook (4.4 square miles) and the unnamed tributary with Water and Point Streets (1.6 square miles).

This study also includes a flooding analysis of properties located adjacent to the West Branch, the peak flows were generated to represent wet, spring season soil conditions also referred to as a High Antecedent Moisture Condition (AMC). Therefore, these peak flows will simulate a worst case flooding analysis, see Section 3.0 Site Hydraulics. Comparison of the HEC-HMS model with the peak flows computed in the NRCS 2003/2007 reports concludes very similar results, which was expected since both analyses utilized similar computational methodologies. A comparison of these results is presented in Table 5.

3.0 SITE HYDRAULICS

a. General.

This section discusses the hydraulic methods and assumptions used to simulate tidal flow to study marsh restoration as well as estimates of flood elevations for selected recurrence intervals. It is noted that flood elevations shown on the Flood Insurance Rate Map (FIRM) represent rounded whole-foot elevations and may not exactly reflect the elevations computed for flood profiling, such as this. Flood elevations shown on the FIRM are primarily intended for flood insurance rating purposes. For construction and/or floodplain management purposes, users are encouraged to use the detailed flood elevation data computed in conjunction with elevations shown on the FIRM.

The existing river channel, culvert crossings and flood plain were hydraulically modeled for several different tide and storm recurrences. Alternatives consist of nine primary alternatives for Ridge Road each modeled with secondary alternatives for various flow conditions and upstream culvert modifications to determine corresponding water elevations, velocities, and acres restored. The results of each alternative were evaluated to compute the total restoration area, impacts of flooding to adjacent properties, flow velocities at roadway crossings, sedimentation and sea level rise (SLR).

The Ridge Road alternatives evaluated with the HEC-GeoRAS model are as follows:

A. No Action.
B. Six 5ft x 2.5ft Box Culverts at Ridge Rd.
C. Six 5ft x 5ft Box Culverts at Ridge Rd.
D. New Bridge at Ridge Road (150ft span/ existing upstream culverts)
E. New Bridge at Ridge Road (150ft span/enlarged culverts at Addison Road & flap gate at Water Street.)
F. New Bridge at Ridge Road (150ft span/enlarged culverts at Addison Road, Point Street and Water Street.)
G. New Culvert at Ridge Road (45ft x 12ft, or equivalent area, with existing upstream culverts.)
H. New Culvert at Ridge Road (45ft x 12ft, or equivalent area, and enlarged culverts at Addison Road, Point Street and Water Street.)
I. New Culvert at Ridge Road (45ft x 12ft, or equivalent area, and enlarged culverts at Addison Road and flap gates at Water Street.

b. Elevation Data and Datums.

Study area ground survey was obtained from Light Detection and Ranging (LIDAR) topography collected in 2012 and is available through NOAA Coastal Services Center. This data was processed, using the HEC-GeoRAS

geographical information system (GIS) arc-map processor, into cross-sections that follow the West Branch channel, tributaries and floodplain.

Photogrammetric topographic mapping was collected by James W. Sewall Company in 2004 with detailed 1-5 foot contour mapping at 1:40 scale. This topography included area at and below elevation 12.0 ft NGVD with elevations being converted to NAVD88. Additionally, this data included 201 spot elevations within the wetlands and limited ground field survey conducted on 20-21 August 2005 along Ridge Road, Water Street and Addison Road to validate the given elevations. (Reference 4). Culvert and bridge elevations were obtained from the NRCS report for culverts located at the following roadway crossings: Ridge Road, Addison Road, Water Street, Point Street, Ingersoll Brook and Route 1. (Reference 3).

All topographic and water elevations shown in this study are referenced to NAVD88 datum. It is important to note that prior studies/reports, including the Addison Maine FIS reference the NGVD29 datum. Ground, structure and water elevations may be compared and/or referenced to NGVD29 by applying a standard conversion factor. The conversion from NGVD29 to NAVD88 is -0.7 feet and from NAVD88 to NGVD29 is +0.7 feet.

c. HEC-RAS Development.

The Corp's one-dimensional Hydrologic Engineering Center's River Analysis System (HEC-RAS) computer model was used to conduct unsteady flow analyses. The HEC-RAS model calculates the water surface elevations (WSE) along a river channel using backwater analysis through a network of open channels. This model was used to simulate the WSE along the West Branch under conditions representing different culvert and bridge alternatives during the spring, 2-yr and 100-yr tide events. The model has the capability to accurately model culverts and bridges. Input for the model included boundary conditions, flow regimes, loss coefficients, structure characteristics, and LIDAR topography that was processed into cross-sections. Outputs from the model include computed water surface elevations, channel velocities, acres restored and floodplain mapping.

The Hydrologic Engineering Center's River Analysis System ArcGIS extension, HEC-GeoRAS, was used to layout cross sections and reaches based on topography (LiDAR). The existing marsh was divided into five reaches: Branch Brook, Bells Brook, Ingersoll Brook, Point Street marsh and West Branch. All reaches, cross sections, banks, and bridge/culvert alignments were georeferenced and their elevations extracted from the LiDAR data with HEC-GeoRAS for use in HEC-RAS. In HEC-RAS, water surface elevations were dynamically calculated to fluctuate with the tide and culverts were modeled both with their existing geometries (see Table 6) and proposed alternative configurations.

Table 6
Existing Culvert and Roadway Geometry
(Referenced from 2007 NRCS Culvert Survey)

Roadway	Existing Culvert Size (ft)	Top of Roadway Elev (ft NAVD88)	Downstream Culvert Inv. (ft NAVD88)	Upstream Culvert Inv. (ft NAVD88)
Ridge Road	(6) 5'x5'	13.0/11.3	-4.5	-4.0

Route 1 (Branch Bk)	10.5	NA	3.0	3.3
Route 1 (Bells Bk)	10.0	NA	7.0	7.5
Ingersoll Brook	6'Dia.	NA	13.5	14.0

d. Model Calibration.

Due to the West Branch Pleasant River being restricted to tidal flow by the roadway embankment and tide gates; calibration of the model relied on evaluation of historical documentation and photos of the tidal floodplain preceding the 1940 bridge construction. For calibration, the model was simulated with mean spring high water (MWHW) hydrographs through a channel opening representing the historic, pre-bridge conditions.

Roughness coefficients (Manning's "n") used in the hydraulic computations were determined by engineering judgment and were based on field conditions of the channel and floodplain areas. These values as well as minor modifications to the channel cross-sections were considered calibrated when the MSHW tide elevations reached the historic marsh floodplain footprint. The calibrated "n" values are presented in Table 7.

The hydraulic analysis was based on unobstructed flow. The flood elevations shown on the profiles are thus considered valid only if hydraulic structures remain unobstructed and do not fail.

Table 7

Calibrated Manning "n" values

e.West Branch Restoration Analysis.

The intent of modeling the West Branch was to evaluate the nine primary alternatives presented in Section 3.0 and the correlating tidal exchange to restore the salt marsh, without adversely affecting adjacent properties, roadways, or infrastructure.

i. Alternative A, Alternative B & Alternative C. Alternative A represents a 'no action' alternative, therefore, changes in either tidal or freshwater flow under this scenario is considered null. The model simulated Alternative B and alternative C, which include six box culverts of 5ft x 2.5ft and 5ft x 5ft, respectively, with neither alternative including flap gates. Alternative B culverts equal a 75 square foot opening that is equivalent to

half the existing six culverts and the Alternative C culverts equal a 150 square foot opening – the existing configuration. Additionally, Alternative B included no upstream culvert improvements while Alternative C included improvements at both Point Street and Water Street from 4-ft diameter to 5-ft diameter culverts to increase tidal exchange into the marshes upstream of these roadways. Increasing the culverts to 5-ft does not require the roadways to be raised.

The spring MHW reached at both Addison Road and Water Street is only 5.2 ft NAVD and 6.1 ft NAVD for Alternative B and Alternative C, respectively, while the spring MHW at Point Street is only 4.7 ft NAVD and 5.1 ft NAVD, respectively. These spring tide elevations are considerably lower than the spring tide elevation of Pleasant River (7.5 ft NAVD) and the marsh elevations adjacent to the channel. Therefore, a total 132 acres and 260 acres, respectively, would be restored under these scenarios out of the potential 470 acres.

Stormwater runoff hydrographs evaluated in Section 2.c and presented in Table 5 were simulated in the HEC-RAS model during spring tide conditions. Stormwater runoff increases the peak water surface elevation in the marsh but does not impact either Addison Road or Water Street. Increased water elevations at Point Street would encroach on the top of road surface during a spring tide/10-yr rain event and potentially overtop the roadway by 12-inches during a spring tide/100-yr rain event. Local observations indicate the roadway at Point Street currently experiences annual overtopping from stormwater particularly during saturated snowmelt conditions due to overgrown channel and flat gradient causing backwater effects. Therefore channel improvements in combination with an enlarged culvert may alleviate stormwater flooding in this area.

Tide hydrographs representing the 2-yr, 10-yr and 100-yr tide events were simulated in HEC-RAS to compute the expected peak water surface elevation in the marsh. Both Alternative B and Alternative C indicate increases in water elevation, although significantly lower than the correlating peak tide predicted in the Pleasant River downstream of Ridge Road. This is due to the 75 square foot and 150 square foot opening restriction at Ridge Road. Impacts to upstream roadways include no encroachment at Addison Road, encroachment at Water Street during the 10-yr flood and overtopping at Point Street of 0.6-ft to 1.6-ft during the 10yr to 100-yr tide events.

ii. Alternative D, Alternative E & Alternative F. Each of these alternatives includes replacing the existing Ridge Road causeway's six 5ft x 5ft culverts with a 150-ft open span bridge. Alternative D includes no upstream culvert improvements while Alternative E includes culvert improvements at Addison Road, Point Street and Water Street to increase tidal exchange into the marshes upstream of these roadways. Alternative F includes a culvert improvements at Addison Road only and a flap gate at Water Street to restrict tidal flow exchange upstream of Water Street into the Point Street swamps but will allow stormwater draining upstream of Water Street to discharge to the West Branch during periods of low tide. It is important to note, that stormwater will discharge through the flap gate when the tide begins to recede.

Increasing the Ridge Road opening to a 150-foot open bridge increases the tidal exchange to the West Branch marsh and significantly with the spring high water at Addison Road increasing to 1.5-1.8 feet greater than Alternative B and 0.6-0.9 feet greater than Alternative C. Similarly at Water Street, spring high water increases by 0.7-1.0 feet and 1.7-2.0 feet. The Point Street spring tide elevations increase by only 0.6 feet with the existing culvert size at Water Street (Alternative D) but increase by 2.2 feet when the Water Street Culvert is increased to a 12'x5' box (Alternative E). Alternative F includes a flap gate at the Water Street Culvert; therefore, tidal exchange is not introduced upstream of this point under this scenario. A total acres restored were computed as 349 acres, 385 acres and 314 acres, respectively, out of the potential 470 acres. It is interesting to note that the flap gate at Water Street reduces the total acres restores; however, Alternative F does include a respectable increase in total acres restored over Alternatives B and C. This is due to the increased volume of tidal flow entering the 150-foot bridge distributing across the West Branch flood plain.

The stormwater analysis evaluated in conjunction with a spring tide condition for Alternatives D, E and F determined no impact to the top of roadway at either Addison Road or Water Street, as also determined in Alternatives B and C. However, the increased volume of tidal flow entering the West Branch during these alternatives with the 12ft x 12ft box culvert at Water Street and Point Street significantly increases the flood

elevations at Point Street. Flooding at Point Street could be in excess of nearly 1-foot during a 2-yr frequency rain event coupled with peak spring tide.

Tide hydrographs representing the 2-yr, 10-yr and 100-yr tide events were simulated in HEC-RAS to compute the expected peak water surface elevation in the marsh for Alternatives D, E and F. Impacts to upstream roadways include encroachment at Addison Road during a 100-yr tide only, encroachment at Water Street during the 10-yr, 50-yr flood and 100-yr tides, and significant inundation at Point Street during each of these tide events.

iii. Alternative G, Alternative H & Alternative I. These alternatives include replacing the existing Ridge Road causeway with six 5ft x 5ft culverts with a 45ft x 12ft (or equivalent) culvert and include similar upstream culvert scenarios as Alternatives D, E and F. Alternative G includes no upstream culvert improvements while Alternative H includes culvert improvements at Addison Road, Point Street and Water Street to increase tidal exchange into the marshes upstream of these roadways. Alternative I includes a culvert improvements at Addison Road only and a flap gate at Water Street to restrict tidal flow exchange upstream of Water Street into the Point Street swamps but will allow stormwater draining upstream of Water Street to discharge to the West Branch during periods of low tide. As was noted for Alternative F, the stormwater will discharge through the flap gate when the tide begins to recede.

Increasing the Ridge Road opening to a 45ft x 12ft box culvert (or equivalent – realistic culvert dimensions will be determined during cost estimation) computed nearly identical spring tide elevations as Alternatives D, E and F with the 150-ft open bridge at each of the roadway crossings, Addison Road, Water Street and Point Street. The astronomical high water elevations for the 45ft x 12ft culvert alternatives were only 0.1-0.2 ft below those achieved in 150-ft open bridge alternatives. Total acres restored were computed as 346 acres, 377 acres and 309 acres, which was very similar to the total acres restored in Alternatives D, E and F. Again, the acres restored are reduced due to the flap gate at Water Street however some of this restricted tidal flow is distributed across the West Branch floodplain.

As expected, water elevations computed for both the stormwater analysis and tidal analysis were very similar to those computed in Alternatives D, E and F. This is due to the similar flow volume entering the marsh for the 150-ft span open bridge and 45ft x 12ft culvert opening as well as identical upstream culvert scenarios. The greatest impacts are seen at Point Street due to the low lying roadway and adjacent floodplain.

f. Channel Velocities and Sedimentation.

According to the American Society of Civil Engineers publication, Sedimentation Engineering, published in 1977, the critical water velocity for a median grain size of 0.4mm ranges between 0.45 feet per second (fps) and 0.84 fps with 0.82 fps being the critical velocity, indicating a small amount of movement, or sedimentation will occur. The critical water velocity represents the point at which the grain is suspended.

The velocities of the existing channel, computed by the model, ranged between 0.26 fps and 1.64 fps during the mean high spring water tide cycle and 0.46 fps and 1.79 fps during the 1-yr storm event. The model computed lower velocities for the 100-yr storm event because the WSE will inundate the channel and marsh. The velocity will be determined at critical locations for the alternatives that remain after the first round of feasibility selection. These velocities will be used to size rip-rap and potentially model scour/erosion/sedimentation for the selected alternative(s).

g. Sea Level Rise.

Sea level rise (SLR) was evaluated to predict the sea level change (SLC) at the West Branch and how this may impact the study area. The SLR analysis was conducted as directed in the USACE guidance, EC 1165-2-212, dated 1 October 2011. This EC requires a multiple scenario approach for three sea level rise scenarios, with each being considered equally plausible. These curves are; the historic rate of SLC at the project area, an intermediate SLC curve (modified NRC Curve I), and a high SLC curve (modified NRC Curve III). Formulation of the NRC curves from a defined starting date, and for localized su subsidence was also provided in the EC which allows from SLC to be calculated for specific project time frames and for specific geographic areas. This is critical since

SLC along the coast varies due to local subsidence, uplift, water body movement, etc. The three scenarios proposed by the NRC result in global eustatic sea-level rise values, by the year 2100, of 0.5 meters, 1.0 meters, and 1.5 meters. Adjusting the equation to include the historic Global mean sea level (GMSL) change rate of 1.7 mm/year and the start date of 1992 (which corresponds to the midpoint of the current National Tidal Datum Epoch of 1983-2001), results in updated values represented as the constant, b, in the SLC equation.

Using the SLC equation below, which is equation (3) from the EC, and a spreadsheet provided by the USACE ERDC, Figure 1 was developed for Bar Harbor, Maine. Bar Harbor was used since it is the closest NOAA station to the project site and includes historic SLC information required for this analysis.

$$E(t2) - E(t1) = 0.0017(t2-t1) + b(t22-t12)$$

Where:
t1 = is the time between the project's construction date and 1992
t2 = is the time between a future date at which one wants an estimate for sea level rise and 1992
b = 2.71 E-5 for modified NRC Curve I (low, 0.5 meter rise)
b = 7.00 E-5 for modified NRC Curve II (intermediate, 1.0 meter rise)
b = 1.13 E-4 for modified NRC Curve III (high, 1.5 meter rise)

As can be seen in both Figures 1 and 2, the historical rate (0.2 meter curve) would result in a rise of only 0.27 feet (0.04 meter) or 3.2 inches over the first 50 years. However, the level of SLR increases for each of the NRC curves as specified for use in the EC. As shown in Figure 1, the low curve (0.5 meter curve) predicts a rise of 0.4 feet (0.12 meter) or 4.8 inches, the intermediate curve a rise of 0.6 feet (0.18 meter) or 7.2 inches, and the high curve a rise of 0.81 feet (0.32 meter)or 9.7 inches.

4.0 SUMMARY

A final decision has not yet been made. The alternatives are going through cost estimation and additional, more detailed modeling, will be done on those that appear financially feasible, constructable and socially and environmentally acceptable. Additional modeling might include a sensitivity analysis of the bridge modeling approach and scour analysis, particularly for piers. Sedimentation/erosion analysis is also being considered, depending on the selected plan. Other factors will undoubtedly affect the final decision as well, and this report will be expanded.

COMPLICATIONS ASSOCIATED WITH MAINTAINING AUTHORIZED CHANNEL DIMENSIONS DURING LOW WATER PERIODS

Michael Rodgers, P.E., Project Manager, US Army Corps of Engineers – St. Louis District, St. Louis, Missouri, Michael.T.Rodgers@usace.army.mil

INTRODUCTION

The St. Louis District is responsible for maintaining a safe and dependable navigation channel on 300 miles of the Mississippi River between Saverton, Missouri and Cairo, Illinois. The southernmost 195 mile section of the Mississippi River in the St. Louis District, located between the confluences of the Missouri River and the Ohio River, is referred to as the Middle Mississippi River (MMR). The MMR is a vital artery in the inland navigation system and vital to the nation's safety and economy. There are two locations (Grand Tower, Illinois river miles 80-79 and Thebes, Illinois river miles 46-38) on the MMR where the river crosses a sedimentary rock outcrop. Previous attempts to remove portions of the rock outcrop were successful (as recent as the late 1980s); but, remnants of the rock outcrop still exist and pose a hazard to commercial river navigation at low river stages. These remnants are termed "pinnacles" due to their shape and size. The task of maintaining authorized channel dimension for commercial navigation on the MMR is a highly visible, politically sensitive, and extremely complex endeavor. While always a challenge, maintaining a safe and dependable navigation channel was made far more challenging during the summer, fall and winter of 2012 – 2103 due to extreme low water conditions on the MMR.

PROJECT DESCRIPTION

The drought of 2012 was equal to or exceeded any drought or low water period experienced on the MMR within the past five decades. Water levels in the MMR reached record lows, which posed a significant risk to commercial navigation traffic due to shallow channel crossings, reduced channel widths, and the rock pinnacles located along the channel bottom at Grand Tower and Thebes Illinois. The St. Louis District (MVS) was required to operate in an environment of competing demands for scarce water resources including; agriculture, recreation, environmental programs, energy production, and commercial navigation. MVS relied heavily upon diverse USACE core competencies and resources. Additionally, unique expertise was sought from other federal agencies (United States Coast Guard (USCG), United States Fish & Wildlife Service (USFWS), United States Department of Agriculture (USDA), Federal (Department of Transportation (DOT)) as this mission crossed organizational boundaries.

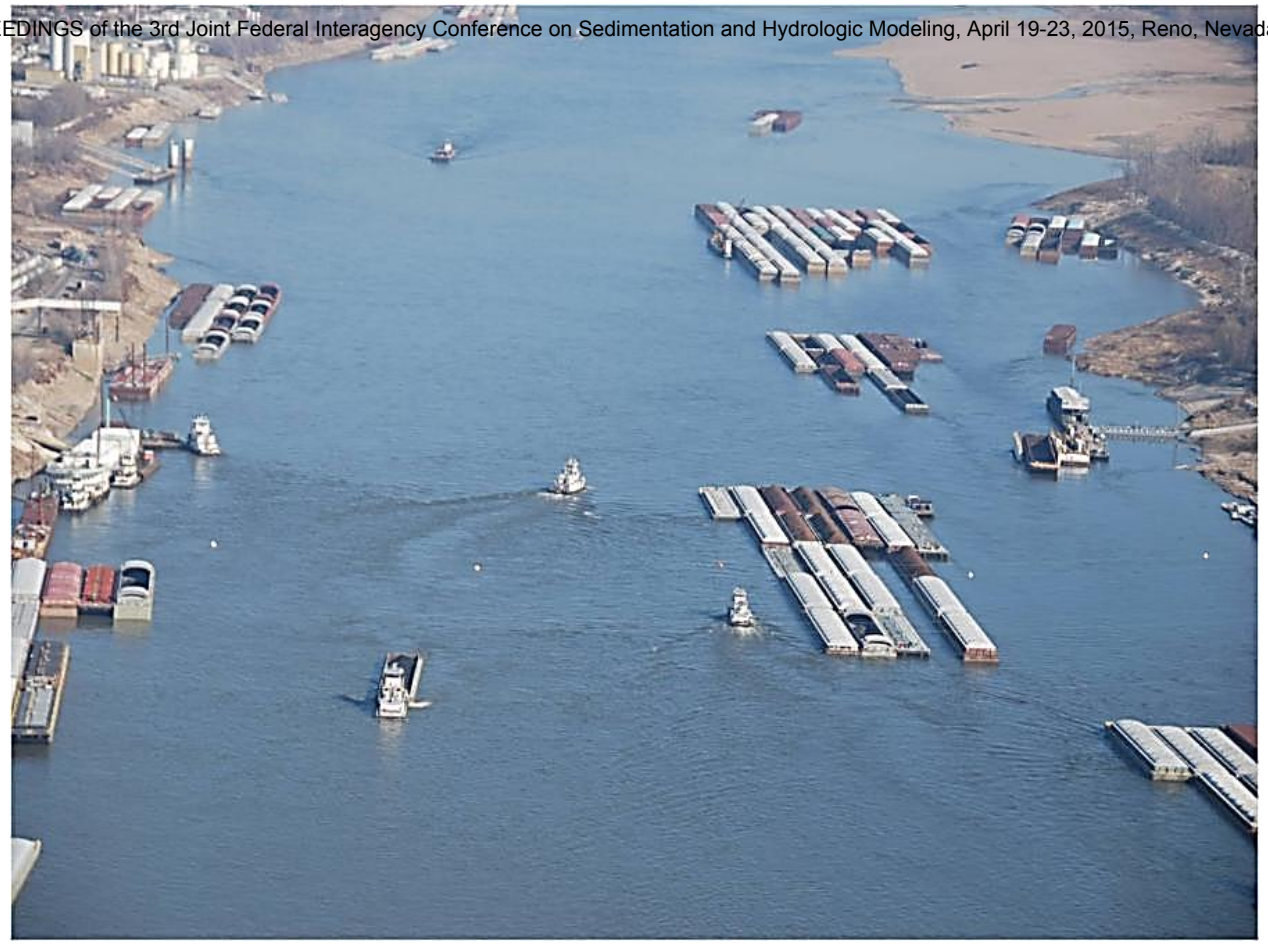

Figure 1: Low water conditions within St. Louis Harbor meant that space for fleeting is limited

The St. Louis District is responsible for planning and overseeing all aspects of providing a safe and dependable navigation channel at these record low river stages. This included (1) identifying critical specialties and disciplines required for the mission while balancing against competing demands; (2) determining and resourcing the needs of the team while maintaining cost, time, and quality assurance objectives; (3) extensive coordination with project stakeholders including (but not limited to) the River Industry Action Committee (RIAC), the River Industry Executive Task Force (RIETF), the United States Coast Guard (USCG), and the United States Fish and Wildlife Service (USFWS); (4) compliance with all relevant environmental regulations (National Environmental Policy Act (NEPA) and Fish and Wildlife Coordination Act (FWCA)); (5) managing pool and reservoir elevations; (6) forecasting river levels; (7) removing underwater rock pinnacles; (8) dredging shoals; (9) providing and utilizing a nearly continuous flow of channel and rock pinnacle surveys. Water management PDT members constantly collected water data, monitoring a number of hydrological and meteorological factors to forecast river conditions the rest of the Nation relied upon. Additionally, extensive coordination with the Kansas City District of the Northwest Division was a daily occurrence as the Missouri River releases were closely monitored. The complexity and significance of the rock removal component of the mission cannot be overstated. This work required integrated and coordinated management along with the application of innovative technology and tools / removal methodologies. Risks associated with barge tow collisions with rock pinnacles were high from a fiscal perspective as well as from an environmental perspective. Current and future river construction contract needs were adjusted in order to fund the rock removal project. River engineering projects were reprioritized to allow for detailed plans and specifications to be

produced to accommodate a tight project schedule. Removal of the pinnacles involved advanced surveying techniques coupled with innovative removal methodologies. Work locations within the rock removal areas were prioritized to get the most dangerous (highest elevation) rock removed first, with a secondary focus on providing optimal channel widths. The Project Management Plan (PMP) for the Regulating Works Project on the Middle Mississippi River includes a cost estimate, the project schedule, and all performance objectives and key assumptions. MVS was able to not only meet, but exceed the requirements outlined in the PMP through effective partnering and collaboration. During this low water event, due to the exhaustive efforts of MVS and partnering agencies, there were no accidents, groundings or unplanned closures of the Middle Mississippi River. This performance is unprecedented given that a similar drought in the late 1980's featured numerous groundings, accidents, channel closures, restrictions and a generally unreliable channel. With all eyes on the Middle Mississippi River – the White House, Congress, River Industry, and the US and international media – MVS efficiently and effectively coordinated all phases of the mission, exceeded expectations, and delivered what was promised.

Figure 2: A 20 barge tow transits upbound through the Thebes, Illinois rock removal reach

PROJECT RESULTS

Prior to the drought conditions reaching critical levels, MVS was carefully planning and preparing for strategic low water operations by identifying key problematic locations and putting into place the designs and resources to act when called upon. This foresight enabled the MVS to act quickly once critical levels were imminent and allowed USACE to provide authorized navigation channel dimensions during periods of extremely low water. The project consisted of maintaining the authorized channel dimensions in the Middle Mississippi River from St. Louis to Cairo, IL from July 2012 through February 2013 while monitoring 195 miles of river bed obstructions and moving river sediments that would have otherwise impeded navigation.

Highly specialized survey crews used the latest multi-beam technology to differentiate between sand and rock, enabling them to identify small but hazardous rock pinnacles in the navigation channel. As water levels continued to fall, the river bed material was transported and additional critical rock pinnacles were identified for removal. Expedited rock removal was required in several areas containing dense limestone to safely allow barge traffic to continue without groundings or accidents. This was accomplished using unique drilling and blasting as well as mechanical (hydro hammer) techniques. The minimum authorized channel dimensions were achieved in 30 days (approximately 30 days ahead of schedule) from award of the contracts with minimal channel closures that were coordinated with contractors, the USCG, and navigation industry. Contracts needs were adapted in order to fulfill the most critical low water needs as the drought progressed. The composition of the team responsible for the success of this project consists of many members including specialists such as engineers, technicians, project managers, construction and dredging specialists, skilled laborers, surveyors, GIS specialists, construction contractors, public affairs, barge industry representatives (port captains), towboat pilots, biologists, contracting officers, safety officers, meteorologists, and the U.S. Coast Guard. Several Corps elements throughout the U.S. provided team members in these fields. The contractual mechanisms and logistics plan were implemented as part of the strategic first step. Implementing an effective communication plan within MVS assisted project coordination and increased the efficiency of handling stakeholder concerns locally, regionally, and nationally. The effective and detailed project communication overall stakeholder collaboration nullified many coordination complexities. Dredge surveys and channel patrols surveys were posted to the district's website. Navigation channel status reports were sent out weekly. Rock pinnacle information (electronic chart overlays, surveys, rock locations, slides, etc.) were posted to a dedicated webpage. The successful completion of the Urgent and Compelling Rock Removal Project of 2012 has help restore America's faith in USACE and has established lifelong partnerships across Federal, State and Local agencies.

ESTIMATING FLOOD MAGNITUDE AND FREQUENCY FOR URBAN AND SMALL, RURAL STREAMS IN GEORGIA, SOUTH CAROLINA, AND NORTH CAROLINA

Toby Feaster, Hydrologist, U.S. Geological Survey, Clemson, SC, tfeaster@usgs.gov;
Anthony Gotvald, Hydrologist, U.S. Geological Survey, Atlanta, GA, agotvald@usgs.gov;
Curtis Weaver, Hydrologist, U.S. Geological Survey, Raleigh, NC, jcweaver@usgs.gov

Abstract: Reliable estimates of the magnitude and frequency of floods are essential for such things as the design of transportation and water-conveyance structures, Flood Insurance Studies, and flood-plain management. The flood-frequency estimates are particularly important in densely populated urban areas. A multistate approach was used to update methods for determining the magnitude and frequency of floods in urban and small, rural streams that are not substantially affected by regulation or tidal fluctuations in Georgia, South Carolina, and North Carolina. The multistate approach has the advantage over a single state approach of increasing the number of stations available for analysis, expanding the geographical coverage that would allow for application of regional regression equations across state boundaries, and building on a previous flood-frequency investigation of rural streamflow-gaging stations (streamgages) in the Southeastern United States. In addition, streamgages from the inner Coastal Plain of New Jersey were included in the analysis.

Generalized least-squares (GLS) regression techniques were used to generate predictive equations for estimating the 50-, 20-, 10-, 4-, 2-, 1-, 0.5-, and 0.2-percent annual exceedance probability flows (also referred to as the 2-, 5-, 10-, 25-, 50-, 100-, 200-, and 500-year recurrence interval flows) for urban and small, rural ungaged basins for three hydrologic regions: the Piedmont-Ridge and Valley, Sand Hills, and Coastal Plain. The GLS regression included 116 urban streamgages and 372 rural streamgages of which 32 came from small, rural basins draining less than 1 square mile. Incorporation of urban streamgages from New Jersey allowed for the expansion of the applicability of the predictive equations in the Coastal Plain from 2.1 to 53.5 square miles. Explanatory variables in the regression equations included drainage area (DA) and percent of impervious area (IA) for the Piedmont-Ridge and Valley region; DA and percent of developed land for the Sand Hills; and DA, IA, and 24-hour, 50-year maximum precipitation for the Coastal Plain. An application spreadsheet also was developed that can be used to compute the flood-frequency estimates along with the 95-percent prediction intervals for an ungaged location.

INTRODUCTION

Building on the success of a multistate approach for developing regional flood-frequency equations to estimate the magnitude and frequency of floods at ungaged rural streams in the Southeast, (Feaster and others, 2009; Gotvald and others, 2009; Weaver and others, 2009), a similar approach was applied to urban and small, rural streams (Feaster and others, 2014). For this investigation, Southeast refers specifically to Georgia, South Carolina, and North Carolina. The analytical techniques used incorporate both urban and rural streamgages and, therefore, can be applied to urban and small, rural streams. The lower limit of drainage area for basins included in the Southeast rural flood-frequency study was 1 square mile (mi^2). The lower limit of drainage area for rural basins included in this investigation was 0.1 mi^2. Consequently, in this study, small, rural streams refer to those with drainage areas less than 1 mi^2. Some of the

benefits of including both urban and rural streamgages in the regression analysis are (1) smoother transition between urban and rural flood-frequency estimates, (2) larger database than would be available with urban streamgages alone, and (3) larger geographical coverage in the hydrologic regions, which will represent a broader range of hydrologic conditions likely to occur at ungaged locations. More details on this investigation can be found in Feaster and others (2014).

DESCRIPTION OF STUDY AREA

The study area includes all of Georgia, South Carolina, and North Carolina with the exception of the Blue Ridge ecoregion, which lacks a sufficient number of urban streamgages to allow for a regional regression analysis, and the tidally influenced regions of the Coastal Plain. Georgia, South Carolina, and North Carolina encompass seven U.S. Environmental Protection Agency (USEPA) level III ecoregions—Southwestern Appalachians, Blue Ridge, Ridge and Valley, Piedmont, Southeastern Plains, Southern Coastal Plain, and Middle Atlantic Coastal Plain (fig. 1; U.S. Environmental Protection Agency, 2007a). The ecoregions represent areas of general similarity in ecosystems and in the type, quality, and quantity of environmental resources. The ecoregions provide a spatial framework for the research, assessment, management, and monitoring of ecosystems and ecosystem components. The ecoregions were determined from an analysis of the spatial patterns and the composition of biotic and abiotic phenomena that include geology, physiography, vegetation, climate, soils, land use, wildlife, and hydrology (Griffith and others, 2002). The Fall Line separates the higher elevation Southwestern Appalachians, Blue Ridge, Ridge and Valley, and Piedmont ecoregions from the low-lying Southeastern Plains, Southern Coastal Plain, and Middle Atlantic Coastal Plain ecoregions.

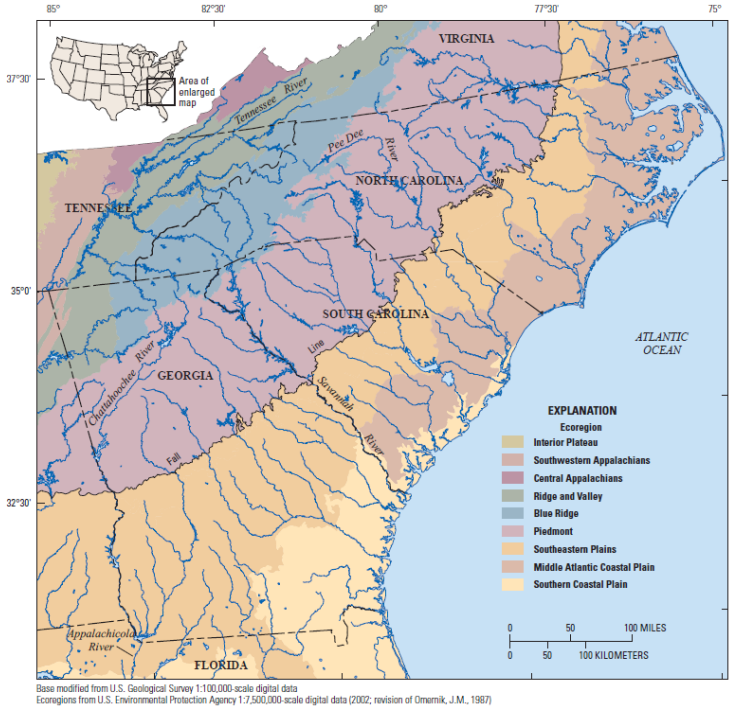

Figure 1 Study area and ecoregions in Georgia, South Carolina, North Carolina, and surrounding States.

DATA COMPILATION

For this investigation, urban and small, rural streamgages with 10 or more years of annual peak-flow record were considered for inclusion in the analysis. Additional rural flood-frequency data included in the study were based on a subset of the stations previously included in the Southeast rural flood-frequency investigation by Gotvald and others (2009), Weaver and others (2009), and Feaster and others (2009), which included annual peak-flow data for rural stations through water year 2006. Generally, the data from those studies selected for inclusion in the current study were based on the upper limits of the drainage area size for the urban streamgages. This was done to maintain some level of uniformity with respect to the range of drainage area sizes for the urban and rural basins. In the Sand Hills, which has the fewest number of streamgages in the hydrologic regions analyzed, all of the streamgages from the Southeast rural flood-frequency investigation were included.

After compiling the peak-flow data for the urban stations, quality assurance and quality control (QAQC) methods were used to assess homogeneity of the annual peak-flow data for the period being analyzed and to assess other potential issues. The QAQC methods used to review the rural streamgages previously included in the Southeast rural flood-frequency study can be found in the reports by Gotvald and others (2009), Weaver and others (2009), and Feaster and others (2009). Similar QAQC methods also were used for the urban streamgages included in this investigation. Kendall's tau was chosen to assess the significance of temporal trends in the peak-flow record for each streamgage (Helsel and Hirsch, 1992). For the urban streamgages in South Carolina and North Carolina, historical aerial photographs from Google Earth were reviewed to assess stable periods of urbanization. Along with the aerial photographs, plots of the annual peak flows also were reviewed. If the Kendall's tau analysis indicated a trend, all of the available information was used to determine whether there was a sufficient period of record available that indicated a relatively stable period of urbanization. If so, that period of record was used in the at-site flood-frequency analysis. Otherwise, the station was excluded from the analysis. For the Georgia urban stations, Gotvald and Knaak (2011) also reviewed historical information to determine periods of relatively stable urbanization.

Peak-Flow Data: Streamgages were used in the analysis only if 10 or more years of annual peak-flow data were available and if peak flows at the streamgages were not affected substantially by dam regulation, flood-retarding reservoirs, channelization, or tides. Based on results from the QAQC reviews, peak-flow data from 340 rural stations, of which 336 were previously published as part of the USGS Southeast rural flood-frequency investigation, 32 small, rural stations, and 116 urban stations were included in the analysis (fig. 2).

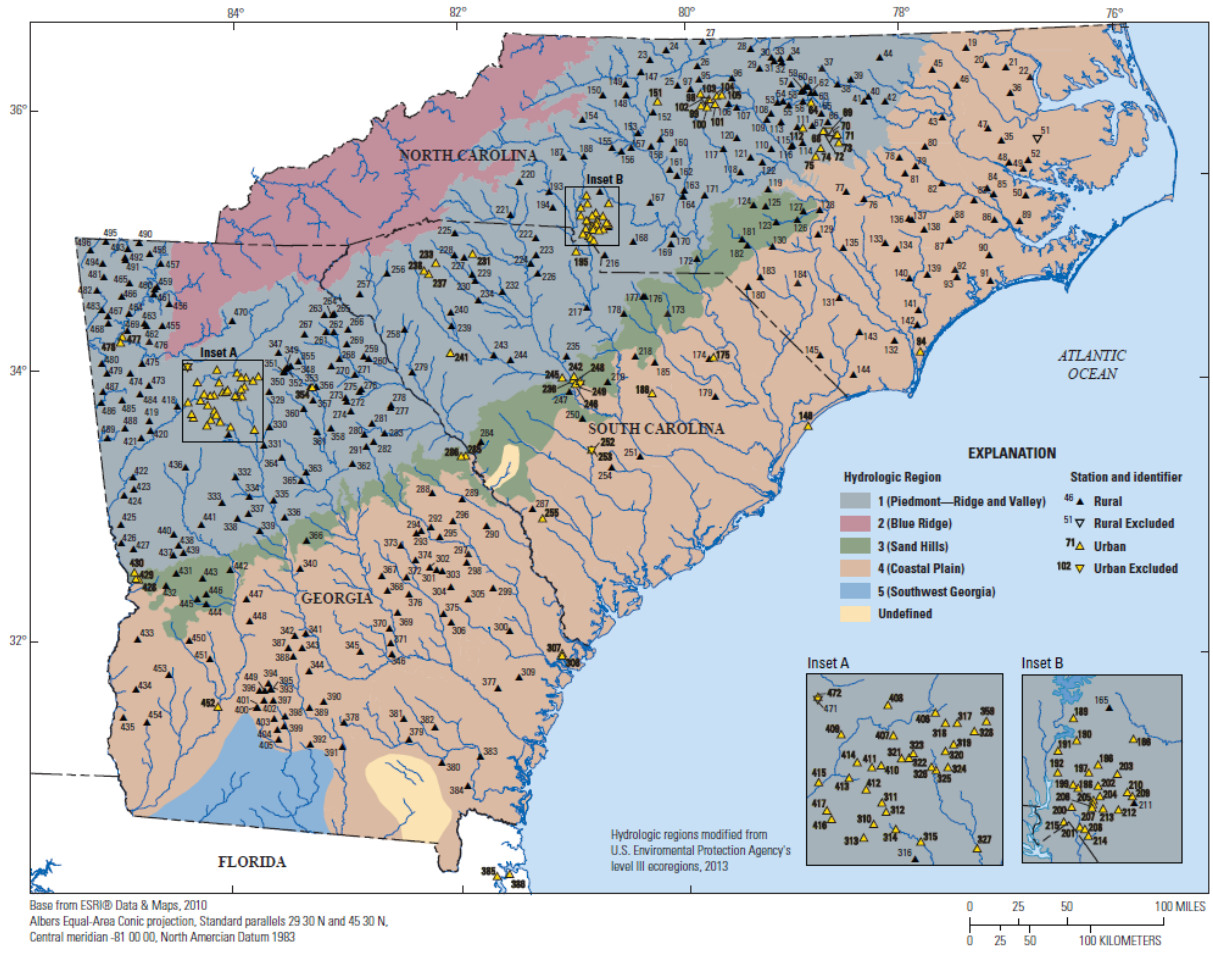

Figure 2 Locations of hydrologic regions and U.S. Geological Survey streamgages with 10 or more years of record that were included in the Southeast regional-regression analysis for urban and small, rural streams.

In an effort to increase the range of drainage basin area for the urban streamgages in the Coastal Plain, USGS flood-frequency reports from other States along the Atlantic Coastal Plain (fig. 3) were reviewed in an effort to find additional urban streamgages to include in the regression analysis. In order to verify that the Coastal Plain flood-frequency characteristics were similar to those in Georgia, South Carolina, and North Carolina, the published 1-percent annual exceedance probability (AEP) flows for rural basins in Virginia (Austin and others, 2011), Maryland (Ries and Dillow, 2006), Delaware (Ries and Dillow, 2006), and New Jersey (Watson and Schopp, 2009) were graphically compared with published 1-percent AEP flows from the Southeast rural flood-frequency study (Feaster and others, 2009; fig. 4A and 4B). As shown in figure 4B, the New Jersey inner Coastal Plain (ICP) 1-percent AEP flows are well within the dataset of the Southeast Coastal Plain streamgages whereas the New Jersey outer Coastal Plain data fall either below or on the lower edge of the Southeast data as do much of the Delaware Coastal Plain data. The Virginia and Maryland Coastal Plain data also plot well within the Southeast Coastal Plain data. Because the New Jersey ICP rural data were comparable to the Southeast rural Coastal Plain data, it was concluded that the urban streamgages from the Coastal

Plain in Virginia and Maryland as well as the New Jersey ICP would be appropriate to include in the Southeast urban flood-frequency analysis. This conclusion assumes that with respect to streamflow, the effect of urbanization in the Virginia, Maryland, and the New Jersey ICP is similar to that in the Southeast Coastal Plain. From a review of previously published peak-flow data for urban streamgages in the Coastal Plain regions of Virginia, Maryland, and the New Jersey ICP, it was determined that only New Jersey had sufficient measured urban peak-flow data that could be included in the Southeast study. Similar QAQC reviews were done for the New Jersey ICP urban streamgages as were done for the Southeast urban streamgages. Consequently, peak-flow data from 16 urban and 2 rural stations from the New Jersey ICP also were included in the analysis. Incorporation of urban streamgages from the New Jersey ICP allowed for an increase in the range of drainage area size from 2.1 to 53.5 mi^2 for which the predictive equations for the Southeast Coastal Plain are applicable.

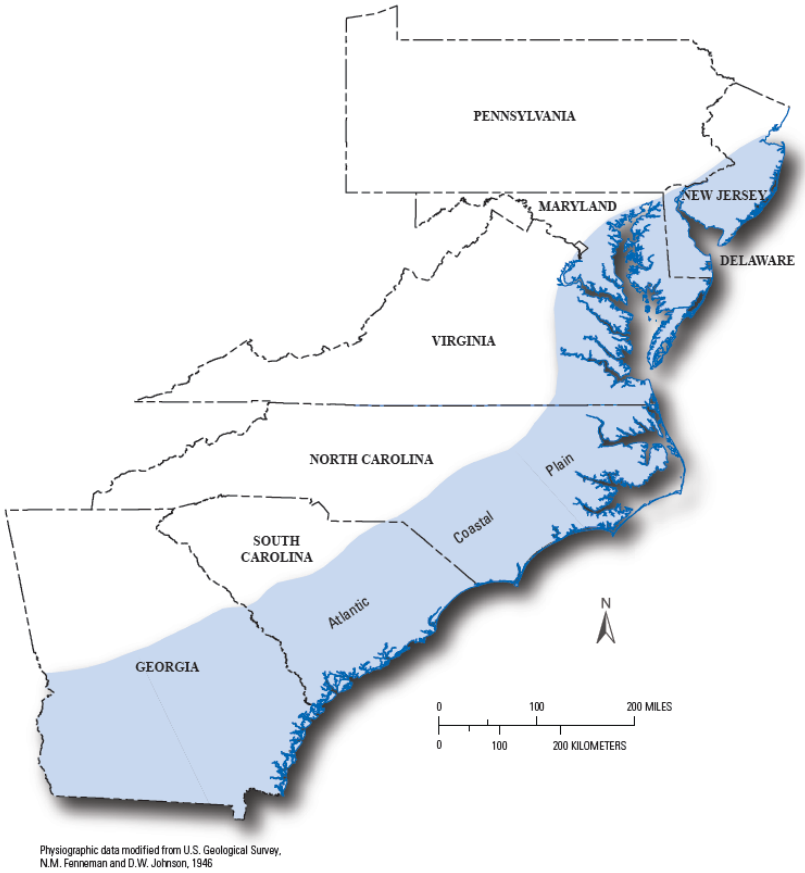

Figure 3 The Atlantic Coastal Plain from Georgia to New Jersey.

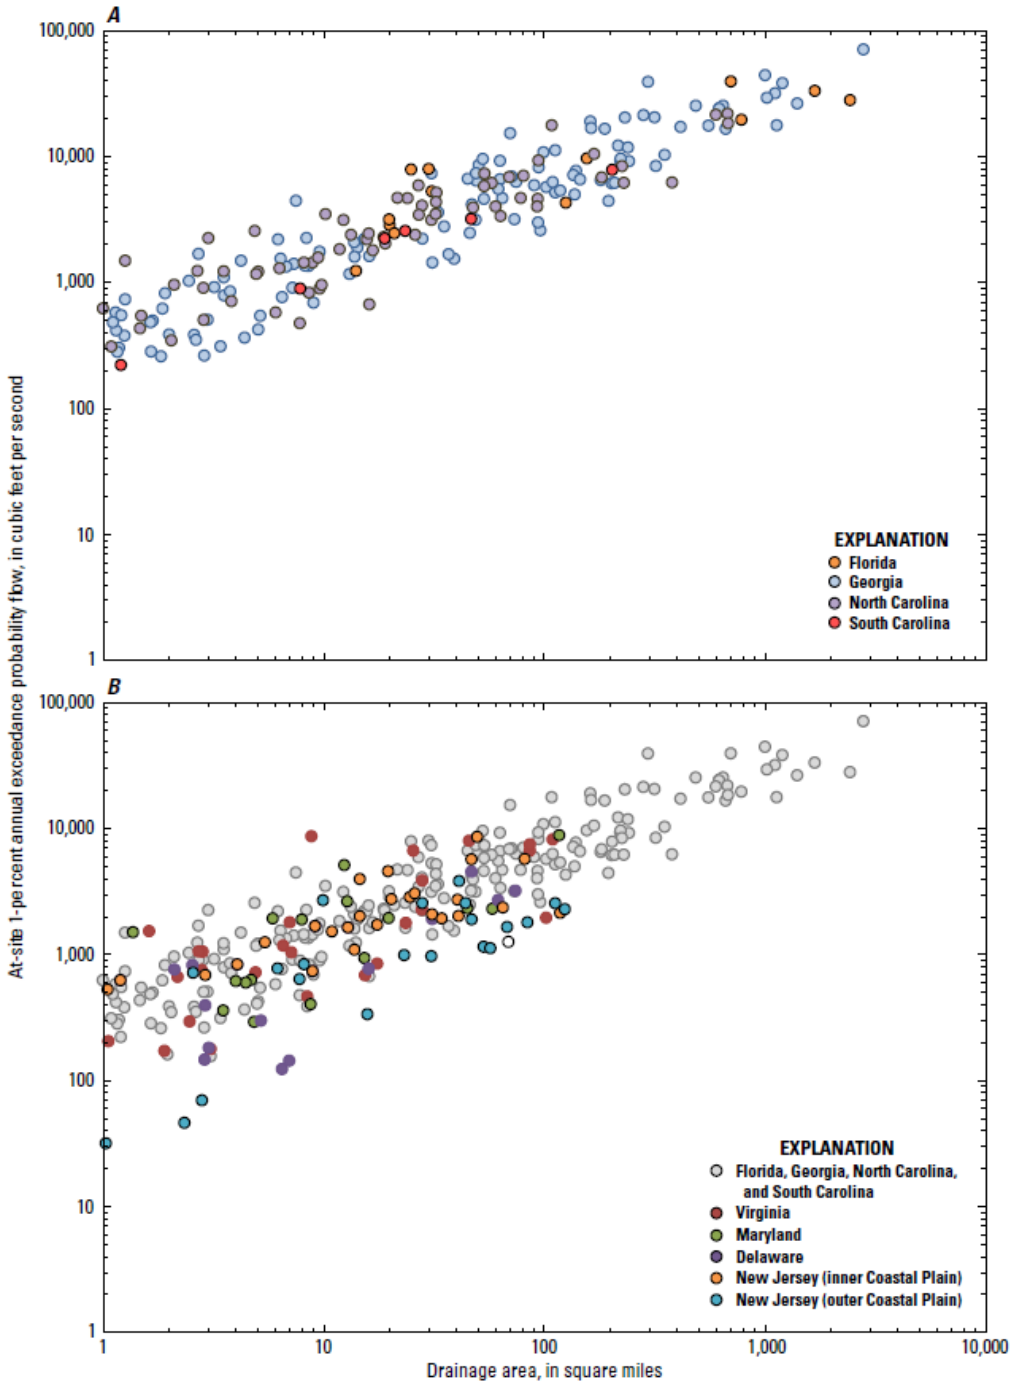

Figure 4 At-site 1-percent annual exceedance probability flow and drainage area for (A) U.S. Geological Survey rural streamflow-gaging stations (streamgages) in Florida, Georgia, South Carolina, and North Carolina that were included in the Southeast rural flood-frequency investigation (Feaster and others, 2009) and (B) rural streamgages from Virginia, Maryland, Delaware, and New Jersey (Austin and others, 2011; Ries and Dillow, 2006; and Watson and Schopp, 2009).

Physical and Climatic Basin Characteristics: The frequency and magnitude of floods can be estimated at ungaged sites through multiple regression analysis, which relates streamflow characteristics such as the 1-percent AEP flow, (also often referred to as the 100-year flood), to selected physical and climatic basin characteristics for gaged drainage basins. Physical and climatic basin characteristics were selected for use as potential explanatory variables in the regression analyses on the basis of the conceptual relation to flood flows and the ability to measure the basin characteristics using digital datasets and Geographic Information System (GIS) technology. The following 23 basin characteristics were determined for each streamgage included in the analysis: drainage area, main channel length, basin perimeter, main channel slope, mean basin slope, basin shape factor, mean basin elevation, maximum basin elevation, minimum basin elevation, percentage of impervious area, percentage of developed land, percentage of forested land, percentage of storage, mean annual precipitation, maximum 24-hour precipitation with recurrence intervals of 2-, 10-, 25-, 50-, and 100-years, soil drainage index, hydrologic soil index, drainage density, and population density.

FLOOD-FREQUENCY ANALYSIS AT URBAN AND SMALL, RURAL STREAMGAGES

A frequency analysis of annual peak-flow data at a streamgage provides an estimate of the flood magnitude and frequency for that specific stream site. Flood-frequency estimates for streamgages are computed by fitting the series of annual peak flows to a known statistical distribution. Flood-frequency estimates for streamgages included in this study were computed by fitting logarithms (base 10) of the annual peak flows to a Pearson Type III distribution. This method follows the guidelines and computational methods described in Bulletin 17B of the Hydrology Subcommittee of the Interagency Advisory Committee on Water Data (1982), which has been the standard methodology for flod-frequency analysis in the United States since 1981. However, the authors of Bulletin 17B noted that the guide was designed to *"...meet a current, ever-pressing demand that the Federal Government develop a coherent set of procedures for accurately defining flood potentials..."* but that additional studies were needed to address a number of items identified in Bulletin 17B as "Future Studies". On the basis of studies made in response to those recommendations, adoption of the expected moments algorithm (EMA) is among the changes that have been suggested (Cohn and others, 1997, 2001; Tim Cohn, U.S. Geological Survey, written commun., September 27, 2012) and are starting to be applied in USGS flood-frequency studies (Gotvald and others, 2012; Zarriello and others, 2012; Kessler and others, 2013). The flood-frequency estimates for the urban streamgages were completed using a modified version of the methods described in Bulletin 17B, by including the EMA, which allows for a more generalized approach to representing observed annual peak-flow information by using an interval range as compared to the conventional method of using point data (Cohn and others, 1997). In addition, a generalized Grubbs-Becks test, which allows for the detection of multiple potentially influential low outliers (Cohn and others, 2013), also was used.

For the rural streamgages in Georgia, South Carolina, and North Carolina, the flood-frequency estimates were obtained from those previously published in the Southeast rural flood-frequency investigation (Feaster and others, 2009; Gotvald and others, 2009; Weaver and others, 2009). In addition, the flood-frequency estimates for the Georgia urban and small, rural streamgages

included in Gotvald and Knaak (2011) were updated by including additional data collected through September 2011. Updating the flood-frequency analyses for the Georgia urban and small, rural streamgages allowed for the inclusion of the historic floods that occurred in northern Georgia during September 2009 (McCallum and Gotvald, 2010). For the streamgages included from the New Jersey inner Coastal Plain, the flood-frequency estimates were updated in consultation with USGS New Jersey Water Science Center hydrologists and also included peak-flow data through September 2011.

ESTIMATION OF FLOOD MAGNITUDE AND FREQUENCY AT UNGAGED URBAN AND SMALL, RURAL SITES

A regional regression analysis was used to develop a set of equations for use in estimating the magnitude and frequency of floods for ungaged urban and small, rural sites in Georgia, South Carolina, and North Carolina. These equations relate the 50-, 20-, 10-, 4-, 2-, 1-, 0.5-, and 0.2-percent AEP flows (also referred to as the 2-, 5-, 10-, 25-, 50-, 100-, 200-, and 500-year recurrence interval flows) computed from available peak-flow records for streamgages to measured physical and climatic basin characteristics of the associated drainage basins. For the initial analysis, the upper limit for the drainage area of the rural streamgages included in the regression analysis was established based on the upper limit of the drainage area for the urban streamgages in each hydrologic region (HR; fig. 2) so that reasonable representation of basin characteristics for both urban and rural streamgages would be included in the analysis. Additionally, only the Southeast rural streamgages that drained 100 percent from a single HR were included in the regression analysis (all the urban streamgages drained 100 percent from individual HRs). Some of the benefits of including urban and rural streamgages together in the regression analysis are (1) smoother transition between urban and rural flood-frequency estimates, (2) larger database than would be available with urban streamgages alone, and (3) larger geographical coverage in the HRs, which will represent a broader range of hydrologic conditions likely to occur at ungaged locations (fig. 2).

Regression Analysis: Selection of the explanatory variables for each hydrologic region was based on all-possible-subsets (APS) regression methods (Neter and others, 1985). The final explanatory variables for each hydrologic region were selected on the basis of several factors, including standard error of the estimate, Mallow's *Cp* statistic, statistical significance of the explanatory variables, coefficient of determination (r^2), and ease of measurement of explanatory variables. Multicollinearity, a situation in which two or more explanatory variables in a multiple regression model are highly correlated, in the candidate exploratory variables also was assessed by the variance inflation factor (VIF) and the correlation between explanatory variables. Generalized least-squares regression methods, as described by Stedinger and Tasker (1985), were used to determine the final regional P-percent chance exceedance flow regression equations, using the USGS computer program GLSNET (Tasker and Stedinger, 1989; G.D. Tasker, K.M. Flynn, A.M. Lumb, and W.O. Thomas, Jr., U.S. Geological Survey, written commun., 1995). As was done for the rural streamgages included in the Southeast rural flood-frequency investigation by Gotvald and others (2009), Weaver and others (2009) and Feaster and others (2009), the urban streamgages were assessed for redundancy. Redundancy occurs when the drainage basins of two streamgages are nested, which is when one basin is contained inside the other basin and most or all of the peak-flow data at the two streamgages are concurrent. In

order to remove the redundancy from the GLS regression analysis associated with streamgages that represent the same basin, two streamgages on the same stream where the percentage change in drainage area from one station to the second was within 50 percent were considered redundant pair streamgages. If the peak-flow record of the station with the shorter period of record was predominantly captured within the record of the station with the longer period of record and the urbanization characteristics of the two streamgages were relatively similar, the station with the shorter period of record was omitted from the analysis. Based on that criteria, three streamgages were excluded from the regional regression analysis due to redundancy.

Generalized least squares (GLS) regression methods, as described by Stedinger and Tasker (1985), were used to determine the final regional regression equations with the use of the weighted-multiple-linear regression (WREG) program version 1.06 (Julie Kiang, U.S. Geological Survey, written commun., May 2013; Eng and others, 2009). The GLS regression analysis included flood-frequency estimates generated for 488 USGS streamgages: 340 rural; 32 small, rural; and 116 urban. The regional-regression analysis resulted in predictive equations that can be used to estimate the 50-, 20-, 10-, 4-, 2-, 1-, 0.5-, and 0.2-percent AEP flows at urban and small, rural ungaged locations in the Southeast (table 1). Explanatory variables included in the equations are as follows: HR1, drainage area (DA) and percentage of impervious area (IA); HR3, DA and percentage of developed land; and HR4, DA, IA, and the 24-hour, 50-year maximum precipitation (fig. 2, table 1). Average standard error of prediction for the predictive equations, which is a measure of the average accuracy of the regression equations when predicting flood estimates for ungaged sites, ranged from 25 percent for the 10-percent AEP regression equation for the Piedmont--Ridge and Valley region to 73 percent for the 0.2-percent AEP regression equation for the Sand Hills region. An application spreadsheet also was developed that can be used to compute the flood-frequency estimates along with the 95-percent prediction intervals for an ungaged location and is available at http://pubs.usgs.gov/sir/2014/5030/.

SUMMARY

This paper presents methods for determining the magnitude and frequency of floods at urban and small, rural streams in the Southeast United States, which for this investigation includes Georgia, South Carolina, and North Carolina. The regional regression analysis for the investigation includes at-site flood-frequency estimates for 488 streamgages: 340 rural; 32 small, rural; and 116 urban. The at-site flood-frequency analyses for 336 of the 340 rural streamgages were previously published as part of a U.S. Geological Survey (USGS) Southeast rural flood-frequency investigation, which included annual peak-flow data through water year 2006. The at-site flood-frequency analyses for the remaining 152 urban, rural, and small, rural streamgages were completed using annual peak-flow data through water year 2011 and was done using a modified version of the Bulletin 17B procedures by including the expected moments algorithm and a generalized Grubbs-Becks test that allows for the detection of multiple potentially influential low outliers.

In order to expand the range of the drainage area sizes for which the Coastal Plain regression equations would be applicable, 16 urban and 2 rural streamgages were included from the inner Coastal Plain of New Jersey. Analyses comparing rural flood-frequency estimates for streamgages in Virginia, Maryland, Delaware, and New Jersey with streamgages included in the Southeast rural flood-frequency investigation indicated that the 1-percent chance annual exceedance probability (AEP) flows from Virginia, Maryland, and the inner Coastal Plain of New Jersey respond similarly to the 1-percent AEP flows from the Southeast. Consequently, it seemed reasonable to assume that the 1-percent AEP flows from the urban basins in these States also would have characteristics similar to urban basins in the Southeast. However, only the inner Coastal Plain of New Jersey had streamgages with sufficient measured annual peak-flow data to be included in the regression analysis. Including the New Jersey urban streamgages allowed the upper range of the applicable drainage area size for the urban streamgage regression equations to be increased from 2.1 to 53.5 square miles.

The regional regression analysis was completed using generalized least squares regression. The regional-regression analysis resulted in predictive equations that can be used to estimate the 50-, 20-, 10-, 4-, 2-, 1-, 0.5-, and 0.2-percent AEP flows (also referred to as the 2-, 5-, 10-, 25-, 50-, 100-, 200-, and 500-year recurrence interval flows) at urban and small, rural ungaged locations in three hydrologic regions (HR) of South Carolina, North Carolina, and Georgia: HR1, Piedmont--Ridge and Valley; HR3, Sand Hills; and HR4, Coastal Plain. In addition, similar predictive equations for urban and small, rural ungaged locations in HR5, Southwest Georgia, which were published in 2011 in a USGS flood-frequency investigation of urban and small, rural basins in Georgia, were included in this report. There was not a sufficient number of urban streamgages from the Blue Ridge region to allow for generation of urban and small, rural predictive equations. Average standard error of prediction for the predictive equations, which is a measure of the average accuracy of the regression equations when predicting flood estimates for ungaged sites, range from 25.0 percent for the 10-percent AEP regression equation for the Piedmont--Ridge and Valley region to 73.3 percent for the 0.2-percent AEP regression equation for the Sand Hills region.

IMPACTS OF ARTIFICIAL SNOWMAKING ON THE HYDROLOGY OF A SMALL STREAM

Travis A. Dahl, Research Hydraulic Engineer, ERDC Coastal & Hydraulics Laboratory, Vicksburg, MS, Travis.A.Dahl@usace.army.mil; James P. Selegean, Hydraulic Engineer, USACE Detroit District, Detroit, MI,, James.P.Selegean@usace.army.mil

Abstract: Ski areas often turn to artificial snowmaking, in an effort to provide a consistent and desirable product for their customers. This additional snow increases the water that contributes to spring runoff events, but the magnitude of the impact is not always clear. In this paper, we will discuss the hydrologic impacts of artificial snowmaking on Knowlton Creek, a small (~5km^2) watershed in Duluth, MN. Spirit Mountain Recreation Authority (SMRA) is a ski area that occupies 5% of the watershed (~0.25km^2) and relies extensively on artificial snowmaking. Increasing the potential impact on hydrology, the entirety of the water used for artificial snowmaking at this site is imported from outside of the watershed. We will discuss the development of a Hydrologic Modeling System (HEC-HMS) model for the watershed that has been used to compare the impacts of the artificial snowmaking on both the winter snowpack of the watershed and the spring runoff. We will also compare the magnitude of these impacts to those of common design storms.

INTRODUCTION

Knowlton Creek is a tributary to the St. Louis River, which drains to Lake Superior through the St. Louis River and Duluth-Superior Harbor in Duluth, MN and Superior, WI. Large portions of the watershed are within the City of Duluth and the entire watershed is in St. Louis County. Figure 1 shows the location of the watershed.

There has been significant sedimentation at the mouth of Knowlton Creek, behind Tallas Island, since the early 1960s. The timeframe for the increased sedimentation roughly coincides with the opening of a ski area (Spirit Mountain Recreation Authority, SMRA) in the watershed and the use of artificial snowmaking for the ski runs. The snow at SMRA is produced using treated City of Duluth water that is brought in from outside of the Knowlton Creek watershed.

The Knowlton Creek watershed is 5 km^2 (1.94 miles^2), while an additional 1.1 km^2 (0.4 miles^2) contributes to the same area of the St. Louis River Estuary, immediately behind Tallas Island. The majority of the watershed is forested. The exceptions are the ski runs at SMRA and associated buildings and parking lots; the I-35 corridor; and some light residential areas scattered throughout the watershed. The ski runs at SMRA account for approximately 0.25 km^2 (0.10 miles^2) or 5.0% of the Knowlton Creek watershed and 0.33km^2 (0.13 miles^2) or 5.4% of the entire area contributing to the region behind Tallas Island. The Knowlton Creek watershed and the adjacent contributing watersheds are shown in Figure 2.

The topography of the watershed can be roughly split into three categories. The uppermost portions of the watershed consist of rolling hills. The middle section of the watershed, where the ski area is located, is very steep with some areas approaching 25% slopes. The lowest portions of the watershed are relatively flat. The maximum elevation difference from the top of the watershed to Tallas Island is 232.9 m. Soils consist primarily of glacial tills with areas of exposed bedrock along Knowlton Creek.

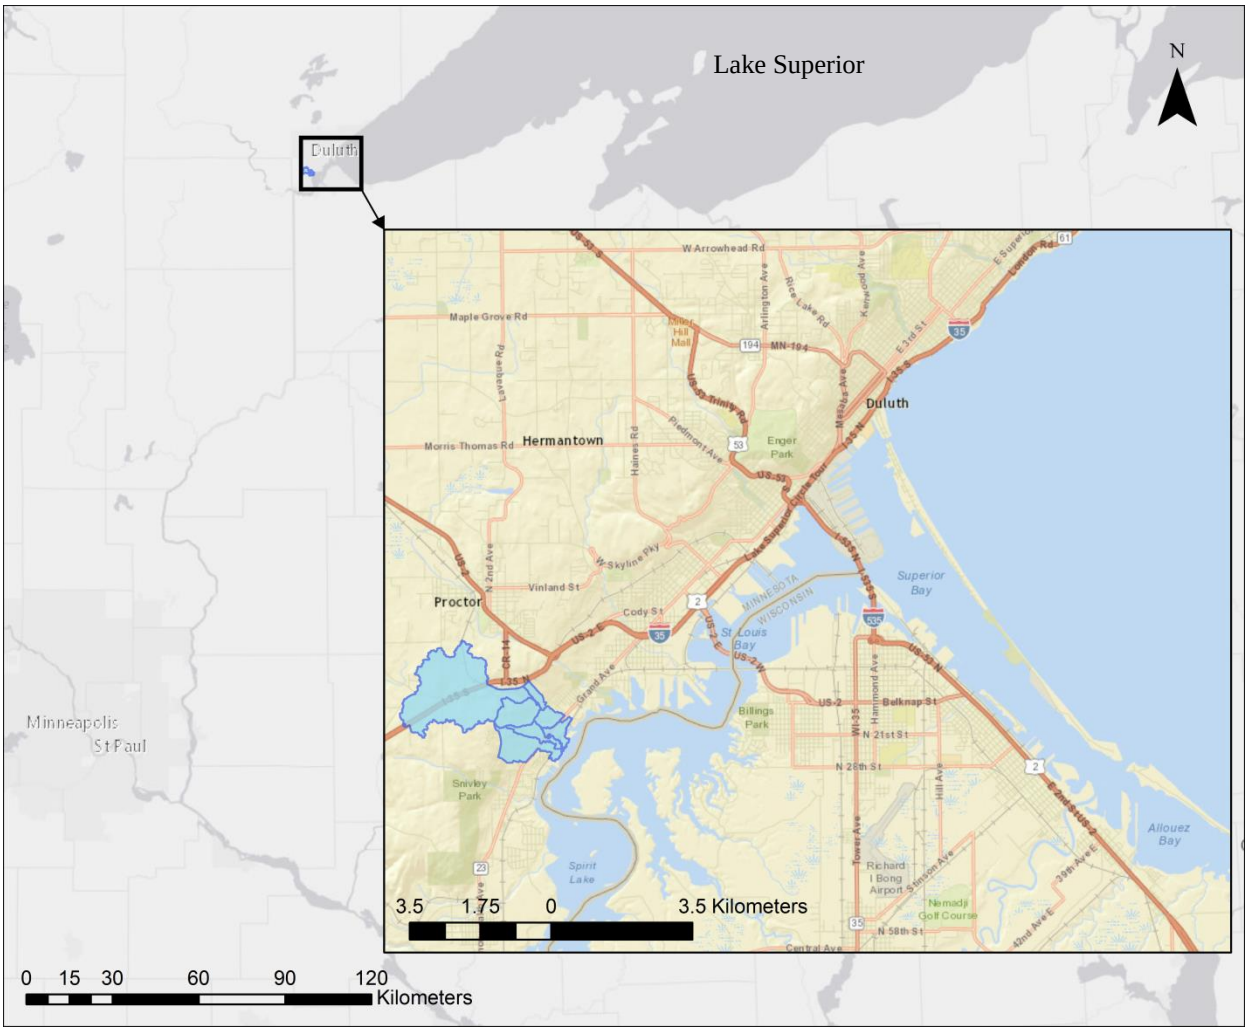

Figure 1 Location map of the Knowlton Creek watershed.

METHODS

In order to estimate the impacts of runoff and snowmaking activities, a hydrologic model was developed using the Hydrologic Engineering Center's Hydrologic Modeling System (HEC-HMS) Version 4.0 (Scharffenberg, 2013). HEC-HMS is a process-based, lumped parameter hydrology model designed to simulate rainfall-runoff processes.

Two cross-sections were surveyed on 4-Nov-2010 as part of a separate, regional bank erosion study. One of the cross-sections was located on the mainstem of Knowlton Creek and one on the eastern tributary. Onset Hobo water level loggers, model U20-001-04, were installed at both cross-sections on 3-Jun-2011 (Figure 2). An additional logger was attached to a tree in the floodplain, approximately 30 m upstream of the mainstem gage, to record atmospheric pressure. The loggers recorded at five minute intervals from 3-Jun-2011 to 17-Aug-2011 and 17-Oct-2011 to 4-Nov-2011. Data were logged at 15 minute intervals from 4-Nov-2011 to 8-Jun-2012. The stage and water temperature data are shown in Figure 3. Water level data between 2-Dec-2011 and 19-Mar-2012 were considered unreliable, since the measured water temperature was 0°C, indicating frozen water. Additionally, the total volume of streamflow estimated for the snowmelt event was greater

than the combined water that was used for snowmaking and the winter precipitation from the entire contributing area. This problem was likely due to the presence of snow and ice in the channel.

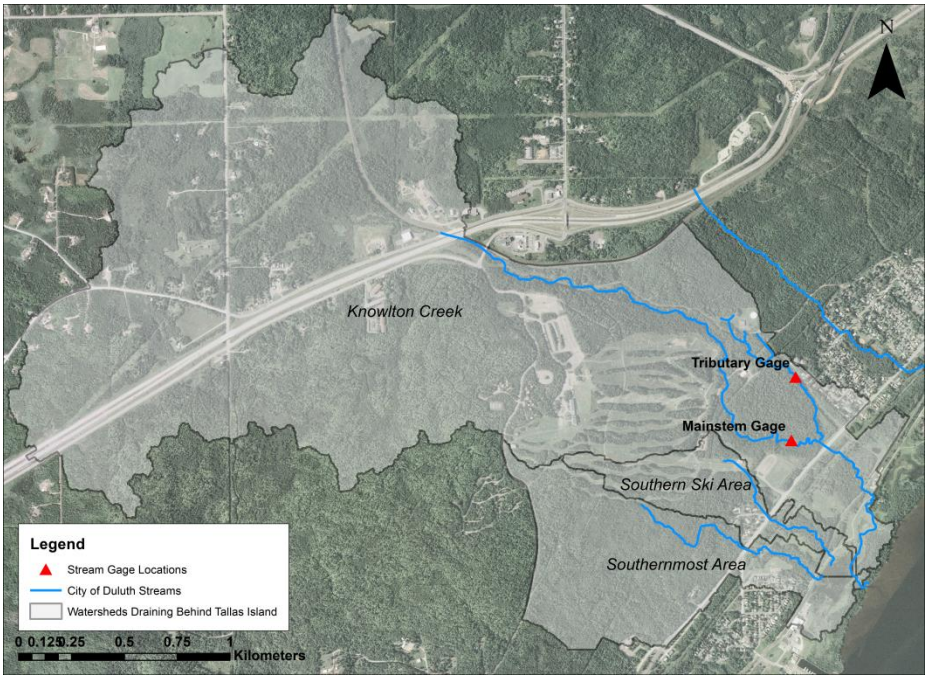

Figure 2 Aerial photo of Knowlton Creek and adjacent watersheds draining to the region behind Tallas Island. The largest watershed, to the north, is Knowlton Creek. The two watersheds on the south side of the aerial photo also drain portions of the Spirit Mountain ski area the same vicinity. The ski runs are visible as the East-West stripes in this picture. Stream gage locations are indicated by red triangles.

Flow measurements were made using a Sontek FlowTracker handheld ADV. Flows were measured on 17-Oct-2011, 19-Oct-2011, 4-Nov-2011, 7-Jun-2012, and 8-Jun-2012. Due to the small size of the watershed and the lead time necessary to reach the site, it was not possible to measure a high flow event. In order to convert the water levels to flows at each site, the collected data were used to estimate a roughness coefficient for Manning's Equation (Chow, 1959). Manning's Equation was then applied to the remainder of the water level data to generate a time series of streamflow. The resulting flows can be seen in Figure 4.

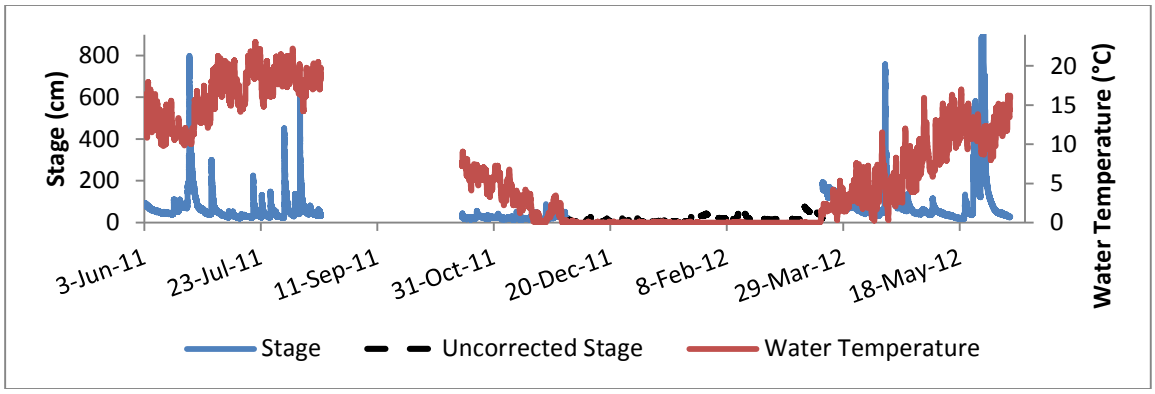

Figure 3 Stage and water temperature observations at the Knowlton Mainstem Gage. The uncorrected stage (black dashed line) indicates the portion of gage record that was not used due to concerns about its reliability.

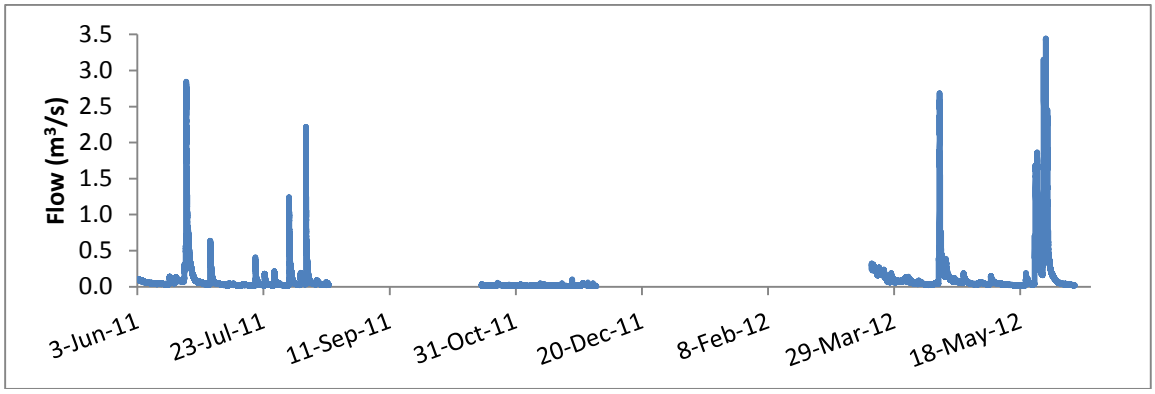

Figure 4 Flow at the Knowlton Mainstem Gage calculated from the level logger stage.

A number of data sets were collected for use in developing the HEC-HMS model. A high resolution LIDAR digital elevation model (DEM), collected in 2011, was obtained from the Minnesota Department of Natural Resources, as was a 2009 aerial photo. A shapefile of the stream network in and around Knowlton Creek was provided by the City of Duluth. SSURGO soils data were acquired from the U.S. Department of Agriculture.

In order to estimate the primary physical characteristics of the watershed, data were processed using the Geospatial Hydrologic Modeling Extension (GeoHMS, version 2010 EAP) for ArcGIS 10 (ESRI, 2011). The stream network from the City of Duluth was modified to include the section of stream extending up to the City of Cloquet pump station. This modified stream shapefile was then "burned" into the digital elevation model (DEM), in order to ensure that water would move along the known flowpaths. The DEM Reconditioning in GeoHMS was iterated several times in order to arrive at a stream network that matched the aerial photo data.

Several of the smaller subwatersheds were combined for modeling purposes. The final watershed map is shown in Figure 5 and the HMS schematic is displayed in Figure 6.

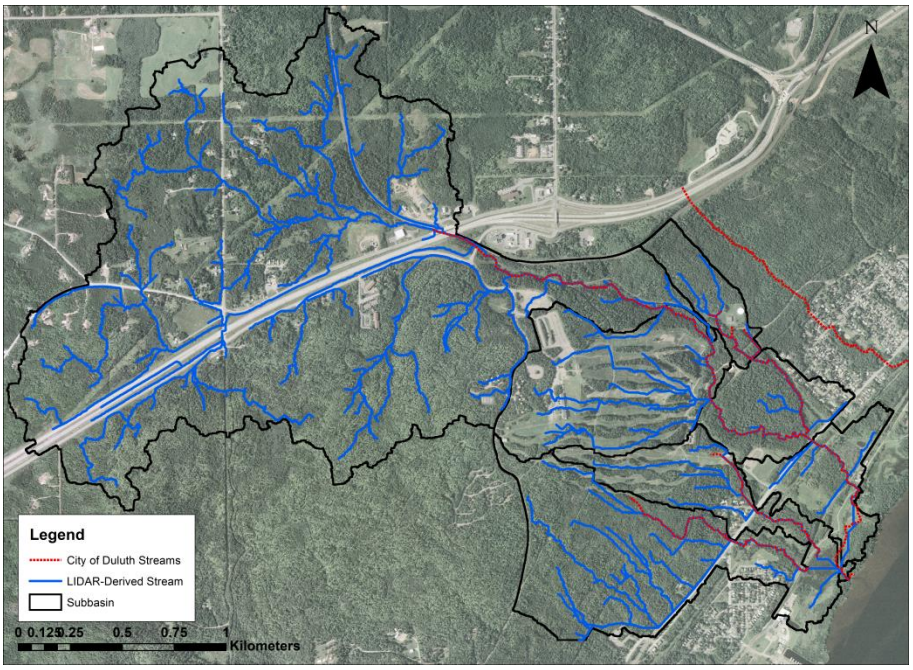

Figure 5 Modeled subwatersheds are outlined in black. The dashed red lines are the stream network provided by the City of Duluth. The blue lines indicate the LIDAR-derived stream network.

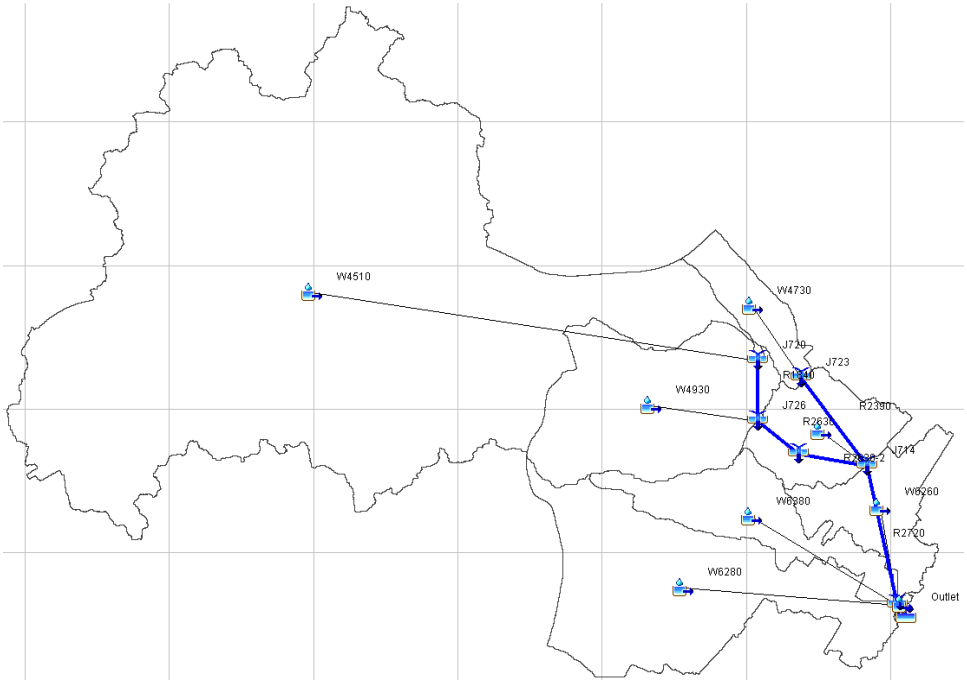

Figure 6 Schematic of the HMS model showing the relation to the modeled subwatersheds.

Precipitation and temperature data were obtained from the National Climatic Data Center (NCDC) for both Duluth International Airport (Duluth, MN) and Richard I. Bong Airport (Superior, WI). In conversations, Spirit Mountain personnel indicated that the precipitation measured at Duluth International Airport tends to be much higher than what is received at the ski area. It was decided to use the precipitation data from the Richard I. Bong Airport for the entire watershed.

HMS subwatersheds were set up with the Soil Moisture Accounting loss method. Clark Unit Hydrograph was chosen as the transform method to calculate runoff timing. The Simple Canopy and Simple Surface methods were also used. Baseflow was set to the Linear Reservoir method and the initial baseflow discharge was calculated by dividing the low flow in Knowlton Creek by the contributing watershed area.

The Kinematic Wave method was used for routing in the reach elements, due to the steep slopes (up to 6%) in the area. Channel parameters were estimated using the survey data and LIDAR-derived DEM.

The model was calibrated at the mainstem gage for the time period 24-Apr-2012 to 4-Jun-2012, since this included both a dry period and a large rain event. Calibration parameters included the Clark Unit Hydrograph time of concentration and storage coefficients, the maximum canopy and surface storages, and the Manning's roughness coefficient of the reaches. The results from the final calibration can be seen in Figure 7. After calibration, the Nash-Sutcliffe efficiency (Nash and Sutcliffe, 1970), a measure of how well the modeled values match the observed data, was 0.89. Nash-Sutcliffe efficiencies can range from $-\infty$ to 1, with 1 indicating a perfect fit of the observed data. A Nash-Sutcliffe efficiency above 0.5 is considered necessary for a good model (Moriasi et al., 2007).

The parameters from the subwatersheds upstream of the mainstem gage, including those associated with the Clark Unit Hydrograph and Soil Moisture Accounting methods, were translated to the other subwatersheds by scaling relative to the longest centroidal flowpath. The calibrated model was then run for the 2-year SCS Type 2 24-hour storm as an example of a common rainfall-driven event that would be likely to move significant sediment and could be compared to snowmelt events.

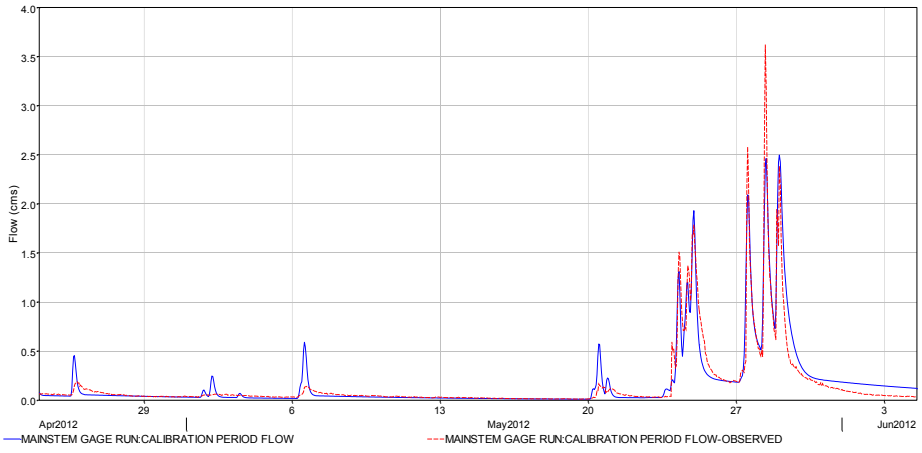

Figure 7 Calibration of the HMS model. The red line is the gaged data while the blue line is the output from the HMS model.

According to SMRA's records, provided by Johnson Controls, the ski area used an average of 238,073 m^3 of water per season between the winter of 1999-2000 and the winter of 2011-2012. It was applied at an average rate of 0.09 m^3/s. In order to determine the impacts of these snowmaking activities on the hydrology of Knowlton Creek, the HMS model was modified to calculate snow accumulation and melt. This version of the model was then run both with and without the additional water applied during snowmaking.

The accumulation and melt of snow were handled by using the Temperature Index snowmelt routine in HMS (Daly et al., 2000). To simulate the effects of frozen ground, the maximum infiltration rates for all of the watersheds were decreased. The lack of valid winter streamflow data prevented calibration of the snowmelt modeling. Instead, two sets of simulations were conducted in order to provide a range of values that would likely contain the actual snowpack and flows. The first set used typical values for the temperature index model parameters (Scharffenberg, 2013; Steve Daly, personal communication) and is referred to as the "Base" snowmelt model in this document. The second set used the high end of the suggested parameter ranges, in order to produce greater snowpack and melt. This set of parameters is called the "Peaked" snowmelt scenario. Due to the uncertainties regarding infiltration and frozen ground under the snowpack, each set of simulations was run for three different infiltration conditions: 100%, 10%, and 0% of the unfrozen infiltration.

According to SMRA, snowmaking operations run 24-hours per day during the entire snowmaking period. It was assumed that the water was applied equally to all of the ski runs maintained by SMRA. The precipitation equivalent of the snowmaking was calculated by dividing the total amount of water used by the hours of snowmaking for each season and then divided by the total area of all of the ski runs.

The ski runs are spread across three different subwatersheds in the model. HEC-HMS is a lumped parameter model and the watersheds were defined to include both ski run and non-ski run areas, so the water used for snowmaking was apportioned to each subwatershed based on the percentage of ski run area they contained. For example, 23.37% of the Southern Ski Area receives artificial snowmaking, so the hourly precipitation for the entire subwatershed was increased by multiplying the average amount of water used for snowmaking on all ski runs (as a depth in mm) by 23.37%, during the entire snowmaking period. This is illustrated graphically in Figure 8. This precipitation equivalent was calculated for each subwatershed and added to the precipitation applied using HEC-DSSVue. The area of each subwatershed, the area of ski runs, and the percentage of watershed area occupied by ski runs are summarized in Table 1.

While the magnitude of the streamflows collected during the snowmelt event in 2012 were not considered valid, the timing of both the onset of flow and the peak indicated by the gage data matched those from the simulation to within a day.

Table 1 Information used in calculating the contribution of snowmaking water to each subwatershed.

	Watershed Area (m^2)	Ski Run Area in Watershed (m^2)	% of Watershed occupied by Ski Runs	% of Total Snowmaking Water	Average Increase in Winter Precip (2007-2012)
Main Ski Area	605,740	249,866	41.25%	75.0%	326%
Southern Ski Area	292,010	68,235	23.37%	20.5%	50%
Southernmost Area	792,900	14,905	1.88%	4.5%	1%

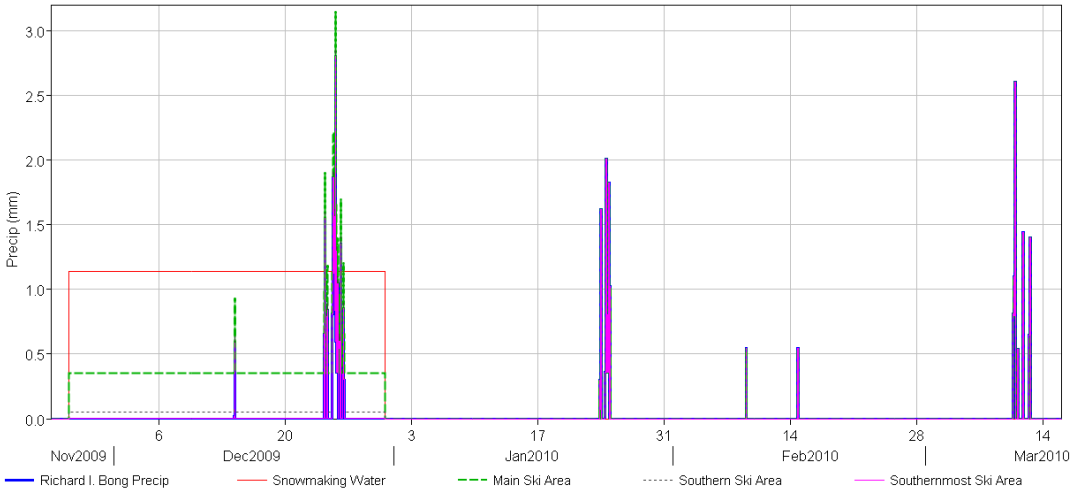

Figure 8 Example of snowmaking precipitation, for the winter of 2009-2010. The blue line is the background precipitation at Richard I. Bong Airport. The red line is the average rate of water applied for snowmaking. The dashed green line is the precipitation applied to the Main Ski Area subwatershed. Outside of the dates of snowmaking, all of the lines are identical.

The HMS model was run for five different winters (1-Oct to 1-May) between 2007 and 2012. The results were then examined and the dates of the snowmelt event, the time period that represents the conversion of the majority of the snowpack to runoff, for each winter were determined by looking at the air temperature records. The snowmelt event was started a few days before the temperature first reached 0 °C and was extended until after all of the snow had melted in the model. The same date range was used to summarize the output for each scenario covering that winter. The dates used for the modeled winters are listed in Table 2.

Table 2 Dates used to summarize the snowmelt event for each simulated winter.

Winter	Snow Melt Dates
2007-2008	30-Mar – 11-Apr-2008
2008-2009	15-Mar – 17-Apr-2009
2009-2010	7-Mar – 20-Mar-2010
2010-2011	15-Feb – 9-Apr-2011
2011-2012	11-Mar – 19-Mar-2012

RESULTS

Peak flow and volume were both reported, in order to better understand the hydrology and potential impact on sediment transport in Knowlton Creek. Figure 9 displays the locations where flow was summarized for this report. Table 3 shows the five-year average peak flow and Table 4 gives the average outflow volume results for all of the snowmelt simulations. These two tables also report the results for the simulation of the 2-year storm event. The Base and Peaked simulations produced nearly identical peak flows, but differed in the volume of the snowmelt event. On average, snowmaking increased the peak flow at the mainstem gage location by 0.2 – 0.3 m^3/s, or 27 - 66% (assuming the same infiltration conditions). The average volume of water in the snowmelt event at this location increased by 124,400 - 152,100 m^3, or 230 - 307%, on average (with identical infiltration conditions). The total volume of water delivered to the area behind Tallas Island increased by 149,300 – 208,500 m^3 (253 - 296%) and the five-year average peak flow at this point increased by 0.3 – 0.5 m^3/s (35 - 76%), assuming unchanged infiltration.

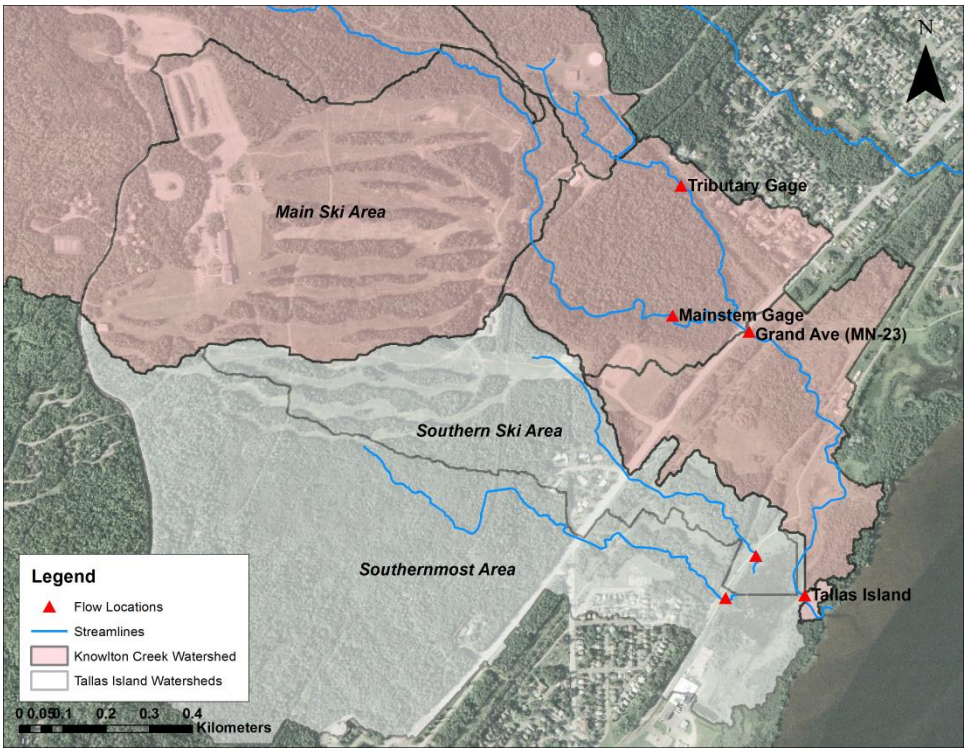

Figure 9 Map showing flow locations and watersheds where Maximum SWE was reported. The Tallas Watershed includes the shaded areas of both colors.

During the course of the winter, the accumulation of snowpack, measured as Snow Water Equivalent (SWE), is also calculated by the model. Figure 9 shows the watersheds where the snowpack was calculated for this report. Table 5 contains the five year average of maximum SWE that occurred for each scenario. Changing the infiltration did not affect the peak SWE, so only one set of results is reported for each combination of snowmaking and snowmelt parameters. The numbers shown for "Knowlton Watershed" and "Tallas Watershed" are area-weighted averages of all the component subwatersheds. This table shows that the peak SWE of the Knowlton Creek watershed increased by 40.9 - 45.3 mm while the peak SWE for the entire area contributing to the flow by Tallas Island increased by 41.4 – 47.3 mm due to snowmaking. The peak snowpack volumes (SWE) in the subwatersheds where the snowmaking took place were affected even more dramatically. The most extreme example of this is the "Main Ski Area" watershed that contains most of SMRA's ski runs. This area experienced an increase in peak SWE of over 340 mm due to snowmaking, during an average winter.

CONCLUSIONS

Snowmaking activities by SMRA have increased the peak flow in the mainstem of Knowlton Creek from the annual snowmelt event by up to one half, on average. Sediment transport is a non-linear function of the flow in a stream, meaning that the ability of the stream to move sediment has likely increased by even more than that amount during these events.

It is important, however, to view these increased snowmelt flows in the context of those resulting from less frequent storm events. This can be done by comparing the values in Table 3 with those in Table 6. The typical snowmelt event resulting from snowmaking activities over 2007-2012 had a peak flow that is less than one-fifth the flow from a 2-year design storm at the Mainstem Gage location. In a well-functioning forested watershed, it is often assumed that the flow most responsible for forming the shape of the stream channel, and the one that will carry the majority of sediment over long periods of time, occurs every one to two years (Leopold et al., 1964). Therefore, it can reasonably be hypothesized that the flow increase above the background

snowmelt caused by snowmaking would play only a minor role in the sediment transport and geomorphic adjustment of Knowlton Creek.

A literature search for studies of snowmaking impacts turned up very little work. Wemple et al. (2007) studied a ski area in Vermont that used water from within its watershed for snowmaking. They found that water yield increased by 18-36%, a much smaller increase than the snowmelt volume in the Knowlton Creek model. In the Vermont study, this resulted in a 2.5-fold increase in suspended sediment yield. The suspended sediment yield typically consists of silts and clays while larger material will move as bed load, except in extreme events. Unfortunately, no estimates of changes to bed load sediment transport or overall sediment yield were given by the Wemple et al. study.

It should also be noted that another significant hydrologic impact of the ski area has likely been the clearing of the ski runs themselves. Historically, the entire hillside of Spirit Mountain was completely covered by forest, which tends to reduce both overland flow and sediment yield. The effects of tree removal and other mechanical activity in the ski area, as well as the addition of impervious surface area across the watershed were not examined in this study.

It may be advisable to reduce the effects of runoff from the snowmelt events caused by artificial snowmaking, even though this impact is likely not large enough to drive the observed changes in the mainstem of the Knowlton Creek channel. If this reduction is done by the use of runoff control on and at the base of the ski slopes, it would also partially mitigate the effects of the land cleared of forest to create the ski area.

COLORADO FRONT RANGE FLOOD OF 2013: PEAK FLOWS AND FLOOD FREQUENCIES

Steven E. Yochum, Hydrologist, US Forest Service, National Stream & Aquatic Ecology Center, Fort Collins, CO, steveneyochum@fs.fed.us

prepared for the 5th Federal Interagency Hydrologic Modeling Conference
April 19-23, 2015, Peppermill Hotel, Reno, Nevada, USA

Abstract: In September of 2013, the Colorado Front Range foothills experienced an extensive period of rainfall that culminated in a major flood that peaked in many streams on Friday, the 13th. Rainfall depths of up to 18 inches were recorded over a 10 day period, with a large proportion of the rainfall falling over a 36 hour period. These foothill locations on average receive between 17 and 19 inches of precipitation annually; this event delivered an average year of rainfall at some locations. In response, many streams in the South Platte and Arkansas River basins flooded. To quantify the magnitude of the flood peaks, several entities implemented forensic hydrology methods to develop peak flow estimates, including the NRCS, USGS, and retired USGS hydrologist Bob Jarrett. Peak discharges of up to 60,000 cfs were quantified. Peak flow unit discharges varied by catchment size, as would be expected. Unit discharges as large as 1340 cfs/mi^2 were measured. For locations with streamgages, revised flow frequency estimates were developed using the logPearson methodology as presented in Bulletin 17B. The 2013 peaks were included in this analysis. For the larger streams impacted by the flooding, this flood had return intervals ranging from a 5- to 25-year flood (Fountain Creek), 25- to 50-year flood (Cache la Poudre River, South Platte River), 100-year flood (Big Thompson River), 100- to 200-year flood (Boulder Creek, Coal Creek), and greater than the 200-year flood (Lefthand Creek, Saint Vrain Creek, Fish Creek).

INTRODUCTION

In September of 2013, large portions of the Colorado Front Range foothills (Figure 1) received an unusual amount of rainfall, with up to 18 inches falling in 10 days. Raingage data over the most severely-impacted foothills indicate up to 15 inches fell in Larimer County, 18 inches fell in Boulder County, and 16 inches fell in El Paso County, the three counties most impacted by the flooding. The highest measured rainfall depths are similar to the average annual rainfall for these areas. The majority of the precipitation fell during 36 hours, on September 11th and 12th. These rainfall data were collected in settled areas and primarily within valley bottoms in many portions of the flood extent; rainfall depths and intensities may have been even greater on some mountain slopes (driven by orographic lift) and in remote areas that were void of ground-based data collection.

As a result, large floods occurred in the South Platte and Arkansas basins, in the Cache la Poudre, Little Thompson, Big Thompson, and South Platte Rivers, and in the Saint Vrain, Left Hand, Boulder, Coal, and Fountain Creeks (Figure 1). Peak flow estimates were developed using forensic hydrology methodologies in these and their contributing streams. Using these peak flow estimates, revised flood discharge relationships were developed at streamgage locations. This report provides a summary of peak flow estimates developed primarily by the Natural Resources

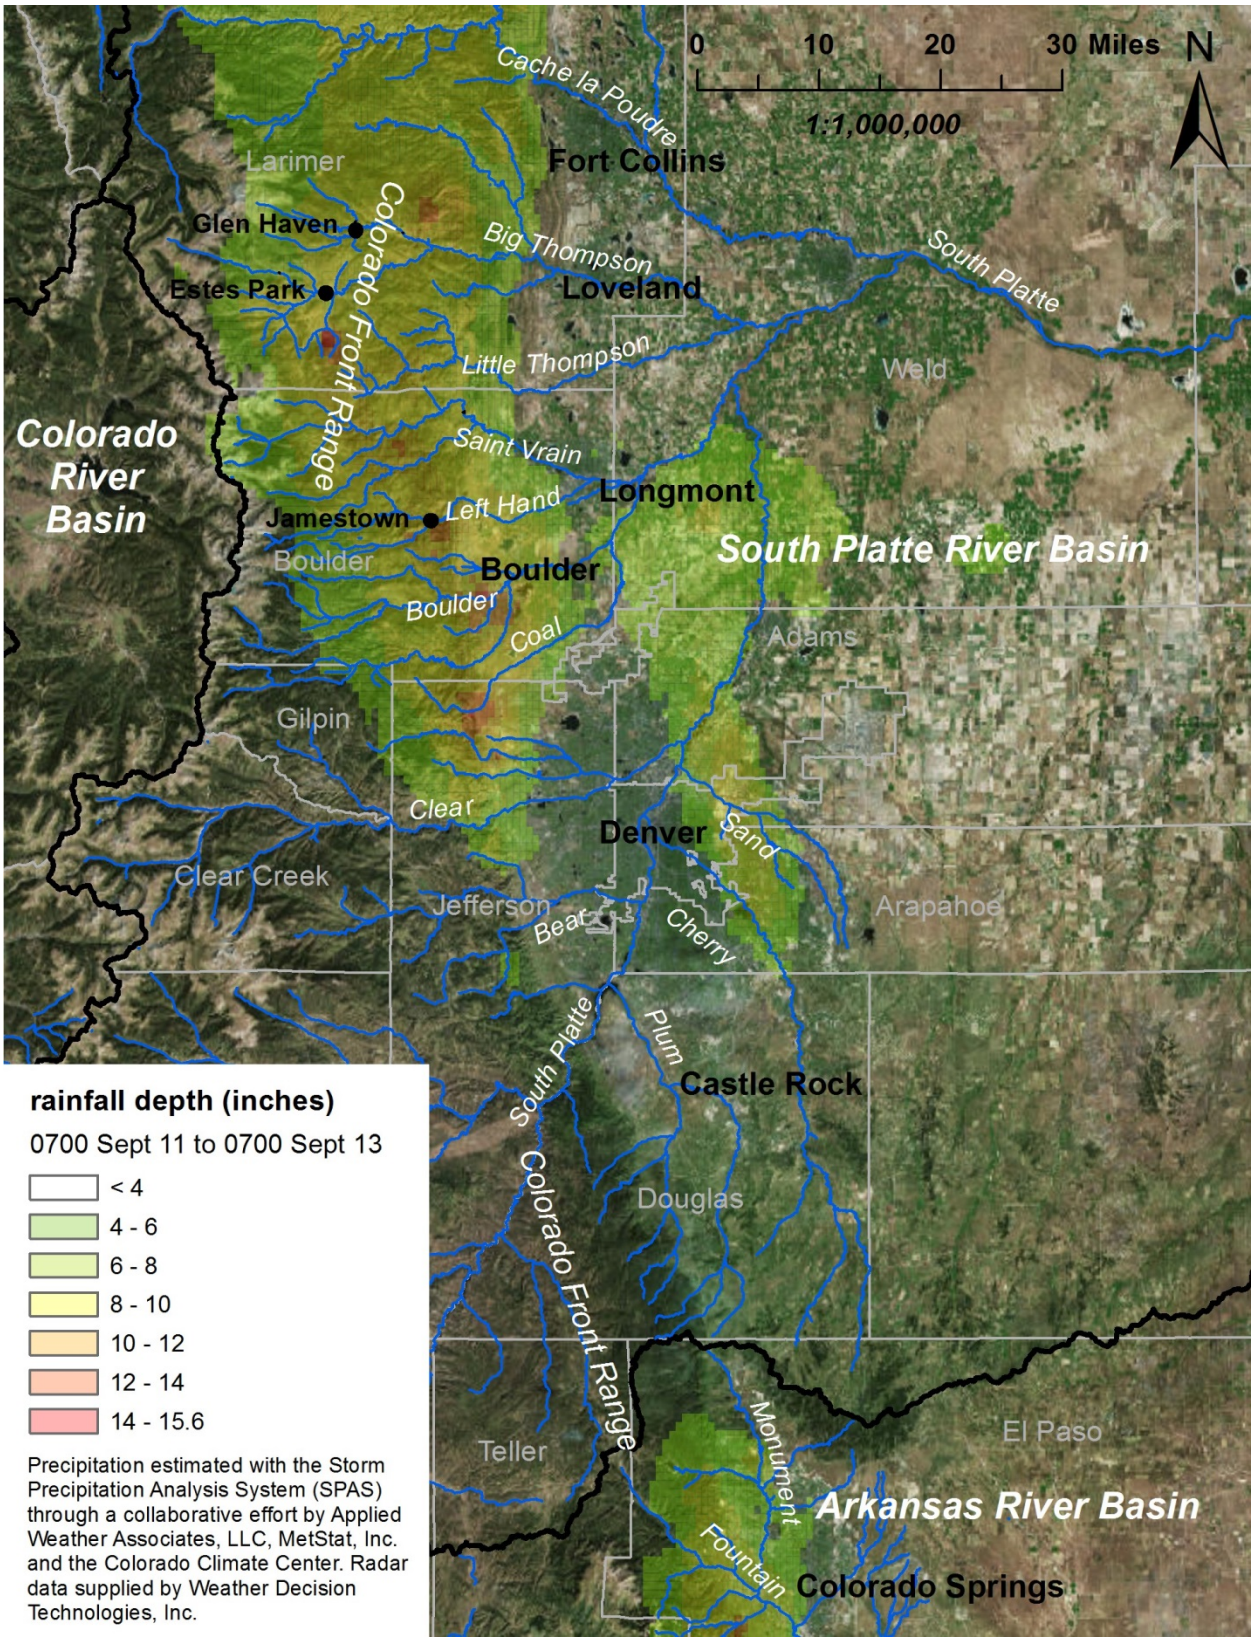

Figure 1 Rainfall depths and streams impacted by the 2013 Colorado Front Range Flood.

Conservation Service (NRCS), the U.S. Geological Survey (USGS) and by Bob Jarrett, a retired USGS research hydrologist. Unit discharges are also presented. Based on updated streamgage analyses, return intervals of the flood peaks are provided.

METHODS

Peak Flow Estimation

Data collection efforts were performed by the NRCS (Steven Yochum and Dan Moore), the USGS, and Bob Jarrett. Peak flow estimates were developed using several methods, including the slope-conveyance, step-backwater, and critical depth methods. Two-dimensional computational modeling was also performed for one site (St. Vrain Creek in Lyons). The slope-conveyance method assumes uniform flow and applies the Manning's equation to cross sectional data. This method requires a Manning's *n* estimate, which is problematic since *n* varies by stage and debris loading (Limerinos, 1970; Bathurst, 1985; Lee and Ferguson, 2002; Wilcox and Wohl, 2006; Reid and Hickin, 2008; Ferguson, 2010; Yochum et al. 2012), and since little field-based data has been collected during large floods for informing the computations. The step-backwater method implements a series of cross sections and 1-dimensional gradually-varied flow computations using such software as HEC-RAS. Discharge is varied until a series of high water marks are matched by the simulated water surface. This method also relies upon uncertain Manning's *n* estimates. The critical depth method assumes critical flow at a control cross section, such as at a constriction or drop off of a channel, or assumes critical flow in a high gradient channel. For slopes over 1 percent, it has been found that a critical depth assumption, with 3 to 6 replicate estimates from multiple cross sections within the reach of interest, can obtain estimates within $\pm 15\%$ of discharges measured with current meters (Jarrett and Tomlinson 2000; Webb and Jarrett 2002; Jarrett and England 2002). This method avoids estimation errors imposed by unknown Manning's *n* coefficients for large flood events, but is instead reliant upon the critical depth assumption and is sensitive to such conditions as backwater and localized supercritical flow. A more detailed discussion of each method is provided in Webb and Jarrett (2002).

Peak flow data were obtained from Jarrett (2014) – Applied Weather Associates, Yochum and Moore (2013) – NRCS, from Kimbrough (2014) – USGS, and from the USGS's National Water Information System (NWIS, http://waterdata.usgs.gov/co/nwis/sw). The majority of the estimates (NRCS, Jarrett) were developed using the critical depth method, in higher-gradient channels (> 1 percent). (The USGS primarily relied upon the slope-conveyance and step-backwater methods.) Using the critical-depth method, peak flow estimates are made using a single cross section, implementing high water marks at each location. Replicate measurements (separate flow estimates developed for several adjacent cross sections) were made for each reach of interest, to assess the reliability of the overall estimate. During floods, higher-gradient channels can flow at or near critical depth, where the Froude number (*Fr*) is unity and the following equation is applied to each cross section:

$$Fr = 1 = \frac{V}{\sqrt{gD}} \qquad (1)$$

where, V is the average cross section velocity, D is the average flow depth ($D = A/T_w$), A is the

flow area, T_w is the top width, and g is the acceleration due to gravity. Using the continuity equation, $Q = VA$, the Froude number equation can be reformulated to obtain flow rate:

$$Q = A\sqrt{\frac{gA}{T_w}} \quad (2)$$

where Q is the discharge in cubic feet per second (cfs).

Flood-Frequency Analysis

The flood frequency analyses at streamgages where 2013 flood peaks are available were performed using logPearson frequency analyses as described in Bulletin 17B (Interagency Advisory Committee on Water Data, 1982), with the assumptions of independence and stationarity. The Expected Moments Algorithm (EMA) method, to be presented in Bulletin 17C, was not implemented. 2013 peak flows were included in the analyses. Record lengths varied from 131 to 10 years, with an average of 45 years. All of these streamgage records are affected by flow regulation (stream diversions and reservoirs). Weighted generalized skews were implemented for streamgages that had a sufficient number of similar watersheds for grouping, to adjust results for stream gages with a shorter record length. Flagged outliers were typically retained, unless they were confirmed as high outliers associated with significant dam failures. The historic peak algorithm was implemented for records that included historic peaks. Peak flow values for the remainder of the periods of record were obtained from the USGS NWIS system (http://waterdata.usgs.gov/co/nwis/sw), and the Colorado Division of Water Resources (http://www.dwr.state.co.us/Surfacewater/default.aspx).

RESULTS AND DISCUSSION

Peak flow estimates of up to 60,000 cfs (S. Platte River at Fort Morgan) were computed (Appendix A), with the highest discharges measured in the St. Vrain, Left Hand, Boulder, Little Thompson, and Big Thompson watersheds (Figure 1, Table 2), as well as the S. Platte River into which all of these streams drain. Detailed figures illustrating peak flow measurement points, as well as unit discharges and return intervals, are provided (Figures 3 through 6). In some of these streams, this peak flow was the flood of record (St. Vrain, 122 years of record; Left Hand, 17 years; Little Thompson, 18 years), while other impacted streams have higher flows in their streamgage records (Big Thompson River, 1976; Boulder Creek, 1921; S. Platte River, 1935).

Table 1 Peak flow unit discharges by watershed size.

Watshed Size (mi^2)	< 4	4 to 25	25 to 200	> 200
Maximum Unit Discharge (cfs/mi^2)	1340	480	320	114

Unit discharges of up to 1340 cfs/mi^2 were computed, with these unit discharges varying by watershed size (Table 1). The variation by scale illustrates the variation in precipitation depth and intensity by area, with some local areas, such as mountain slopes, receiving substantially more rainfall than other areas through such a mechanism as orographic forcing. The locations with the highest unit discharges were oftentimes associated with the most severe damages, such as the Glen Haven, Fish Creek, upper Little Thompson, and Jamestown areas (Figures 3 and 4), as well as the foothills immediately adjacent to Boulder (Figure 4). Traditionally, it is often assumed that high-intensity rain events are limited to elevations below 7500 feet in the Colorado

Front Range. However, large unit discharges were computed at some locations with higher elevations (upper Little Thompson, Estes Park, Glen Haven areas); relevant catchments with >95 percent of their area above 7500 feet are marked by the red circles (Figure 3).

The peak flow and unit discharge data indicate that available raingage data appear to have missed some of the key watersheds impacted by the flooding. These raingage data are often biased towards valley bottoms, usually do not include rainfall intensity data but rather provide daily depths (CoCoRaHS data), and are absent in many large areas where public land is dominant. Calibrated radar data have also missed some of these locations (Figure 1), though localized extreme rainfall intensity could be a complicating factor. Examples of where large peak flow estimates (and observed damages) differ from precipitation data include Glen Haven (Figures 1 and 2) and the upper Little Thompson (Figure 1).

Table 2 Peak flow and flood frequency estimates for the 2013 Colorado Front Range Floods.

----: data withheld due to contractual obligations

(1): provisional data (2): problematic flood-frequency statistical analysis

The results of the flood frequency analyses where peak flow data are available at the current and historic streamgages operated by the USGS and the Colorado Division of Water Resources (CDWR) are provided (Table 2, Figures 3 through 6). Record lengths varied from 131 to 10 years, with four gages having more than 100 years of record available and the primary impacted streamgages (≥50 year flood) having at least 22 years of data available. Return intervals ranged from <2 years (>50 percent chance of occurrence in any given year) to >200 year flood (<0.5 percent chance of occurrence). Importantly, these results do not refer to regulatory flows but are instead the results of updated statistical analyses of the streamgage records.

In terms of these streamgage analyses, the most severely impacted watersheds were the Big Thompson (16,200 cfs at canyon mouth, ~100-year flood), the St. Vrain (24,700 cfs in Lyons, >200-year flood), Left Hand Creek (>200-year flood), Boulder Creek (8400 cfs just downstream of Boulder, 100- to 200-year flood), and Coal Creek (100- to 200-year flood). The Little Thompson watershed was also severely impacted, though insufficient data were available for the frequency analysis. Few streamgages exist on streams within the foothills; the only higher-elevation gages in this analysis were in the upper Big Thompson and St. Vrain watersheds. The return intervals of most of the peak flows estimated on smaller foothills streams cannot be easily associated within the context of a frequency analysis, due to the lack of annual peak flow data, though comparison with pre-flood regional regressions (Capesius and Stephens, 2009) indicates high return intervals in the most severely-impacted streams (Yochum and Moore, 2013).

The primary watersheds impacted by this rain event drain into the South Platte River. Just downstream of Chatfield Reservoir, the flow was measured to peak at only 552 cfs (1.05- to 1.25-year). Downstream of Denver, the flow increased to 5220 cfs (~ 2-year) before increasing to 10,300 cfs at Fort Lupton (~25-year), upstream of St. Vrain, Big Thompson, and Cache la Poudre confluences, and 60,000 cfs at Fort Morgan (25- to 50-year), downstream of the major runoff inputs. Lesser impacted watersheds include the Cache la Poudre (peak of 9730 cfs, 25- to 50-year), and Monument Creek, in the Arkansas River basin (peak of 15,300 cfs, ~25-year).

CONCLUSIONS

Peak flows, peak unit discharges, and flood frequencies have been provided for the spatial extent of the September 2013 Colorado Front Range Flood. Peak flows of up to 60,000 cfs were estimated, with documented unit discharges of up to 1340 cfs/mi^2 (in foothills immediately adjacent to Boulder) and return intervals ≥100-year flood in the most heavily-impacted primary streams draining the rainfall area (Big Thompson, Little Thompson, St. Vrain, Left Hand, Boulder, and Coal). Not addressed in this paper are flood duration values; this event had substantial flood durations, which increased damages.

ACKNOWLEDGEMENTS

Bob Jarrett is appreciated for the great deal of fieldwork and computation time spent collecting the majority of the peak flow estimates from the flood. Appreciation is also expressed for Dan Moore, for data collection and peak flow computations for many of the NRCS peak flow estimates. The hydrologists and hydraulic engineers with the USGS and the Colorado Division of Water Resources are valued for the streamgaging efforts, providing the annual peak flow data required to perform the flood frequency analyses. David Levinson and Marie Garsjo are appreciated for reviewing this manuscript.

PERFORMANCE OF SUSPENDED SEDIMENT CONCENTRATION IN TWO DISTINCTIVE LOWER MISSISSIPPI RIVER HYDROGRAPHS

T. (Jerry) Shih, Ph.D., P.E., U.S. Army Corps of Engineers, New Orleans, Louisiana,
Tzenge-Huey.Shih@usace.army.mil
Dave Ramirez, P.E., D.WRE, U.S. Army Corps of Engineers, New Orleans, Louisiana,
David.A.Ramirez@usace.army.mil

Abstract: The U.S. Army Corps of Engineers used to trace soils eroded by rainfall and surface runoff occuring in the Mississippi River frequently. When sediments travelled to the Mississippi River's outfall delta, the suspended sediments settled according to their density as the flow velocity decreased. Approximately 40 percent of the U.S. continental landmass is located in the Mississippi River basin, and much of these suspended sediments empty into the Gulf of Mexico via two Louisiana outlets.

The "LCA Medium Diversion at White Ditch" project plans to divert up to 35,000 cfs of freshwater and sediments from the Mississippi River to the Brent Sound Basin, Plaquemines Parish, Louisiana. Since the sediment concentration is a key factor to the sediment quantity that is ultimately diverted, seeking locations with high sediment concentrations that will optimize sediment delivery becomes extremely important to the project. While at the Feasibility Study phase, the project evaluated five potential sediment intake locations. When the project proceeded to the design phase, the team members decided to perform both hydrodynamic numerical modeling and physical sediment sampling to confirm the tentatively selected location. As for physical sampling, two trips were planned and meant to be executed at high water events. A total of 280 respective samples were collected from eight river mile sites, with five water columns per site, and seven nominal depths per water column in each trip. The targeted sampling depths ranged from -16.0 feet (shallow water) to -40.0 feet (deeper water).

When sampling in the river, many challenges such as logistics, sampling duration, reverse current, objects obstruction, etc. needed to be overcome. Often, the crew members needed to make quick decisions to compromise with the field conditions.

According to the investigation, it could be concluded that high suspended sediment concentrations are directly proportional to high flow rate. High sand concentration could be related to high flow rate as well. Location 3, a location at RM 60.0 which was recommended by the Feasibility Study as the tentatively selected plan (TSP), is not supported by either sampling analysis or numerical modeling. Location 1, a location at River Mile (RM) 69.0 which was not selected by the Feasibility Study, turns out to be the most favorable location based on physical sampling and laboratory analysis performed for two distinctive Mississippi River hydrographs. This location is supported by a hydrodynamic numerical model, Flow-3D, as well. The numerical model predicts the location will have Sediment Water Ratios (SWRs) greater than 1.0, i.e. sediment concentration is higher than that is occurring in the River. This conclusion is also supported by a sediment rating curve prepared for Belle Chase, located at RM 76. One lesson learned from the levels of suspended sediment concentration in two distinctive lower Mississippi River hydrographs is that seeking locations with high sediment concentrations needs to be a primary consideration when planning and designing a sediment diversion project.

INTRODUCTION

Louisiana coastal wetlands are a significant national environmental and economic resource. The erosion of wetlands has threatened the long-term stability of humans, fish, wildlife, and other resources in Louisiana. A report to Congress submitted by the Secretary of the Interior dated March 1994 stated that "from 1900 to 1978, Louisiana lost about 20 percent (901,200 acres) of its coastal wetlands, with 3.17 million acres remaining in 1978. Conservatively, an additional 300,000 acres have been lost since then. Current loss rates are estimated to be about 0.75 percent per year." [1]

Authorized by the 2007 Water Resources Development Act, the Louisiana Coastal Area (LCA) Program was immediately formed for the coastal restoration effort. Identified by the program, the 35,000 cubic feet per second "Medium Diversion at White Ditch" was selected as a near-term project and needed to transition from planning to design after a Feasibility Study. Goals and objectives of this diversion project were to provide river sediment, freshwater, and nutrients to the River aux Chenes sub-basin and other nearby portions of the upper Breton Sound Basin in order to restore and protect marsh soils, vegetation, and maintain a functional salinity regime.

The Feasibility Study was completed in 2009 and a Chief Report was presented to Congress in December 2010. The study was meant to reproduce two successful freshwater diversion structure experiences, Davis Pond (commissioned in July 2002) and Caernarvon (commissioned in August 1991), which had intake channel inverts at elevations of -11.3 feet and -12.3 feet NAVD88, respectively. The study investigated five potential sites, which all are located at the River's left descending bank for a TSP. They were Locations 1, 2, 3, 4, and 5 located at River Mile (RM) 69.0, 64.2, 60, 57.8, and 52.2, respectively. Among these five locations, Location 3 was recommended by the Study as the TSP. Presented in Figure 1 is the project vicinity map.

Figure 1 Medium Diversion at White Ditch

As shown in the figure, all except a reach between Locations 2 and 3 have a back levee in this 16.8 mile stretch. The back levee prevents the outfall channel flows from passing into the marsh. An outlet structure would need to be designed and constructed through in back levee.

Restricted by time, the study did not evaluate the River's sediment source and its distribution profile. The investigation was meant to be postponed before the pre-construction (design) phase. Led by the U.S. Army Corps of Engineers (USACE) New Orleans District (MVN), a project delivery team (PDT) was formed to take the project from planning to design, and continued to construction and operation. The pre-construction PDT members decided both numerical modeling and physical sampling needed to be performed so as to support the recommended TSP. The investigation also extended its scope of work by seeking rich sediments down to a depth of -40.0 feet NAVD88.

PHYSICAL SAMPLING PLAN

Scope of Work: Three additional sampling sites, located at the vicinity of Location 3, were added to the sediment sampling plan to support the TSP and to maximize the sediment diversion effort. They were at RMs 63.0, 61.5, and 59.5. The sampling plan had two independent trips and was meant to take samples at the high River flow rates. Suspended sediment (SS) samples were taken from eight RM sites per trip, with five water columns (WC) per site, and seven nominal depths per water column (WC), for a total of 280 total samples in each trip. Samples were taken from each RM site whose WCs were intended to be at the River cross section that was perpendicular to the flow line. The WCs were numbered in sequence starting from the left descending bank to the right descending bank. The first and the fifth WCs were to target shallow depth at -16.0 feet NAVD88. The second and the fourth WCs were to target deeper depth at -40.0 feet NAVD88. The third WC was at the center of the River. Each WC had its own designated longitude and latitude coordinates. The eight RM sampling sites are presented in Figure 2.

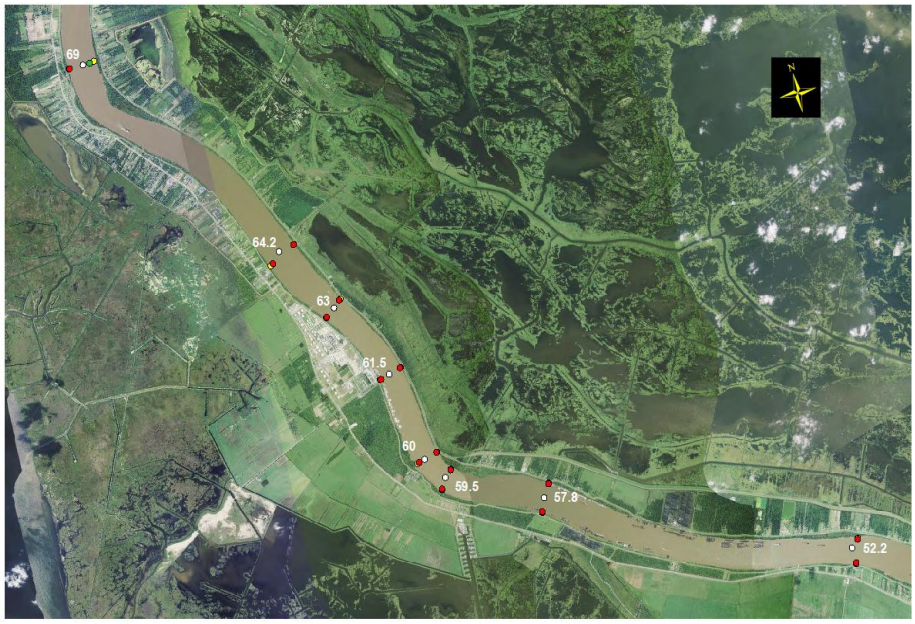

Figure 2 Suspended Sediment Sampling Sites

Boat Trip Observation: The USGS Louisiana Water Science Center in Baton Rouge performed sediment sampling and analysis for both April 23, 2012 and May 13, 2013 trips. To ensure samples were taken from the specified locations, the locations were programmed by a GPS navigator in advance. Sampling boats equipped with Acoustic Doppler current profiler (ADCP) for depth measurement is presented in Figure 3. The Global Positioning System (GPS) navigator used to locate the sampling sites is presented in Figure 4.

Figure 3 Boat Rim Mounted ADCP

Since the river hydrograph is very dynamic, USGS decided to send two crews to complete the field work within a day to minimize sampling deviation.

A few lessons were learned from sampling sediments in the River as follows:

1. Even though sampling locations were mapped by the GPS navigator, the current could carry the boat away. Therefore, samples taken at different normalized water depths may come from a different WC.
2. A slow reverse current can interfere with the sampling work, during which only very little sample volume could be collected in the same duration.
3. The designated sampling location can be occupied by barges or other vessels, which can force the crew to take samples from different places.
4. Always bring extra sampling bottles and labels because pre-labeled bottles can be accidentally broken.
5. The sampler's 12V batteries need to be fully charged for the trip, as the normalized water depth needs to be programmed by battery power.

Figure 4 GPS Navigator Used to Map Sampling Locations

Flow Rate & Stage Adjustments: Since water depths and flow rates constantly change, and the USGS could only provide samples from different normalized water depths, the actual flow rates and stages had to be interpolated from other recorded databases. Flow rates recorded by the USGS Mississippi River station 07374523, located at RM 76.0 (Belle Chasse, Louisiana), were used to interpolate the corresponding flow rates at the time when sampling took place.

Three databases were used to adjust stage readings for eight sampling sites. They were USGS Mississippi River station 07374523 located at RM 76.0, USACE Alliance station located at RM 62.5, and USACE West Point a la Hache station located at RM 48.7.

Two Distinctive Hydrographs: Sampling on April 23, 2012 occurred at the peak of the last hydrograph of that high water season, and was lower than the average flow rate for 82 year period of record for that specific day. The highest and the lowest flow rates recorded at the Belle Chasse, LA, for the first trip were 485,000 cfs and 415,000 cfs, respectively. Stages were also low as well, which were 3.36 feet at RM 69 and 2.92 feet at RM 52.2 for an elevation difference of 0.44 feet. The hydraulic slopes between referenced RM locations varied from 0.02 to 0.08 percent, which were considered very mild. Since the flow rate was so low, brackish water intrusion coming from the Gulf of Mexico could be detected at Belle Chasse (RM 76).

Sampling on May 13, 2013 occurred at the peak of the last hydrograph of that high water season, and was higher than the flow rate averaged for 83 years recorded for that specific day. The highest and the lowest flow rates recorded at Belle Chasse for the second trip were 1,080,000 cfs and 825,000 cfs, respectively. Stages were high as well, which were 8.54 feet at RM 69 and 6.76 feet at RM 52.2 for an elevation difference of 1.78 feet. The hydraulic slopes between referenced RM locations varied from 0.14 to 0.22 percent, which were steeper than the 2011 trip.

SUSPENDED SEDIMENT CONCENTRATIONS

Physical Sampling: Samples collected from the Mississippi River were analyzed for sand and fine categories. Samples collected during April 23, 2012 had very little sand, and almost all samples had fine material only. Total Suspended Sediment (TSS) concentrations were plotted for each WC as an illustration of TSS concentration profile. Five WC profiles were plotted in the same figure for each sampled RM site. Location 4 and RM 61.5 had the highest and lowest TSS concentration for the targeted depths at the lower descending bank, respectively. The second best location was at Location 1 and is presented in Figure 5. TSS concentrations collected at Location 3 are presented in Figure 6, which does not strongly support it as the TSP.

However, at a much higher flow rate, sand and fine materials were found in almost all samples collected from the May 13, 2013 trip. Location 1 and RM 61.5 had the highest and lowest TSS concentrations, respectively. Location 3 had neither the most nor the least TSS concentration; a similar conclusion was obtained during the 2012 trip. Presented in Figure 7 are TSS concentrations collected at Location 1. Presented in Figure 8 are suspended sand concentrations collected at Location 1. Presented in Figure 9 are TSS concentrations collected at Location 3.

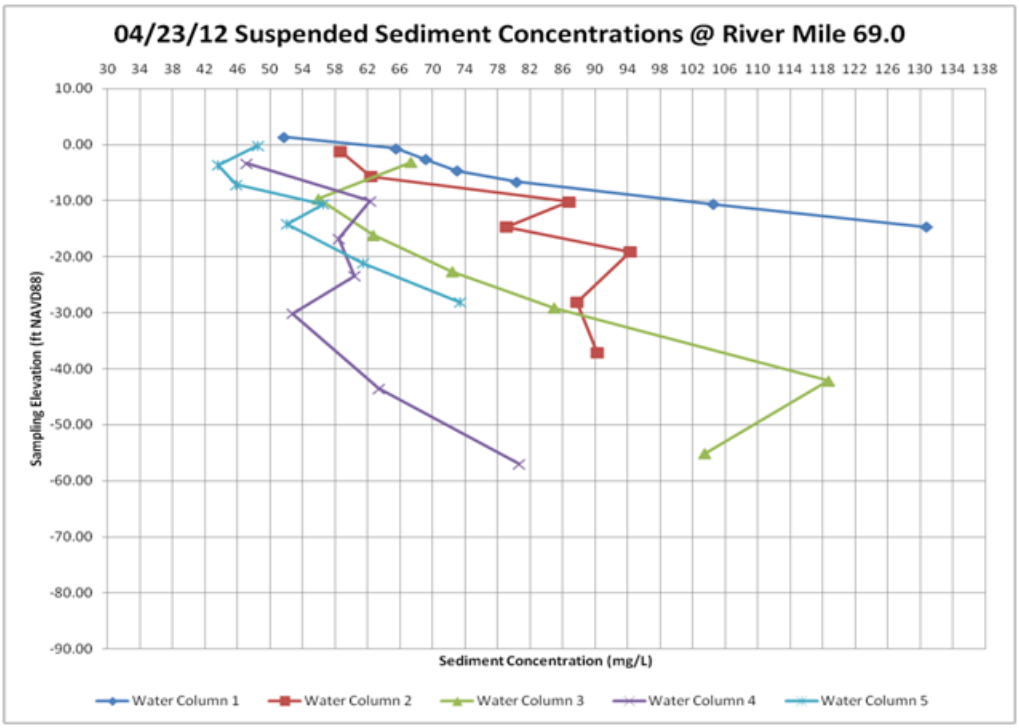

Figure 5 TSS Concentrations Collected in Location 1 from the 1st Trip

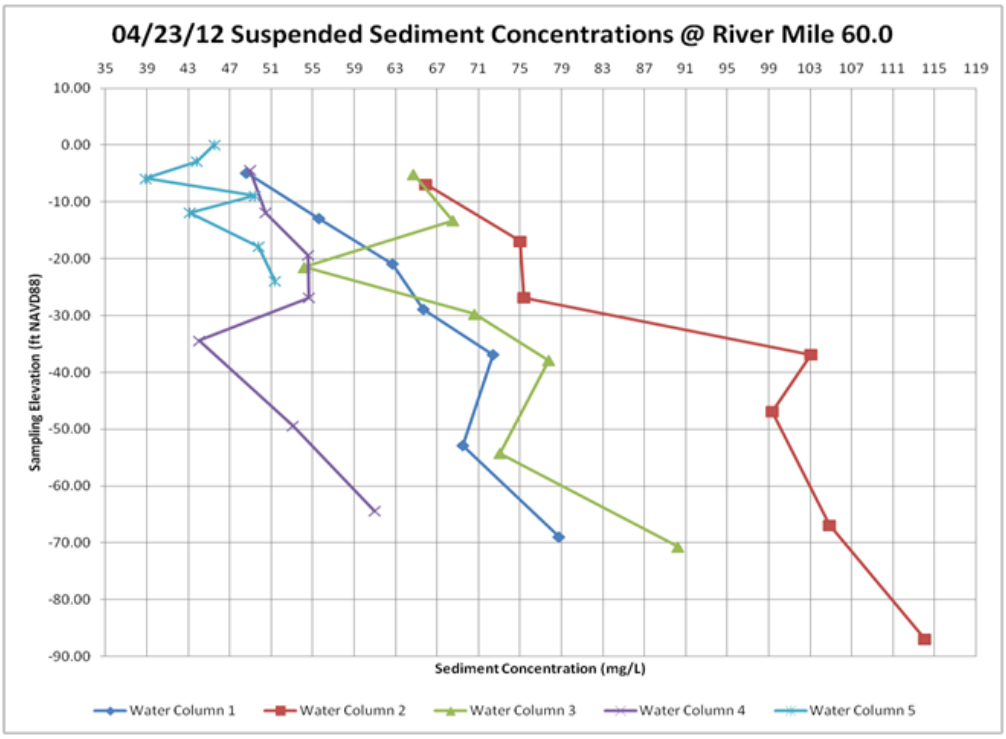

Figure 6 TSS Concentrations Collected in Location 3 from the 1st Trip

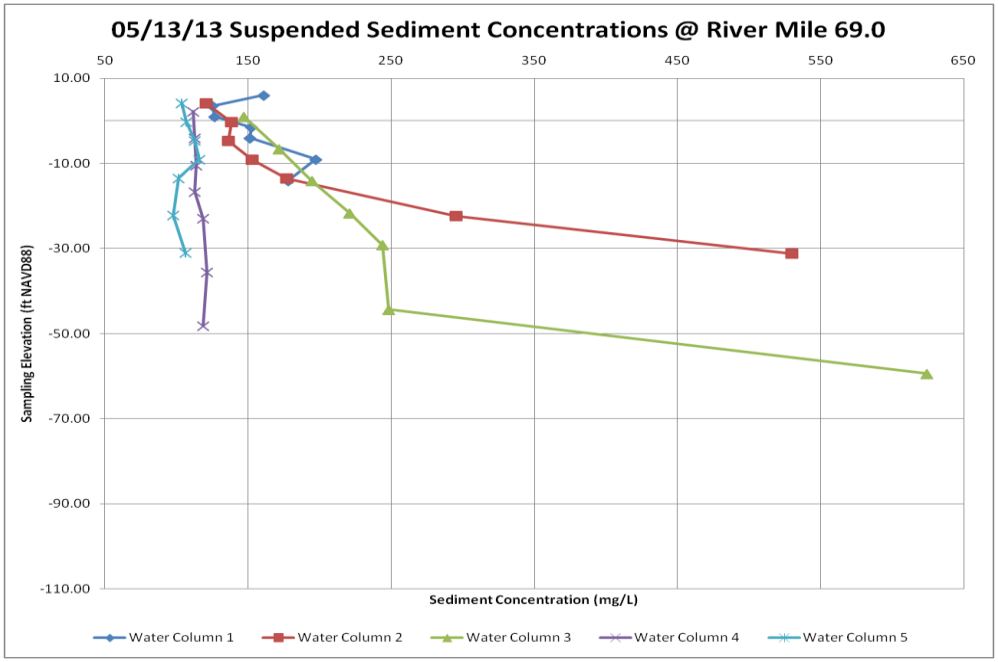

Figure 7 TSS Concentrations Collected in Location 1 from the 2nd Trip

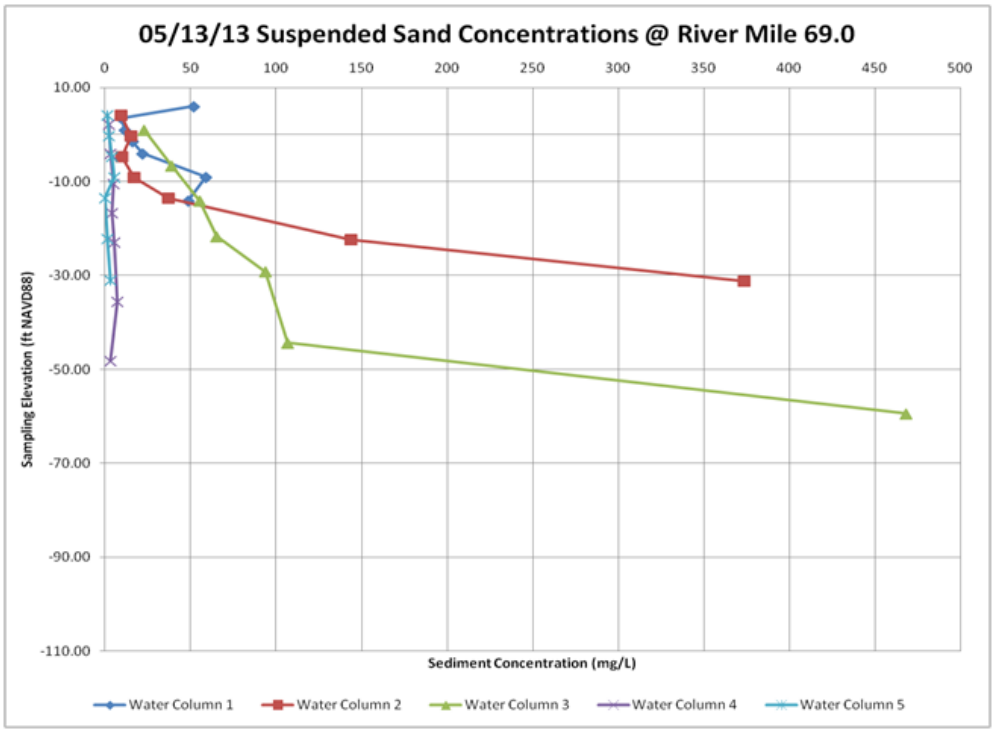

Figure 8 Sand Concentrations Collected in Location 1 from the 2nd Trip

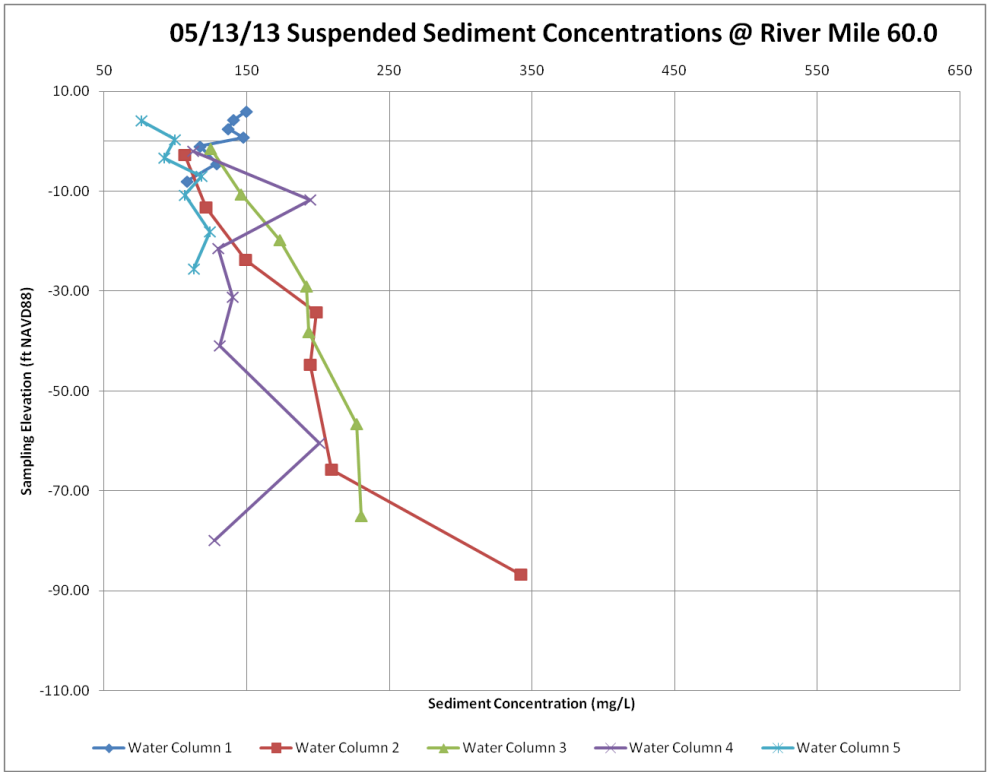

Figure 9 TSS Concentrations Collected in Location 3 from the 2nd Trip

Flow-3D Hydrodynamic Model: Other than the physical sediment sampling, MVN awarded ARCADIS U.S., Inc. to perform hydrodynamic and sediment transport modeling using Flow-3D model for site confirmation and optimization in August 2012. The investigation report was finalized in December 2013.

The study results reached the following conclusions:

1. A diversion at Location 1 or Location 4 would capture the greatest amount of sediment, with Location 1 demonstrating the greatest project benefit.
2. Location 1 is positioned in a river bend where flow patterns carry sediment into the entrance of the diversion structure; and
3. At Location 1, particularly for large material, Sediment Water Ratios (SWRs) are greater than 1.0, i.e. sediment concentration that is higher than that presented in the River will be diverted to the inflow channel by the project.
4. The investigation discouraged Location 3 as the favored sediment diversion location recommended by the Feasibility Study.

RIVER SEDIMENT QUANTITY THEORIES

Sediment Rating Curve: The "Sediment Rating Curve for Mississippi River Diversions: Caernarvon and Davis Pond," prepared by Dr. Jarrell Smith of the USACE's Engineer Research and Development Center (ERDC), dated November 19, 2010 is considered the latest research on prediction of sediment concentration presented in the lower Mississippi River. [2]

Four prediction equations were developed based on two-month long depth-integrated samples collected at the Caernarvon Diversion Structure in St. Bernard Parish, LA. The USGS-ERDC1 equation is favored by Dr. Smith because it has a comparable low bias value and RMS error number and convenience. The USGS-ERDC1 sediment rating curve equation was found to be compatible with the USGS SAND model as well. The USGS-ERDC1 equation is listed as follows:

$$L = 5.5713 \times 10^{-7} Q^{2.007} \quad (1)$$

Where,
L is the sediment load in tons/day, and
Q is the river flow rate in cfs

Sediment quantities corresponding to different river flow rates and their equivalent concentrations are presented in Figure 10.

Based on the USGS-ERDC1 equation, the sediment concentration corresponding to an 83-year averaged Mississippi River flow rate, 700,000 cfs could be 155 mg/L. The same for the average flow rate recorded at the 2012 sampling trip was 450,000 cfs, which could have an average sediment concentration 102 mg/L. The average flow rate recorded for the 2013 sampling trip was 880,000 cfs, which could have an average sediment concentration 200 mg/L.

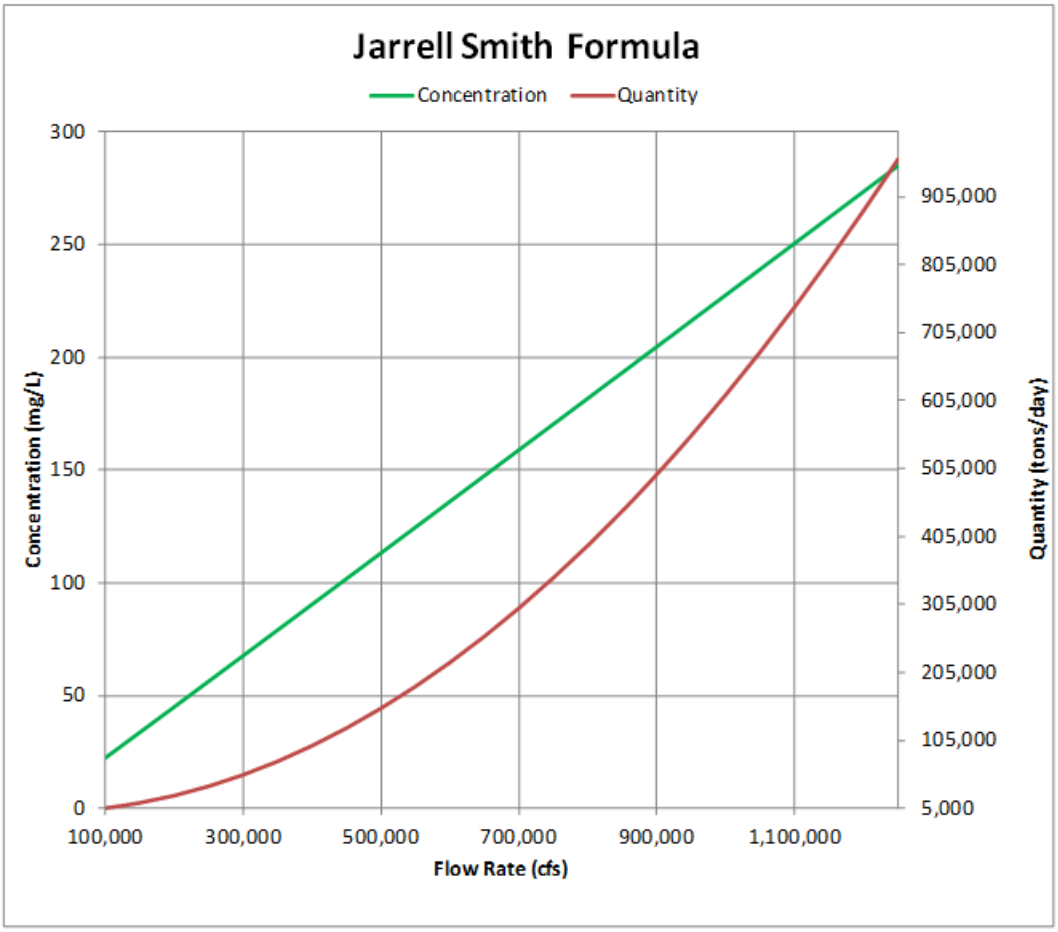

Figure 10 Dr. Smith's Sediment Quantities & Concentration Rating Curve

The 2012 trip showed that, for the targeted depths (-16 feet to -40 feet NAVD88), Location 4's left descending bank (Water Columns 1 and 2) had sediment concentrations ranging from 118 to 152 mg/L, which were higher than the value predicted by the USGS-ERDC1 equation (102 mg/L). Location 1 had concentrations ranging from 90 to 130 mg/L, which were slightly better than the sediment rating curve predicted value. The remaining locations had concentration ranges that were lower than the USGS-ERDC1 predicted value.

The 2013 trip showed that, for the targeted depths, Location 1's left descending bank had sediment concentrations ranging from 178 to 530 mg/L, which were much higher than the value predicted by the USGS-ERDC1 equation (200 mg/L). Location 4 had concentrations ranging from 136 to 359 mg/L, which were also better than the sediment rating curve predicted value. The remaining locations had sediment concentrations whose ranges were lower than the USGS-ERDC1 predicted value. It is to be noted that Location 1's left descending bank had sand concentrations ranging from 49 to 374 mg/L, which were higher than the value predicted by the USGS-ERDC1 equation.

Samples taken from both low and high hydrographs strongly support Location 1 as a favored sediment diversion location.

Other Theories: Other theories, such as impacts of rising and falling hydrographs, frequency of previous high waters, inorganic and organic sediment particle distribution, etc. also contributed to the sediment quantities presented in the river water. However, all have their significant conditions and presumptions.

CONCLUSIONS

According to the above investigation, we may be able to conclude a few highlights as follows. High suspended sediment concentrations could be related to high flow rates in the Mississippi River. High sand concentration could be related to high flow rate as well. Location 1 (RM 69) is the most favorable location based on suspended sediment concentrations, followed by Location 4 (RM 57.8). Location 3 had neither the best nor the worst suspended sediment concentrations measured at both high and low flow rates. The sampling analysis supports location selection simulated by a Flow-3D hydrodynamic modeling.

One lesson learned from the levels of suspended sediment concentration in two distinctive lower Mississippi River hydrographs is that seeking locations with high sediment concentrations needs to be a primary consideration when planning and designing a sediment diversion project.

Although Location 1 proved to be the most favorable sediment diversion location, there were still unfinished tasks, such as optimizing the geometry for the inflow channel to catch rich sediments and to minimize shoaling when the structure is not in operation. Also, sites have back levees that are normally flood-protected areas. Such sites will increase additional costs in building a back levee crossing culverts and sluice gates, rerouting highways, and acquiring costly right-of-way.

Abstract: The Lower Yellowstone Project at Intake is a Bureau of Reclamation (BoR) irrigation project located on the Yellowstone River. The low head dam, constructed in 1906, presents a barrier to fish passage. A bypass channel in eastern Montana is proposed to improve upstream and downstream fish passage for the endangered pallid sturgeon and other native fish. The proposed bypass channel has a bottom width of 40 feet (ft) with side slopes varying from 1V:8H (one vertical to eight horizontal) to 1V:4H. With a length of approximately 11,150 ft and cut depths ranging from 4 to 20 ft, the total excavation quantity is approximately 950,000 cubic yards.

Hydraulic and sediment modeling using the Hydrologic Engineering Center's River Analysis System (HEC-RAS) and Adaptive Hydraulics (ADH) has been conducted by the U.S. Army Corps of Engineers (USACE). Additionally, the BoR's Technical Service Center used Sedimentation and River Hydraulics – Two-Dimensional (SRH-2D) to analyze hydraulics and sediment. The intent of the hydraulics analysis was to evaluate depths and velocities throughout the bypass channel with respect to fish passage. The primary goal of the sediment modeling was to evaluate sediment continuity throughout both the main and bypass channels. Coordination between USACE and BoR began with use of the same topographic and hydrographic surface data. Comparison of similarities and differences in model results allowed for better definition of natural and modeling uncertainties.

The focus of this paper is on HEC-RAS sediment modeling of the proposed bypass channel along with associated sensitivity analyses.

INTRODUCTION

Numerous sediment transport runs were completed with HEC-RAS, version 4.2.0 Beta, July 2013. Geometries representing both the main channel of the Yellowstone River and the proposed bypass channel were evaluated. Results presented herein focus on the proposed bypass channel. Figure 1 shows the project location; Figure 2 shows a general overview of the proposed project.

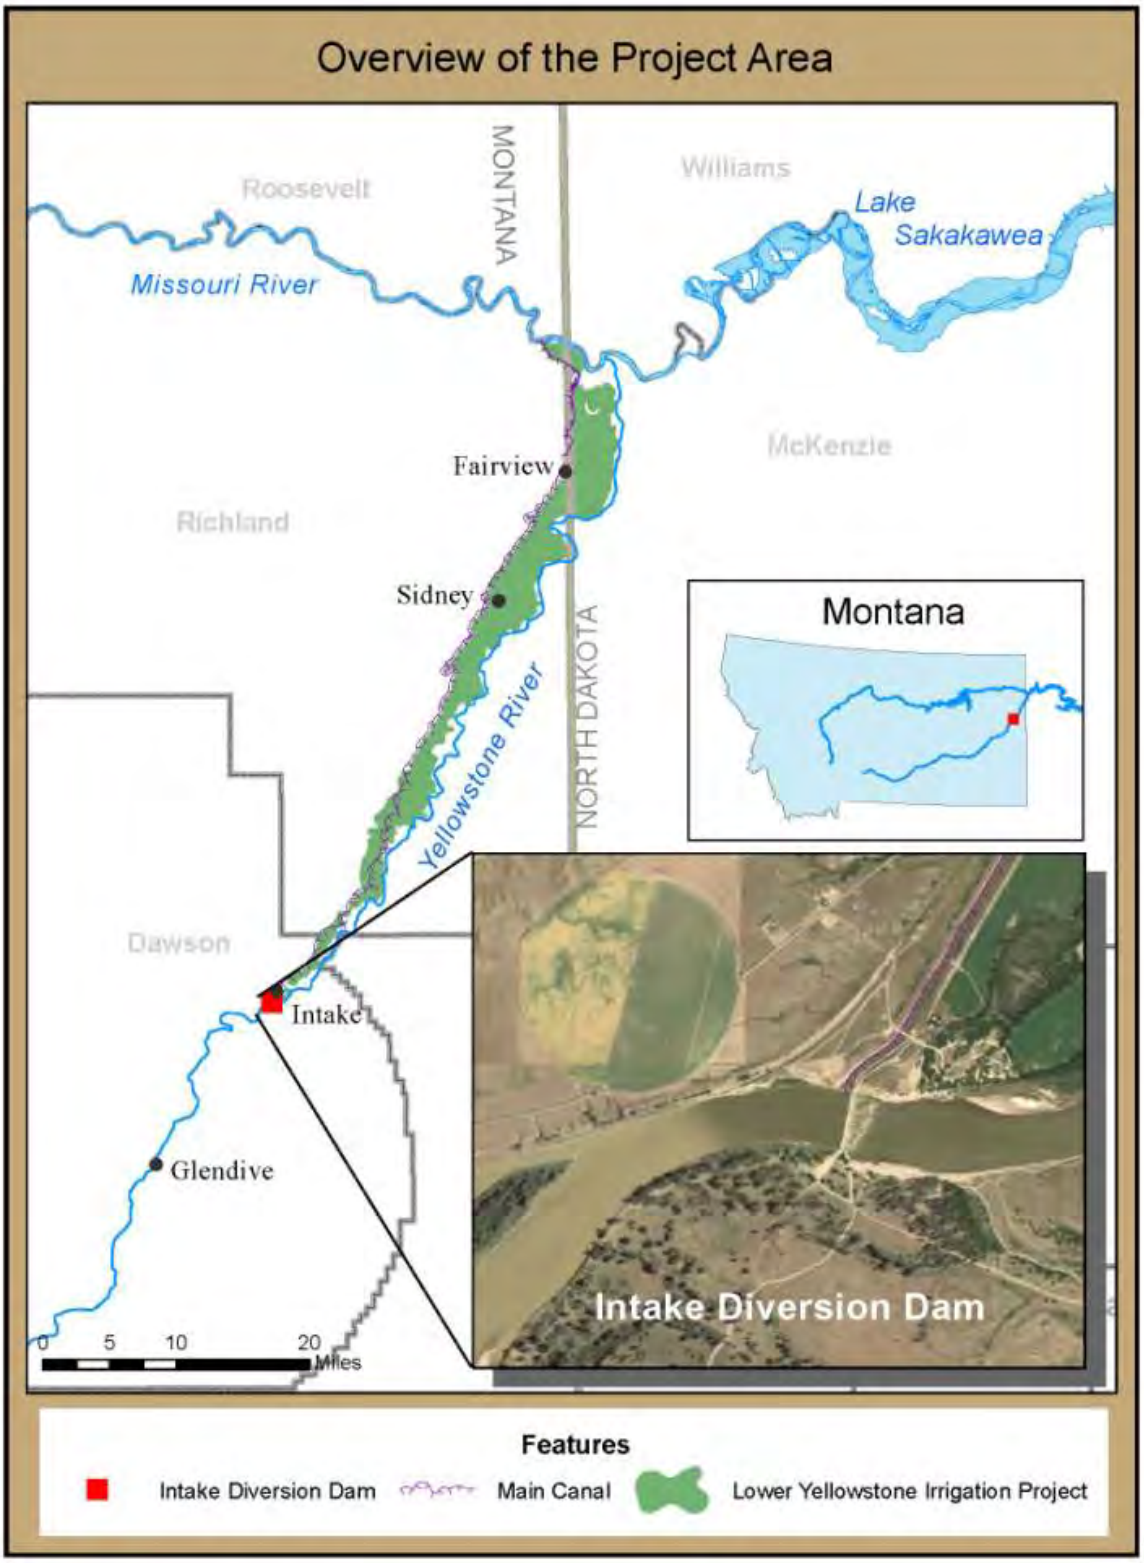

Figure 1 Project location map

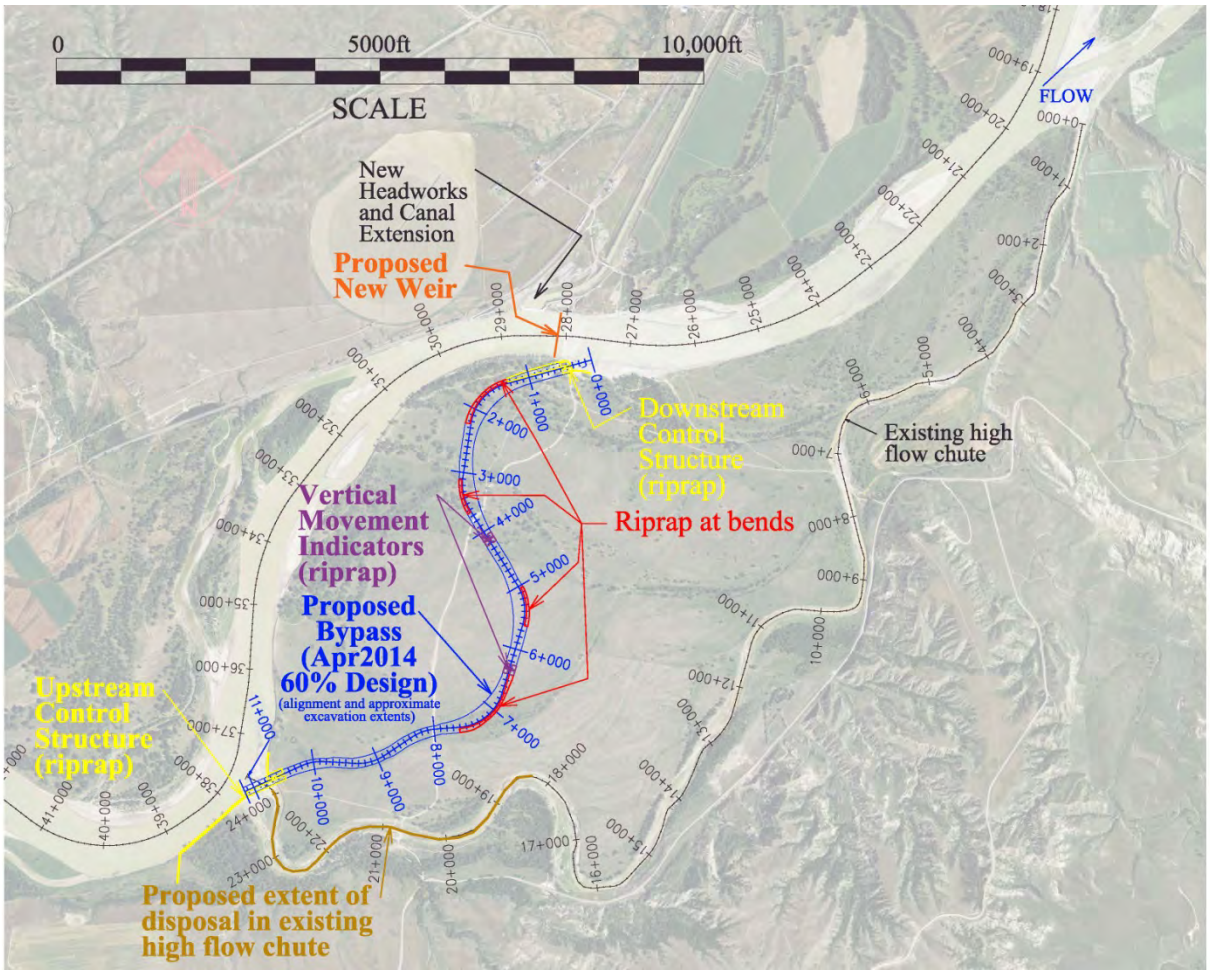

Figure 2 General overview

Because no calibration data are available for the proposed bypass channel, sensitivity runs on multiple sediment loading values, incoming gradation, bed gradation, transport functions, sorting methods, discharges and channel slopes were completed.

Historic flows from USGS gage at Sidney, Montana (approximately 42 miles downstream) were used to evaluate long-term trends. Additionally, constant flows representing the approximate channel-forming discharge were evaluated. Split flow modeling of the 50% annual chance of exceedance (50% ACE, commonly referred to as the two-year discharge) results in approximately 6,500 cfs in the bypass channel; this flow was selected as the channel-forming discharge used to evaluate channel stability. Once a relatively stable channel configuration was selected, model analysis was performed with the post-Yellowtail Dam period of record flows (1967-2014) from the Sidney gage. The maximum flow through the bypass during this analysis was limited to the approximate bankfull discharge, 9,000 cfs (equivalent to 60,000 cfs total Yellowstone flow) due to model instabilities when larger discharges were used. Similar instabilities occur in the main channel when modeling large flows, indicating that model limitations (rather than actual geometry or sediment loading) are the cause. Future evaluation will further investigate modeling of extreme Yellowstone River flows, mainly with 2-D

modeling where overland flows can be modeled with sediment (at the current time, HEC-RAS cannot model more than one reach with sediment).

BASE CONDITIONS

The proposed bypass channel characteristics are summarized below:

- Length ≈ 11,150 ft
- Base cross section shape: 40 ft bottom width, side slopes go from 1V:8H to 1V:6H to 1V:4H
- Channel slope = 0.0007 ft/ft
- Excavation quantity ≈ 950,000 yd^3

Base data used in the sediment transport analysis include the following:

- Median incoming load from the Sidney gage data (USGS Gage #06329500) was used to develop a suspended sediment loading curve for the bypass channel based on the estimated flow split. Figure 3 shows the load in tons/day and compares measured data from the Intake site to the gage data. The load was converted to a concentration which was then used to determine the load in the bypass channel.
- Gradation of incoming suspended load based on estimated median of Sidney gage data. Figure 4 shows the Sidney data as well as the selected load curves for use in HEC-RAS.
- Estimated bedload of approximately 5% of suspended load (varies from 0.5-7% depending on flow) with gradation based on 2008 bar samples (grab samples taken with shovel) collected by USACE and analyzed by USGS. Maximum incoming material size was limited to medium gravel (8-16 mm). Figure 5 shows combined suspended load/bedload as entered into HEC-RAS.
- Transport function used for base is Laursen-Copeland (Copeland 1989 and Laursen 1958), a total load function that was generalized by Copeland for gravel transport so the equation could be used for graded beds.
- Bed gradation was based on Wolman (Wolman 1954) counts collected in 2008. The design includes a processed armor layer in the bypass invert to minimize post-construction degradation. The processed armor layer includes materials greater than one inch diameter screened from the excavation. Figure 6 shows several bed gradations. The Wolman count gradation is coarser than the bar samples or test pits, but is expected to be representative of the processed armor layer after construction.

Figure 7 shows the results of the "base" run using both a constant discharge of 6,500 cfs (between 45,000 and 50,000 cfs in the main channel) and using the gaging record discharges from the post-Yellowtail Dam period (1967-2014). Bypass geometry for the base run does not include natural channel elements that are included in final design. Natural channel elements in the final design include variable cross section shapes and invert elevations representing a pool/riffle sequence (as opposed to the uniform cross section shape and channel slope used in the base run). Design of the natural channel elements generally followed guidance presented in ERDC/CHL CR-01-1 (Soar 2001).

SENSITIVITIES

Numerous sensitivity analyses were run on the proposed bypass channel. Sensitivity runs on multiple sediment loading values, incoming gradation, bed gradation, transport functions, sorting methods, discharges and channel slopes were completed.

In general, the model shows high sensitivity to the incoming gradation and transport function; moderate sensitivity to the incoming load, bed gradation, discharge, and sorting method; and low to moderate sensitivity to the channel slope within the ranges considered.

The model shows particularly high sensitivity to the largest size of the incoming material, especially for certain transport functions. In addition to Laursen (Copeland), Yang (1973, 1984), Toffaleti (1968), and Ackers-White (1973) transport functions were used. When using medium gravel (8-16 mm) as the largest incoming material, Yang, Toffaleti, and Ackers-White showed unrealistic aggradation (on the order of 100+ ft). However, when the maximum size of incoming material was limited to very coarse sand (1-2 mm), results with the alternative transport functions were much more realistic. This trend was similar with the main channel of the Yellowstone River, indicating that limitations of the various transport functions are the cause rather than actual physical predictions of extreme aggradation. Figure 8 shows results from multiple runs using various transport functions and maximum incoming material size.

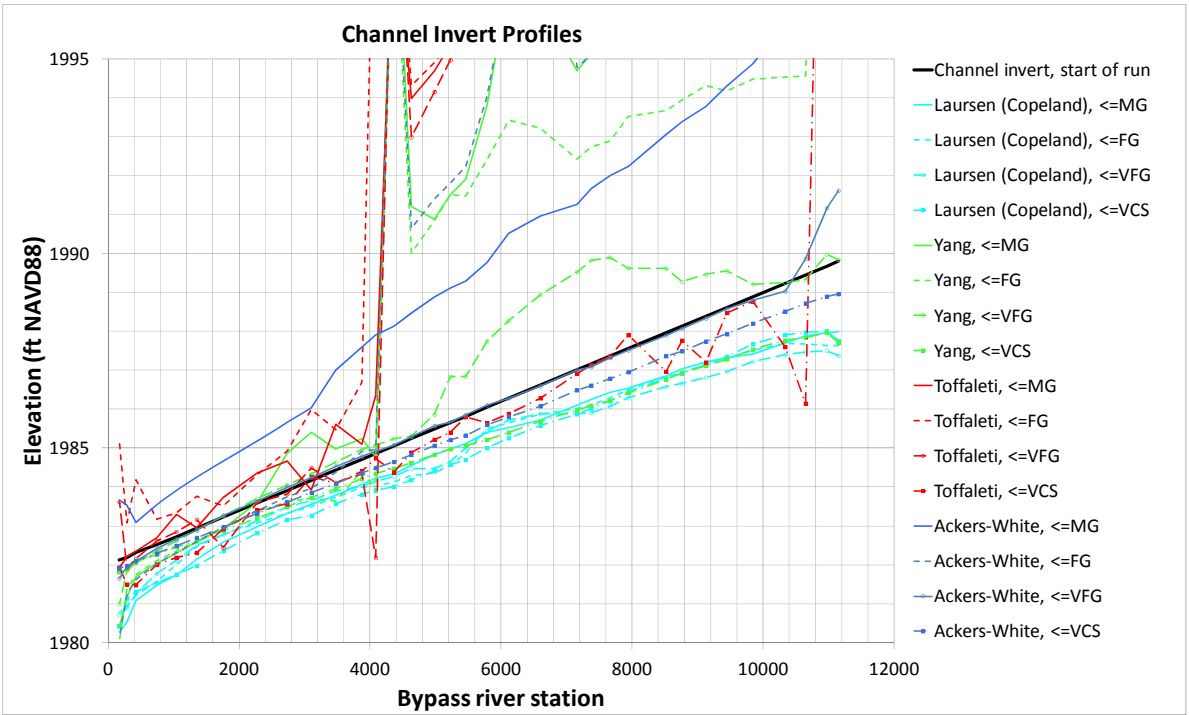

Figure 8 Transport Function and Incoming Gradation Sensitivity (s=0.0007ft/ft)

Figure 8 shows the bypass channel bed invert following the post-Yellowtail Dam flow record (47 years, 1967-2014) limited to a bypass flow of 9,000 cfs. For all runs, the initial channel slope was 0.0007 ft/ft and bed gradation is the Wolman count gradation described above. The legend in the figure indicates which transport function was used, along with the maximum material size of the incoming load (i.e. <=MG indicates the maximum size was medium gravel; FG=Fine Gravel, VFG=Very Fine Gravel, and VCS=Very Coarse Sand).

Figure 9 shows the base runs for slopes of 0.0006 ft/ft and 0.0007 ft/ft. The model shows low sensitivity to the channel slope in this range.

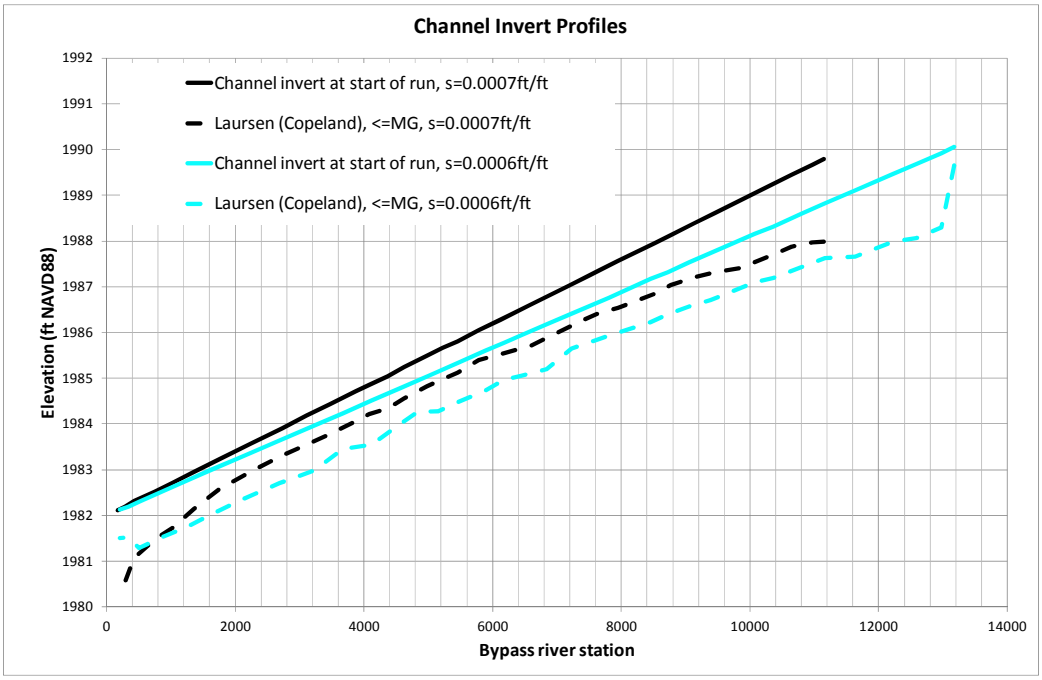

Figure 9 Slope Sensitivity

Sensitivity to the incoming load was evaluated by running the model using the high and low end loads shown in Figure 3. Results of the sensitivity analysis are shown in Figure 10. Unrealistic aggradation at the upstream end of the bypass occurs with the high incoming sediment load which is approximately nine times greater than the base load. This unrealistic aggradation also occurs in the main channel model, indicating that limitations of the transport functions, rather than physical processes are the cause. As shown in Figure 10, a second run was executed with an incoming load of approximately three times the base load.

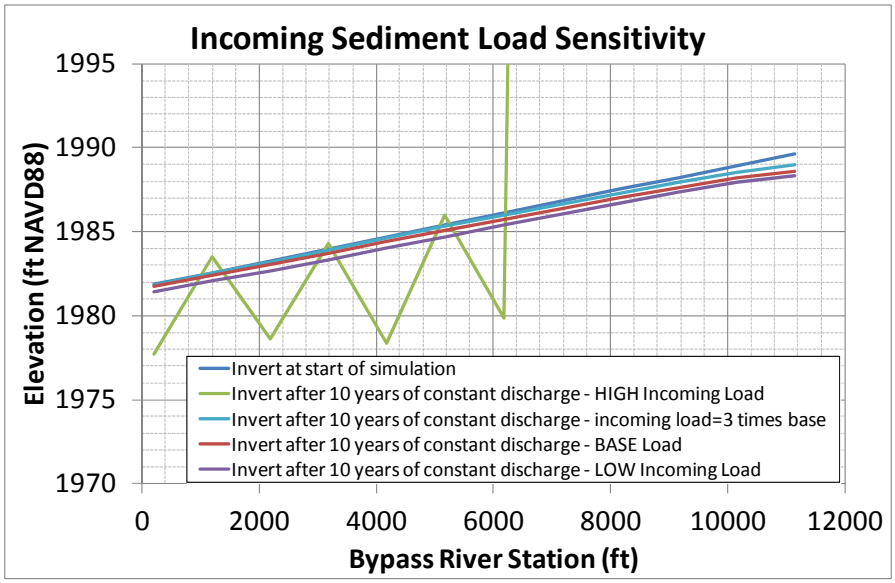

Figure 10 Incoming Sediment Load Sensitivity

Sensitivity to selected sorting method was evaluated by running the model with all three available sorting methods (Brunner 2010): Thomas (Ex5), Active Layer, and Copeland (Ex7). Results of the sensitivity analysis are shown in Figure 11. Runs using the Thomas (Ex5) and Copeland (Ex7) sorting methods produce similar results. The Active Layer method run produced unrealistic aggradation (on the order of 130 ft). Again, this unrealistic aggradation also occurs in the main channel model, indicating that limitations of the sorting method, rather than physical processes are the cause.

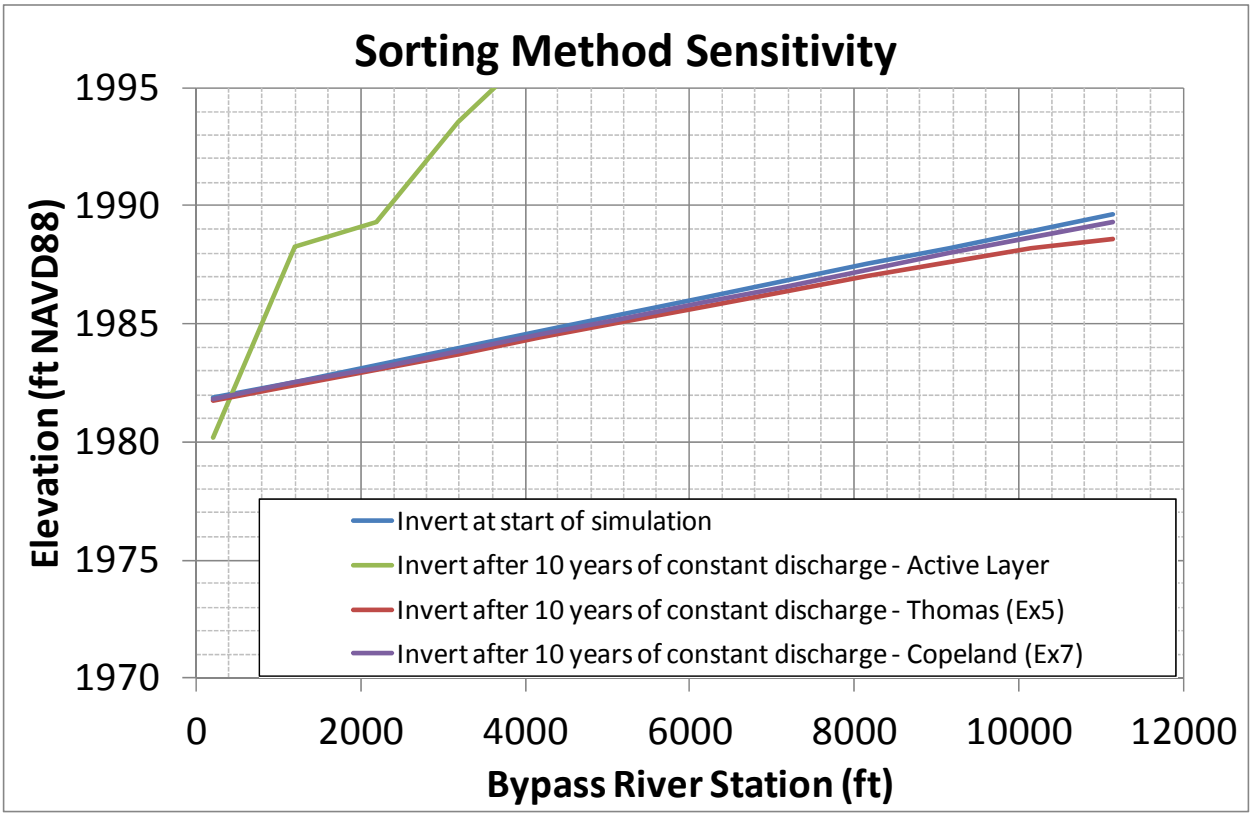

Figure 11 Sorting Method Sensitivity

Because of the large number of alternatives considered, initial sediment runs used uniform cross section shapes and channel slopes. However, the final design includes natural channel elements (varied cross section shapes and inverts). Once the final geometry was selected, the base sediment data were run to evaluate response to the proposed natural channel elements. Figure 12 compares results of the uniform channel vs. the "natural" channel. Figure 13 further compares the results shown in Figure 12. While the general trend of degradation is similar between the uniform and varied channel, HEC-RAS results indicate that some of the pool cross sections may tend to be slightly depositional.

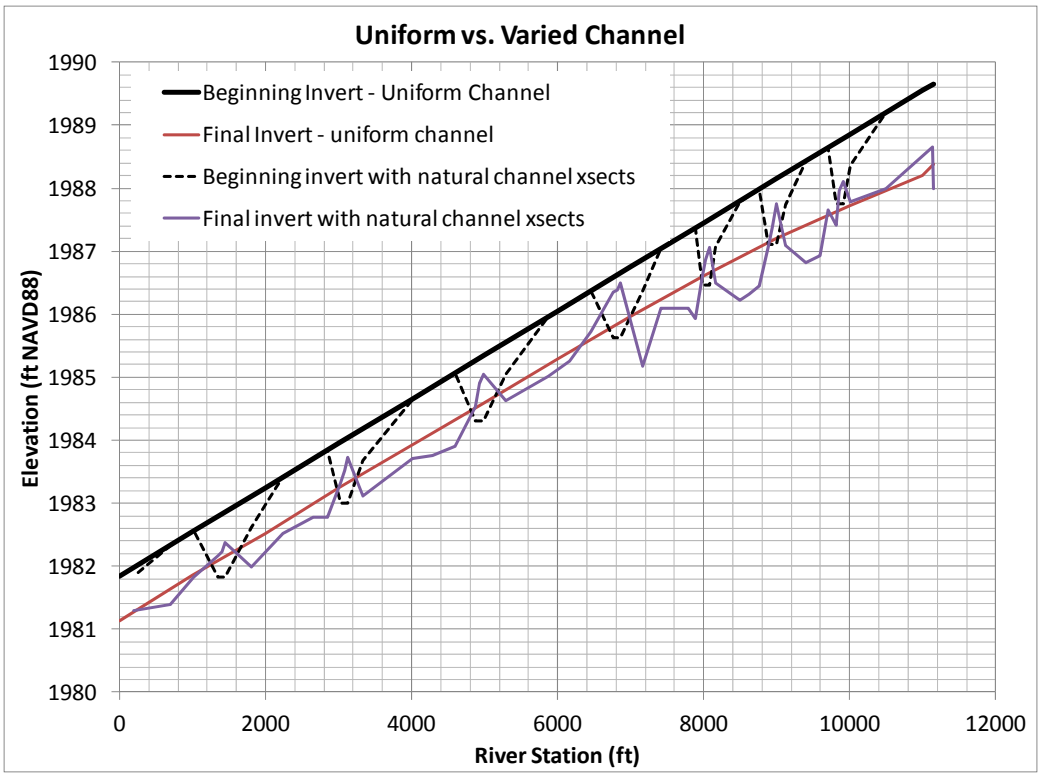

Figure 12 Uniform vs. Varied Channel

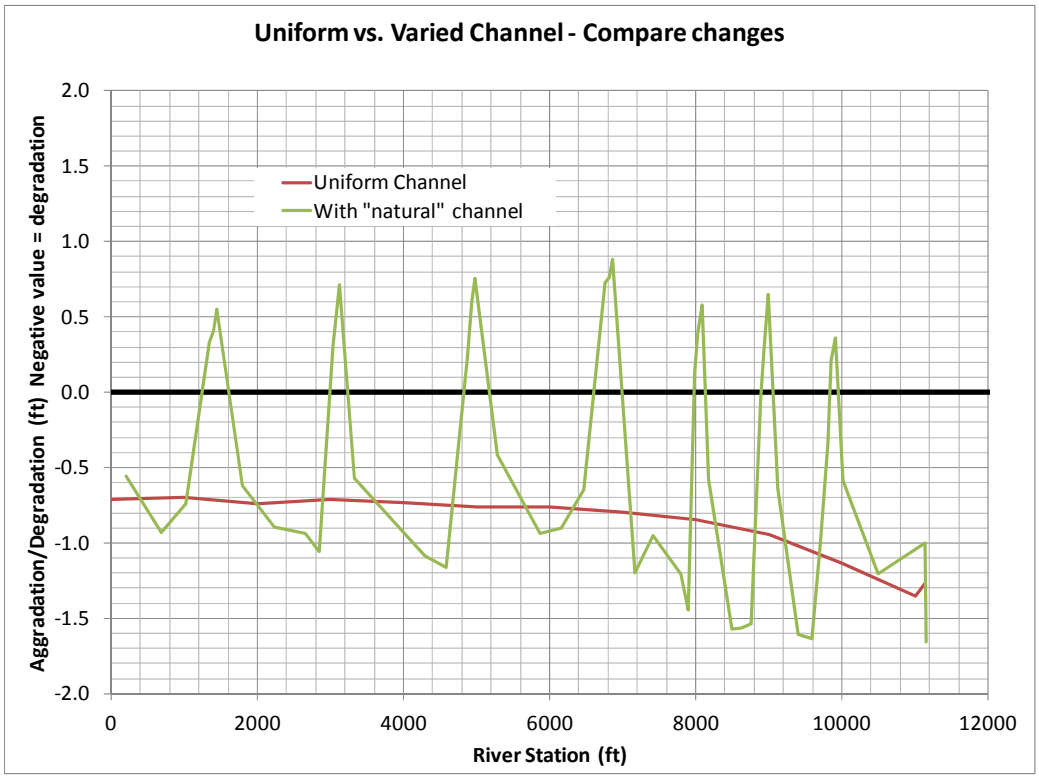

Figure 13 Comparison of Aggradation/Degradation Between Uniform and Varied Channel

SUMMARY AND CONCLUSIONS

Sediment modeling was completed with HEC-RAS to evaluate long term stability of a proposed bypass channel at Intake Dam on the Yellowstone River. Because no calibration data is available, multiple sensitivity analyses were completed to reduce uncertainty.

In general, the model shows high sensitivity to the incoming gradation and transport function; moderate sensitivity to the incoming load, bed gradation, discharge, and sorting method; and low to moderate sensitivity to the channel slope within the ranges considered.

BACKGROUND

The Lower Yellowstone Project is a Bureau of Reclamation (Reclamation) irrigation project built in 1908 under the Reclamation Act of 1902. It is located on the Yellowstone River in eastern Montana approximately 70 miles upstream from the confluence with the Missouri River, and 15 miles northeast of Glendive. The project consists of a low-head diversion dam, a diversion headworks structure, and an irrigation canal system that delivers water to approximately 53,000 acres in eastern Montana and western North Dakota. The diversion dam has become a known barrier to native fish migration including the endangered pallid sturgeon. In addition, the canal has been documented to entrain hundreds of thousands of fish annually during diversion operations occurring from April through September. This entrainment issue was recently addressed through the construction in the spring of 2012 of a new screened headworks structure immediately upstream of the old headworks structure.

Reclamation has an obligation, under the Endangered Species Act, to modify the structure of this facility to address pallid sturgeon concerns raised by the Fish and Wildlife Service and the Montana Department of Fish, Wildlife, and Parks. The U.S. Army Corps of Engineers (USACE) received authority to proceed with the design of the Lower Yellowstone Project. Technical staff from both Reclamation and the USACE were brought together to form a multi-agency team tasked with the development and analysis of designs that would address the recovery goals for both agencies.

INTRODUCTION

The proposed Yellowstone River Intake (YRI) Diversion Dam Modification Project includes the design of a large bypass channel around the diversion dam with the intent of improving upstream and downstream fish passage for adult pallid sturgeon and other native fish. The bypass channel will convey a significant portion of the river flow and sediment. Subsequently, the bed geometry of the reach may change as a result of the project. Reclamation conducted a sediment transport analysis utilizing a two-dimensional mobile bed hydraulics numerical model (SRH-2D; Lai, 2008) on a 5.5-mile reach of the Yellowstone River centered on the intake diversion dam and including the bypass channel. Figure 1 shows a project location map. This evaluation predicted the changes in bed elevations and stream geometry that would result from this project. The sedimentation analysis was further utilized to evaluate one of the other main goals of the proposed design; to minimize the operations and maintenance burden on the local irrigation district.

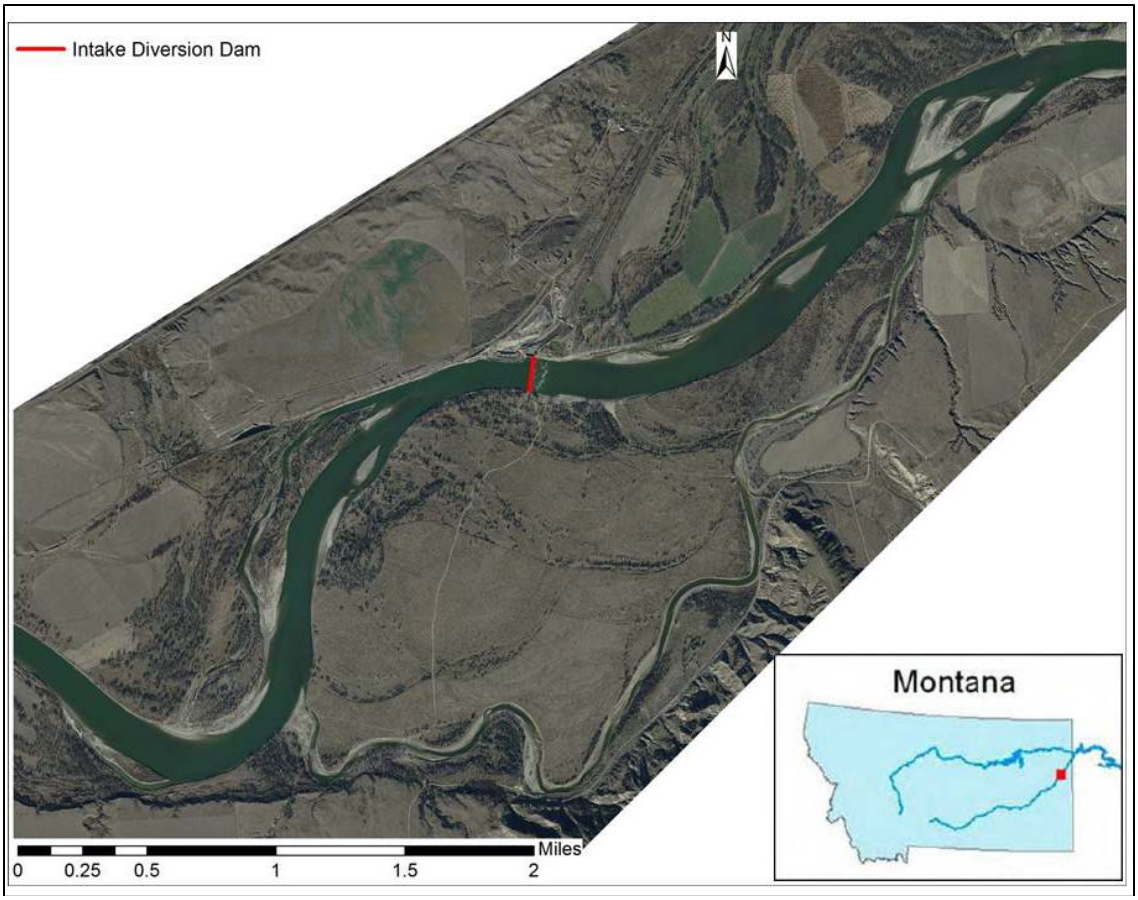

Figure 1 Lower Yellowstone Project location map (flow is from left-to-right).

DESIGN ALTERNATIVES

Reclamation has, to date, numerically modeled and evaluated two (2) iterative bypass channel design alternatives that were at a 30% and 60% completion level. Several bypass channel alignments were evaluated by the USACE before choosing a preferred one for the 30% design. Model results of the 30% design showed low velocities and the potential for sediment deposition at the downstream end of the bypass channel, largely due to backwater effects from the main channel of the Yellowstone River. To compound the issue, the bypass channel was not capturing enough flow from the main stem. These observations prompted the design of a revised bypass channel alignment and geometry, which was included in the 60% design alternative. The 60% alignment had a reduced length that precluded the use of the existing high flow channel. The proposed 60% alignment takes advantage of existing swales and cut-off channels where feasible. In addition, changes in the entrance/exit angles to the Yellowstone River were included to alter the flow direction in these critical locations for both channel stability and fish passage. The proposed 60% bypass channel design is approximately 11,150 feet long with an average channel slope of 0.0007 feet/feet, and bottom and top width of 40 feet and 150-250 feet, respectively. Approximately 900,000 cubic yards of material will need to be excavated to construct the channel (USACE, 2014).

MODELING METHODOLOGY

The model domain spans roughly 5.5 river miles on the Yellowstone River, centered on the intake diversion dam. The main goal of this project was to improve upstream and downstream fish passage for adult pallid sturgeon and other native fish by constructing a bypass channel around the diversion dam. A two-dimensional hydraulics and sediment transport mobile bed model was developed to assess the bypass channel functionality and stability as well as its effect on the main stem of the Yellowstone River. Model results were used to inform and iteratively refine project design concepts at various stages of development. Baseline hydraulic parameters, sediment transport rates, and amounts of erosion/deposition were compared through the design process.

Initially, hydraulic conditions with static channel geometry were simulated to calibrate the flow roughness, compute the quantity of flow entering the bypass, and assess mesh density sensitivity. Modeling of the mobile bed channel dynamics and sediment transport commenced after a satisfactory hydraulics model was constructed and calibrated. Model inputs, which are discussed in detail in this section, included a mesh with topographic information, bed material gradations, and flow-roughness parameters. Model boundary conditions included discharge hydrographs and sediment loads for the upstream domain boundary, while a rating curve specifying the water surface elevations over the range of modeled discharges was used at the downstream boundary.

Model Selection: All numerical models require simplifying assumptions and thus have limitations. The choice of model is often governed by time and budget constraints, knowledge of and access to existing models, and the availability of enough data with which to develop the model. It is important to understand the formulation of the selected model, recognize the model limitations, and apply the model in a manner that takes advantage of its strengths. Numerical model predictions will always include some uncertainty because the physical processes being modeled are not completely represented in the governing equations used in the model.

The numerical models utilized for this study were HEC-RAS (v 4.1.0) and SRH-2D (v 3.0). HEC-RAS is a one-dimensional (1D) step-backwater hydraulic model developed by the USACE. This model was utilized to simulate cross-section averaged river hydraulics for a series of steady flows. The basic computational procedure utilized in this model is based on the solution of the one-dimensional energy equation. Energy losses are represented through friction (Manning's equation) and contraction/expansion (coefficient multiplied by the change in velocity head). The USACE utilized HEC-RAS to develop design criteria, while Reclamation utilized it mainly to set the downstream boundary condition for the SRH-2D model simulations, which consisted of the development of a water surface elevation as a function of flow rate.

SRH-2D is a two-dimensional (2D) mobile-bed hydraulics and sediment transport model for river systems developed by Reclamation at the Technical Service Center in Denver, Colorado (Lai, 2008). SRH-2D solves the depth-averaged dynamic wave equations with a parabolic turbulence model using a finite-volume numerical scheme. The model adopts a zonal approach for coupled modeling of channels and floodplains; a river system is broken down into modeling zones (delineated based on natural features such as topography, vegetation, and bed roughness), each with unique parameters such as flow resistance. One of the major features of SRH-2D is the

adoption of an unstructured hybrid mixed element mesh, which is based on the arbitrarily shaped element method of Lai (2000) for geometric representation. This meshing strategy is flexible enough to facilitate the implementation of the zonal modeling concept; it allows for greater modeling detail in areas of interest that ultimately leads to increased modeling efficiency through a compromise between solution accuracy and computing demand.

Model Topography: To represent the model terrains, a multi-resolution three-dimensional surface was generated in a Geographic Information System (GIS) using a Triangulated Irregular Network (TIN). Topographic representations of the existing and proposed 30% and 60% design conditions were constructed. This was accomplished using a combination of bathymetric and land survey data collected through a joint effort between Reclamation and the USACE, along with Light Detection and Ranging (LiDAR) data. The type of LiDAR acquisition used does not have the ability to penetrate through water. Therefore, bathymetric survey data replaced the LiDAR data in wetted areas. Proposed design condition contours were generated by the USACE in AutoCAD that were subsequently brought into GIS for surface building. An example area from the model domain of the resulting terrain for the 60% design is shown in Figure 2.

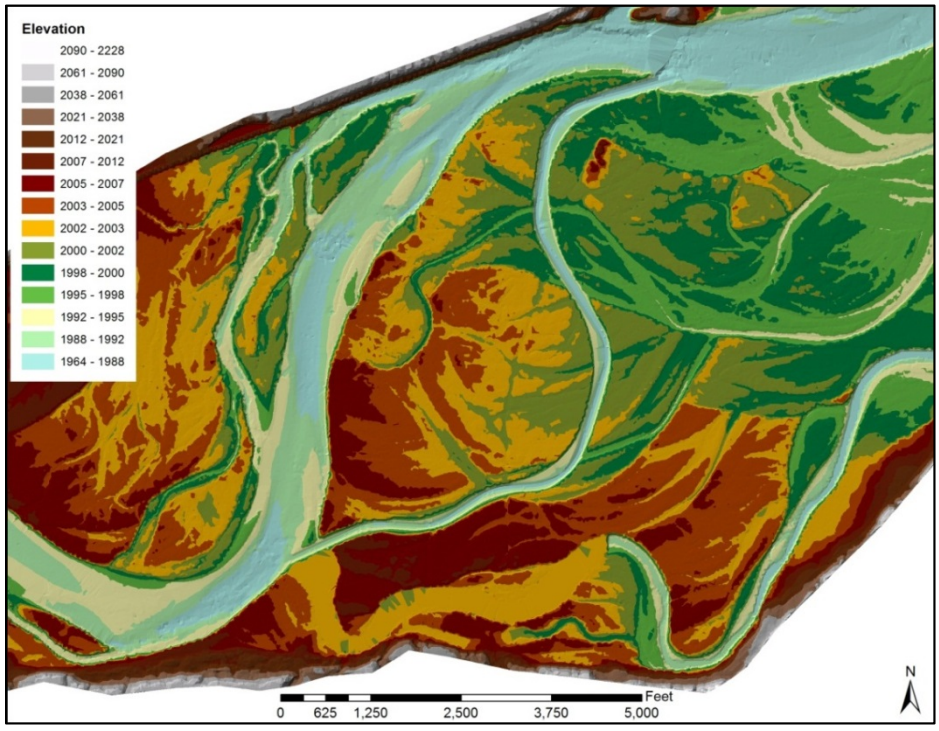

Figure 2 Example area showing the 60% design conditions surface used as input to the model. Elevation values are in feet.

Model Mesh: A 2D mesh defines the SRH-2D model topography and solution spacing. The mesh (nodes) stores ground elevation information from the model surface and consists of quadrilateral and triangular shaped elements. Surface-water Modeling System (SMS) software was used to construct flexible mixed element meshes that allowed for increased definition near areas of interest by using finer mesh cells. Coarser mesh cells were used elsewhere. A hydraulics only (fixed bed) module of SRH-2D was utilized to compare a relatively dense mesh (103,125

elements) to a much coarser mesh (25,350 elements) representing the existing conditions. This comparison was conducted using hydraulic outputs and showed the differences between the computed depths to be minimal. A coarser mesh relative to a fixed bed hydraulics model is needed for mobile bed simulations with sediment transport. This is due to the practical limitations of the number of mesh elements (and nodes) for the computationally intensive calculations in an effort to balance run time with model resolution. SMS was also utilized to delineate model roughness areas and assign model boundary conditions.

Each set of modeled design conditions (existing, 30%, and 60%) had its own computational mesh. The meshes consisted primarily of quadrilateral elements within channel areas and triangular elements in the floodplain/overbank areas. The element size varied based on location. In the main channel, the size of the quadrilateral elements was, on average, 65 feet in the lateral (cross stream) direction and 100 feet in the longitudinal (downstream) direction. The shorter dimension in the lateral direction was used to capture the more rapidly changing topography transverse to the stream flow with respect to horizontal distance. The triangular elements in the floodplain areas increased in coarseness as the model approached the domain boundary to a maximum size of 120 feet. An approximate total of 25,350 elements were used in the model domain to represent the existing topographic conditions. An increased mesh density along the proposed bypass channel alignments was incorporated into the preferred alternative meshes as it was a feature of focus. The 30% design bypass channel had an average element size of 25 by 35 feet while the 60% design bypass channel had an average element size of 20 by 35 feet. As a result the total number of mesh elements representing the proposed conditions model domain increased to roughly 30,450 for the 30% design and 39,000 for the 60% design. An example area of the model mesh for the 60% design conditions is shown in Figure 3.

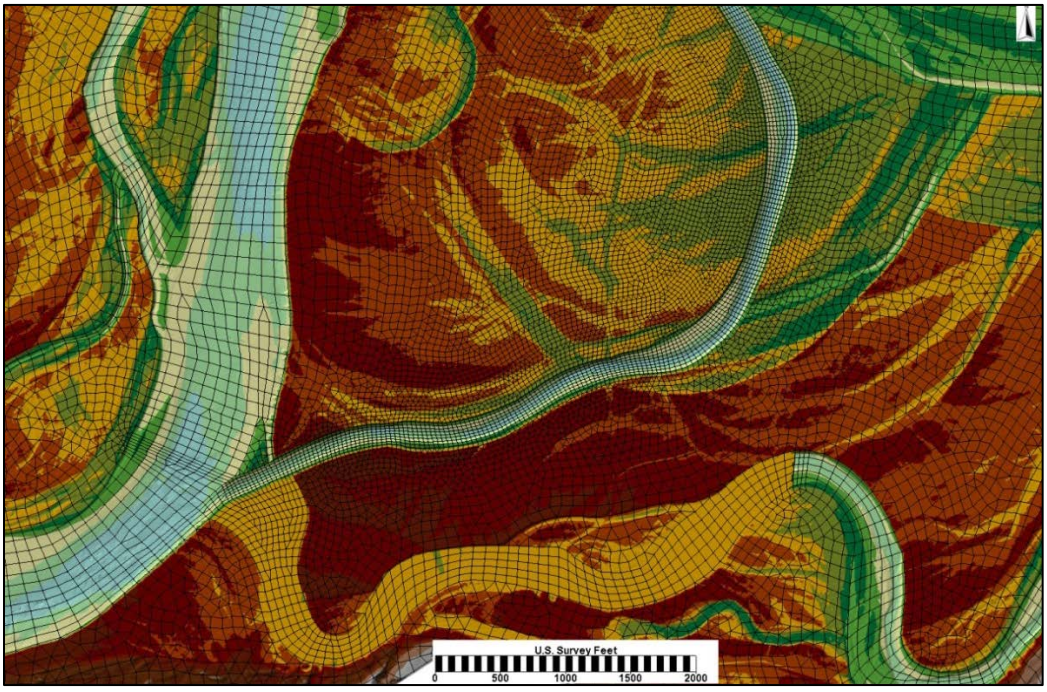

Figure 3 Example area of model mesh for 60% design conditions.

Model Boundary Conditions: Boundary conditions for the SRH-2D model were specified at the upstream and downstream model domain. The upstream boundary condition required both hydrologic (flow) and sediment data as inputs. Two average daily flow hydrographs representing particular events of interest were used for the flow input, while a rating curve relating flow to sediment discharge fluxes according to grain size was used for the sediment input. Another rating curve assigning a water surface elevation to the full range of flows from both hydrographs was used for the downstream boundary condition.

Upstream Boundary Condition – Hydrology: The closest USGS gages to the intake diversion dam are the Yellowstone River at Glendive MT Gage (06327500) which is located roughly 18 miles upstream, and the Yellowstone River near Sidney MT Gage (06329500) located roughly 36 miles downstream. For the SRH-2D sediment modeling, discharge data from only the Glendive Gage was used as it was upstream of the project site and closer in proximity. Average daily data representing two distinct hydrographs were selected to try and represent a range of flow conditions that the project design could encounter. A 2008 hydrograph was chosen as it appeared to roughly represent a typical wet year when looking at the most recent ten years of gage record. This hydrograph spans 107 days (5/19/08 - 9/2/08) with a peak flow of 63,200 cfs, which is roughly equivalent to the 5-year recurrence interval event according a flow frequency analysis conducted by the USACE (USACE, 2012). The other hydrograph used was from 2011 as it contains the flood of record. This hydrograph spans 206 days (3/1/11 - 9/22/11) and peaks at 122,000 cfs, which corresponds to a value above the 500-year event. The 2008 hydrograph is shown in Figure 4.

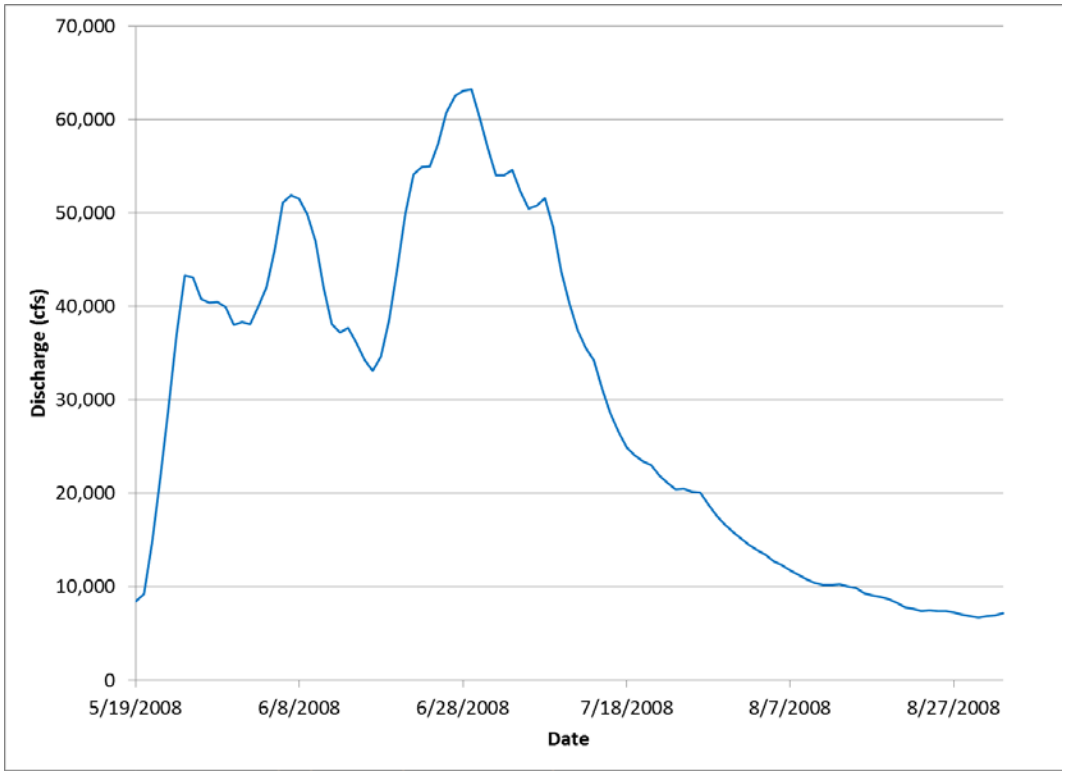

Figure 4 2008 input hydrograph.

Upstream Boundary Condition – Sediment Loads: The Yellowstone River has a mixed sand and gravel bed. Therefore, the consideration of bed load and suspended load sediment transport is necessary to quantify the passage of the total sediment load through the system. For the numerical sediment modeling, the relationship of total sediment load to the inflowing discharge is a necessary input.

To derive this total incoming sediment load relationship, Reclamation's in-house program SRH-Capacity (Huang and Bountry, 2009) was used. This model computes the sediment transport capacity using a specified transport equation for a given set of hydraulics and flow values. The required inputs for SRH-Capacity include 1D (cross section based) hydraulics, particle size gradation data, and hydrology data.

To compute the 1D hydraulics, Reclamation modified a HEC-RAS hydraulics model previously developed by the USACE. Additional cross sections were added to the HEC-RAS model to capture the pool-riffle sequence present in the morphology of the Yellowstone River channel. The geometry of the modified HEC-RAS model was then updated with the new topographic data collected in August 2012 by Reclamation and USACE staff.

Particle size gradation data were derived from gravel bar and bank sediment data collected by the USACE in August 2008 (USACE, 2008). The average of three and four grain size distributions was used in the model to represent the channel areas upstream and downstream of the intake diversion dam, respectively. These average distributions were binned into six different sediment size classes, two representing sand and the remaining four representing gravel.

Given the above input, the incoming sediment loads were calculated using the following three sediment transport equations, which are commonly used for rivers with both sand- and gravel-sized sediments:

1. Parker's (1990) bed load transport capacity equation combined with Engelund and Hansen (E/H, 1972), where the transport capacity of particle sizes greater than 2mm are computed with Parker, and the transport capacity of particle sizes less than 2mm are computed with E/H.
2. Wilcock and Crowe's (W/C, 2003) bed load transport capacity equation combined with Engelund and Hansen (E/H, 1972), where the transport capacity of particle sizes greater than 2mm are computed with W/C, and the transport capacity of particle sizes less than 2mm are computed with E/H.
3. Wu et al. (2000) total load sediment transport equation.

Downstream Boundary Condition: The downstream boundary condition consisted of a water surface elevation versus discharge rating curve. Discharge values encompassed both hydrographs. The associated water surface elevations were derived from the updated USACE HEC-RAS hydraulics model at a cross section whose location was at the downstream model domain boundary.

MODEL RESULTS DISCUSSION

The main objective of the YRI hydraulics and sediment transport model was to evaluate the stability and effect of a proposed bypass channel around the intake diversion dam by quantitatively evaluating short term and long term changes in bed elevations. 2D sediment model runs were performed using topographic representations of the currently existing conditions along with the proposed 30% and 60% project designs. Erosion/deposition results from the 30% design showed the lower half of the bypass channel (downstream of the channel split) experiencing deposition. This led to a complete re-design of the bypass channel for the 60% design. Conversely, the 60% design showed small amounts of erosion throughout the bypass channel. Given the model uncertainties however, this was viewed as being in general equilibrium. A side-by-side comparison of the erosion/deposition results from the 2008 hydrograph for the 30% and 60% designs is shown in Figure 5.

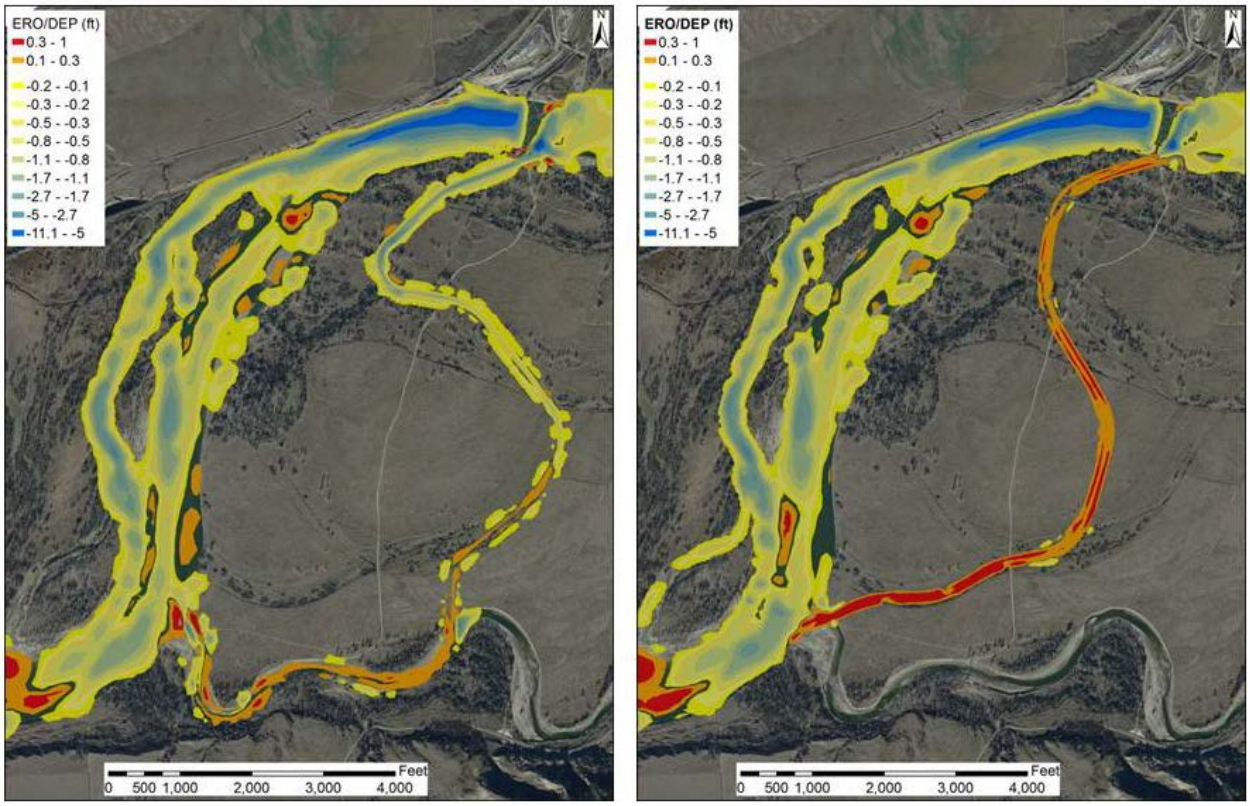

Figure 5 Erosion/Deposition results for the 2008 hydrograph using the Parker and E/H formulation for the 30% design (left) and 60% design (right). A positive (+) value indicates erosion while a negative (-) value indicates deposition.

In addition to evaluating erosion/deposition, monitoring lines were set up at areas of interest throughout the main and bypass channels to track sediment loads during the simulations. Sediment flux was measured at the upstream and downstream ends of both the main and bypass channels under all three modeled scenarios (existing conditions, 30% design, and 60% design).

Results showed the Parker, and Wilcock and Crowe formulations to be comparable, while the Wu formulation yielded noticeably lower sediment transport amounts. The average amount of main channel sediment captured by the bypass channel was roughly 8.5 to 9% for the 30% design and 11.5 to 12% for the 60% design. The relative amount of sediment being deposited in the 30% designed bypass channel is more than the amount of sediment being eroded in the 60% designed bypass channel. According to the Parker and Wilcock and Crowe formulations, an average of 12% and 17% of the incoming sediment load to the 30% design bypass channel is being deposited during the 2008 and 2011 hydrographs, respectively. Conversely, an average of 6% and 2% of the incoming sediment load to the 60% design bypass channel is being eroded during the 2008 and 2011 hydrographs, respectively. These results further indicate that the 60% design bypass channel is more stable with regards to sediment equilibrium during higher flow events. Lastly, sediment flux results showed that neither bypass channel design had a significant effect on the overall sediment balance in the reach. A sample set of sediment flux results are shown graphically in Figure 6 for the 60% design with the 2008 hydrograph that shows some of the above trends.

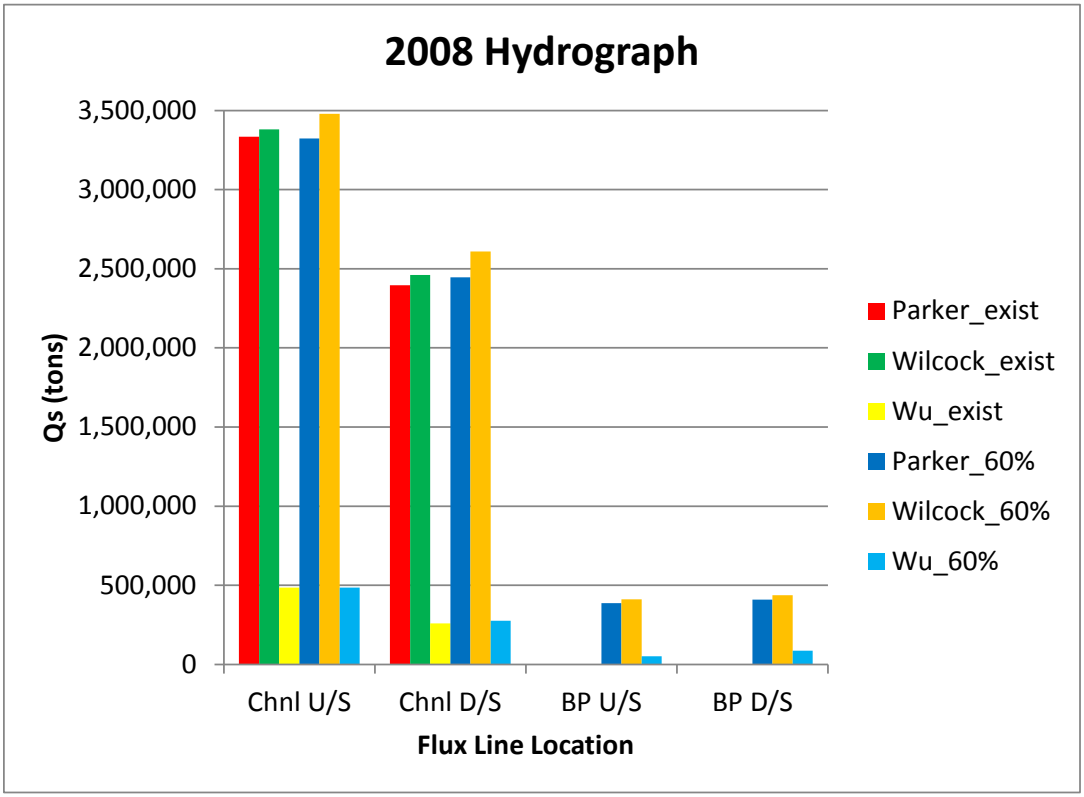

Figure 6 Sediment flux results for the 60% design under the 2008 hydrograph. (Chnl – Main Channel; BP – Bypass Channel)

SUMMARY AND CONCLUSIONS

The Lower Yellowstone Project consists, in part, of a diversion dam that has become a known barrier to migration of native fish, including the endangered pallid sturgeon. To address this, a diversion dam modification project is under design that includes a large bypass channel around the structure to improve the upstream and downstream fish passage. Reclamation evaluated the existing conditions as compared to the 30% and 60% proposed design through conducting a sediment transport analysis utilizing a two-dimensional hydraulics and sediment transport mobile bed model (SRH-2D) on the 5.5 miles of the Yellowstone River centering on the diversion dam and inclusive of the bypass channel. Model results were used iteratively through the design process, aiding the direction of future designs. The evaluation predicted the changes in bed elevations that would result from this project by looking at amounts of erosion/deposition along with overall reach affects.

Model results of the 30% design showed low velocities and corresponding deposition on the lower half of the bypass channel. As a result, the bypass channel was re-redesigned (60% design), which conversely showed small amounts of erosion throughout, but was deemed as being in approximate equilibrium. A sediment flux analysis revealed a significant difference between the Wu sediment transport formula as compared with the Parker, and Wilcock and Crowe formulations. The 30% design captured approximately 9% of the main channel sediment, while the 60% design captured roughly 12% during the 2008 hydrograph. The relative amount of sediment that was shown being deposited in the 30% bypass design was more than the amount of sediment being eroded in the 60% design. Lastly, neither bypass channel design was shown to have a significant effect on the overall sediment balance in the reach.

INACCURACIES IN SEDIMENT BUDGETS ARISING FROM ESTIMATIONS OF TRIBUTARY SEDIMENT INPUTS: AN EXAMPLE FROM A MONITORING NETWORK ON THE SOUTHERN COLORADO PLATEAU

Ronald E. Griffiths, Hydrologist, U.S. Geological Survey, Flagstaff, Arizona, rgriffiths@usgs.gov;
David J. Topping, Research Hydrologist, U.S. Geological Survey, Flagstaff, Arizona, dtopping@usgs.gov

Abstract Sediment budgets are an important tool for understanding how riverine ecosystems respond to perturbations. Changes in the quantity and grain-size distribution of sediment within river systems affect the channel morphology and related habitat resources. It is therefore important for resource managers to know if a channel reach is in a state of sediment accumulation, deficit or stasis. Many studies have estimated sediment loads from ungaged tributaries using regional sediment-yield equations or other similar techniques. While these approaches may be valid in regions where rainfall and geology are uniform over large areas, use of sediment-yield equations may lead to poor estimations of sediment loads in semi-arid climates, where rainfall events, contributing geology, and vegetation have large spatial variability.

Previous estimates of the annual sediment load from the ungaged tributaries to the Colorado River downstream from Glen Canyon Dam vary by an order of magnitude; this range in sediment loads has resulted in different researchers reaching opposite conclusions on the sign (accumulation or deficit) of the sediment budget in the Colorado River. To better estimate the supply of fine sediment (sand, silt, and clay) from these tributaries to the Colorado River, eight gages have been established on previously ungaged lesser tributaries in Glen, Marble, and Grand canyons. The remote locations of these streams and short duration of floods make it prohibitively expensive, if not impossible, to directly measure streamflow or to use conventional depth-integrating suspended-sediment samplers. Discharges are therefore calculated using a stage-discharge relation developed from a series of modeled flows and a stage record measured by a downward looking sonic ranging sensor. Flows are modeled using surveyed high-water marks, surveyed channel topography, and Z_0 bed roughness constrained by pebble counts. Suspended-sediment measurements are made with passive US U-59 samplers and, at some tributary gages, stage-triggered pump samplers. During floods with a sufficient number of suspended-sediment samples, loads are calculated by interpolating sediment concentrations between the physical samples. When few or no physical samples are collected for a given flood event, regression relations between discharge and sediment concentrations are used if the relations are statistically significant. For gages with no significant relation between discharge and sediment concentrations, mean sediment concentrations – averaged over the period of record – are used. Using these methods, suspended-silt-and-clay and suspended-sand loads transported past each of the lesser-tributary gages are calculated.

Results from this sediment-monitoring network show that previous estimates of annual sediment load from the tributaries were too high, and that the sediment budget for the Colorado River below Glen Canyon Dam is in greater deficit than previously concluded by most researchers. In addition, we found that floods of the same magnitude may have different source areas, resulting in large differences in sediment loads between equal magnitude flows. Because sediment loads do not necessarily correlate with drainage size, and cumulative sediment loads may vary by two orders of magnitude on an annual basis, using techniques such as sediment-yield equations to estimate sediment loads from ungaged tributaries may lead to large errors in sediment budgets.

INTRODUCTION

The calculation of accurate sediment budgets can be sensitive to the sediment supplied from ungaged tributaries. Studies have calculated sediment loads from ungaged tributaries using a number of methods, including: mass-balance calculations assuming quasi-equilibrium (Howard and Dolan 1981; Andrews, 1986), regional sediment-yield equations (Webb and et al., 2000), sediment-rating curves (Sutherland and Bryan, 1990) and peak discharge to total sediment-load relations (Rankl, 2002). The above methods can lead to errors when estimating annual sediment loads from semi-arid streams. Depending on the local geology, topography, and vegetation, floods in semi-arid regions can have large (10x) differences in sediment concentrations between equal magnitude flows as the result of locally intense rainfall events with footprints smaller than the receiving basin.

The Colorado River below Glen Canyon Dam is an example of a river reach where quantifying the supply of fine sediment from tributaries could be essential for calculating accurate sediment budgets. The Colorado River below Glen Canyon Dam is currently the focus of a major river restoration program (Campbell and others, 2010); one of the major goals of this program is the restoration of eddy sandbars in the Colorado River in Marble and Grand Canyons. Fine sediment is supplied to this reach from the Paria and Little Colorado Rivers as well as a number of smaller, herein referred to as lesser, tributaries. Sediment budgets calculated using estimates of cumulative sediment load from the lesser tributaries have been used to inform flow alternatives from Glen Canyon Dam with the objective of restoring sandbars (U.S. Department of the Interior, 1995). Over a factor of 5 variation exists in previous studies' estimates of the annual sediment load from the lesser tributaries to the Colorado River in Marble Canyon (BOR, 1956; BOR, 1958; Howard and Dolan, 1981; Randle and Pemberton, 1987; Webb et al., 2000). This large variation in estimated sediment load is large enough to have the effect of changing the sign of sediment budgets in the Colorado River in Marble and Grand canyons under certain conditions. The magnitude of the variation in these estimates and the fact that no direct measurements of lesser-tributary flood hydrographs or sediment transport were used in these estimates were the prime motivators of this study.

To better estimate the sediment supplied from the lesser tributaries to the Colorado River in Glen and Marble canyons, the U.S. Geological Survey (USGS) Grand Canyon Monitoring and Research Center established gages on previously ungaged lesser tributaries for measuring stage and suspended-sediment. This network of lesser-tributary gages was established in late 2000; most of the gages in the network now have over 13 years of data. At these gages, stage is recorded every 15 minutes during dry, or baseflow, periods and every minute during floods. Suspended-sediment measurements are made using US U-59 samplers (Edwards and Glysson, 1999), automatic-pump samplers, and rare dip samples. Channel topography and high-water marks are surveyed for subsequent flow modeling. High-water marks are modeled to determine flow; several sets of high-water marks are used to create a stage-discharge relation (Griffiths, 2010). This indirect method of determining discharge was chosen because of the remote location of the lesser-tributary gages and the short duration of floods. In this paper, we focus on the results from the ephemeral tributaries that discharge into the Colorado River in upper Marble Canyon. Upper Marble Canyon is herein defined as the reach of river from Lees Ferry to the formerly proposed Marble Canyon dam site at river mile 32.5 (by convention, river miles in Marble and Grand canyons begin at Lees Ferry and progress downstream).

PREVIOUS ESTIMATIONS OF LESSER-TRIBUTARY SEDIMENT SUPPLIES

A number of researchers have investigated the sediment supplied to the Colorado River from its lesser tributaries. The first studies were completed by the U.S. Department of the Interior, Bureau of Reclamation (BOR) in preparation for the proposed construction of Marble Canyon Dam (BOR, 1956; 1958). The initial 1956 BOR study estimated the mean-annual sediment load from the lesser tributaries

using the area of ungaged tributaries and the sediment yield from the "roughly similar" San Juan River. This study concluded that the mean-annual sediment load from the lesser tributaries between the Paria River and the proposed dam site was approximately 2.8 million metric tons. A second study by the BOR (1958), based on field observations of geology, geomorphology, vegetation, and sedimentation in stock tanks, concluded that the mean-annual sediment load from the lesser tributaries was approximately 740,000 metric tons (including gravel). In 1981, Howard and Dolan (1981) estimated the mean-annual sediment load from all lesser tributaries upstream from the Grand Canyon gage (USGS 09402500 Colorado River near Grand Canyon, AZ) to be 34 % of the combined mean-annual load from the Paria and Little Colorado rivers, or ~4 million metric tons. Randle and Pemberton (1987) using a regional sediment-yield regression to calculate lesser-tributary sediment loads, estimated that the mean-annual sediment load from the lesser tributaries in Marble Canyon to be ~910,000 metric tons. Of this total, they estimated that the mean-annual sand load from these Marble Canyon tributaries was ~140,000 metric tons (i.e., 15% of the load was sand). Sediment yields are reported in units of mass per unit area-time, whereas annual or cumulative sediment loads (i.e., sediment supplies) are reported in units of mass. A similar regional sediment-yield regression approach was used by Webb et al. (2000), who, in addition, employed a flood-frequency rating-curve method and results from a reservoir-sedimentation study combined with a runoff model to calculate three estimates of mean-annual sediment load from the lesser tributaries; the mean-annual sediment load from all lesser tributaries in Marble Canyon was estimated to be 460,000-610,000 metric tons. Of this total, they calculated the mean-annual sand load (assumed to be 15-75% of total sediment) ranged from 70,000-460,000 metric tons.

The majority of the previous studies reported mean-annual sediment loads calculated on the basis of sediment-yield equations derived for drainages with substantially different geologic and climatic conditions. No direct measurements of sediment transport in the lesser tributaries were used. In addition, the time-averaged nature of the sediment loads reported by the previous studies make these mean-annual loads poorly suited for calculation of sediment budgets over shorter time frames.

In the sections below, we will investigate in more depth some of the methods used in the previous studies. The two BOR studies estimated sediment yields and sediment supplied to the upper Marble Canyon Reach. The remaining studies estimated sediment yields and resulting sediment supplies to longer reaches of the river than the upper Marble Canyon Reach. To allow comparison with the previous study results, and between previous studies, we converted yield values from the disparate studies using drainage area in combination with published bulk sediment density estimates to generate estimates of mean-annual sediment loads from the lesser tributaries to upper Marble Canyon (Table 1).

Table 1 Summary of previous estimations of summed lesser-tributary mean-annual sediment loads to the Colorado River corrected and apportioned to the upper Marble Canyon Reach.

Study	Total sediment (metric tons)	Sand (metric tons)
Reclamation (1956)	1,900,000	No value estimated
Reclamation (1958)	760,000[a]	No value estimated
Howard and Dolan (1981)	1,800,000	No value estimated
Randle and Pemberton (1987)	680,000	100,000[b]
Webb and others (2000)	520,000	78,000-390,000[c]

[a]Includes gravel
[b]Sand assumed to be 15% of total sediment
[c]Sand assumed to be 15-75% of total sediment

The study by BOR (1956) estimated a lesser-tributary sediment yield of 714 m^3/km^2-yr. This initial estimation of sediment yield in combination with the lesser-tributary area of upper Marble Canyon (2,319 km^2) from Webb et al. (2000) and the sediment density of 1,153 kg/m^3 used by Randle and Pemberton (1987) results in a mean-annual sediment load of ~1.9 million metric tons (Table 1). Because of errors

made by BOR (1956) in determining the lesser-tributary area from the 1:500,000-scale map used, this mean-annual sediment load is less than the original study predicted. Because no grain-size distributions are reported by BOR (1956) for the lesser-tributary sediment load, no subdivision of predicted total sediment load into silt and clay supply and sand supply is possible.

The more-comprehensive BOR (1958) study conducted individual investigations in each of the "more-important" lesser tributaries and divided the lesser-tributary area between Glen Canyon Dam and the proposed Marble Canyon dam into 12 sediment-yield units. Correcting the BOR (1958) total drainage area by that reported in Webb et al. (2000) and using the Randle and Pemberton (1987) sediment density, the 1958 BOR study predicts the mean-annual sediment load from all upper Marble Canyon lesser tributaries of 760,000 metric tons of total sediment (Table 1).

Howard and Dolan (1981) estimated the sediment yield from the lesser tributaries to the Colorado River between Lees Ferry and the Grand Canyon gage (USGS 09402500 Colorado River near Grand Canyon, AZ) based on a pre-dam sediment mass balance and the assumption of the bathymetric changes observed at one cross section was representative of all geomorphic changes in this 140-km-long reach. By this approach, they estimated the sediment yield from the lesser tributaries to be approximately 34% of the combined annual sediment load from the Paria and Little Colorado Rivers, or ~780 metric tons/km^2-yr. This sediment yield in combination with the tributary drainage-basin areas from Webb et al. (2000) results in mean-annual sediment load from all upper Marble Canyon lesser tributaries of ~1.8 million metric tons (Table 1). As with BOR (1956, 1958), because no grain-size distributions are reported by Howard and Dolan (1981) for the lesser-tributary sediment yield, no subdivision of predicted total sediment load into silt and clay supply and sand loads is possible.

Applying the sediment yield from Marble Canyon (293 metric tons/km^2-yr) of Randle and Pemberton (1987) to the lesser-tributary area of upper Marble Canyon results in ~680,000 metric tons of sediment. Randle and Pemberton (1987) assumed sand comprised 15% of the total sediment, using this figure we calculate a mean-annual sand load from the lesser tributaries of ~100,000 metric tons.

Webb et al. (2000) used three methods for determining sediment yield from the lesser tributary areas. Because the results from the three methods were similar, they presented the results of the simplest method, the regional data regression. Using their sediment yield equation ($351 \cdot A^{0.88}$ where A is tributary drainage area in km^2) and the individual tributary drainage areas, we calculated the mean-annual sediment load from the lesser tributaries to upper Marble Canyon. In addition to the tributaries listed for Marble Canyon, they estimated an extra 120 km^2 of area that was not included in the list of tributaries. We divided this extra area by river miles and applied the resultant extra 62 km^2 to the upper Marble Canyon Reach. When determining sediment load from each tributary, we assumed this extra area was comprised of small drainages (1 km^2 each) and added the sediment loads to the total load for upper Marble Canyon. Using the Webb et al. (2000) methods, we thus calculated a mean-annual sediment load from the lesser tributaries of ~520,000 metric tons. Using their estimate of 15-75% sand results in ~78,000-390,000 metric tons of sand (Table 1).

LESSER-TRIBUTARY GAGES

There are currently eight gages on the lesser tributaries of the Colorado River in lower Glen, Marble, and Grand canyons where stage and suspended sediment are automatically measured (Figure 1). This monitoring network was established in 2000 and expanded in 2006 to include Bright Angel Creek (Griffiths et al., 2014). In this network, stage, suspended-silt and clay concentration, suspended-sand concentration, and suspended-sand grain-size measurements are made on lesser tributaries representing approximately 69% of the previously ungaged drainage area of upper Marble Canyon. All of the lesser-tributary gages, except for those in Water Holes Canyon and on Bright Angel Creek, monitor streams that

drain into upper Marble Canyon. This paper will focus on the lesser tributaries that flow into upper Marble Canyon, putting aside the gages in Water Holes Canyon and on Bright Angel Creek.

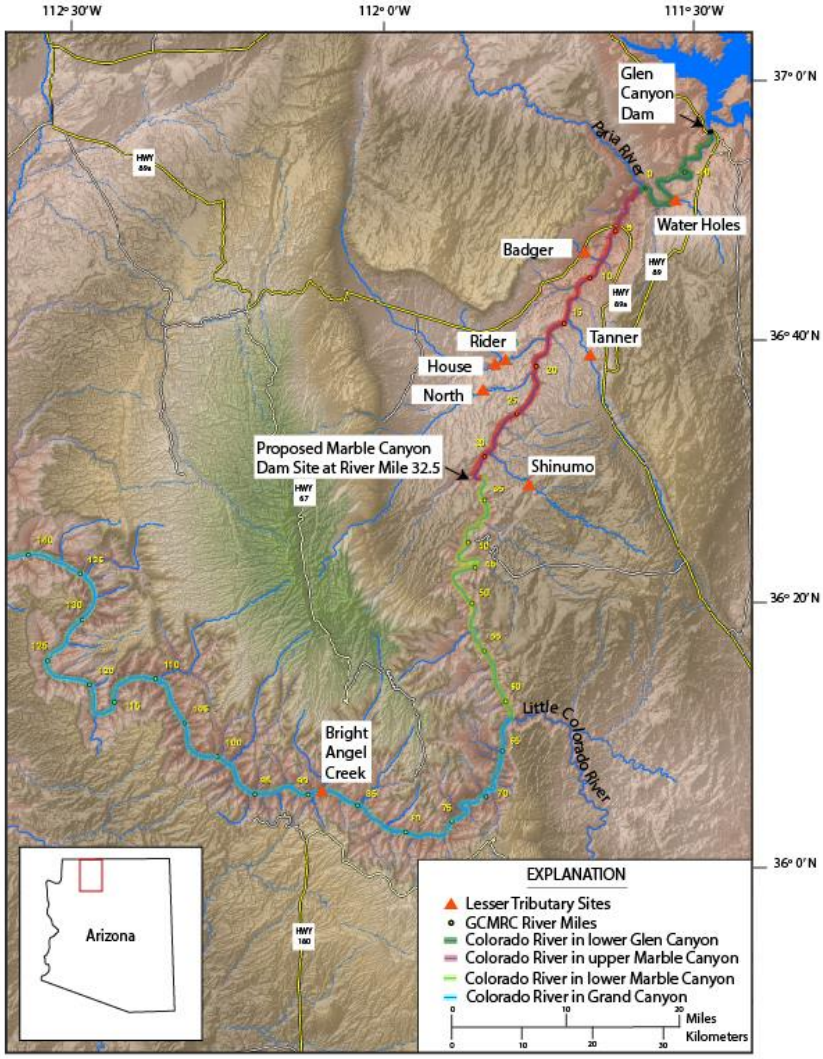

Figure 1 Digital elevation map showing the lesser-tributary gages. Lesser-tributary gages: Water Holes Canyon (Water Holes), Badger Creek (Badger), Tanner Wash (Tanner), House Rock Wash above Emmett Wash (House), House Rock Wash in Rider Canyon (Rider), North Canyon (North), Shinumo Wash (Shinumo), and Bright Angel Creek.

Geology of the lesser-tributary drainage basins can be broadly categorized into areas with higher potential fine-sediment yield associated with Mesozoic sandstones, and areas with lower potential fine-sediment yield associated with Paleozoic limestone. Four gages are located on higher potential fine-sediment yield lesser tributaries that drain into upper Marble Canyon: (1) Badger Creek, (2) Tanner Wash, (3) House Rock Wash above Emmett Wash (herein referred to as House Rock Wash), and (4) House Rock Wash in Rider Canyon (herein referred to as Rider Canyon). At the gage: the streambed of Badger Creek is composed of sand and gravel, the streambed of Tanner wash is composed of gravel and sand, the streambed of House Rock Wash is composed of sand and fine gravel, and the streambed of Rider Canyon is composed of patches of sand and gravel on bedrock. The House Rock Wash gage is located upstream, in the same drainage, as the Rider Canyon gage. The Rider Canyon gage has the most comprehensive

suspended-sediment record of the lesser-tributary gages; at this gage, suspended-sediment measurements are made using arrays of US U-59 samplers and an automatic pump sampler.

North Canyon and Shinumo Wash drain areas that consist primarily of Paleozoic limestone and have lower potential fine-sediment yields. These two tributaries have streambeds that are almost exclusively angular limestone gravel with only minor amounts of interstitial sand. Vegetation at all the gages consists primarily of sparse, low-lying bushes and grasses, with little or no vegetation in the active channel.

METHODS

Discharge calculations The remote location of the lesser-tributary gages coupled with the extremely short duration of flash floods makes it difficult and expensive to measure the discharge of water directly. Calculation of discharge at the lesser-tributary monitoring sites therefore requires the development of a stage-discharge relation constrained by modeled peak discharges from multiple floods. Peak discharges are modeled using the USGS National Research Program multi-dimensional surface water modeling system – now named international river interface cooperative – and the "quasi-three-dimensional flow and sediment transport with morphological evolution of channels solver" (McDonald et al., 2005). The approach used is to:

(1) Select a suitable reach for modeling and complete a base topographic survey. A suitable channel reach is stable and relatively straight, with simple channel geometry that will result in an easier flow-modeling process. Survey the position of the stage sensor and any suspended-sediment sampler intakes. Survey cross sections every 2-3 meters along the channel, depending on channel complexity, and generate a topographic map and model grid of the stream channel from survey data.
(2) Survey multiple sets of high-water marks within the reach corresponding to floods with different peak stages. A wide range of high-water marks allows the development of a comprehensive stage-discharge relation.
(3) Perform successive 2-D model runs varying the discharge and Z_0 (Z_0 roughness values are constrained by pebble count data) to minimize the root-mean-square error between the surveyed high-water marks and the modeled water surface.
(4) Attempt to hold the established Z_0 constant in the model, and model the discharge associated with different high-water marks to develop stage-discharge relations (Griffiths et al., 2010).
(5) Only allow Z_0 to increase with increasing peak flood stage if there is physical evidence that the roughness characteristics of the bed changes with increasing stage, as described below.

The Nikuradse (1933) Z_0 bed roughness parameter is used for flow modeling. This roughness parameter was chosen instead of the more commonly used Manning's n because, unlike the Manning's n roughness parameter, Z_0 does not depend on stage and only depends on the characteristics of the streambed. As discharge increases in gravel-bedded rivers Z_0 should remain constant unless the gravel bed becomes fully mobile or rougher areas of the streambed and banks become inundated. As either vegetated or formerly dry rougher areas of the streambed, banks, and canyon walls become inundated and are added to the model grid, Z_0 may increase. For an immobile gravel bed, Z_0 is approximately equal to $0.1 \cdot D_{84}$ (Whiting and Dietrich, 1989; Wiberg and Smith, 1991), where D_{84} is the 84th percentile grain size of the gravel. As the gravel bed becomes fully mobile, Z_0 increases to approximately equal $0.5 \cdot D_{84}$ (Pitlick, 1992)

Modeled flows are combined with corresponding recorded stages to develop a stage-discharge relation for the gage. This stage-discharge relation is used for all subsequent floods unless major changes in the channel geometry or hydraulic control are observed. If large channel changes occur, a new stage discharge relation must be developed using the steps above. Where an insufficient number or diversity of flood peaks have been modeled to develop a stage-discharge relation, any high-water marks observed

during maintenance visits to the gage are flagged for later survey. The stage-discharge relation and stage record are used to calculate the discharge record for each gage.

Sediment-transport calculations At each lesser-tributary gage, cumulative sediment load is calculated using the discharge record and a combination of physical-sample sediment-concentration data and averaged sediment concentrations or a regression relationship developed between log-transformed discharge and log-transformed sediment concentrations. Logarithmic transformation is used to reduce heteroscedasticity in the data. Samples collected by the US U-59s or the automatic pump samplers are analyzed for silt and clay concentration, sand concentration, and sand grain-size distribution. On the basis of analyses conducted on the Paria River (a similarly steep, sandy river, with similarly high sediment concentrations), the sediment concentrations measured in these "point" samples are assumed to be representative of the sediment concentrations in the entire cross section. The automatic pump samplers record the date and time the samples were collected. The US U-59 samples are assigned a date and time of sampling based on the date they were recovered, the preceding hydrograph, and the surveyed elevations of the sampler intakes. Once the date and time of collection is known for each of the samples and the laboratory analyses are completed, an F-test is preformed to determine if any significant dependence of log-transformed concentration on log-transformed discharge is present (Figure 2). Because of the large variability in suspended-sediment concentrations observed during individual flood events and between different floods, many of the gages do not exhibit significant "stable" relations between discharge and silt and clay concentration and between discharge and sand concentration. However, most sites do show a significant positive relation between discharge and suspended-sand D_{50}.

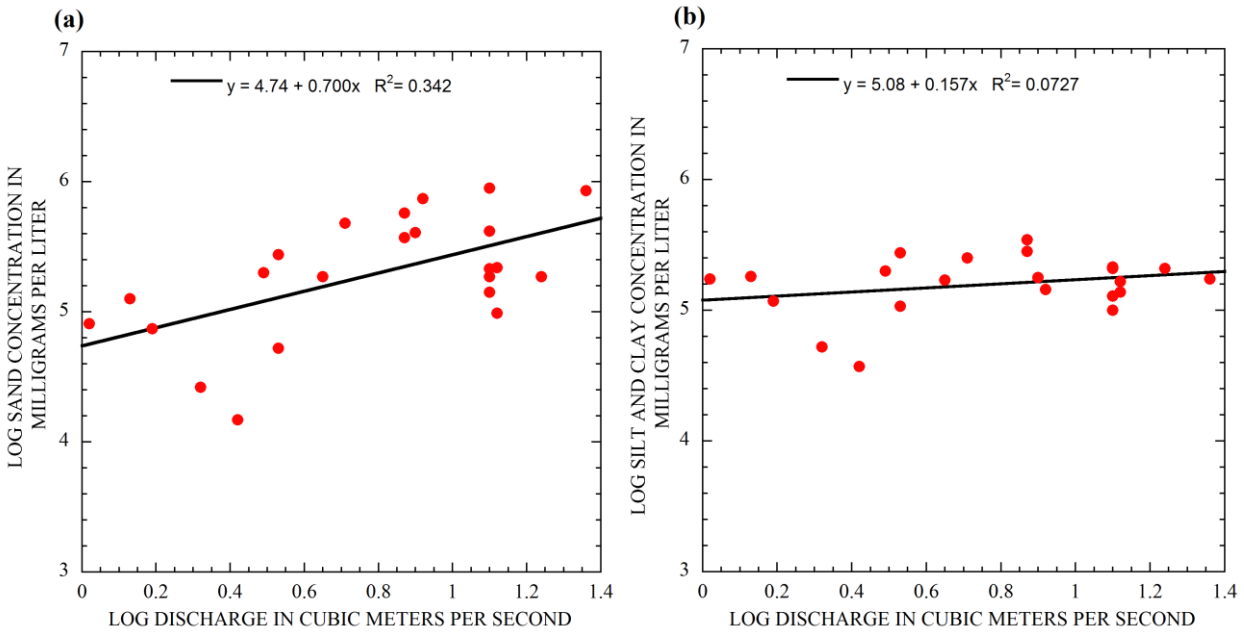

Figure 2 Log-log plots of concentration of sand (a) and silt and clay (b) vs discharge for the Badger Creek gage. Results from F-tests indicate that the linear fit is significant for the relation between log-transformed discharge and log-transformed sand concentration ($p < 0.05$), but not for the relation between log-transformed discharge and log-transformed silt and clay concentration.

For many of the lesser tributaries, suspended-sediment concentration does not correlate well with discharge. Using a F-test, log-transformed suspended silt and clay concentrations were significantly related ($p < 0.05$) to log-transformed discharge in only the Shimumo Wash drainage, while log-transformed sand concentrations are significantly related to log-transformed discharge in two of the five

drainages (Badger Creek and Shimumo Wash). Poor correlation between discharge and suspended-sediment concentration is independent of sampling method; at the Rider Canyon gage, all sampling methods yield similar poor correlations between log-transformed discharge and suspended-sand concentration (Figure 3).

Sediment concentration and discharge are combined to calculate instantaneous loads; these loads are then integrated over the entire hydrograph to calculate the cumulative loads of suspended-sediment transported past each of the lesser-tributary gages. If samples were collected during a flood event, the concentrations from those samples are used for a half hour window surrounding the sample collection time. If no samples were collected during a flood, or not collected within a half hour of a calculated discharge, mean sediment sample concentrations from the entire dataset at that gage are used; gages with significant discharge-concentration relations use these relations in the place of mean concentrations. Silt and clay loads and sand loads are calculated using the same techniques.

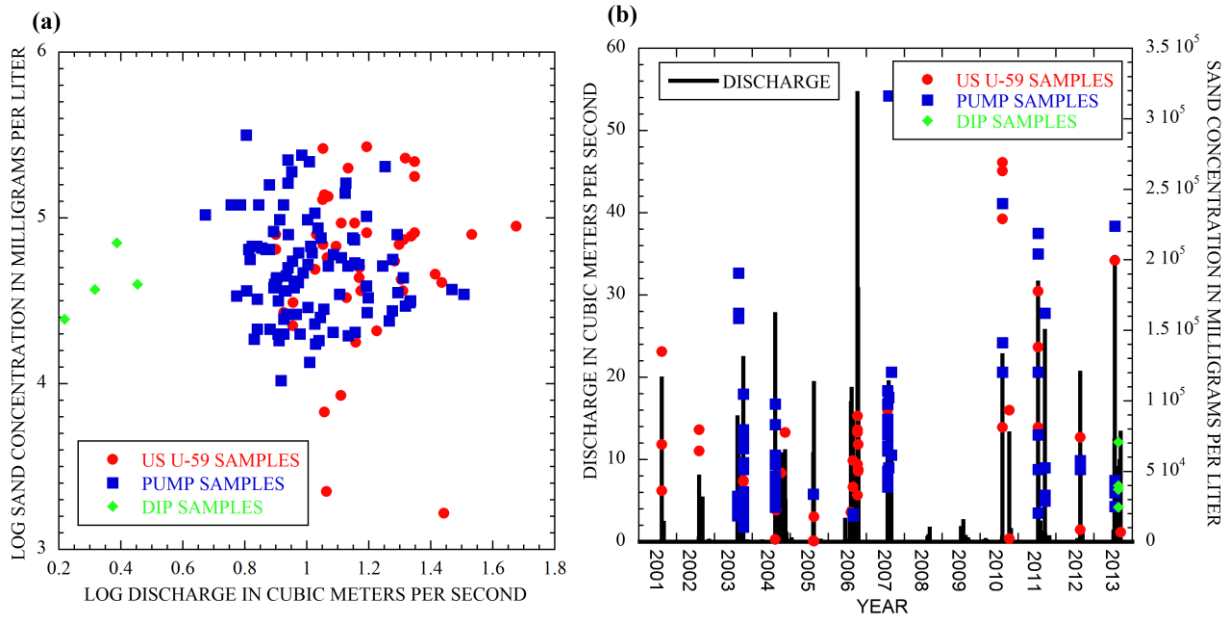

Figure 3 Log-log plot of sand concentration vs discharge for the Rider Canyon gage showing the three sampling methods (a), sand concentration and discharge for the entire period of study (b).

RESULTS AND DISCUSSION

Results from this study We estimate total sediment load from the lesser tributaries to the Colorado River in upper Marble Canyon by applying the mean-annual measured cumulative loads of the gaged tributaries, 69% of the total lesser-tributary area of upper Marble Canyon, to the remaining ungaged 31%. The ungaged area is divided into potentially higher and lower sediment yields based on drainage basin geology and similarity to other, gaged, lesser tributaries. Using this classification, only 25% of the higher-potential-yield tributaries remain ungaged; sediment yield from this ungaged area is estimated based on the annual yield of the three gaged higher-potential-yield tributaries. Ungaged tributaries draining the lower-potential-yield area represent 40% of the total lower-potential-yield tributaries; the sediment yield from this area is estimated from the annual yield of the lower-potential-yield tributaries.

Over the 13 years of this study, annual sediment load from the lesser tributaries to the Colorado River in upper Marble Canyon was found to vary two orders of magnitude from ~1,800 to 340,000 metric tons of

sand and from ~2,900 to 370,000 metric tons of silt and clay (Table 2). The mean-annual sand and silt-and-clay loads in the lesser tributaries were ~72,000 metric tons of sand and ~96,000 metric tons of silt and clay. This is equivalent to ~10% of the measured mean-annual sand load and ~8% of measured mean-annual silt-and-clay load in the Paria River over the same period (Table 2). Although the lesser tributary mean-annual sand load is 10% of the Paria River, the annual sand load of the lesser tributaries as a percent of the Paria River sand load ranges from ~1.6-49% during individual years.

The vast majority of the sediment entering Marble Canyon from the lesser tributaries is supplied from the 57% of the tributary area with higher potential sediment yield. The three gaged higher-potential-yield tributaries, Badger Creek, Rider Canyon, and Tanner Wash, contribute approximately 73% of the total sand and 65% of the total silt and clay to the upper Marble Canyon Reach.

Table 2 Measured annual sediment loads in metric tons (t) from the higher- and lower-potential-sediment-yield lesser tributaries to the Colorado River, the summed annual lesser-tributary sediment loads to upper Marble Canyon including estimates from the remaining ungaged area, and the measured Paria River annual sediment loads.

Year	Higher-Yield Tributaries		Lower-Yield Tributaries		Upper Marble Canyon		Paria River	
	Sand (t)	Silt (t)	Sand (t)	Silt (t)	Sand (t)	Silt (t)	Sand (t)	Silt (t)
2001	8,400	8,000	0	0	11,000	11,000	88,700	399,000
2002	28,000	28,000	62	720	38,000	38,000	78,100	468,000
2003	19,000	30,000	380	3,600	26,000	48,000	341,000	780,000
2004	47,000	59,000	970	6,200	64,000	89,000	676,000	1,530,000
2005	54,000	54,000	3,900	32,000	79,000	130,000	976,000	1,280,000
2006	260,000	270,000	350	5,200	340,000	370,000	1,590,000	2,080,000

2013	76,000	98,000	12,000	34,000	120,000	190,000	1,950,000	2,150,000
Mean	**52,000**	**58,000**	**1,400**	**710**	**72,000**	**96,000**	**712,000**	**1,170,000**

Annual sediment loads from the lesser tributaries vary greatly between drainages and from year to year (Table 2, Figure 3). Drainages have diverse geology and topography, storm cells that produce locally heavy rain may have a footprint much smaller than the size of the receiving drainage basin. While regional precipitation events do occur, precipitation events are typically more spatially variable with many higher-discharge events recorded in one tributary not present in the discharge record of other, nearby, tributaries (Figure 3a). In addition, a tributary may experience several large floods within days followed by years of quiescence. Over the course of this study, three of the gaged tributaries, Tanner Wash, Shinumo Wash, and North Canyon, have cumulative discharges that are approximately the same; however, the observed sediment loads, as well as the timing of events, differ dramatically (Figure 3). Both North Canyon and Shinumo Wash contributed very little sediment (combined less than 2% of the total sand and approximately 8% of the silt and clay), while Tanner Wash alone contributed approximately 28% of the sand and 18% of the silt and clay.

The ratio of suspended sand to suspended silt and clay varies considerably even among drainages of similar geology. Higher-potential-yield tributaries average approximately 47% sand and 53% silt and clay while the lower-potential-yield tributaries average only 17% sand. Because the higher-potential-yield tributaries contribute much more sediment than do the other tributaries, sand comprises, on average, approximately 45% of the sediment supplied to the entire Marble Canyon Reach by the lesser tributaries. Sediment yield varies within drainages as well as between different tributaries. A drainage representing

approximately 25% of the total drainage area enters between the House Rock Wash gage and the Rider Canyon gage (these gages are located on the same drainage, with House Rock Wash being the upstream gage). This drainage, which is similar to Badger Creek in geology and topographic relief, is responsible for approximately 53% of the sand passing the Rider Canyon gage, but only 22% of the silt and clay.

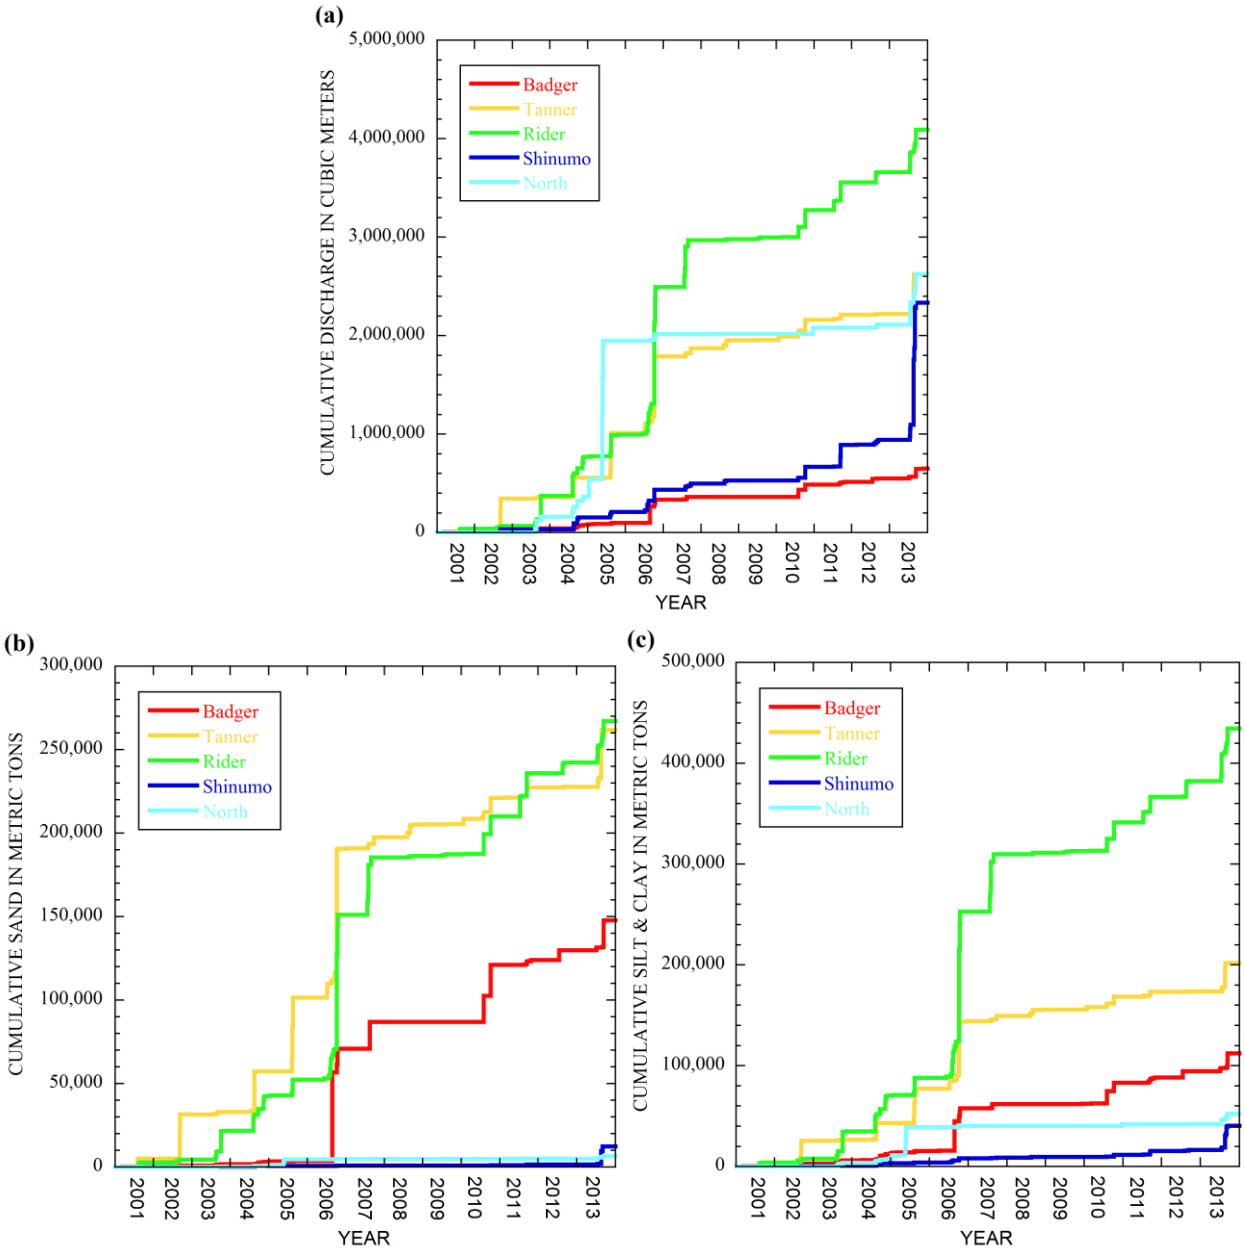

Figure 3 Cumulative water discharges in cubic meters (a) sand loads in metric tons (b) and silt and clay loads in metric tons (c) for the gaged lesser tributaries in upper Marble Canyon.

Comparison with previous work The results from this study show that previous studies all over-estimated the sediment supply from the lesser tributaries to the Colorado River in Marble Canyon (Table 1, Table 2). Two of the previous studies, BOR (1956) and Howard and Dolan (1981), overestimated the quantity of total sediment entering from the lesser tributaries by an order of magnitude. The other three

previous studies estimated mean-annual lesser-tributary sediment loads ranging from ~520,000 to 760,000 metric tons. Our study measured a mean-annual lesser-tributary sediment supply of ~170,000 metric tons, a factor of 3.1-4.5 lower than the previous estimates. Previous studies also greatly overestimated the amount of lesser-tributary sand supplied to the Colorado River in upper Marble Canyon. Only the low-end estimates of lesser-tributary sand load from Webb et al. (2000) seemingly agree with our measurements of lesser-tributary sand load; this apparent agreement is, however, misleading as Webb et al.'s (2000) low-end estimates assumed that only 15% of the total sediment load was sand. Our suspended-sediment measurements show that this estimate of percent sand is too low, the measured value is actually much larger at ~45% sand. If Webb et al. (2000) had used a more-correct higher percentage of sand, their lowest estimate of lesser-tributary sand supply would have been roughly 3.3 times larger than the values calculated in our study.

The differences in lesser tributaries sediment loads between previous studies and our study can be attributed to previous studies not using direct measurements of stage, discharge, or sediment concentrations, but relying on relations from drainage basins that do not accurately reflect the local geology, climate and vegetation. Additionally, previous studies, using older established sediment-yield relations, are based on data that do not reflect current climatic conditions. Lastly, previous studies present mean-annual results that do not capture the year-to-year variation in sediment loads measured in our study.

SUMMARY

Relying on indirect methods to estimate the cumulative sediment load from ungaged tributaries and close sediment budgets may result in substantial errors in these budgets. This study found that previous, indirect, methods that used no actual measurements of sediment transport greatly overestimated the amount of sand and the amount of silt and clay supplied by the lesser tributaries to the Colorado River in upper Marble Canyon. Because large variation exists in annual tributary sediment loads, additional error will be introduced into shorter-term sediment budgets (with durations of several years or less) even when measured mean-annual lesser-tributary sediment loads are used in these budgets; sediment supply to the Colorado River in upper Marble Canyon from the lesser tributaries was found to vary over a factor of 100 on an annual basis. For sediment budgets that vary greatly as a function of the sediment supplied from tributaries, direct measurement of the sediment loads in these tributaries may be necessary to accurately close sediment budgets, and provide valid recommendations to resource managers.

Keywords: sediment budgeting, rivers, monitoring, management

Abstract: Decision-support tools providing accurate, near-real-time data and user-friendly interactive visualizations are of critical value to resource managers tasked with planning and carrying out management programs in their domain. Creating a system to continuously aggregate datasets and recompute derived values is difficult and error-prone when attempted by hand. To address this need for river managers in support of sediment budgeting, we have created a web-based, open source suite of tools and processes that 1) continually aggregate data of interest, 2) recompute derived values based upon latest available data, and 3) update visualizations on-demand, providing simple front-end tools available to resource managers and the public. For the first time, engineers and scientists can access these tools freely over the web to assist them with planning and adaptive management decisions.

INTRODUCTION

Fine sediment (sand, silt, and clay) forms the template for riverine ecosystems in many rivers with naturally large sediment loads in the western United States. By disrupting the natural transport of fine sediment, the construction of dams and subsequent regulation of flows has dramatically affected the aquatic and riparian ecosystems in many western rivers (Schmidt and Wilcock, 2008). Depending on the locations of the sources of water and sediment in a watershed relative to the location of a dam, and depending on how that dam is managed, the reaches downstream from a dam may undergo sediment evacuation or accumulation (Topping et al., 2000a,b; Grams et al., 2007; Dean and Schmidt, 2011). Substantial changes in the mass balance of sediment downstream from a dam may have important environmental consequences that may require flow remediation (e.g., U.S. Department of the Interior, 2012). The development of environmental flows for ecosystem management in rivers with naturally high sediment loads that are perturbed by upstream water development thus requires the ability to manage sediment. The preferred scientific tool for such management is the sediment budget (e.g., Erwin et al., 2012; Grams et al., 2013).

Accurate sediment budgets require differencing accurate measurements of the amount of sediment entering and leaving a river reach (e.g., Topping et al., 2010). In rivers dominated by suspended-sediment transport, the amount of sediment entering or leaving a reach is determined through integration of the product of water discharge and suspended-sediment concentration (Porterfield, 1972). Both discharge and sediment concentrations are subject to potential biases that accumulate over time. Uncertainty in a sediment budget cannot be accurately quantified without propagating the biases through the calculations (Topping et al., 2000a, 2010).

To assist river science and management in Grand Canyon National Park, Big Bend National Park, Dinosaur National Monument, and Canyonlands National Park (Figure 1), the U.S. Geological Survey's (USGS)

Grand Canyon Monitoring and Research Center (GCMRC) in partnership with the USGS Center for Integrated Data Analytics (CIDA) have designed and built a database and web application for serving, and operating on, time-series measurements of those key water discharge and suspended-sediment concentration values. This web application is the Discharge, Sediment, and Water Quality Monitoring web application, hereinafter referred to as the "GCMRC web application."

Figure 1 The current geographic scope for the GCMRC web application.

The GCMRC web application consists broadly of two subparts: the GCMRC Data And Workflow System (GDAWS) data warehouse (including its associated data collection and computation processes, and the services that provide that data on request); and the web application itself, which consists of back-end services that perform real-time computation on datasets, and a highly capable browser-based client presented to the user in their web browser.

The GCMRC web application is a decisive advance in the state of the art for sediment budget work. The benefits, however, are differently distributed between administrative, scientific, and technological areas of interest.

Administrative benefits: In terms of budgets and operations, the GCMRC web application's most important characteristic is its 100 percent open source implementation. This resolves to both short-term and long-term cost containment advantages. In brief: nobody is paying for licenses; more importantly, nobody's hands are tied by restrictive covenants, nondisclosure agreements, et cetera; more important still, open source projects are future- proofed against withdrawal of licensing permissions (unlike proprietary software whose terms and conditions may change); and perhaps most important, open source technologies have an inherent network effect (software with obvious value is supported and thrives) that reduces concerns about ongoing staffing for extension and maintenance.

Another significant administrative benefit of the GCMRC web application is its standards-based nature. The programming code powering the application consists of well-documented and accepted protocols and methods to deliver and visualize information. This is not a single purpose solution that is useful only in Grand Canyon, Big Bend, Dinosaur, and Canyonlands. It is readily adaptable, at no licensing cost and reasonable scope of project effort, to sediment-budgeting requirements in other reaches on other rivers. The custom programming code and open source frameworks supporting the application are provided as public

domain software via the USGS GitHub instance online at https://github.com/USGS-CIDA. While the software currently serves river science and management within the scope of the GCMRC project areas, the same code base and architecture could be used to support data integration, data services and online applications and visualizations in other domains.

Scientific benefits: The scientifically interesting aspects of the GCMRC web application are 1) the unprecedented combination of sediment/streamflow data and computation in a single real-time-capable application, and 2) the flexibly expanding suite of visualization and analysis capabilities of the client.

GDAWS handles unit-value time-series of gage height, discharge, water-quality, and sediment-transport data. These data are available for download using the same services that provide data to the web client.

In addition to building user-interactive tools for visualizing these data within a web browser, we continue to design tools for operating on multiple datasets. The first of these is a user-interactive tool that constructs sediment budgets (with propagated uncertainty) for various river reaches in these national parks.

The user-interactive sediment budgets calculated and displayed by the application are always improving in accuracy as they incorporate the latest data. Calculations performed behind the scenes are recomputed with a constant flow of near-real-time data, providing increasingly accurate outputs, allowing management decisions to be made using the most complete and accurate data.

Technological benefits: It is worth noting that GDAWS is, from a technological standpoint, fairly standard (data warehouse design, implementation, and provisioning are well-understood disciplines; there was no need to reinvent them). The interesting technological accomplishments embodied in the GCMRC web application are the clean division between service and client responsibilities, and the implementation of powerful clientside visualization and analysis without recourse to any proprietary software libraries whatsoever. The most interesting aspect of the GCMRC web application from a software developer's point of view is probably the use of clientside open source libraries to achieve remarkable visualization and real-time analysis, and overcoming the challenges of delivering attractive, responsive visualizations built on real-time data as requested by the user in their browser.

DATA AND METHODS

For the sediment budgeting application presented here, the main data types for this project include 1) continuous time-series data and 2) discrete episodically collected suspended- and bed-sediment data. These data, whether collected via automated sensors or human observations, or computed post-collection, are maintained in a single database. The web application is directly driven by that database; integrity and provenance of the data are thus easily confirmed.

The continuous time-series data are typically spaced at 15-minute intervals and include gage height, discharge, water temperature, specific conductance, dissolved oxygen, turbidity, and acoustic measurements of suspended-silt-and-clay concentration, suspended-sand concentration, and suspended-sand median grain size (Griffiths et al., 2012, 2014; Topping et al., 2003, 2007, 2015; Voichick, 2008; Voichick and Topping, 2010, 2014; Voichick and Wright, 2007).

The discrete sample data include equal-discharge-increment (EDI), equal-width-increment (EWI), single-vertical, and calibrated-pump suspended-sediment measurements, and bed-sediment measurements (Edwards and Glysson, 1999).

All of these data are collected using standard USGS methods and other peer-reviewed methods. 95-percent-confidence-level field and laboratory-processing errors for the EDI and EWI measurements are calculated using the methods of Topping et al. (2010, 2011); similar errors for the calibrated-pump measurements are calculated using unpublished analyses based on the methods of Topping et al. (2011). These errors are depicted in the user-interactive plots in the GCMRC web application.

In order to construct the visualization and modeling capabilities displayed within the GCMRC web application, the different datasets are aggregated, and derived-values calculations are performed and stored on new incoming data. The flow of this process is depicted in Figure 2.

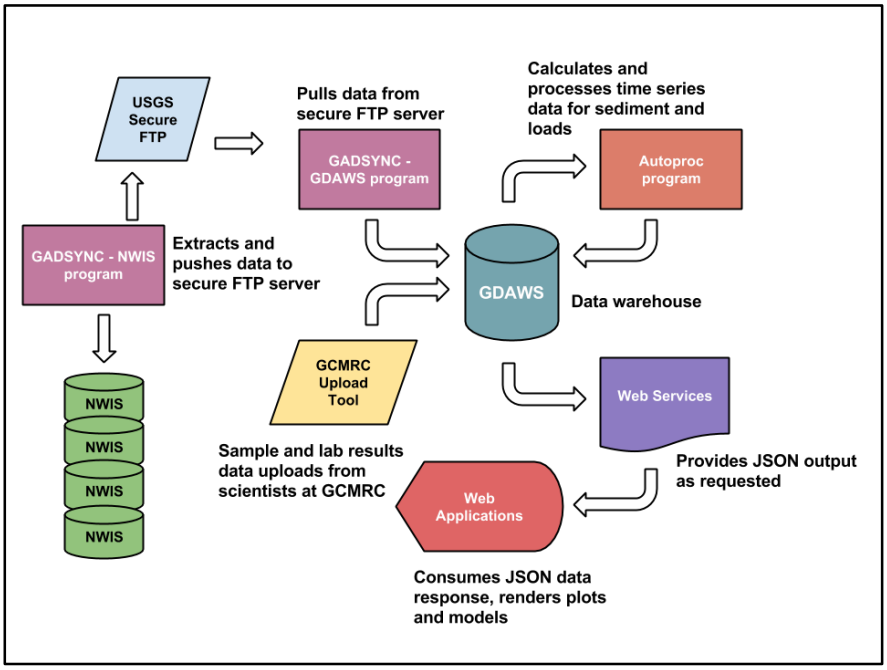

Figure 2 Data flow diagram depicting the movement of data from raw form to client-side visualization.

- GDAWS is a single database organized with the star schema typical in data warehousing. It is implemented on an Oracle database server.
- Time-series data about our stations of interest from the U.S. Geological Survey's National Water Information System (NWIS) database (USGS NWIS, 2014) are extracted twice daily and placed on a secure USGS File Transfer Protocol (FTP) site by a Python program called GADSYNC-NWIS.
- Twice daily, a C# program called GADSYNC-GDAWS retrieves the data placed on the secure FTP site, lightly processes them, and inserts their data into GDAWS. Time-series data not included in NWIS, and discrete sample data, are manually uploaded into GDAWS periodically using a custom web application (the GCMRC Upload Tool) that extracts, transforms and loads the comma-separated data values. To date, the data warehouse contains over 92 million time-series measurements from 57 sites throughout the aforementioned networks. The discrete sample data are critical for calibrating and verifying the acoustic suspended-sediment data and for calculating sediment loads.
- A C# program called Autoproc runs daily, calculating both instantaneous and cumulative sediment loads from the aggregated discharge, acoustic suspended-sediment time-series, and discrete suspended-sediment-sample information in GDAWS. Autoproc extracts data from the GDAWS database, processes parameter values based on the latest time-series data, and re-inserts the newly calculated values back into the database.

Computation of concentrations: major rivers: On the Little Snake, Yampa, Green, and Colorado rivers, and the Rio Grande, suspended-sediment concentrations and grain-size distributions are measured using a combination of 15-minute acoustic data and episodic discrete EDI, EWI, and calibrated-pump sample measurements. The discrete sample measurements are used to both calibrate the acoustic data and then subsequently the acoustic calibrations using the methods of Topping et al. (2007, 2015).

Computation of concentrations: major tributaries: On major tributary rivers where the suspended-sediment concentrations exceed the upper limit where acoustic measurements are possible, suspended-sediment concentrations are computed using a two-step process. First, suspended-silt-and-clay and suspended-sand concentrations are estimated using either physically based model curves (Topping, 1997) or statistically based curves (Topping et al., 2010). Second, these initial sediment-concentration estimates are adjusted to agree with EDI, EWI, single-vertical, and calibrated-pump measured sediment-concentrations as samples get processed through the laboratory, a time-consuming process (Topping et al., 2010). As more samples are incorporated, and the initial estimates become bona fide measurements of suspended-sediment concentration, the uncertainties applied to the tributary suspended-sediment data decrease in the web application.

Computation of concentrations: minor tributaries: The suspended-sediment concentrations in smaller, less important tributary streams are determined using a combination of measurements (Griffiths et al., 2010, 2014, 2015) and indirect estimates (Topping et al., 2010). The uncertainties assigned to the sediment loads in these streams are much larger (typically 50 to 100 percent), but because the loads in these streams are much smaller than the loads in either the mainstem rivers or major tributaries, these large uncertainties do not generally affect the sediment-budget results.

Computation of sediment loads: Sediment loads are calculated using 15-minute discharge and suspended-sediment-concentration data using the method of Porterfield (1972). Because sand, and silt and clay serve different physical and ecological purposes, sand loads and silt and clay loads are calculated independently. This approach allows construction of separate user-interactive mass-balance sand budgets and silt and clay budgets in the GCMRC web application. Construction of these mass-balance sediment budgets require sediment loads to be known on the mainstem rivers, major tributaries, and lesser tributaries, all with assigned uncertainties that are propagated through the budgets.

Computation of mass-balance sediment budgets: The mass-balance sediment budgets for each river reach are calculated using the methods described in Topping et al. (2010) and Grams et al. (2013).

Computed uncertainty: Uncertainties are applied to all sediment loads used in these budgets. The default uncertainties in the web application are chosen such that they represent the largest potential persistent bias in the computed loads at each site. The user can modify these default uncertainties to explore their effect on the uncertainties in the sediment budgets. These bias-type uncertainties result largely from instrumentation bias and include the greatest likely persistent bias in both the discharge of water and the suspended-sediment concentration, and are constrained by consistent measured differences in either discharge or sediment concentration at adjacent cross sections (Topping et al., 2010). Because no difference in either water discharge or sediment concentration occur between these closely spaced cross sections, the differences in the measurements between these cross sections represent biases (generally < 5 percent) in how acoustic-Doppler current profilers, current meters, and suspended-sediment samplers perform in slightly different cross sections. As there is no way to independently know which measurement in which cross section is correct, there is no way to know the “true” value. Thus, uncertainties that represent the greatest likely magnitude of these persistent differences are assigned to each load value. Because these uncertainties are biases, they accumulate over time, resulting in mass-balance sediment budgets in the GCMRC web application with uncertainty that gets larger over time.

Service/browser interaction in handling of computed data: To serve the aggregated and calculated sediment data for use in the front end application, the system organizes requested data into JavaScript Object Notation (JSON) responses. In order to allow the user to adjust the above-described load uncertainties in real-time on their computer, the browser requires all the data be delivered as separate pieces in the JSON response. Usually, the required data are two to five 15-minute time series that need to be transferred to the browser, which can be roughly a million values for an example span of six years. However, in order to accommodate the spectrum of browser memory capacities and variety of internet connection speeds, the application filters the plotted data to windowed local minimums and maximums on requests of periods of that length. The number of values that make it to the browser for the six-year example would therefore be reduced to a few hundred thousand. Because the application attempts to serve the truest visual representation of the data, it is set up to scale the windowed filtering based on the amount of data the user requests.

THE GCMRC DISCHARGE/QW/SEDIMENT WEB APPLICATION: USER EXPERIENCE

When the GCMRC web application at http://www.gcmrc.gov/discharge_qw_sediment/ is visited, the user has a choice of selecting between the monitoring networks for the four national parks, and selecting whether to visit the gateway web page to the time-series data at the monitoring stations or the gateway web page for the user-interactive sediment budgets. These gateway web pages provide a map and list of either the monitoring stations or the sediment-budget reaches.

The map views are supported by an open source mapping library called OpenLayers (http://openlayers.org/). Interactive sediment budget geographic feature layers are represented as shapefile data stored in an open source geospatial server called GeoServer (http://geoserver.org/). GeoServer allows for the management and support of standards-compliant services which can be consumed by many standards-supporting mapping frameworks. The GCMRC web application pulls data from GeoServer into the OpenLayers maps using the Open Geospatial Consortium's (OGC) Web Mapping Service (WMS) Standard (Open Geospatial Consortium, 2006); see also http://docs.geoserver.org/latest/en/user/services/wms/reference.html).

If the user navigates in the GCMRC web application to the monitoring station gateway and selects a specific monitoring station, a new page appears with a photograph of the river at the station, an overview map, and the list of parameters available to plot and download for that station. Within the parameter explorer on this station page, a user may select one or more classes of data (e.g., gage height, discharge amount, or water temperature) and select a date range across which the parameter values are graphed or downloaded. Once the server has returned the JSON response called by the browser and the user's request, dynamic charts consume the response contents and display returned data. To power the dynamic graphs, a JavaScript, open source graphing and charting library called Dygraphs (http://www.dygraphs.com/) is employed (see example Figure 3). Once the graphs are produced in the browser, the user can further refine the time-series displayed by adjusting its related slider to a specific time period, or get more details by hovering over the display to highlight and call out specific point in time values. The download function on each station page allows downloading of any of the time-series data with time stamps in any user-defined format. This function also allows downloading of the full laboratory-processed suspended- and bed-sediment datasets (including all ancillary data fields).

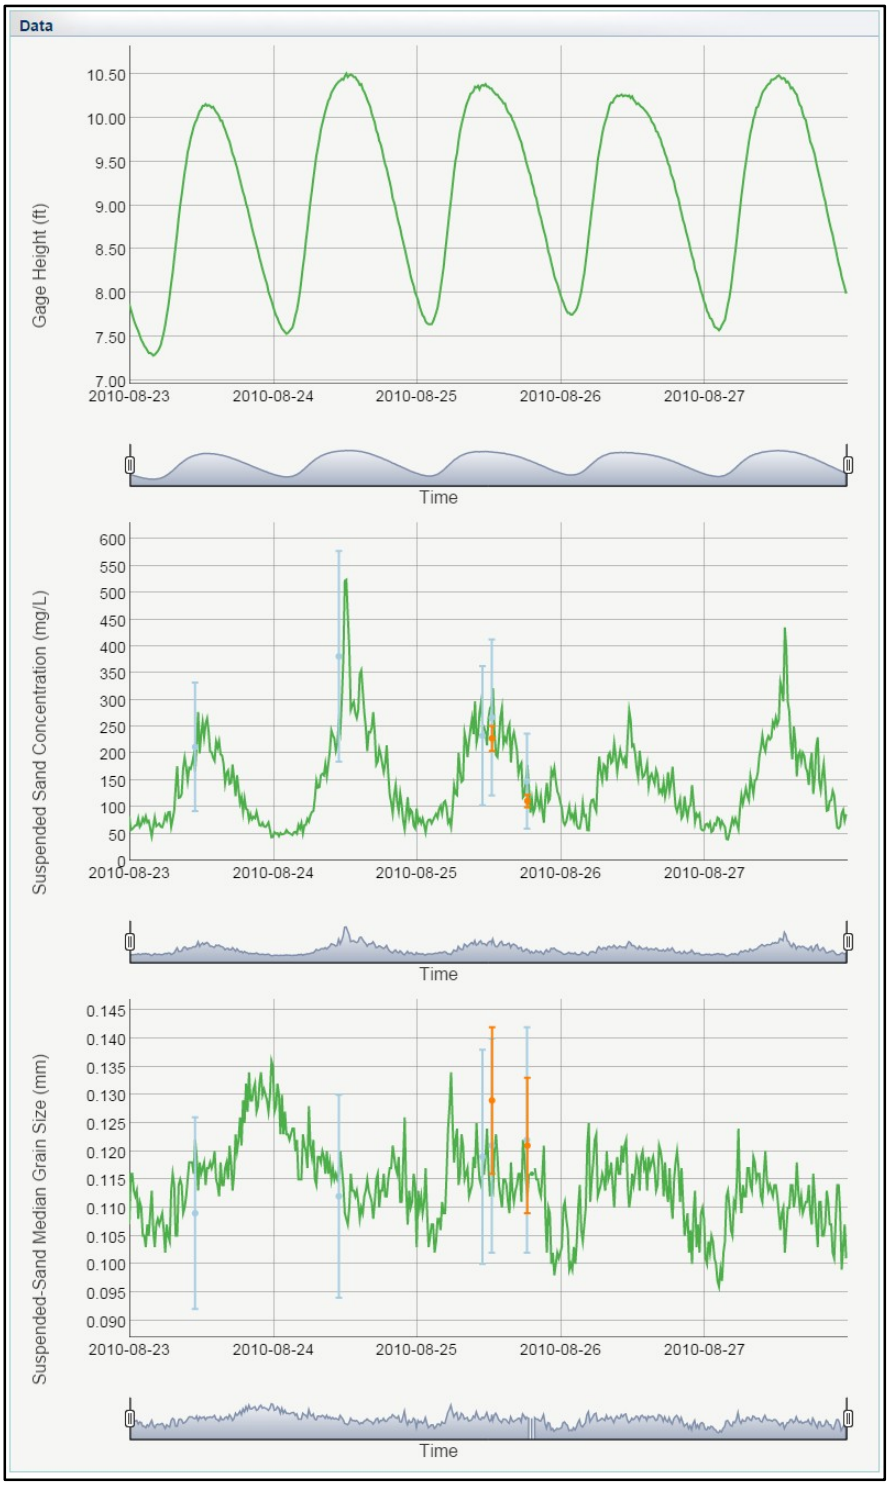

Figure 3 Example of plots of discharge, suspended-sand concentration, and suspended-sand median grain size at the Colorado River near Grand Canyon, AZ, 09402500 gaging station. Acoustic measurements of suspended-sand concentration and median grain size are depicted in green in the lower two plots. Orange points are EDI measurements, light blue points are calibrated-pump measurements. Error bars are 95%-confidence-level errors.

In addition to exploring specific stations' stacked parameter plots, scientists and managers can enter the sediment-budget gateway web pages and select a reach for construction of a mass-balance sediment budget. For any selected reach, the user has the option of setting the time period, modifying the uncertainties (i.e., possible persistent biases) in the various sediment-load time-series used to construct the budget, and modifying the bedload coefficient used to account for bedload in the river, in addition to the measured suspended-sediment load. For all reaches, default values of the possible persistent biases and bedload coefficients based on the best-available scientific information (e.g., Rubin et al., 2001) are pre-selected. An example of a mass-balance sand budget is provided in Figure 4.

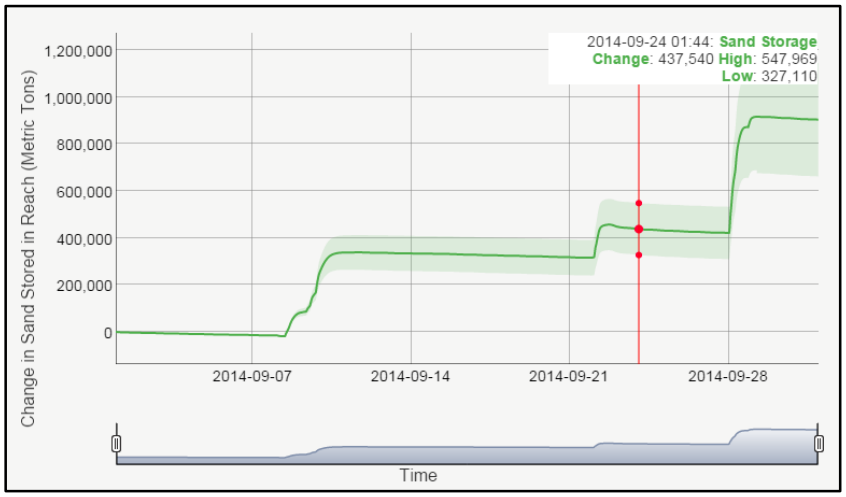

Figure 4 Example of Dygraphs plot of sand storage in the Upper Marble Canyon reach in Grand Canyon National Park.

The zero-bias value is plotted as the solid green line; the green shaded region indicates the region of uncertainty about the zero-bias value. Moving the red slider across the budget allows the user to see the zero-bias, upper, and lower bounds (given the chosen uncertainties) of the change in sediment mass for the selected time period. The ability of modifying the uncertainties in the loads is important because it allows river managers to evaluate "how well the sediment budgets need to be known" in their decision-making process.

RESULTS AND DISCUSSION

When viewing data, a user needs more than mere numerical accuracy. Meaningful conceptual and spatial presentations are essential for grasping the meaning of data. This is particularly crucial in decision-support uses of datasets. The GCMRC web application allows the user, whether a scientist, manager, or member of the lay public, easy access to user-interactive visualizations of discharge, water quality, and sediment data.

The advantage of open web applications—that they require no tools beyond a modern web browser for access and use—needs no elaboration. The GCMRC web application is built with open source components running against a standard relational database interface, making the cost of enhancements and extensions predictable and moderate. The use of web services to provide the data on request allows external users to integrate GDAWS data into other applications or models. The combination of open web services and the open browser application client allows the user easy, verifiable, and clearly comprehensible access to complicated datasets at essentially no cost.

An unprecedented resource: The user-interactive sediment-budgeting tools provided in the GCMRC web application are unique in the world. We have, for the first time, made well-established sediment-budgeting methods available on demand.

Using this tool, river scientists and managers can create a new sediment budget for a selected river reach for any time period of interest (limited only by data availability) with different levels of uncertainty within a matter of minutes. Prior to the development of this tool, the construction of a mass-balance sediment budget was a tedious process that required hours of data downloading, manual data entry, data manipulation, and mathematical operations (all the time running the risks of mistakes because these procedures were not automated in a repeatable workflow). This work was primarily done only by scientists and then presented to managers. Now, managers and members of the lay public can create sediment budgets on their own, on demand, and in real-time using the most up-to-date data available.

The real thing: The GCMRC web application is a working system in production use by multiple teams and programs. It is not a temporary proof of concept. The user-interactive sediment-budgeting tools are being used by river managers and science teams in multiple programs.

First and foremost, these tools are being used on a monthly basis by engineers in the Bureau of Reclamation working within the Glen Canyon Dam Adaptive Management Program (GCDAMP) to plan and implement the release of controlled floods from Glen Canyon Dam to rebuild sandbar habitat in Grand Canyon National Park when downstream sand conditions warrant (U.S. Department of the Interior, 2012). The sediment-budgeting tools are also being used in GCDAMP to evaluate the sediment response to these controlled floods and to evaluate the effects of hydropower operations at Glen Canyon Dam on the sand resources in multiple reaches of the Colorado River in Grand Canyon National Park and Lake Mead National Recreation Area. National Park Service managers also employ the sediment-budgeting tool to seasonally evaluate the effects of flows released from Flaming Gorge Dam on the Green River in combination with natural flood flows from the Yampa River on the sediment resources in Dinosaur National Monument (e.g., Mueller et al., 2014a,b). Finally, the sediment-budgeting tool is being used by scientists to evaluate the effects of upstream Mexican dam releases and local tributary floods on channel and floodplain evolution in the Rio Grande in Big Bend National Park (Dean et al., 2015).

Still generating useful new capabilities: Additional user-interactive functions are being developed for the GCMRC web application over the next few years to continue to improve access to managers and the lay public of tools previously only available to scientists. Some of these may prove as powerful as the sediment-budgeting tools described in this paper. Chief among these new additions will be the development of a duration-curve tool that will allow the user to plot the time equaled or exceeded for any parameter served via the GCMRC web application.

More information about the loosely coupled architecture described and all of the open source components developed for the GCMRC web application are available in a USGS-supported GitHub repository (https://github.com/USGS-CIDA). Anyone interested in expanding the work is welcome to fork the main repository and contribute their own ideas and working code to the project.

UPDATE ON ISSDOTv2 METHOD FOR MEASURING BED-LOAD TRANSPORT WITH TIME SEQUENCED BATHYMETRIC DATA

David Abraham, Research Hydraulic Engineer, David.D.Abraham@erdc.dren.mil, Tate McAlpin, Research Physicist, Tate.O.McAlpin@erdc.dren.mil, David May, Research Hydraulic Engineer, David.P.May@erdc.dren.mil, Thad Pratt, Research Physicist, Thad.C.Pratt@erdc.dren.mil, USACE-ERDC-CHL, Vicksburg, MS, and John Shelley, Civil Engineer, John.Shelley@usace.army.mil, USACE-Kansas City District, Kansas City

Introduction

The ISSDOTv2 (Integrated Section Surface Difference Over Time version 2) method to compute bed-load transport has been employed in the field for several years. This method utilizes difference plots of time-sequenced three-dimensional bathymetric data to calculate bed-load transport. Scour volumes determined from the difference plots are related to the average transport in a sand wave. The method is described in Abraham et al. (2011) and Shelley et al. (2013).

Purpose

The need to quantify bed-load sediments moving along the bottom of large sand bed rivers varies depending on agency perspective. Sands moving in the bed of a river are no longer viewed simply as a nuisance or problem related to dredging requirements, but as a ***resource***. River engineers and managers are now asked on a regular basis to allocate bed sediment resources to a variety of competing purposes and interests. Critical issues must be addressed such as land-building in the Louisiana Coastal Areas (LCA) and commercial sand mining in many locations throughout the country. With regards to environmental concerns related to the Endangered Species Act (ESA) and Environmental Impact Statements (EIS), managers must assess the availability of sand to maintain ecological habitat features of rivers such as islands and bars. These concerns must be addressed in addition to the requirements of maintaining adequate draft depths in the navigation channels and functionality of locks and dams. In order to adequately address the varied interests, river managers must have some idea of how much bed material is available, which is directly related to its rate of movement through a river system. If the mass transport rate can be determined and related to changes in river flow, a bed-load rating curve can be produced which provides a quantitative management tool for those tasked with allocating the river's sand resources.

With regards to dredging needs, dredging records have in the past provided an estimate of future dredging requirements. However, they are only applicable to that location. Dredging records also do not provide information about the rate at which the bed-load sediments are moving. If a bed-load rating curve is produced as mentioned above, a yearly average hydrograph can be used with the bed-load rating curve to produce a bed-load transport curve for the year. Integrating under this curve provides the total mass (or volume) of bed-load sediments that moved through a reach during that year.

Theoretical Basis

By way of review and for those who are reading about this method for the first time, a brief discussion of the theoretical basis is presented here. With the new bathymetric imaging and mapping techniques developed in the mid-1990's, the ability to accurately measure the bed surface of water bodies in three dimensions became a reality. The equipment and processing of the bathymetric data were of sufficient quality that the individual features of river bottoms such as dune fields could be adequately resolved to the sub-dune scale. For the duration of this paper the terms sand waves and dunes are used interchangeably and all bed-load transport values are reported in US tons per day (1 US ton/day = 0.907 metric tons/day). Figure 1 shows a swath of bed elevation data obtained from the Mississippi River at Red-Eye-Crossing, just south of Baton Rouge, Louisiana. The dune lengths varied from about 21 to 46 meters (~70 to 150 ft), with their direction of travel being from the top of the figure to the bottom. When the same area is surveyed a second time, the two sequential data sets can be subtracted to obtain a difference plot. In such a plot, the eroding portion of any dune will be noted by a decrease in surface elevation from time 1 to time 2, while the depositional side of the dune will show an increase in elevation. These differences can be plotted as positive and negative values using two colors to show areas of scour and deposition. Such a plot is shown in figure 2 where scour is plotted as red and deposition as blue. The lateral extent of the scour occurring on any dune as well as its depth of scour is available in the difference plot. Thus the volume of scoured bed material can be determined for any individual dune or for any selected group of dunes.

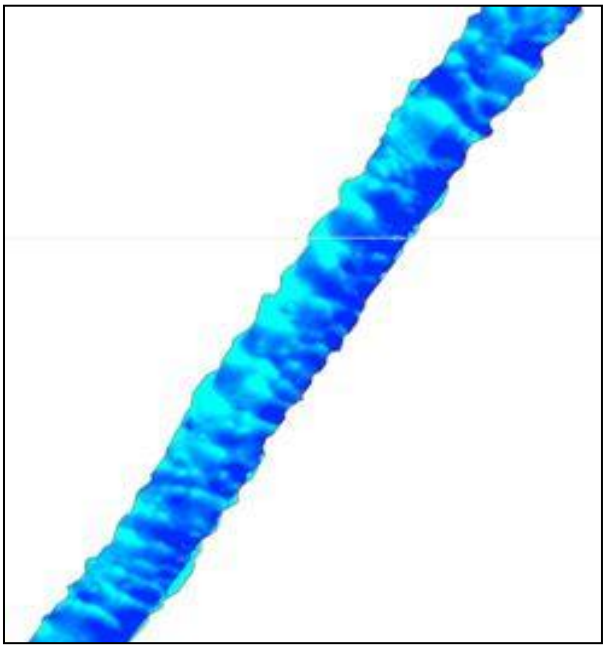

Figure 1 Plotted bathymetric data clearly delineating the individual dunes.

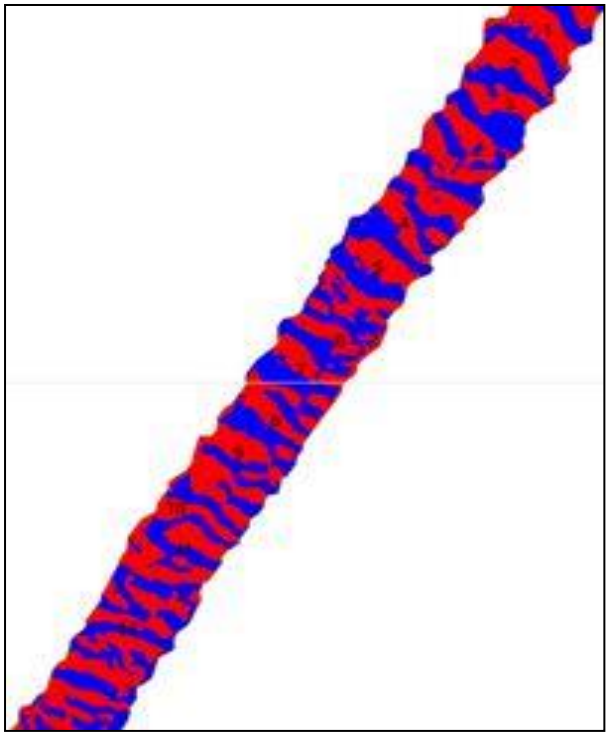

Figure 2 Bathymetric differences showing scour (red) and deposition (blue).

The relationship between the rate of scour on the eroding side of the dune and the average transport rate of the same dune is explained in Abraham et al (2011). The equation developed to quantify this relationship is shown in Equation 1

$$q_{sbi} = \frac{\rho(1-p)V}{2\Delta t} \quad (1)$$

where q_{sbi} is the bed-material load moving in the sand wave computed by the ISSDOTv2 method, ρ is the density of the submerged sand, p is the porosity of the sand, Δt is the time difference between measurements, and V is the scoured volume during the time interval Δt. Equation 1 is mathematically equivalent and dimensionally homogenous to the equation developed by Simons and Richardson (1965), provided in Equation 2.

$$q_{sb} = \frac{\rho(1-p)c\eta}{2} \quad (2)$$

where q_{sb} is the bed-material load moving in the sand wave, ρ and p are as above, c is the dune speed, and η is the dune height.

Equation 1 for the ISSDOTv2, or scour volume method, was applied to flume data [56 data sets representing 6 different flow rates varying from 0.203 cms (7.17 cfs) to 0.426 cms (15.04 cfs)] for which actual transport values were measured in a clear water scour

condition. This implies the volume of eroded bed-material on the upstream side of the dune should be equal to the volume deposited on the downstream side of the same dune. The results are shown in figure 3, which is more completely described in Abraham et al (2011). Significant to note is that assumptions of uniform wave velocity and minimal wave deformation were made in analyzing these flume data. These are conditions associated with steady uniform flow maintained during these flume experiments. The comparisons in figure 3 illustrate both the validity of those assumptions and the ability of the equation to accurately measure bed-load transport.

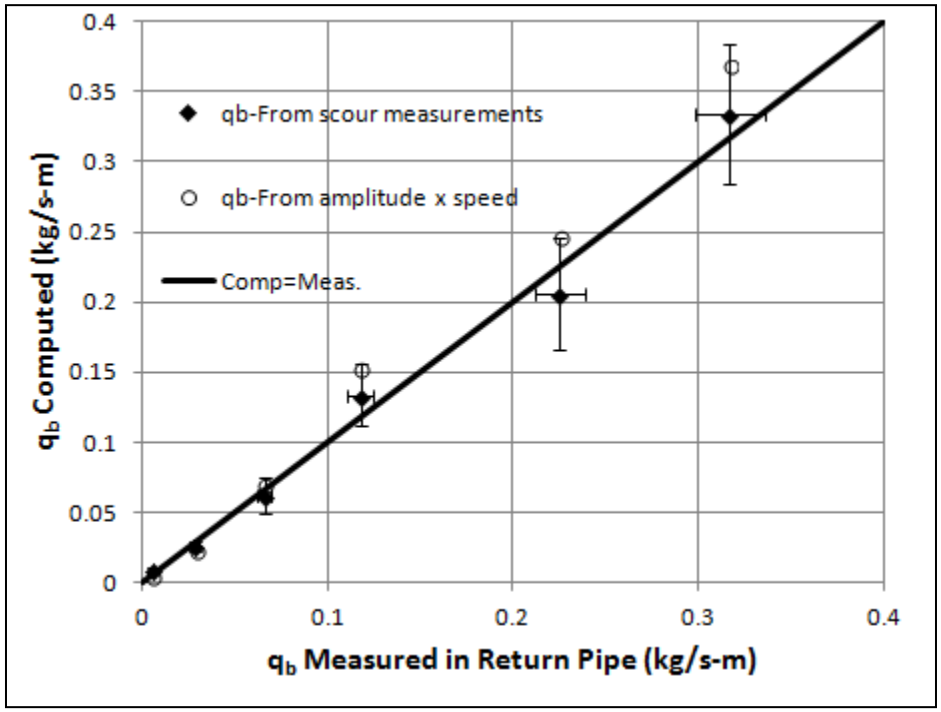

Figure 3 ISSDOTv2 computed versus measured bed-load transport in a flume study (Figure from Abraham et al. 2011).

The aforementioned discussion and results were presented in order to show that the method is founded on a sound theoretical basis that was substantiated with a large quantity of measured flume data. However, in river field applications, such ideal conditions rarely exist and present additional challenges for applying the scour volume method.

Practical Application of the Method

The high shear stresses and turbulent nature of natural channels result in a sizeable amount of the bed-material load moving in suspension. The unsteady nature of gradually varied flow also means that the rate of suspension or deposition can change significantly with time over a given river reach. In the aforementioned flume experiments, there were no suspended sediments, and therefore the assumption of the scoured volume moving to the depositional side of the same wave was a valid assumption. In a natural meandering

channel one cannot expect scoured volume to be equal to depositional volume. Some of the scoured bed-material does go into suspension and can travel far enough that it is not deposited on the dune from which it originated, thus adding depositional volume to other dune(s). The result is that for a given dune, and/or for a large dune field, the assumption of scour volume being equal to deposition volume is violated. It was noticed early on that this is often the case in natural rivers. How does this affect the computations? If, for example, 30% of the scoured volume went into suspension and was carried to some other dune, then that same 30% volume was not deposited on the same dune and thus did not participate in the dune movement. Thus the computed value of bed load transport could be in error by calculating 30% more transport in the dune than actually occurred. Based on these considerations, comparing the scour-deposition ratio should be a way to avoid data sets in which the river was excessively erosional or depositional. Such events could be caused by a rising or falling limb of a hydrograph. For ISSDOTv2 computations, scour-deposition ratios are computed for all difference plots. Those with values from 0.8 to 1.2 are retained while plots with values outside this range are deemed unsuitable for this method.

Another necessary correction occurs as a systematic bias inherent in the methodology. Figure 4 shows a translating wave form. The volumes of triangles C and D do not show up in the difference plots. These values get increasingly large as Δt gets larger and thus the 'missed' volumes result in smaller and smaller computed values of transport. So when Δt is very small, this systematic error is small, and when Δt is large, the corresponding error is large. This error was kept small in the flume study by using small time differences. In field conditions, however, this is seldom possible when surveying multiple swaths at a given river section. The later surveys could be hours apart. Shelley at al. (2013) details a procedure to correct for this systemic bias, which allows the longer time differences to still be used to obtain an accurate estimation of the true dune transport value.

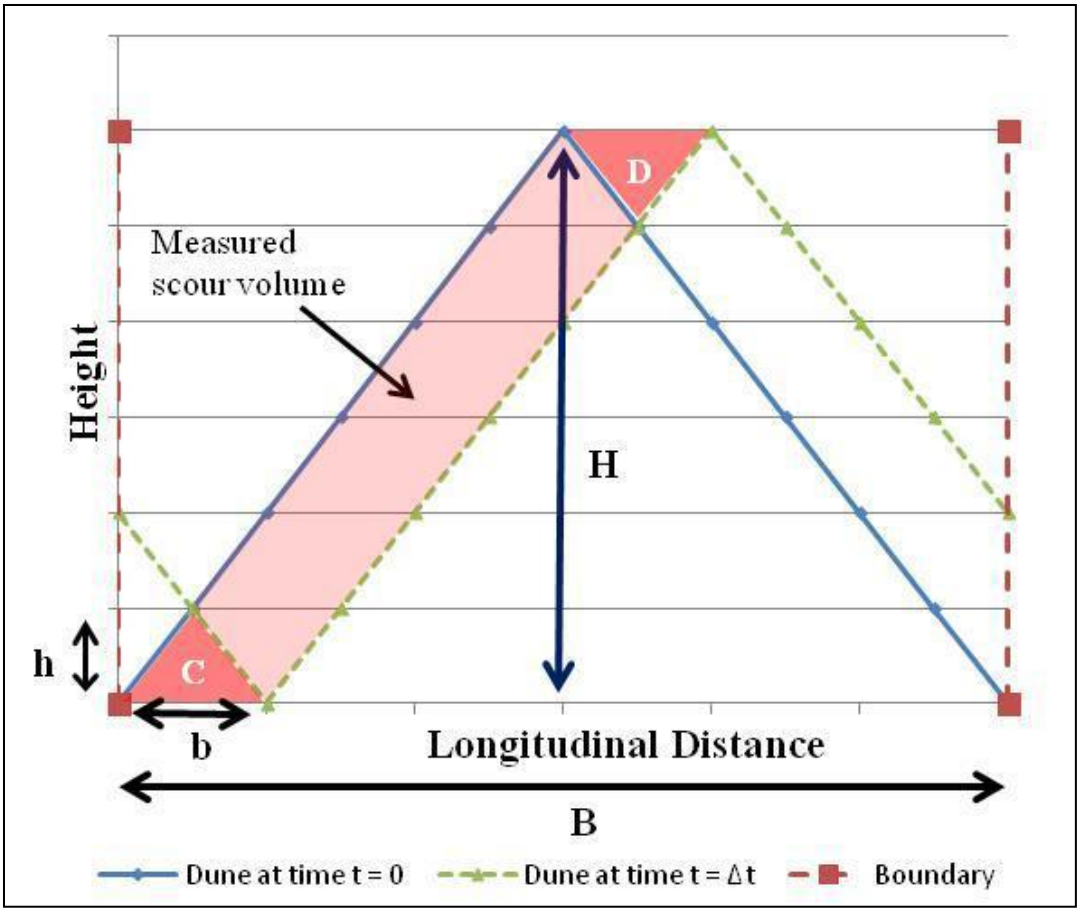

Figure 4 Schematic showing a systematic error due to lost volumes.

Example

When the two quality control procedures mentioned above are applied to the ISSDOTv2 computational method for a single bathymetric swath location, for which several repetitions were made, (temporally sequential), a transport value can be computed for that portion of the river. When multiple swaths cover a river from bank to bank, the values for each swath can be summed to provide the total bed-load transport at a river section. Figure 5 shows an example of such computations on the Ohio River near Mound City, IL. Additional information on the particular project methods and procedures are available in Abraham, Clifton and Vessels (2014).

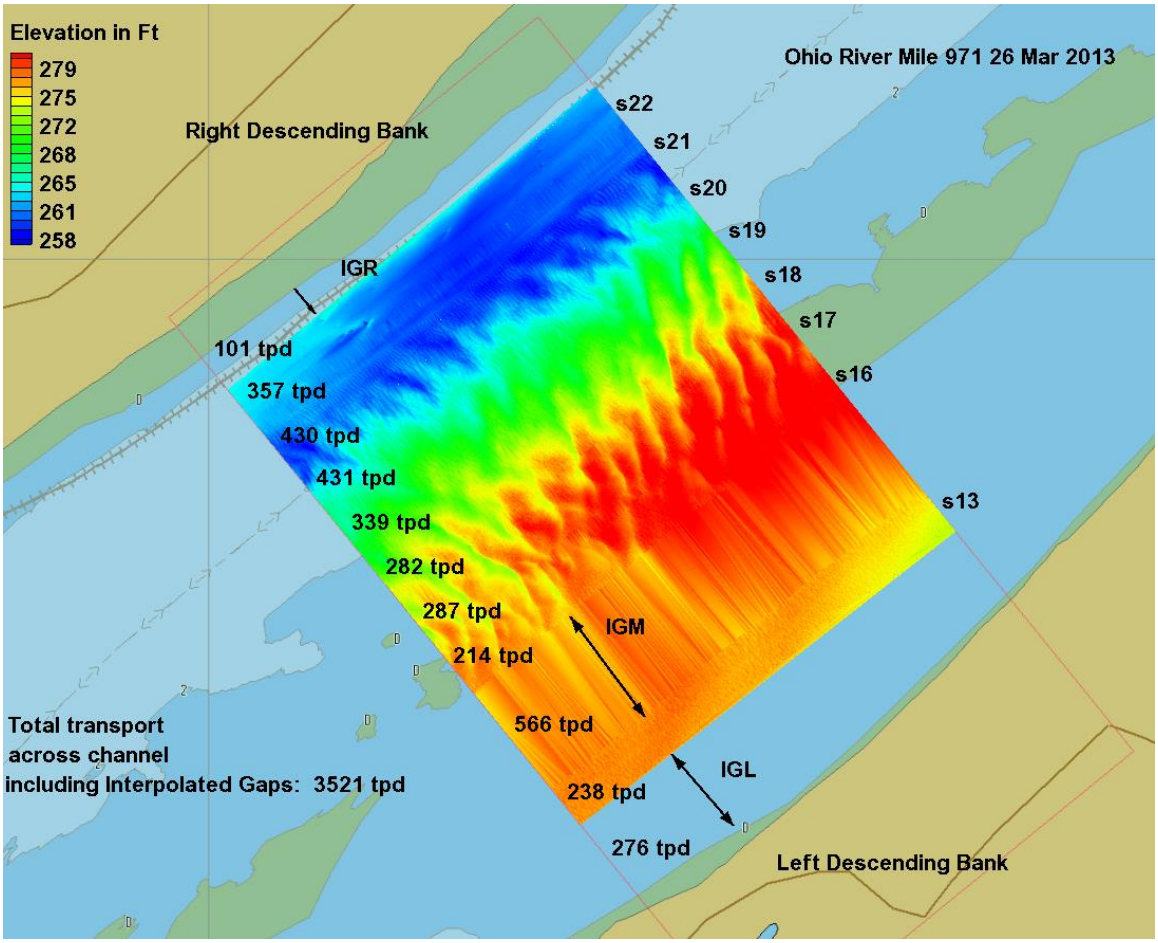

Figure 5 Multiple swaths and computed transport across a river section.

A MATLAB code has been created to calculate the transport for each swath. For this location each swath was divided into 1.524 m (5 ft) wide sections with the transport being calculated in each section using Equation 3

$$transport(tons/day) = \frac{43.2 * \rho(1-\mathrm{p}) * \mathrm{V}(ft^3)}{1.82 * \Delta t(\mathrm{sec}) * (\#waves)} \tag{3}$$

where 43.2 is a conversion from kg/s to tons/day and 1.82 is a parameter that accounts for the non-triangular shape of the dunes. The total transport for a given swath is then determined by integrating across the width of the swath. After determining the transport for various difference data sets (and different time steps), the previously discussed systematic bias was removed to obtain an accurate bed load transport value for each swath.

In figure 5, flow is from top to bottom. Swath numbers are at the top of each swath, and the computed bed load is at the bottom. The entire section was not covered, so linear interpolation was used for the gaps identified in the figure as IGR, IGM and IGL (values

of 0 were assumed for the bed-load transport at the left and right banks). They stand for Interpolated Gap Right, Interpolated Gap Middle and Interpolated Gap Left respectively. The total transport across the channel section was computed as 3,521 US tons per day including the interpolated gaps.

Field-data results from other large sand-bed rivers (Mississippi, Missouri, and Snake) have also been taken from 2011 to 2014. The measurements include bed-load transport values for various flow rates and river locations as well as suspended sediment concentrations and bed gradations. These data allow for the separation of wash load from bed-material load and also to compare total bed-material load (suspended bed material + bed load) to the ISSDOTv2 calculated bed load. In figure 6, data are plotted for a site on the Mississippi River just downstream of the Old River Control Complex (ORCC). The red square data points are the computed bed-load values (the sand moving in the dunes). As expected this value increases with increasing flow, and does so in a linear fashion as seen at this site and in most others that have been measured with three or more different flow rates. The blue diamond data points represent the bed load as a percentage of the total bed-material load. This is not a constant value and at this site varies from a low of about 10 % to a high value of over 45%.

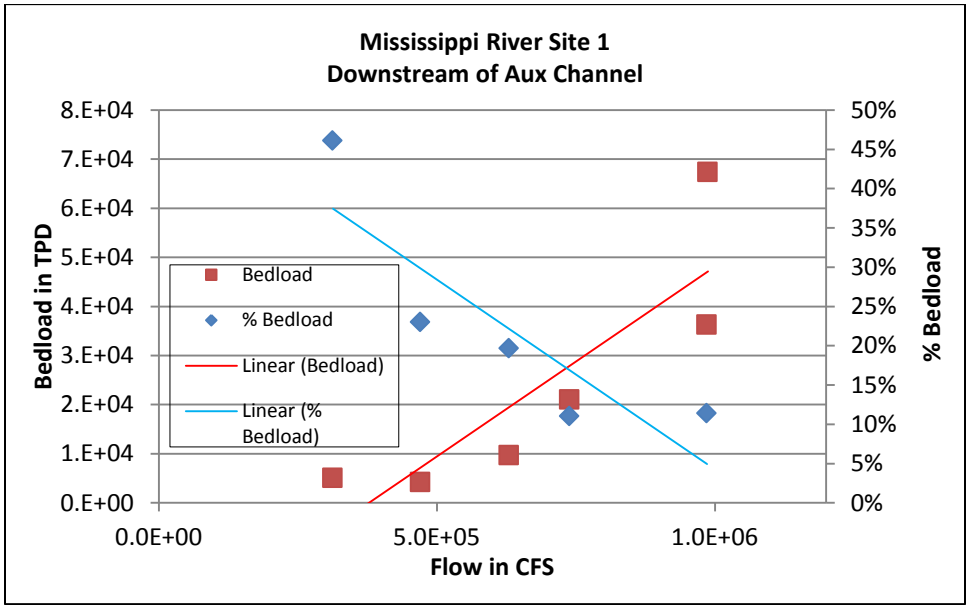

Figure 6 Bed load and % Bed load vs Flow rate on the Mississippi River.

In addition to Site 1 near the ORCC, whose data are plotted in figure 6, three other sites were measured during the same time periods, all of which were on the main channel of the Mississippi River. The bed-load computed values from all four sites (in total 22 independent data points) are plotted in figure 7. They show the same linear trend over a range of flows varying from 8,496 cms (300,000 cfs) to about 48,145 cms (1,700,000 cfs). By visual observation of the graph one can still make the case (similar to site 1) for a linear relationship between flow and bed load, with the R-squared value of 0.82 lending mathematical support to that conclusion.

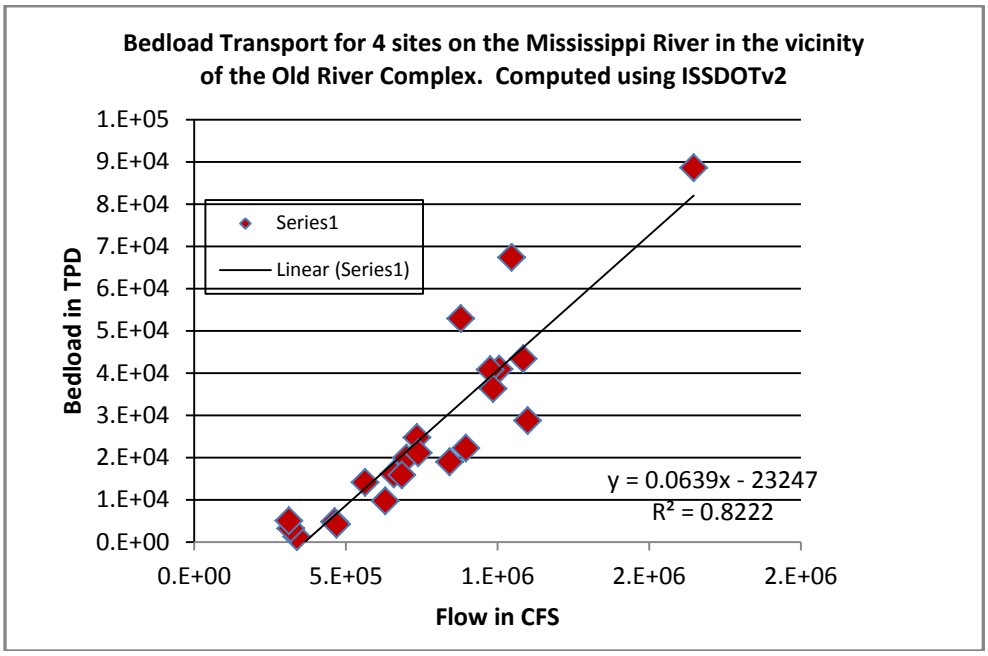

Figure 7 Mississippi River rating curve for flow versus bed-load transport.

Conclusions and Recommendations

Some of the more important conclusions noted to date are:

- The method clearly captures the lateral variability of the bed load transported in the moving sand waves for each swath, and when summed across the section provides the total bed-load transport for that river cross section.
- With sufficient measurements a bed-load rating curve can be developed.
- A bed-load rating curve can be very helpful to U.S. Army Corp of Engineers (USACE) District personnel in helping meet congressionally mandated sediment distributions as in the case of the Old River Control Complex.
- Using a bed-load rating curve and a yearly hydrograph, the net annual bed load moving through a river section can be approximated.
- Initial results on the Mississippi River indicate that bed load increases with increasing flow in a linear manner.
- Bed load is *not* a set percentage of total bed-material load, but can vary considerably depending on flow.
- Bed load *as a percentage* of bed-material load decreases with increasing flow.

The ORCC data shown here are representative of that collected and processed for 8 USACE Districts. They are St. Paul, Rock Island, Kansas City, Omaha, New Orleans, Vicksburg, Walla Walla, and Louisville, and they represent four major US Rivers; the Mississippi, Missouri, Ohio and Snake.

Corps Districts and other Federal Agencies want to know more about the method and the possibility of applying it themselves. To this end the authors have presented several workshops in the last year. An estimate of uncertainty must also be assigned to the computational results. Several proposals have been put forth for funding, including both flume and in-river studies. If funding can be secured for either case, the uncertainty of the measurements can be reduced and quantified with greater fidelity than is presently being done.

ABSTRACT

Quantitative understanding of bed-load and bed-material-load fluxes in sandy rivers would afford greater understanding and prediction of channel form, river behavior, and habitats of river corridor biota. However, practical difficulties and cost ineffectiveness often exclude bed-sediment measurements from studies and monitoring efforts aimed at estimating sediment loads in rivers. An alternative to direct sampling is through the measurement of evolution of bed topography constrained by sediment-mass conservation. Historically, the topographic-evolution approach has been limited to systems with negligible transport of sand in suspension. We show that by loosening the constraint on mass conservation (that is, allowing divergence of sediment flux to vary temporally when averaged over a bed form length) bed load and bed-material load can be distinguished by their effects on the evolution of bed topography. As was shown decades ago, pure bed load transport is responsible for the mean migration of trains of bed forms when no sediment is exchanged between individual bed forms. In contrast, the component of bed-material load that moves in suspension is responsible for changes in the size, shape, and spacing of evolving bed forms; collectively this is called deformation. The sum of the effects of deformation and translation on bed topography reflects the total movement of bed material. Similarly, the difference between bed-load flux and bed-material-load flux equals the flux of suspended bed material. This approach is demonstrated using a set of repeat multibeam sonar bathymetric surveys coupled with point-integrated suspended-sediment profiles and acoustic Doppler velocimetry.

USING HYDROPHONES AS A SURROGATE MONITORING TECHNIQUE TO DETECT TEMPORAL AND SPATIAL VARIABILITY IN BEDLOAD TRANSPORT

Scott Wright, Research Hydrologist, USGS, Sacramento, CA, sawright@usgs.gov

Abstract Collecting physical bedload measurements is an expensive and time-consuming endeavor that rarely captures the spatial and temporal variability of sediment transport. Technological advances can improve monitoring of sediment transport by filling in temporal gaps between physical sampling periods. We have developed a low-cost hydrophone recording system designed to record the sediment-generated noise (SGN) resulting from collisions of coarse particles (generally larger than 4 mm) in gravel-bedded rivers. The sound level of the signal recorded by the hydrophone is assumed to be proportional to the magnitude of bedload transport as long as the acoustic frequency of the SGN is known, the grain-size distribution of the bedload is assumed constant, and the frequency band of the ambient noise is known and can be excluded from the analysis. Each system has two hydrophone heads and samples at half-hour intervals. Ten systems were deployed on the San Joaquin River, California, and its tributaries for ten months during water year 2014, and two systems were deployed during a flood event on the Gunnison River, Colorado in 2014. A mobile hydrophone system was also tested at both locations to collect longitudinal profiles of SGN. Physical samples of bedload were not collected in this study. In lieu of physical measurements, several audio recordings from each site were aurally reviewed to confirm the presence or absence of SGN, and hydraulic data were compared to historical measurements of bedload transport or transport capacity estimates to verify if hydraulic conditions during the study would likely produce bedload transport. At one site on the San Joaquin River, the threshold of movement was estimated to have occurred around 30 m^3/s based on SGN data. During the Gunnison River flood event, continuous data showed clockwise hysteresis, indicating that bedload transport was generally less at any given streamflow discharge during the recession limb of the hydrograph. Spatial variability in transport was also detected in the longitudinal profiles audibly and using signal processing algorithms. These experiments demonstrate the ability of hydrophone technology to capture the temporal and spatial variability of sediment transport, which may be missed when samples are collected using conventional methods.

INTRODUCTION

Estimating bedload transport rates and determining the timing of incipient motion is desired for a variety of ecological and engineering purposes. High-quality data, however, are often unavailable or collected too infrequently (Gomez, 2006) due to the time and expense associated with collecting physical bedload samples (Gomez, 1989, Gray et al., 2010). Sediment transport is driven by a variety of mechanisms at a range of spatial and temporal scales (Hoey, 1992). Many practitioners use empirical relations between streamflow discharge and sediment discharge rates to predict transport during unmeasured periods (Gray and Simoes, 2008). Infrequent sampling will often fail to capture temporal variability, and therefore transport relations developed from these data may not adequately predict transport rates. An example of this is provided in Figure 1. A regression equation was developed from a simple discharge-bedload relation using physical measurements of bedload between 2010 and 2013 on the San Joaquin River (Figure 1A). The predicted bedload is shown during a 2011 flood event (Figure 1B) with the physical measurements of bedload overlaid. When compared to the physical measurements of bedload, the regression equation in this example will often either underpredict or overpredict bedload (from -70 percent to 310 percent,). The cause of such error in bedload transport prediction may be attributed to one of two (or both) sources: sampling error or temporal variations in bedload transport (Gomez and Troutman, 1997). To improve estimates of sediment transport, a low-cost surrogate technique could be used to fill in the temporal gaps between physical measurements or aid in identifying erroneous samples. This is analogous to using continuous measurements from a turbidity sensor calibrated to measurements of suspended sediment concentration to calculate sediment transport rates. Hydrophones are one example of such technology which can be used for coarse bedload transport.

Hydrophones were first used to listen to sediment-generated noise (SGN) in the 1930s (Bedeus and Invicsics, 1963). Since that time, others have conducted lab and field experiments to attempt to correlate the acoustic signal to particle size and transport rates (e.g. Thorne, 1986; Rouse, 1994, Barton et al., 2010). Several surrogate sediment monitoring technologies currently exist, each with their own advantages and disadvantages (Gray et al. 2010). Advantages of

hydrophones include: (a) low cost, (b) ease of deployment (c) minimal interference with the bed, and (d) they provide a spatially-weighted average of transport over the detection area. Disadvantages include: (a) hydrophones may detect unwanted noises in addition to SGN, (b) the precise detection area is not known and may change during a flood event, and (c) the relation between particle size and sound transmission loss is also not well understood.

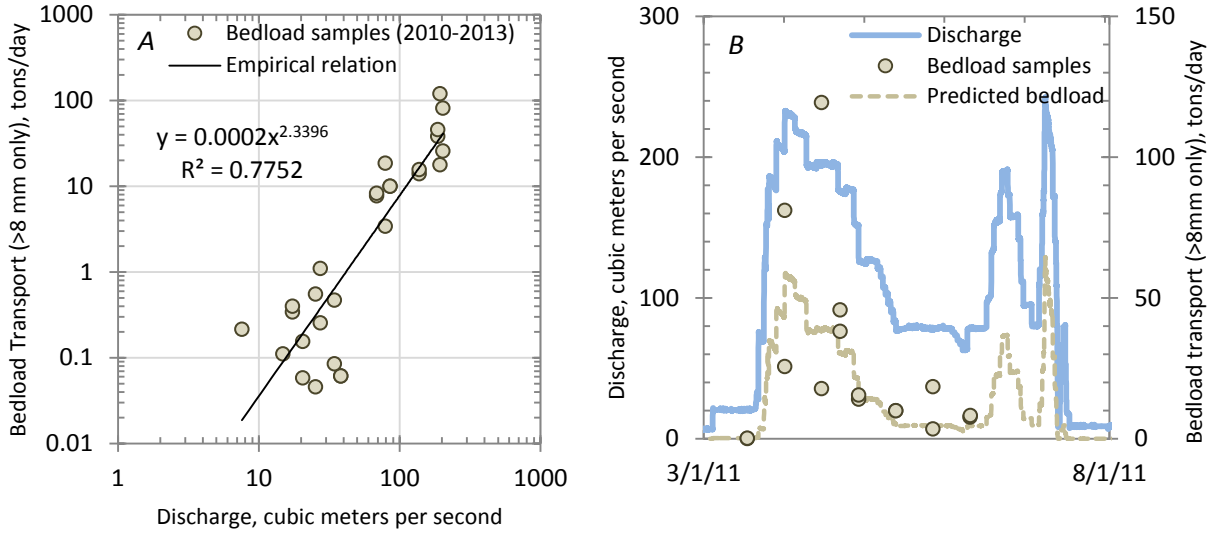

Figure 1 Example of temporal variability of bedload discharge in the San Joaquin River at Hwy 145 (USGS Site Number 11252975). Bedload measurements are plotted as a function of streamflow discharge to obtain a power law regression equation (A). The hydrograph during a 2011 flood event is shown with bedload measurements and predicted bedload discharge based on the empirical regression equation (B).

The general principle behind using hydrophones as a surrogate bedload monitoring technique is that they detect the rigid body radiations (i.e. sounds) generated by the collisions of sediment particles as the particles roll and saltate along the bed (Thorne, 2014). The sounds produced by the sediment collisions are often referred to as *sediment-generated noise* (SGN). The hydrophone uses a piezoelectric element to convert the sound pressure waves to an electrical signal. The electrical signal is proportional to the pressure acting on the piezoelectric element which is assumed to be proportional to the magnitude of bedload transport occurring near the hydrophone.

Our recent work has focused on developing a low-cost, long-term monitoring system to collect and record underwater sounds to supplement physical bedload measurements and to identify the timing of incipient motion. In addition, we developed an experimental mobile hydrophone recording system intended to measure relative spatial variability of SGN on a reach scale.

STUDY AREA

The majority of the hydrophone monitoring work was conducted on the San Joaquin River in California as part of the San Joaquin River Restoration Program (SJRRP). SJRRP is a multi-agency effort to increase populations of Chinook salmon (*Oncorhynchus tschawytscha*) in the San Joaquin River downstream of Friant Dam. This reach of the San Joaquin River consists largely of deep pools with gravel-bedded riffle clusters. There are only two major tributaries to this reach: Cottonwood Creek and Little Dry Creek. Both of these creeks are unregulated ephemeral streams. No measurable discharge occurred on the tributaries during WY 2014. Discharge on the mainstem San Joaquin River in the study area is regulated by Friant Dam. Particle-size distribution of the bed-material was measured in the San Joaquin River at hydrophone monitoring sites (using Wolman pebble counts). Median particle size (D_{50}) ranged between 26 and 80 mm on the mainstem and between 2 and 23 mm on the tributaries (which were generally a mix of sand and cobbles). Figure 2A shows the hydrophone monitoring sites on the San Joaquin River as well as the start and stop locations of the mobile hydrophone longitudinal profiles. The hydrophones were also tested on the Gunnison River, Colorado, during a spring flood event in 2014. The Gunnison River is a tributary to the Colorado River. Discharge on the Gunnison River was primarily regulated by the Blue Mesa Dam. Pitlick et al.

(1999) conducted particle-size distribution measurements at several locations along the Gunnison River. Our study reach was nearest to RM 55.6 which was measured by Pitlick et al. (1999) to have a surface D_{50} of 59 mm, and a subsurface D_{50} of 29 mm. Figure 2B shows the location of one of the hydrophone monitoring stations on the Gunnison River, as well as the start and end locations of the mobile hydrophone longitudinal profiles.

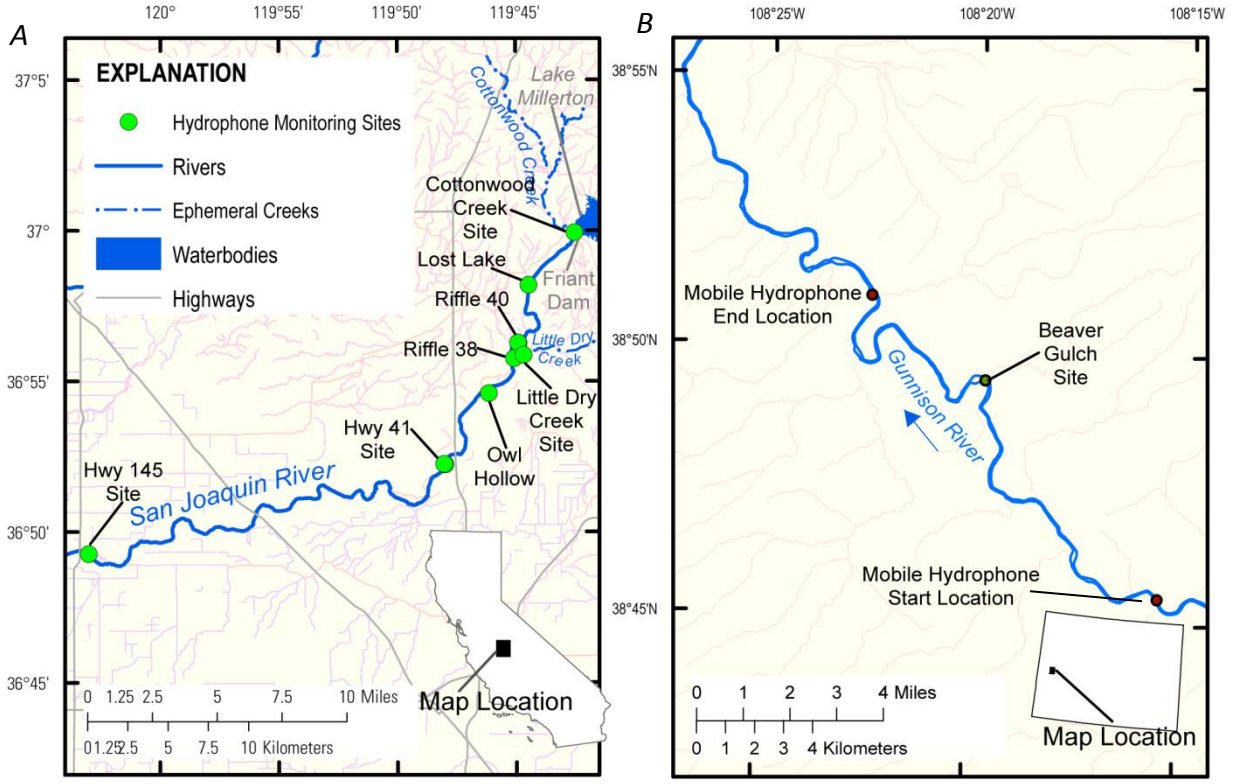

Figure 2 Study area map showing long-term hydrophone monitoring sites along the San Joaquin River, California (a), and testing locations for stationary and mobile hydrophones in the Gunnison River, Colorado (b)

METHODS

Data Collection Each hydrophone monitoring station consisted of two Aquarian H1a hydrophones and one recording system. The hydrophone recording systems were programmed to collect a 1-minute audio recording at a preset sample interval. Typically the sampling interval was set to 30 minutes; however, at the flashier tributary creeks the sampling interval was set to 20 minutes. The recording system was contained in a Pelican case and secured to the bank. The systems were capable of operating continuously for four to five weeks before they required routine servicing. Routine servicing involved downloading data and replacing batteries. At that time, the hydrophone heads were inspected (when conditions were wadable) and any debris found was removed. A pressure transducer was also installed nearby at each site to record water levels. The sensitivity of the H1a hydrophones is -190 dB re 1V/uPa (+/- 4 dB) (Aquarian Audio, 2013). The preamplifier gain was set to 14 dB, which provided a clear overall signal without clipping higher amplitude sounds.

At each site, the hydrophones were installed in the river by attaching them to a vertical piece of steel rebar approximately 30 cm above the bed. Prior to attaching the hydrophone, the rebar was driven into the bed 45-60 cm. A second piece of rebar was installed approximately 30 cm directly upstream to block debris which may otherwise accumulate on the hydrophone and result in sound transmission loss (Figure 3B). The audio cable was routed through a flexible polyvinyl chloride (PVC) conduit which was buried in a shallow trench. The PVC conduit was also secured in place using several pieces of u-shaped rebar which were driven into the bed.

Ten hydrophone recording systems were deployed across eight California sites in November 2013 (Figure 2a). Two of ten system were deployed in the tributary creeks. In addition, at two sites (Hwy 41, and Riffle 40) a hydrophone monitoring station was installed on each bank of the river in an attempt to collect a better spatial average of SGN. Due to the multi-year drought in California, peak flow during the study period was only about 37 m^3/s on the San Joaquin River, which is relatively low with minimal bed movement. In an effort to field test the hydrophone systems under a range of flow conditions, two systems were deployed on the Gunnison River, during a late-spring flood event.

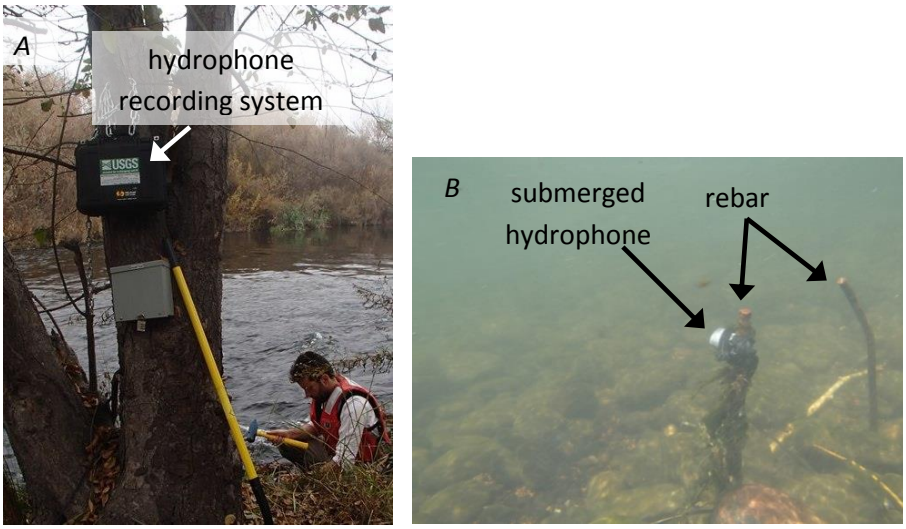

Figure 3 Photo of hydrophone recording system installed at the Owl Hollow Site (A), and photo of submerged hydrophone with additional piece of rebar installed upstream to deflect debris (B).

A mobile hydrophone system was used to record a longitudinal profile using one hydrophone mounted to a hard-shell kayak. Audio data were recorded on a portable tablet computer. Location, depth and streamflow velocity were measured using a real-time kinematics global-positioning system (RTK-GPS) and a StreamPro acoustic Doppler current profiler (ADCP). At the time of publication, GPS data were not fully processed, therefore "distance downstream" on any plots shown are approximate, and were calculated using the assumption that boat speed was constant throughout data collection. Three longitudinal profiles of underwater sounds at three different flows (303 m^3/s, 234 m^3/s, 48 m^3/s) were collected on the Gunnison River, and one longitudinal profile (at 37 m^3/s) was collected at two reaches on the San Joaquin River.

Discrimination of Sediment-Generated Noise and Ambient Noise Previous work (Jonys, 1976; Millard, 1976; Thorne, 1985; Thorne, 1986) has shown an inverse relation between the acoustic frequency of SGN and the particle size. Thorne (1986) proposed an empirical equation using those data to relate the resonance frequency of SGN and particle size (shown in Figure 4). Thorne's equation was based on particles from 0.2 mm to 43 mm. More recently, Belleudy et al. (2010) conducted experiments to measure the SGN of larger sized particles (15 to 110 mm). The hydrophones are most suited for applications in gravel-bedded rivers (Gray et al., 2010). Therefore, results from coarser particles are of particular interest, and we present a revised equation (Equation 1) using only experimental results for particles coarser than 4 mm (which includes pebbles, gravels and cobbles) (Figure 4). The following is the revised equation which provides a better approximation of experimental data for the larger sizes.

$$f_r \approx 55/D^{1.16}\ Hz \tag{1}$$

where f_r is the resonance frequency, and D is the particle diameter in meters. Assuming those results are transferable to particles in motion in a streambed, the intensity, or level, of sound in these ranges should correlate with SGN of bedload particles in transport.

Ambient noise (e.g. water motion, wind, and/or biological), however, may still overlap the same frequency range as SGN. Tonella et al. (2009), for example, found that underwater noise related to turbulence and bubble formation were most pronounced between 125 Hz and 2 kHz. Zakarauskas (1986) noted that wind noise can occur between 50

Hz and 10 kHz, but maximum wind noise is generated between 100 Hz to 1000 Hz. Therefore it is important to determine if ambient noise is present in audio recordings as well as the likely frequency range of such noise. Aural listening (i.e. listening through the ear) is particularly useful at distinguishing various sources of noise in the audible range (Camp, 1970). Aural review was combined with automated signal processing tools to analyze the audio recordings and identify if there were periods in which either ambient noise or SGN noise was dominant.

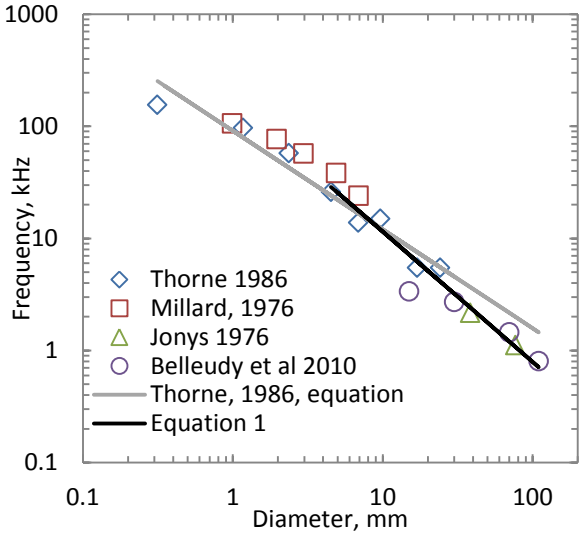

Figure 4 Measurements of acoustic frequency of sediment-generated noise (SGN) as a function of particle size. Thorne 1986 empirical equation, and Equation 1 of this study are also shown.

Signal Analysis The audio recordings were processed in MATLAB by first transforming the signals from the time domain to the frequency domain using a short-time Fourier transform to obtain the power spectral density (PSD). A spectrogram is a convenient way to display the PSD of an audio recording. Time is displayed on the x-axis, frequency on the y-axis, and the sound level for any given frequency and time is represented by color. The sound level for the recordings were averaged over a 1-minute time period. Marineau et al. (2010) found that a 1-minute sample was sufficient to average short-term temporal variability of SGN (such as a loud shock in very close proximity of the hydrophone). For the mobile hydrophone systems, however, a 1-minute time period may not be appropriate. For example, a 1-minute averaged sample may smooth over a local peak of SGN while traveling through a riffle. Therefore, the mobile audio data was split into 15-second time periods for analysis.

Hydrophones are typically calibrated in a specialized underwater-acoustics facility which involves measuring the precise voltage response of the electrical signal output to a given sound pressure at a specific frequency. Low-cost hydrophones (such as the ones used in this study) are generally not calibrated. Therefore, it is not possible to determine the exact sound pressure level from the measured voltage signal output. Sound level is generally referred to in decibels (dB), and sometimes more specifically as decibels of sound pressure level (dB SPL) where 0 dB SPL is the lower threshold of human hearing. The decibel scale is a logarithmic scale and is used because sound pressure can vary by many orders of magnitude. Since the hydrophones used in this study were not calibrated, sound levels are expressed in *dB* rather than *dB SPL*. This means that 0 dB does not necessarily correspond to the lower threshold of human hearing and also that any two hydrophones may have slightly different levels of sensitivity. Though the hydrophones are not calibrated, they can still provide useful information regarding the relative magnitude of underwater sounds. For each 1-minute sample recorded at a hydrophone monitoring station (or 15-second subsample of the mobile hydrophone recording), decibels were calculated using the following equation (Erbe, 2011) assuming cylindrical spreading sound due to shallow water (e.g. Urick, 1983):

$$dB = 10*\log(dv/FS) - M - G - S \quad (2)$$

where dv = digital values in the .wav file, FS = full scale value (for 16-bit floating point, FS is 1), M is the digital gain of the pre-amplifier, I = hydrophone sensitivity level, expressed in dB re 1V/uPa, G = preamplifier gain setting

(in dB). Each spectrogram was calculated in MATLAB using a Hamming window, with a 1 second (44,100 sample) window size, 50 percent window overlap, and fast-Fourier transform (FFT) length of 4410.

RESULTS

Temporal Variability During WY2014, streamflow on the San Joaquin River was generally not sufficient to mobilize coarse sediment at most sites. This was evidenced by audio recordings from several sites and bedload samples collected by the California Department of Water Resources (CADWR) at four sites (Matt Meyers, CADWR, written communication). Of the monitoring sites along the San Joaquin River, the most downstream site, Hwy 145 (Figure 2A), had the smallest bed-material size (D_{50} of 26 mm) and the hydrophone monitoring station at this site detected higher levels of SGN than any other site. During a portion of the deployment, streamflow was very low (4.2 m^3/s) and the hydrophone sensors were at or just above the water surface. Figure 5 shows a spectrogram (5A) and time series of average sound levels for 1.3 to 6.7 kHz frequency range (5B). Data from only one of the two hydrophones is shown in this figure. The frequency range was calculated using Equation 1 with particle diameters of 16 to 64 mm (approximately 70 percent of the bed-material was within this size range). The data includes the period when the hydrophones were out of the water and periods when the water level was at the hydrophone. Releases from Friant Dam were increased starting in early May and held steady during most of the summer. An aural review of several audio recordings revealed that during early low-flow (4.2-11.3 m^3/s) period, the dominant noise sources was water motion. Ambient noise associated with water motion was generally below 2 kHz, but at times was as high as 5 kHz. During period of higher stage, the noise associated with water motion could not be heard in any audio recordings; therefore we concluded that the average sound levels calculated during these periods was primarily SGN. The time series data was refined to exclude low-flow periods which were dominated by ambient noise (Figures 5B and 5C). The ambient noise was easily identified by ear, but could not be discerned from SGN using the signal analysis methods employed in this study. The data from the 5-month period with sustained 36.8 m^3/s flows show some temporal variability in transport; however the elevated sound levels measured during the months of data collection prior to the reservoir releases were from ambient noise, not SGN. In the absence of physical bedload measurements, an aural review of the audio recordings was helpful in distinguishing the SGN from noise originating from other sources. Based on SGN data, coarse bedload was found to generally start and stop at this site when streamflow was around 30 m^3/s.

The hydrophone monitoring station at the Beaver Gulch Site on the Gunnison River (Figure 2B) recorded audio data during the peak of a 10-year flood event. Since the hydrophones were installed in the bank during the rising limb of the flood event, as the streamflow decreased, they were no longer submerged and thus were repositioned to continue data collection. Figure 6B shows the hydrograph with the average sound-level time series overlaid. Figures 6C and 6D show scatter plots of sound level vs discharge. The colors indicate the date starting around June 1 and ending June 10. This figure shows clockwise hysteresis in the sound level. Assuming the SGN was directly proportional to the sediment discharge, these results indicate a decrease in transport which suggests a reduction in sediment supply, bed armoring, or perhaps that the geometry of the channel changed such that sound transmission decreased with time.

Spatial Variability Two longitudinal profiles of SGN were collected in two separate reaches of the San Joaquin River during a discharge of 36.8 m^3/s. Only results from the downstream-most 2.5 km are reported (Figure 7). The spectrogram (Figure 7A) indicates that near-continuous noise was present in the lower frequencies through the entire profile. Aural review of the audio recordings suggested that the source was water noise, likely generated by either the kayak or the paddle movement. The two black rectangles in Figure 7A highlight areas where SGN was audibly detected. Figure 7B shows a time series of the average sound levels for two different frequency ranges. The lower frequency range (1.3 to 6.7 kHz) overlaps with the boat/paddler-generated noise; therefore a time-series calculated from the average sound levels in this range does little to elucidate locations of bedload transport. In the mobile recordings, however, water motion noise was detected in the slower-moving pools (during which the operator was using the paddle to propel the kayak downstream), and this noise was generally limited to less than 4 kHz. The second frequency range shown in Figure 7B (4.5 to 6.7 kHz), however, excludes most of the ambient noise, and two potential riffle clusters with SGN are easily identified in the time series (black rectangles in Figure 7B). The last figure (7C) shows longitudinal profiles of depth, velocity, and water-surface elevation for the same reach. Two sections with increased water-surface slope correspond roughly to the potential riffles identified in Figure 7B. The downstream riffle is a known riffle at the Hwy 145 Site.

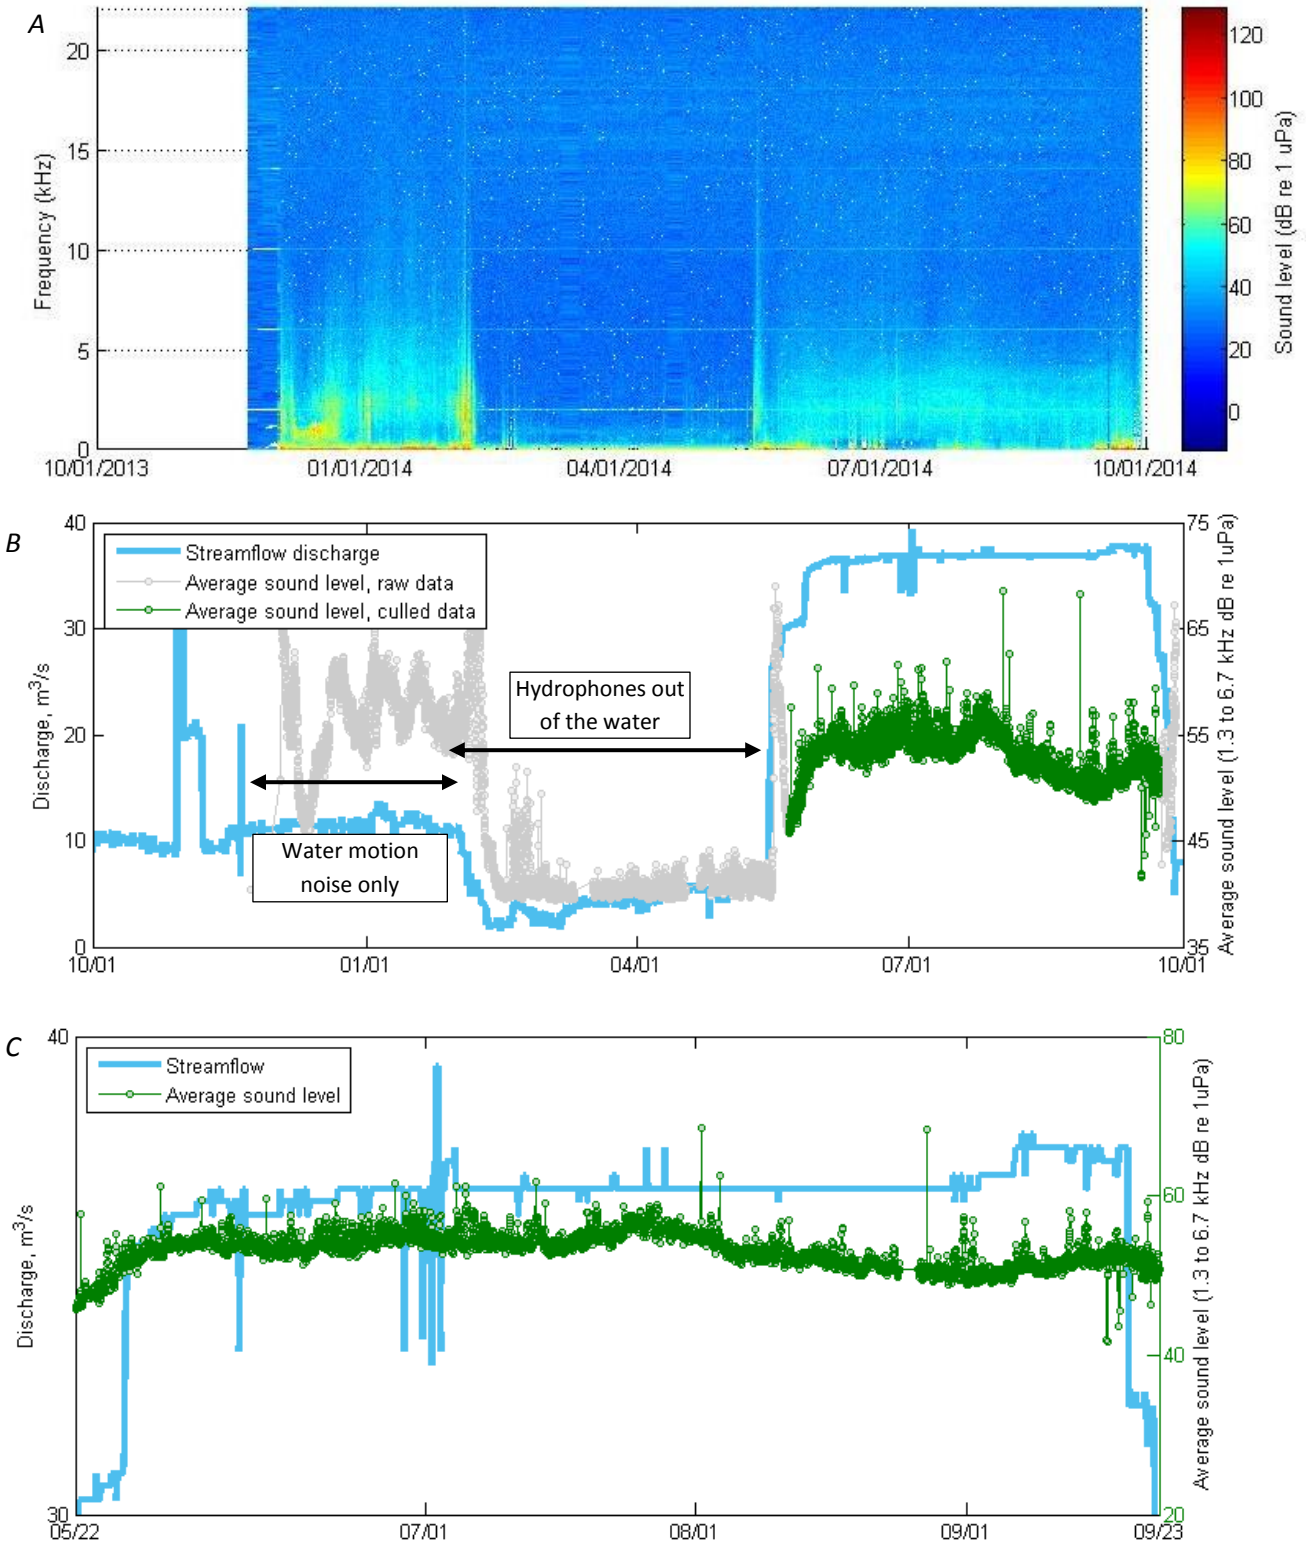

Figure 5 Spectrogram (A) and time-series of raw and refined data overlaid on the hydrograph (B) recorded in the San Joaquin River, California at Hwy 145 monitoring site, WY2014. A close-up of the period when sediment-generated noise was detected is also shown (C).

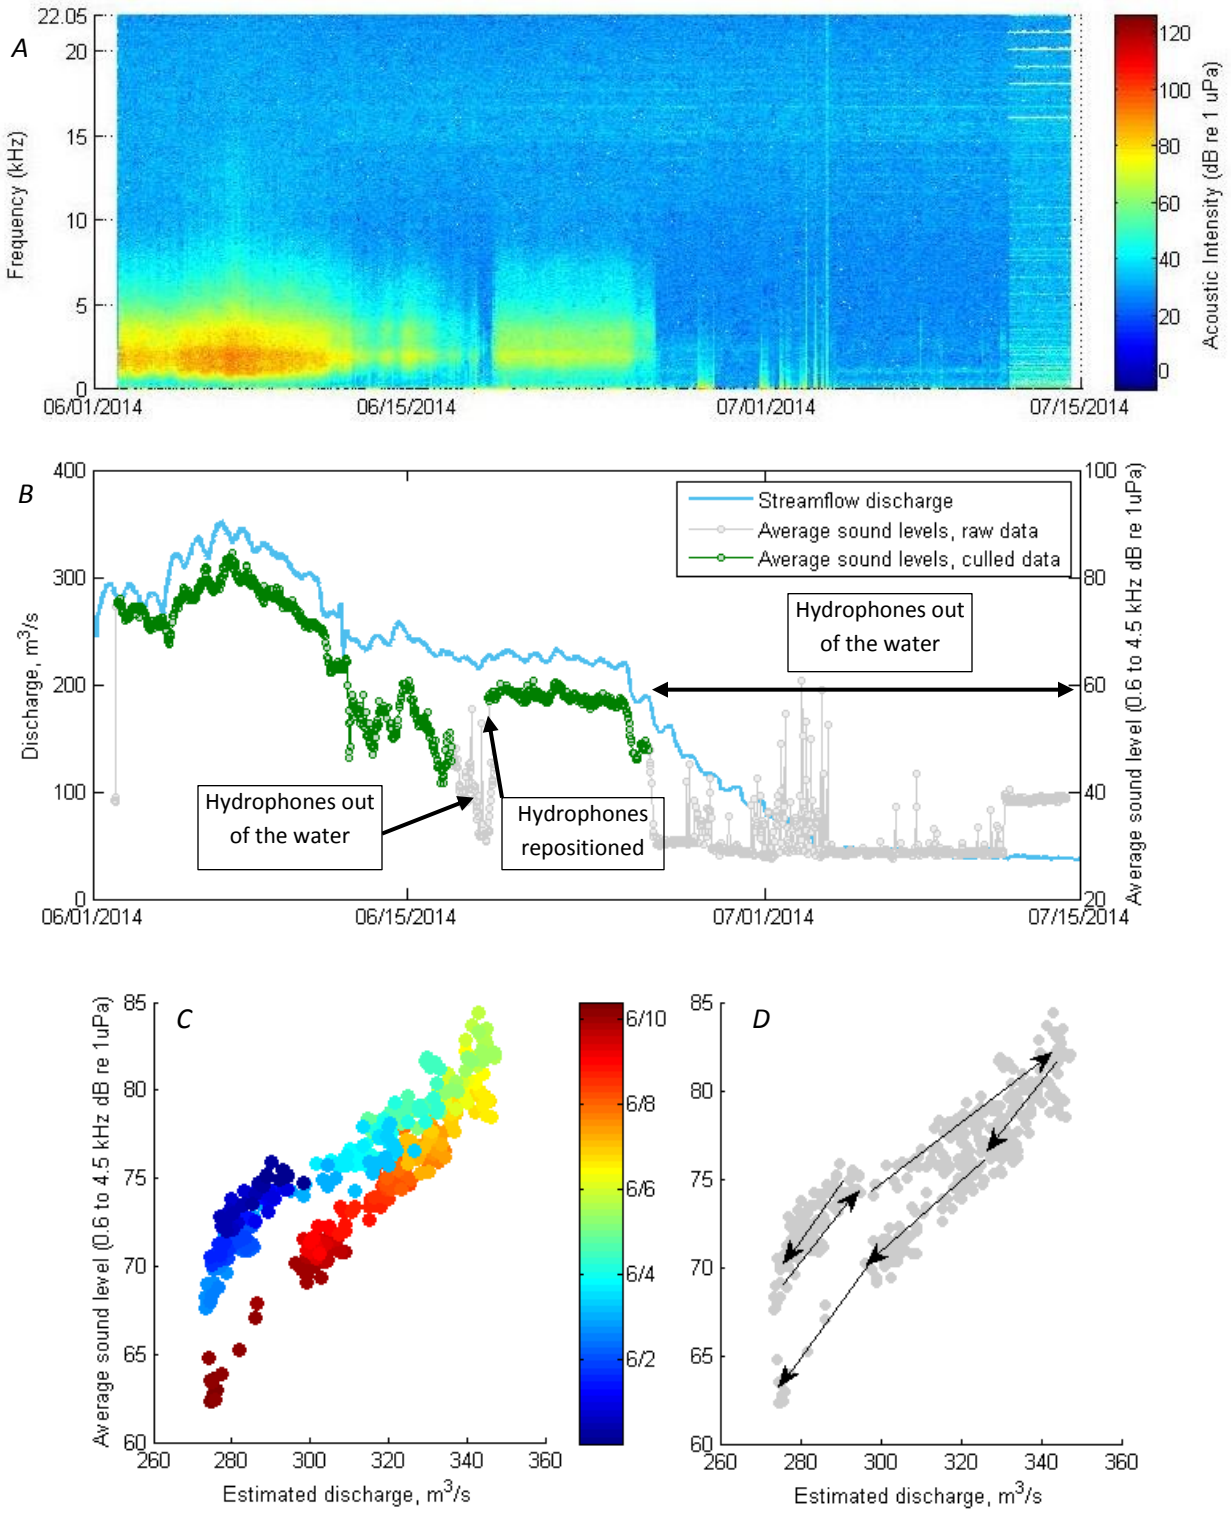

Figure 6 Spectrogram (A) and time-series (B) of 1-minute averaged sound level (0.6-4.5 kHz) in the Gunnison River, CO, Beaver Gulch Site. Scatterplot (C, D) of days 1-10 showing clockwise hysteresis of sediment-generated noise

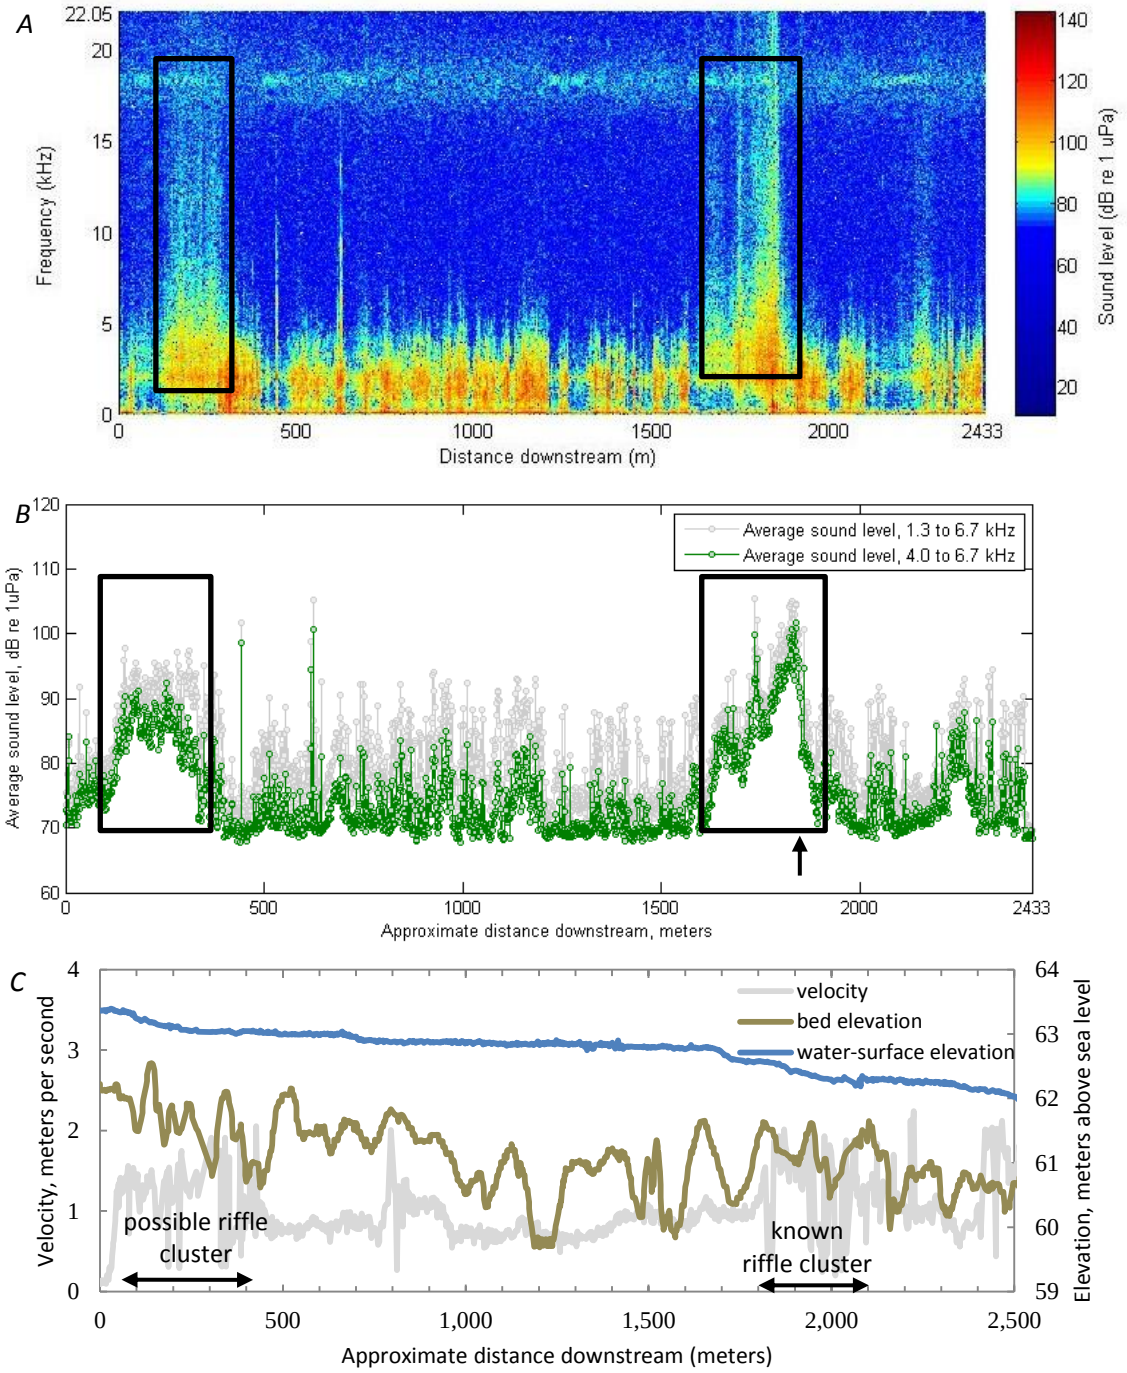

Figure 7 Longitudinal profile of San Joaquin River, California (2.5 km reach near Hwy 145) shown as spectrogram (A), time-series of average sound level for two different frequency ranges (B), and bed elevation, water velocity, and water-surface elevation (C). Boxes indicate periods in which bedload was audibly detected. Vertical arrow indicates approximate location of hydrophone monitoring station at the Hwy 145 Site.

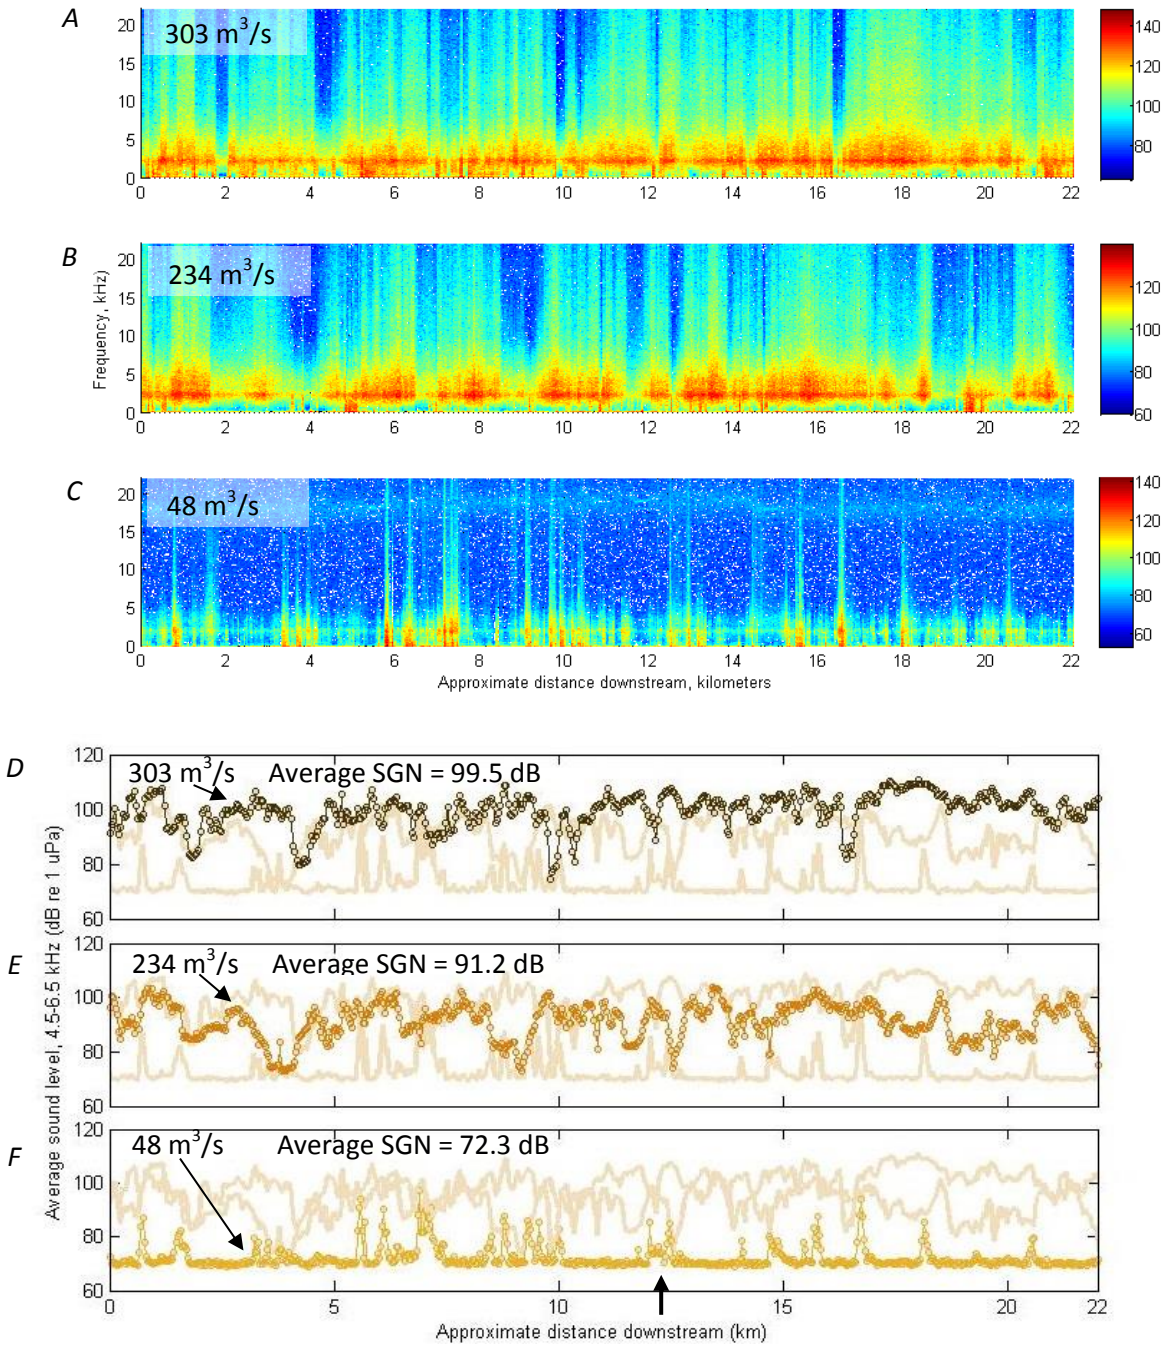

Figure 8 Spectrograms (A-C) and fifteen-second averaged sound level (D-E) recorded from mobile hydrophone system at three different flows: 303 m^3/s, 234 m^3/s, and 48 m^3/s Gunnison River, Colorado. Vertical arrow indicates approximate location of hydrophone monitoring station at the Beaver Gulch Site.

Longitudinal profiles of audio recordings were collected in the Gunnison River at three flows: 303 m^3/s, 234 m^3/s, 48 m^3/s (Figure 8). These time-series were calculated from the same frequency range as the San Joaquin River time series to reduce any potential influence of boat/paddle noise. During the higher flows, elevated sound levels were recorded over most of the reach, suggesting that most or all of the bed was at least partially mobilized. During the lowest flow, only discrete sections of the river had transport occurring. Between these sections were quiescent pools which have an ambient noise floor of about 70 dB.

Statistical information of the longitudinal profiles is also shown in Figure 8D-8F. Generally, average sound levels of SGN decreased with lower flows, however, there was still a high degree of spatial variability at all flows. Critical discharge (i.e. discharge that initiates bedload transport) in this reach, was estimated to be between 195 m^3/s and 269 m^3/s (Pitlick et al., 1999).

CONCLUSIONS

The results from this first year of data collection demonstrate that the hydrophone recording system can be used to collect high-resolution surrogate sediment data in gravel-bedded rivers. The sound level of the signal recorded by the hydrophone is assumed to be proportional to the magnitude of bedload transport as long as the acoustic frequency of the sediment-generated noise (SGN) is known, the grain-size distribution of the bedload is assumed constant, and the frequency band of the ambient noise is known and can be excluded from the analysis. These data can be calibrated and used to fill temporal gaps between physical bedload measurements or as a stand-alone qualitative measure of the timing and variability of transport. At one site on the San Joaquin River, the threshold of movement was estimated to have occurred around 30 m^3/s based on SGN data. The results from the Gunnison River show a clockwise hysteresis during a flood event, which may not be detected using traditional physical sampling at typical sampling return intervals. Previous research has found that gravel transport can occur in waves at different temporal and spatial scales. Pairing physical samples with high-resolution surrogate data may provide a method to determine if a particular sample was collected at high or low point of a sediment wave, and reduce error in estimates of sediment transport. These data may be calibrated to physical samples to obtain a continuous, quantitative estimate of bedload transport. Previous attempts (e.g. Barton et al., 2010) have attempted to relate the average acoustic intensity over a large frequency range to bedload flux. Future work should compare the acoustic signal of SGN in known mixtures from laboratory or field experiments.

The initial testing of the mobile hydrophone system shows that it could be a useful tool to identify fine-scale spatial variability in sediment transport over large reaches, something that is not possible using conventional sampling techniques. This type of qualitative information may be applicable for verifying localized transport in a hydraulic or sediment transport model. Quantifying the transport rate occurring in any particular place, however, has additional challenges; primarily that changes in depth and channel geometry will affect sound transmission and spatial variability in bedload particle-size distributions will change the acoustic signature of the SGN.

Finally, for both the stationary and mobile hydrophone systems, methods are needed to identify and reduce noise from non-sediment sources. Noise reduction may be achieved physically (e.g. changes in the hydrophone mount configuration, hydrophone placement), or through various signal processing tools. In this study, the relative magnitude of transport was quantified by calculating the average sound level over certain frequency ranges. By adjusting these (as was done for the mobile hydrophone data on the San Joaquin River), ambient noise can be excluded from the final results. In the case of the hydrophone monitoring station at the Hwy 145 Site on the San Joaquin River, the selected frequency ranges span bedload noise as well as background noise from water motion. At this site, a different mount style or site may reduce unwanted noise. Future work will consider alternative hydrophone locations and mount configurations to determine which combination will provide optimal performance.

Abstract: The use of multiple-frequency, active acoustics through deployment of acoustic Doppler current profilers (ADCPs) shows potential for estimating bedload in selected grain size categories. The U.S. Geological Survey (USGS), in cooperation with the University of Montana (UM), evaluated the use of multiple-frequency, active and passive acoustics as surrogates for bedload transport during a pilot study on the Kootenai River, Idaho, May 17-18, 2012. Four ADCPs with frequencies ranging from 600 to 2000 kHz were used to measure apparent moving bed velocities at 20 stations across the river in conjunction with physical bedload samples. Additionally, UM scientists measured the sound frequencies of moving particles with two hydrophones, considered passive acoustics, along longitudinal transects in the study reach. Some patterns emerged in the preliminary analysis which show promise for future studies. Statistically significant relations were successfully developed between apparent moving bed velocities measured by ADCPs with frequencies 1000 and 1200 kHz and bedload in 0.5 to 2.0 mm grain size categories. The 600 kHz ADCP seemed somewhat sensitive to the movement of gravel bedload in the size range 8.0 to 31.5 mm, but the relation was not statistically significant. The passive hydrophone surveys corroborated the sample results and could be used to map spatial variability in bedload transport and to select a measurement cross section with moving bedload for active acoustic surveys and physical samples.

INTRODUCTION

Background: Active acoustics, through deployment of acoustic Doppler current profilers (ADCPs), have been tested as a surrogate for bedload transport in Canada's Fraser River (Rennie and others, 2002) and the United States' Trinity River (Gaeuman and Pittman, 2007) and lower Missouri River (Gaeuman and Jacobson, 2006). However, little work has been done to evaluate the performance of multiple frequency ADCPs outside a laboratory environment and whether the response of the various frequencies can help identify types and thicknesses of bedload based on differences in perceived velocities of the moving layer and water depths.

One feature of an ADCP is that it transmits a sound wave, called a bottom track pulse, to keep track of its position as it moves across a stream (Gordon, 1996). If material is moving along the bed at a particular site, the ADCP will falsely appear to move upstream, which introduces bias in a streamflow measurement unless it is corrected (Mueller and others, 2013). If the specific location of the ADCP is known (by fixing its position or by connecting it to a differential global positioning system (DGPS)), and the apparent or false movement of the ADCP is measured over time, an apparent moving bed velocity can be inferred. Bedload transport rate can be estimated based on the apparent moving bed velocity and empirical parameters or through correlations between near-simultaneous measurements of apparent moving bed velocity and bedload samples.

The average velocity of the bedload layer depends on the various sizes and velocities of the particles. Apparent moving bed velocity should be representative of the average surface velocity within the volume measured by the ADCP; however, the measurement is influenced by the frequency of the instrument and the size of the particles. An ADCP preferentially measures reflections from particles with a diameter equal to or greater than the wavelength of the instrument's sound wave (Thorne and others, 1995). For example, a 1200 kHz ADCP should be most sensitive to particles with diameters equal to or greater than 0.8 mm, and the weighting of these particles in the apparent moving bed velocity should be greater. The use of multiple ADCPs with different frequencies should theoretically allow the computation of apparent moving bed velocities for different grain sizes. As a result, relations between bedload and apparent moving bed velocity may be developed separately for various grain size categories.

Passive acoustics, through deployment of hydrophones, have been tested as a surrogate for bedload transport in the United States' Trinity River (Barton and others, 2007) and Middle Fork Flathead River (Lorang and Tonolla, 2014) and France's Isère River (Belleudy and others, 2007). Most research with hydrophones has been focused on measuring

coarse gravel transport, and little work has been done to evaluate the ability of hydrophones to detect a wider range of bedload grain sizes. Additionally, research is needed to determine whether passive acoustics could be used in conjunction with active acoustics to optimize sampling design and development of surrogate relations.

STUDY SITE AND METHODS

The U.S. Geological Survey (USGS) has operated a sediment monitoring and hydrodynamic modeling project in the Kootenai River basin (fig. 1) since 2003 as part of the Kootenai River White Sturgeon Recovery Plan. Recovery efforts for the endangered Kootenai River population of white sturgeon require an understanding of the characteristics and transport of suspended and bedload sediment which have an effect on egg suffocation and mortality rates in the critical habitat reach of the river (fig. 1) as described in Fosness and Williams (2009). The pilot study site, Kootenai River at Crossport near Bonners Ferry, ID (USGS 12308500; fig. 1), is near the upstream end of the Kootenai River white sturgeon critical habitat. The site was selected for the pilot study based on observed conditions in 2010-12: consistent bedload at streamflows greater than 30,000 ft^3/s, a mixture of sand and gravel in bedload samples, and apparent moving bed velocities greater than 0.04 ft/s detected by ADCPs used to measure streamflow.

Field data collection for the pilot study was conducted May 17-18, 2012, during a controlled release of about 14,800 ft^3/s from Libby Dam (fig. 1) and fairly steady streamflow around 38,000 ft^3/s at the study site. All sampling and ADCP equipment were deployed from a jet boat. Four ADCPs with frequencies ranging from 600 to 2000 kHz (fig. 2) were used to measure apparent moving bed velocities and streamflow depths at 20 stations across the river:

- Teledyne RD Instruments (TRDI) 600 kHz Rio Grande
- TRDI 1200 kHz Rio Grande
- TRDI 2000 kHz StreamPro
- SonTek/Xylem multi-frequency RiverSurveyor M9 (1000 kHz beams used)

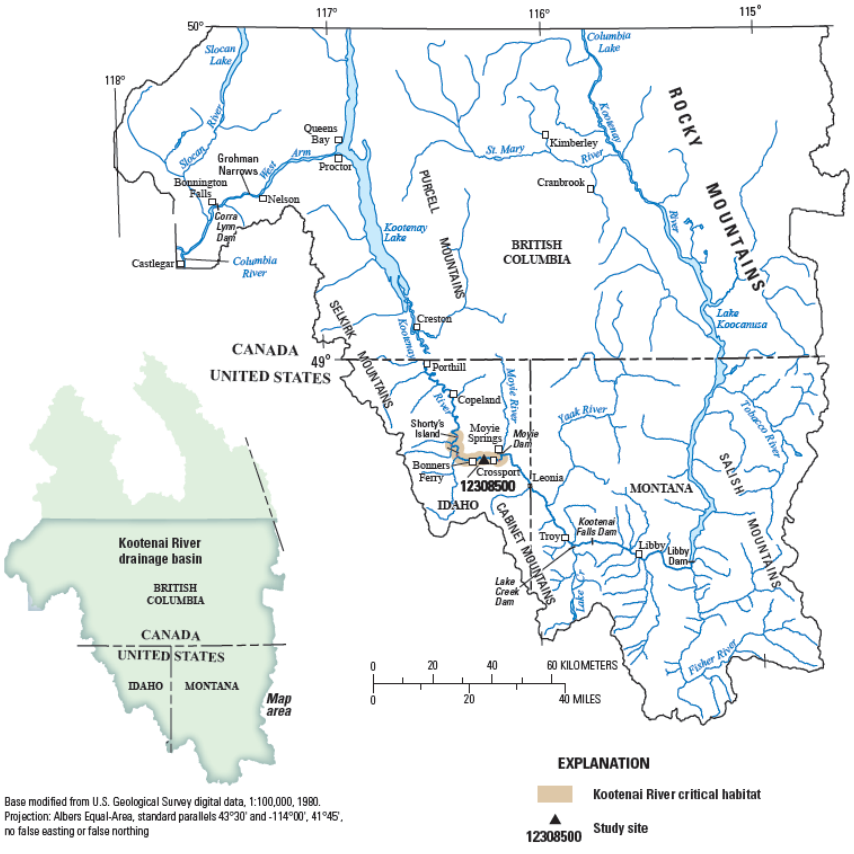

Figure 1 Map showing location of pilot study site, Kootenai River at Crossport near Bonners Ferry, Idaho (USGS 12308500).

Figure 2 Mounting configuration for ADCPs used to measure apparent moving bed velocities in the Kootenai River at Crossport near Bonners Ferry, Idaho (USGS 12308500), May 17-18, 2012. ADCPs are (from left to right): TRDI StreamPro, TRDI 600 kHz Rio Grande, TRDI 1200 kHz Rio Grande, and SonTek/Xylem RiverSurveyor M9.

All ADCPs except the TRDI StreamPro were equipped with DGPS equipment. Use of a DGPS requires a compass within the ADCP. For the TRDI StreamPro, the compass is contained within the electronics housing, which is separate from the ADCP transducer. The electronics housing must be aligned in a specific way relative to the transducer if the compass is to be used, which was not possible during the study. The compasses in all other ADCPs that were used were calibrated according to manufacturer recommendations and USGS policies in Mueller and others (2013) prior to further data collection.

The ADCPs were deployed to collect stationary moving bed tests for 5 minutes at each station. USGS personnel were unable to anchor the boat during ADCP data collection because of safety considerations and difficulty in attaching the anchor in the cobble substrate. The boat was held as stationary as possible during each moving bed test but some movement was unavoidable. Apparent moving bed velocities were calculated by determining the apparent distance moved upstream according to the ADCP's bottom track pulse. Apparent moving bed velocities for the TRDI StreamPro were taken directly from the stationary moving bed tests assuming boat position was held relatively steady (no "real" upstream movement). For all other ADCPs, the apparent moving bed velocities were calculated relative to actual boat movement determined from DGPS (equation 1):

$$V_{mb} = \frac{DU_{BT} - DU_{DGPS}}{T} \quad (1)$$

Where

V_{mb} is the apparent moving bed velocity in ft/sec,
DU_{BT} is the distance the ADCP appears to move upstream in ft when referenced to bottom track,
DU_{DGPS} is the distance the ADCP moves upstream in ft when referenced to DGPS, and
T is the duration of the test in seconds.

For all ADCPs equipped with DGPS, the National Marine Electronics Association (NMEA) "Global Positioning System Fix" (GGA) string was selected over the "Track Made Good and Ground Speed" (VTG) string as the best DGPS reference.

Immediately before or after ADCP data collection, bedload samples were collected at each of the 20 stations using an Elwha US-ER1 sampler with a 0.5 mm bag mesh size. Additionally, an underwater video camera was attached to the bedload sampler to monitor its orientation and performance at four stations. Samples were collected utilizing USGS methods for single equal width increment (SEWI) samples (Edwards and Glysson, 1999), but samples were not composited. Each station's sample was separately analyzed for mass in 12 grain size categories from 0.063 mm to 128 mm. Bedload was calculated according to equation (2) adapted from Edwards and Glysson (1999):

$$Q_b = K\left(\frac{W_t}{T_t}\right)M_t \quad (2)$$

Where

Q_b is the bedload in tons/day,
K is a conversion factor calculated as 86,400 sec/day x (1 ton/907,200 g) x (1 ft/N_w), where N_w is the width of the sampler opening in ft, or 0.67 ft,
W_t is the width of the stream represented by each station in ft, or about 23 ft on average,
T_t is the total time the sampler rests on the bed at each station in seconds, or 60 s, and
M_t is the mass of sample from each station in grams.

Sampling was repeated on May 18 at three stations that were measured on May 17 that had the highest apparent moving bed velocities and most bedload collected. Overall, 23 samples were attempted, but because no material was present in one sample collected near the left bank, data from 22 samples were available for analysis. USGS personnel intended to repeat sampling at all 20 stations but were unable to do so within the short time frame of the controlled release out of Libby Dam.

Simultaneous with the sample and ADCP data collection, UM scientists measured the sound frequencies (0.020−20 kHz; then combined in 10 octave bands from 0.0315 to 16 kHz) of moving particles with a pair of co-located Brüel and Kjaer 8103 hydrophones, amplified and connected to a digital recorder, along longitudinal transects in the study reach. The hydrophones were mounted parallel to each other at about 1 ft depth below water on the frame of a jet boat (a separate boat from the one used to collect bedload samples and ADCP data).

RESULTS AND DISCUSSION

Bedload Characteristics: Total bedload from the composite of all stations contained 3 percent sand and 97 percent gravels, with less than 0.5 percent organics. Sand was considered to include sediment retained on 0.063 to 1 mm sieves, and gravel was considered to include sediment retained on 2 mm and larger sieves, according to the Wentworth scale (Wentworth, 1922). Throughout this paper, bedload is referenced by how much material was retained on that sieve size (for example, "2 mm bedload" is bedload comprised of grain sizes passing through the 4 mm sieve but retained on the 2 mm sieve).

The most sand bedload at any station was measured at station 7, about 160 ft from the right bank (fig. 3). About 20 percent of the total bedload in the sample collected at station 7 was sand. The most gravel bedload was measured at stations 8 and 9, 180 to 203 ft from the right bank. Overall, nearly all the measured bedload was in the right 35 to 45 percent of the cross-section. The gravel bedload measured at station 1 is suspected to be the result of the sampler scooping bed (non-moving) gravel because (1) sampler control was difficult because of turbulence caused by a

submerged tree, and (2) the gravel sizes measured (16.0-31.5 mm) are unlikely to be transported by the low stream velocities observed at station 1.

Overall, bedload size distribution was unimodal and contained a much higher percent of gravel than expected. The largest sediment mass was observed in the grain size categories of 8.0 and 16 mm. Fairly equal proportions of sands were measured in the 0.5 and 1.0 mm size categories. Any sands less than 0.5 mm were assumed to be attached to other particles or were present in the bag due to occlusion of the 0.5 mm mesh openings from other particles. As a result, sand particles smaller than 0.5 mm were not considered in relations with acoustic data. None of the samples contained sediment in the 63 and 128 mm (gravel) grain size categories.

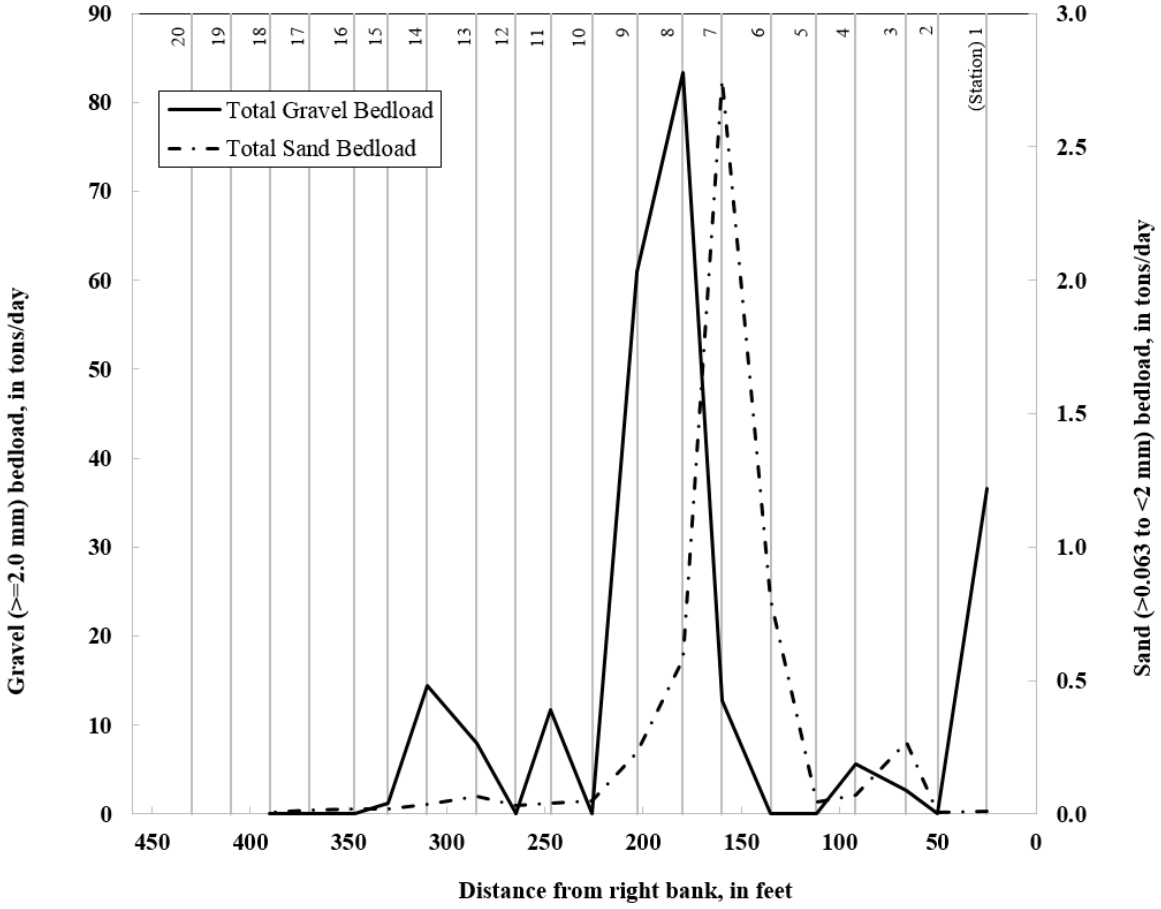

Figure 3 Total gravel and sand bedload at each station measured in the Kootenai River at Crossport near Bonners Ferry, Idaho (USGS 12308500), May 17, 2012.

Bedload Sampler Performance: Underwater video camera reconnaissance of the bedload sampler, attempted at stations 1-4, showed that the sampler often turned sideways or backwards when deployed, which raises concerns about sampler performance. The camera and accessory cable were tested in different configurations (fig. 4) in an attempt to reduce their hydraulic drag and resulting effect on sampler orientation. After several attempts the camera was removed because a proper sampler orientation could not be attained and meaningful bedload samples could not be collected. After camera removal, collected bedload samples made sense based on observed substrate and velocity distribution in the cross-section, which suggests that the sampler oriented correctly without the presence of the camera. Post-study consultation with other bedload sampling experts revealed that the weight distribution of the sampler may not have been ideal to handle the added weight and hydraulic disturbance due to the video camera (Smokey Pittman, Graham Matthews and Associates, written commun., 2013). The video reconnaissance of the bedload sampler showed some concerning behavior, which could be further verified through controlled experiments in a laboratory flume or in a river where water clarity allows direct observation of the sampler on the bed.

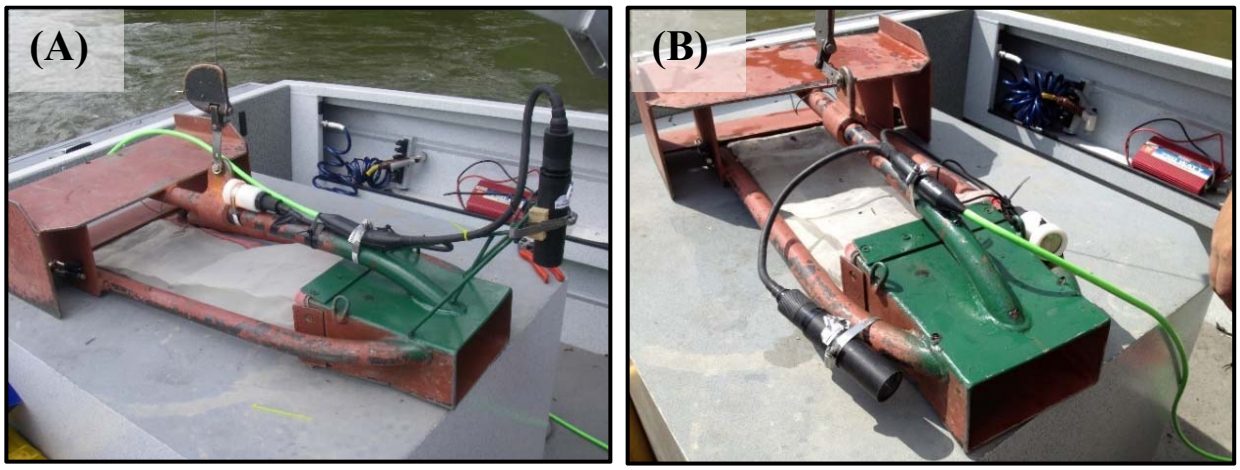

Figure 4 Elwha US-ER1 sampler used to measure bedload in the Kootenai River at Crossport near Bonners Ferry, Idaho (USGS 12308500), May 17-18, 2012. An underwater video camera was temporarily attached to the sampler, (A) looking down on the sampler opening and (B) attached to the lateral sampler supports, to evaluate sampler performance and orientation.

Active Acoustic Relations: Apparent moving bed velocities were low (0.001-0.064 ft/sec) during the selected sampling event due to the unforeseen low percentage of sands in the total bedload. In theory, sand should be more detectable by the ADCPs than gravels for the frequencies tested. Apparent moving bed velocities greater than 0.04 ft/sec were measured at only 5 stations. An apparent moving bed velocity of 0.04 ft/s is used as an uncertainty threshold for correcting ADCP streamflow measurements for moving bed using a loop correction described in Mueller and others (2013). Average apparent moving bed velocity among all instruments and sampling stations was 0.013 ft/s. As a result, uncertainty was high in identified relations between bedload and apparent moving bed velocities for all ADCPs. However, some patterns emerged in the relations that show promise for future studies.

Apparent moving bed velocities measured by the 1200 kHz ADCP had the best statistically significant, though scattered, linear relations with sands in the 0.5 – 1.0 mm size categories and very fine gravels in the 2.0 mm size category (table 1, fig. 5). The 1000 kHz ADCP showed similar, though slightly more scattered, relations with sands and very fine gravels. The 2000 kHz ADCP showed statistically significant relations with individual bedload grain size categories 0.5 and 1.0 mm but not 2.0 mm and larger. No statistically significant relations were found between bedload transport for gravels 4.0 mm and larger and apparent moving bed velocities measured by any ADCP, which was expected. However, apparent moving bed velocities measured by the 600 kHz ADCP related better to gravels in the 8.0 to 31.5 mm grain size categories than the other ADCPs (correlation = 0.46, $R^2 = 0.21$; p-value = 0.11 (table 1)). Otherwise, use of a range of frequencies did not improve the ability to define relations for individual bedload size categories.

Apparent moving bed velocities measured by the 1200 kHz ADCP had the best relations with sand and very fine gravel bedload of all tested ADCPs. The highest apparent moving bed velocities were measured by the 1200 kHz ADCP at 4 stations located 135-203 ft from the right bank. Samples collected from these stations contained 89 percent of the total sand and very fine gravel bedload measured in the cross-section.

Relations between apparent moving bed velocities measured by ADCPs with frequencies in the 1000-1200 kHz range and sand and very fine gravel bedload transport show promise for future work, but further testing is needed during an event when total bedload consists of a greater percentage of transport in these size categories and apparent moving bed velocities are consistently higher than 0.04 ft/sec.

Table 1 Regression statistics of selected relations between apparent moving bed velocities measured by acoustic Doppler current profilers and bedload in various grain-size categories in the Kootenai River at Crossport near Bonners Ferry, Idaho (USGS 12308500), May 17-18, 2012.

[A table entry of "--" indicates the regression was not statistically significant at a significance level of 0.10. The regression model between the 600 kHz Rio Grande and gravel bedload is shown because it is noteworthy and discussed in the text, even though it is not statistically significant at a significance level of 0.10. Regression model form developed in all cases is log(bedload) = m(log(V_{mb}))+b, where m is the regression slope and b is the regression constant. Abbreviations: V_{mb}, apparent moving bed velocity; kHz, kiloHertz; mm, millimeter; n, number of samples used in regression; R^2, coefficient of determination; SE, standard error; p, statistical significance or probability that the two compared variables are linearly related by chance]

[1]Some data points were removed from the regression with the 2000 kHz StreamPro because the StreamPro reported downstream instead of upstream movement at those stations.
[2]Bedload in the 2.0 mm grain size category was not present in one sample.
[3]Bedload in the 8.0 to 31.5 mm grain size categories was not present in nine samples.

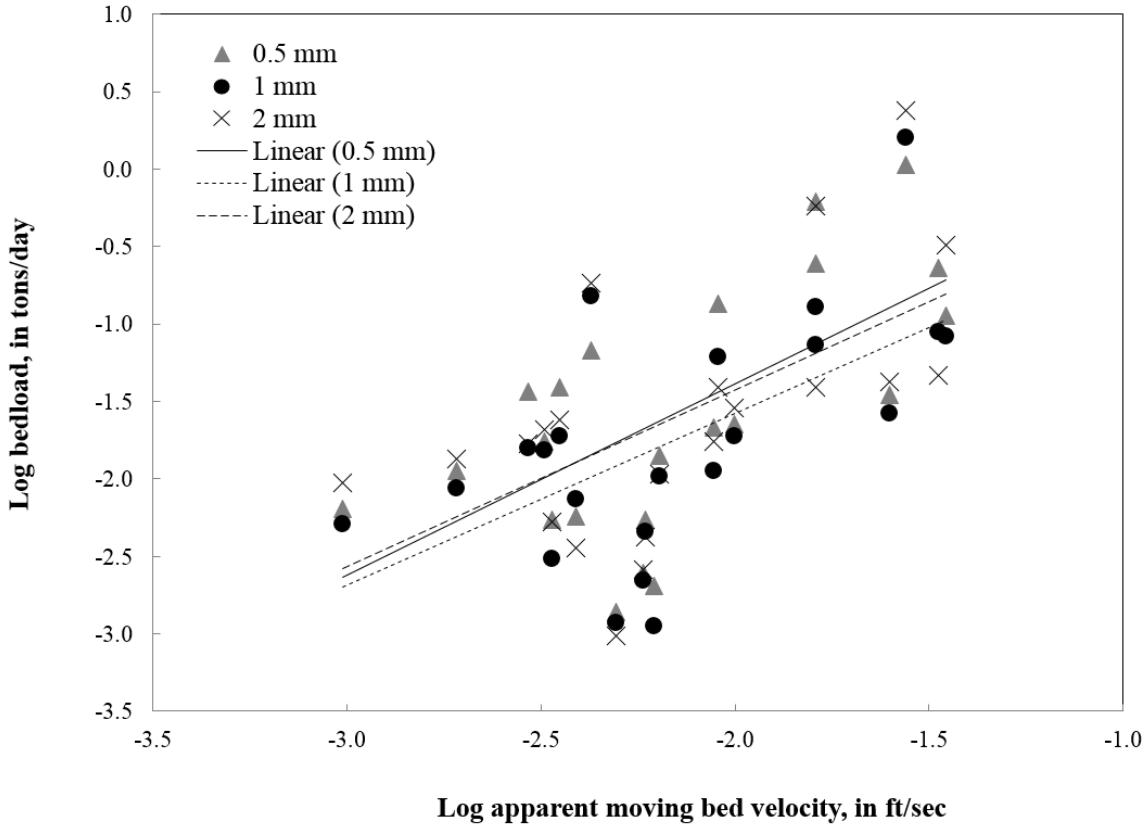

Figure 5 Selected linear relations between apparent moving bed velocities measured by the 1200 kHz TRDI Rio Grande ADCP and bedload at individual stations sampled in the Kootenai River at Crossport near Bonners Ferry, Idaho (USGS 12308500), May 17-18, 2012.

Active Acoustic Depth Differences: Streamflow depth readings from each ADCP were compared at each station, and an overall cross-sectional area was calculated based on each ADCP's depth readings using the USGS AreaComp2 program (Lant and Mueller, 2012). Differences in depth and area readings among ADCPs were examined for patterns in an attempt to determine thickness of bedload layers in various size categories. Safe anchoring was not possible during the pilot study, and, as a result, considerable uncertainty exists when comparing average depths among ADCPs because of movement of the boat. Additionally, each ADCP measured depth in a slightly different ensonified area due to their mounting configuration on the boat (fig. 2) and differences in beam angle and diameter.

Depths measured by the 600 kHz ADCP resulted in the largest cross-sectional area, which was expected because the acoustic signal strength of the 600 kHz ADCP is higher than the other ADCPs and is able to penetrate finer material moving near the bed. No clear patterns were observed between cross-sectional area and the other ADCP frequencies. Overall, the coefficient of variation among cross-sectional areas calculated from the various ADCP depths was 0.6 percent, which is small compared to the uncertainties mentioned above. Future testing would benefit by selecting a site where anchoring could be ensured; however, the other mentioned uncertainties would likely still exist.

Passive Acoustic Surveys: Selected results of the passive acoustic hydrophone surveys along longitudinal transects in the study reach are presented here as they relate to the active acoustic (ADCP) and bedload sample data in the pilot study cross-section. Further details on the results of the hydrophone surveys are presented in Lorang and Tonolla (2014).

In general, the hydrophone surveys corroborated the bedload sample results and apparent moving bed velocities measured by the ADCPs. Lorang and Tonolla (2014) state that frequency responses from 2 to 8 kHz probably correspond with gravel bedload transport and 8 to 16 kHz correspond with sand bedload transport. The hydrophones recorded highest response in the expected frequency range for gravels (2-8 kHz) where the highest gravel transport was sampled about 180-200 ft from the right bank (3rd panel from top, fig. 6) and highest response in the expected frequency range for sand (8–16 kHz) where the highest sand transport was sampled about 160 ft from the right bank (2nd panel from top, fig. 6). The hydrophones also recorded a high response in the 2-6 kHz frequency range about 300-350 ft from the right bank at the sampling cross-section (3rd panel from bottom, fig. 6) that seems to correspond with an increase in gravel transport measured in the bedload samples at station 14 (fig. 3). All of the ADCPs reported lower than average apparent moving bed velocities in this area. In the future, passive acoustic surveys could be used to measure spatial variability of bedload in a river reach and could aid in selecting locations with moving bed for sample and active acoustic data collection.

SUMMARY

The USGS, in cooperation with UM scientists, evaluated the use of multiple-frequency, active and passive acoustics as surrogates for bedload transport during a pilot study in the Kootenai River at Crossport near Bonners Ferry, Idaho (USGS 12308500), on May 17-18, 2012. Four ADCPs with frequencies ranging from 600 to 2000 kHz were used to measure apparent moving bed velocities at 20 stations across the river. Bedload samples were collected at each station with an Elwha US-ER1 sampler immediately before or after the ADCP data collection. At four sampling stations, an underwater video camera was used to monitor performance of the bedload sampler. Additionally, UM scientists measured the sound frequencies (0.020−20 kHz; then combined in 10 octave bands from 0.0315 to 16 kHz) of moving particles with a pair of co-located hydrophones along longitudinal transects in the study reach. USGS scientists attempted to correlate apparent moving bed velocities measured by the active acoustics (ADCPs) and qualitatively compare frequency response from the passive acoustics (hydrophones) with the sample data at each station to determine whether surrogate relations could be developed for various bedload grain-size categories.

Some patterns emerged in the preliminary analysis which show promise for future studies. Apparent moving bed velocities were much lower than expected (average less than 0.04 ft/sec), and 97 percent of the total bedload was gravel, which in general was too large to be detected in most of the ADCP measurements but was detected by the hydrophones. Apparent moving bed velocities measured by the 1200 kHz ADCP had the best statistically significant, though scattered, linear relation with sands and very fine gravels in the 0.5-2 mm size range (highest $R^2 = 0.41$). Apparent moving bed velocities measured by the 600 kHz ADCP had a positive correlation (+0.46) and weak linear relation ($R^2 = 0.21$) with gravels in the 8.0 to 31.5 mm size range, but the p-value of the regression (0.11) was just above the threshold for statistical significance (0.10) selected for this study. Significant relations could not be developed between apparent moving bed velocities for any ADCP and sample data in individual bedload size categories of 4.0-31.5 mm. Relations between apparent moving bed velocities measured by ADCPs with frequencies in the 1000-1200 kHz range and bedload transport of sands and very fine gravels show promise for future work, but further testing is needed during an event when total bedload transport consists of a greater percentage of sands and apparent moving bed velocities are consistently higher than 0.04 ft/sec.

The passive hydrophone surveys generally corroborated the sample results. The hydrophones recorded highest response in the expected frequency range for gravels (2-8 kHz) and sand (8-16 kHz) where the most gravel and sand transport, respectively, was measured in the cross-section. In the future, active and passive acoustics used together show promise for bedload characterization. Passive acoustics could be used to characterize types and location of bedload transport in a river reach and to select an appropriate cross-section for collection of active acoustic and physical sample data, possibly resulting in development of surrogate relations, particularly for the sand fraction of bedload transport.

Underwater video reconnaissance of the bedload sampler showed that the sampler often turned sideways or backwards when deployed, which raises concerns about sampler performance. The camera was attached to the sampler in several different configurations in an attempt to reduce the camera's hydraulic drag. After several attempts, the camera was removed because it likely altered the hydraulic characteristics of the sampler, preventing proper alignment with streamflow. However, questions remain about the true performance and orientation of the sampler, which could be answered through controlled experiments in a laboratory flume or in a river where water clarity allows direct observation of the sampler on the bed.

ABSTRACT

Changes in Mississippi River bed material gradations between Cairo, Illinois and Head of Passes, Louisiana have been previously determined. In November 2013, bed material samples were collected from the thalweg and across the channel width along a reach extending from Grafton, IL, to Head of Passes, LA. In all, 754 samples were collected at 496 locations. Results were compared to the earlier 1932 and 1989 sampling programs. Since 1932, after the completion of the Mississippi River cut-off program, there has been a general reduction in very fine materials (clay, silt, very fine sand) and very coarse materials (very coarse sand and gravel), replaced by fine to coarse sand fractions. On average the median grain size in 2013 (0.43 mm) is about 50% less than that of 1932 (0.96 mm), but little change in median grain size has occurred since 1989 (0.46 mm). In general, very little change has occurred since the 1989 sampling program.

INTRODUCTION

In 1932 and again in 1989 the U.S. Army Corps of Engineers (USACE) sponsored efforts to collect and analyze data to investigate bed sediments from the Mississippi River channel thalweg along a 1,070-mile reach between Cairo, Illinois and the Head of Passes, Louisiana. The 1932 data are reported in the 1935 Waterways Experiment Station Paper Number 17, "Studies of River Bed Material and Their Movement with Special Reference to the Lower Mississippi River" (WES, 1935). The 1989 data are reported in the Lower Mississippi Valley Division Potamology Program Report 7, "Particle Size Distributions of Bed Sediments along the Thalweg of the Mississippi River, Cairo, Illinois, to Head of Passes, September 1989" (Nordin and Queen, 1992).

The many changes that occurred on the Mississippi River between 1932 and 1989 were considered a significant reason for investigating changes in the river bed sediments for that period of time. The three predominant changes were construction of dams on the Missouri River, shortening of the river by cutoffs and channel realignment, and construction of bank revetments and training works. Since 1989 there has been a continued effort to construct bank revetments and training works, but there have been no additional reservoirs or cutoffs. Comparatively, the magnitude of changes in the Mississippi River that have occurred between 1989 and 2013 are not significant. Yet, recent data and studies indicate that the Mississippi River continues to adjust in response to earlier and on-going construction works (USACE, 2007). Recent studies involving the update of the Low Water Reference Plane in 2007 indicate continued adjustment in the river profile. The profile adjustments along with field observations signify continued change in bed material composition throughout the lower Mississippi River channel. There have been unsubstantiated claims that the bed is finer within the New Orleans District reach than in previous sampling programs. It was also conjectured that the bed has further coarsened in the upper reaches of the Memphis District.

In 2013, the Corps of Engineers determined to undertake a sampling program to duplicate as closely as possible the previous sampling programs from 1932 and 1989. The concerns with volume and gradation of sediments moving through the Mississippi River identified a need to also assess sources of sediment in the upper reaches of the basin. Historically the Missouri River was a predominant contributor of these sediments and was altered by construction of major flood control reservoirs on its main channel (Meade et al., 2009). For this reason the sampling program was extended to include the Upper Mississippi River to Grafton, Illinois.

SAMPLE LOCATIONS

The 2013 study collected 754 samples between Grafton, IL and Head of Passes, LA. Sample locations were sited to coincide with locations previously sampled by WES (1935) and Nordin and Queen (1992). Additional sites were added to capture cross channel variations and to acquire data needed for specific model studies. In addition to sampling the Mississippi River downstream of Cairo, a base line sampling was completed for the Upper Mississippi River between Grafton and Cairo. General sample locations are shown in Figure 1; red markers denote upper Mississippi River sites and green markers denote lower Mississippi River sites. The additional cross-channel samples were collected at every 10th sample location or as required for specific sediment modeling studies. The 1989 sampling program only documented three locations where multiple samples were taken across the channel.

Where transect locations were indicated, a total of five samples were collected— one at the thalweg and the other 4 equally distributed across the remaining open water subject to safe boat access. In some cases, it was not possible to obtain a total of five samples because of water levels or other situations that limited access. A few samples on sand bars were obtained from land where access permitted.

Transect sample names were appended A through E; 'A' indicated the right descending bank and 'E' the left descending bank (Figure 2).

Figure 1 Location map of thalweg samples taken November 2013. The upper Mississippi River samples are denoted by red markers.

SAMPLE ACQUISITION AND LAB ANALYSIS

The bed samples were taken by field parties on two research vessels from Engineering Research and Development Center (ERDC). Field parties on each vessel were comprised of a core staff of ERDC researchers, a representative from the USGS, and USACE District staff. Each District was responsible for providing support staff to sample their respective areas of responsibility. Each vessel covered approximately 50-60 river miles per day, for a combined 100 river miles. Table 1 shows the dates when the various portions of the river were traversed along with the number of samples obtained for each District.

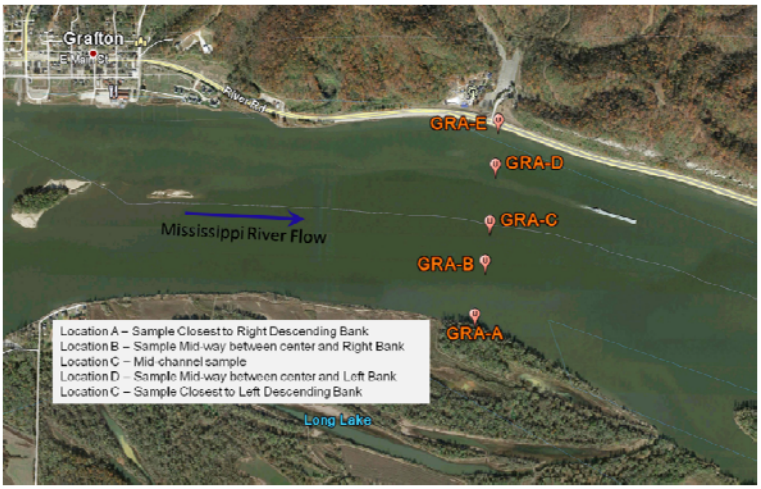

Figure 2 Multiple sample locations taken across channel.

Table 1 Samples of Bed Material of Mississippi River and Tributaries

River	USACE District	River Mile[1]	Number of Samples	Sampling Dates
Upper/Middle Mississippi	St. Louis	5 – 218 Above mouth of Ohio River (Mouth Ohio River = 953.8 AHP)	110	Nov 7-8, 2013
Mississippi	Memphis	595.6 – 958.8 AHP	291	Nov 9-11, 2013
Mississippi	Vicksburg	321.1 – 592.1 AHP	183	Nov 12-13, 2013
Mississippi	New Orleans	0 – 316 AHP	170	Nov 14-15, 2013
[1] AHP refers to river miles Above Head of Passes, Louisiana				

The sampling device used was the same WES drag sampler design used in 1932 and again in 1989, which consists of a four-inch inside diameter steel pipe four feet long closed at one end and flared to eight inches diameter at the other end (Figure 3). The sampler is lifted by use of a crab-pot puller mounted to the base of a boom arm that extends over the side of the boat (Figure 4).

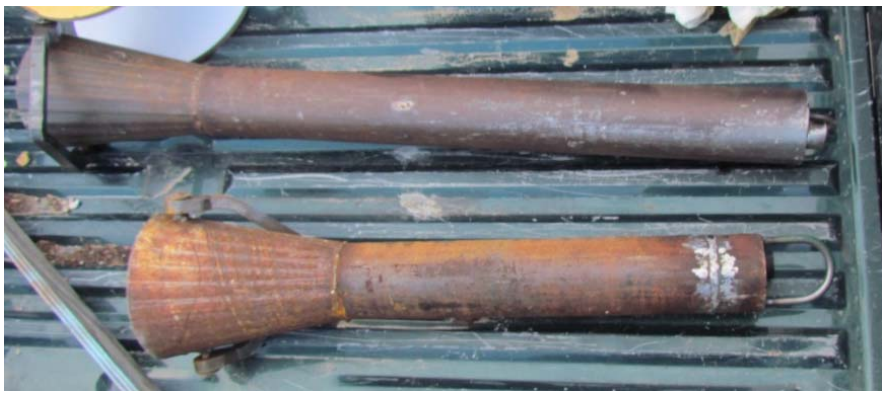

Figure 3 WES drag samplers: Original 4-ft long sampler (top); Sampler shortened by 11-inches (bottom).

Figure 4 Crab pot puller and boom after retrieving sampler.

Collected field samples were shipped to the sediment laboratory at ERDC for analyses. Initially, samples were analyzed using standard ASTM sieve techniques for non-cohesive materials larger than 1mm and laser diffraction (LD) techniques for material 1mm and smaller. Malvern (2013), Stojanovic and Markovic (2012), Wedd (2003), Ma et al. (2000), Loizeau et al. (1994), Wanogho et al. (1987), and McCave et al. (1986) describe particle size analysis using LD. Maximum particle sizes for samples containing outlying coarse grains that would bias the weighted percent grain size distribution were separated (Figure 5). Maximum sizes for these grains were determined by direct measurement. These grains were not included in the grain-size distribution data.

Figure 5a Well sorted sample, no D_{max}

Figure 5b Moderately sorted sample, 1 D_{max}

Figure 5c Poorly sorted sample, 3 D_{max}

An independent check of ERDC lab analysis was included in the original study scope. This check included duplicate analysis of ten percent of samples by the USGS Kentucky Water Science Center Sediment Laboratory. The quality control samples were selected from two pools of samples that were processed at the ERDC lab. Selection was done by random selection from each of the pools. Original sample material was split using standard ASTM splitting techniques. One part was processed using ERDC facilities and techniques. The remaining part was shipped to the USGS sediment lab in Kentucky for analysis using conventional sieve-pipet (SP) procedures for analysis of particle size distributions. Shreve and Downs (2005) provide a description of laboratory procedures at the USGS Kentucky Sediment Lab. Stevens and Hubbell (1986) give methods for calculating particle size distributions.

Once results from the USGS laboratory became available they were compared with the ERDC results. Comparison of sieve results indicated that percentage finer values were in good agreement for particle sizes 1.0 mm and larger. However, distributions for particles finer than 1.0 mm did not agree. Figure 11 shows the QC results between the ERDC and the USGS laboratories. Investigation into why the percent finer values 1.0 mm and smaller differed between the two methods pointed to differences between conventional sieving techniques employed by the USGS and the ERDC laboratory techniques, which used a combination of sieving (64 mm to 1 mm) and laser diffraction (< 1 mm). Previous literature (Eshel, et al., 2004) indicates that laser diffraction results, which are dependent on particle shape, would typically yield coarser sizes than would be obtained with conventional sieve analysis. In other words, sieving biases toward a minimum particle diameter whereas laser diffraction biases toward a maximum diameter. As a result, there is good agreement for sieved QC samples (dashed oval, Figure 6) but significant divergence for percent finer values less than 1 mm obtained by laser diffraction. This trend was verified across all QC samples evaluated in this study.

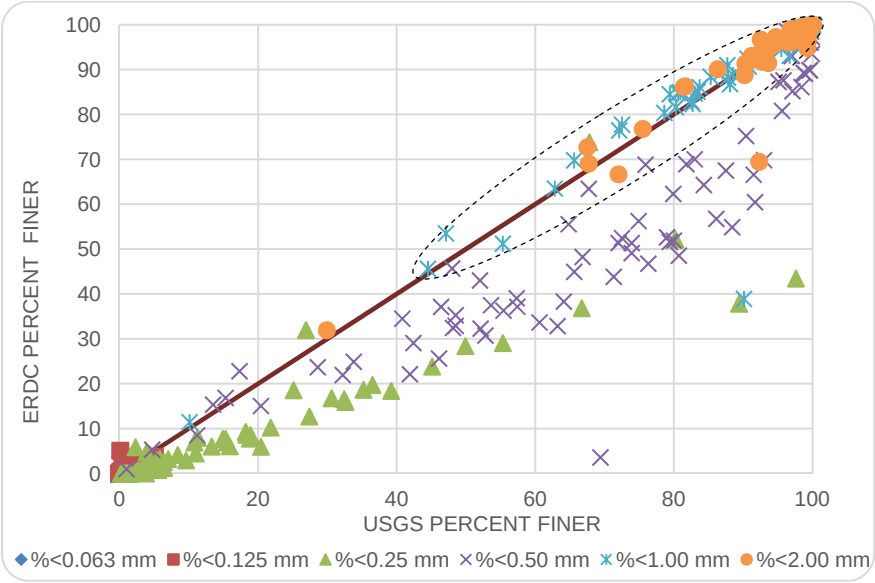

Figure 6 Comparison of size fraction results for quality control samples (particle sizes less than 2.00 mm to less than 0.063 mm). QC results show good agreement for sieve-only samples (dashed oval).

Differences between results obtained using the Sieve-Pipet (SP) method or Laser Diffraction (LD) method identified a need to review variability within the two methods. To assess variability a series of ten replicate analyses using both methods was run using a single sample as the source of material. The primary focus of the assessment was for finer particle sizes because standard sieve analysis was used to determine weights for larger particle sizes.

The average results from replicate analysis shown in Figure 7 provided two significant findings. First, as expected, the LD method consistently produced coarser particle size distributions than the SP method; similar results are reported in the literature (Eshel, et al., 2004). However, a combination of wet sieving with LD produced results similar to the SP method. Second, the SP method estimates greater percentage of very fine silt and clay fractions relative to LD due to prolonged settling times of those particles.

Because a critical component of this study included comparing bed material particle size distributions with the WES (1935) and Nordin and Queen (1992) data, it was necessary to rerun the ERDC samples using sieve analysis for material 0.063 mm and larger.

RESULTS

Grain size distributions for 2013 samples are given in Gaines and Priestas (2014, submitted). The first reach presented is defined as the upper Mississippi River and extends from Grafton to Cairo, Illinois. Grain size distributions for this reach are shown in Figure 8. Sediments of the upper Mississippi River are composed of coarser sand sizes and gravels ranging between 0.5 and 3.5 mm.

The second reach, the lower Mississippi River, extends from Cairo, Illinois to Head of Passes, Louisiana. Grain-size distributions for this reach are shown in Figure 9, and show relatively coarse materials dominating the upper 500 river miles and relatively finer materials dominating the lower 500. The lower Mississippi River sampling locations coincide with reaches sampled in 1932 and 1989. A decreasing trend in median particle size is shown in the downstream direction (Figure 10). This trend is typical of deltaic rivers.

The 2013 sediments were generally finer, more uniform and less variable than sediments collected in 1932 and 1989, though few changes occurred between 1989 and 2013 (Table 2, Table 3, WES, 1935, Nordin and Queen, 1992, and Gaines and Priestas, 2014).

As shown in Table 2 and Figure 11 the relative fractions of gravel and very coarse sand decreased in the upper reaches (above RM 500) since 1932, while the relative fractions of clay, silt and very fine sand have decreased throughout the entire length of the lower Mississippi River, mostly downstream of Baton Rouge (RM 200). These size fractions have been replaced by fine, medium and coarse sands. Essentially, bed materials have fined upstream of RM 500 and coarsened below RM 500. Based on sorting coefficient calculation results given in Table 3 (also see Gaines and Priestas, 2014), the 2013 data have less variability than either the 1989 or 1932 data for all particle size ranges.

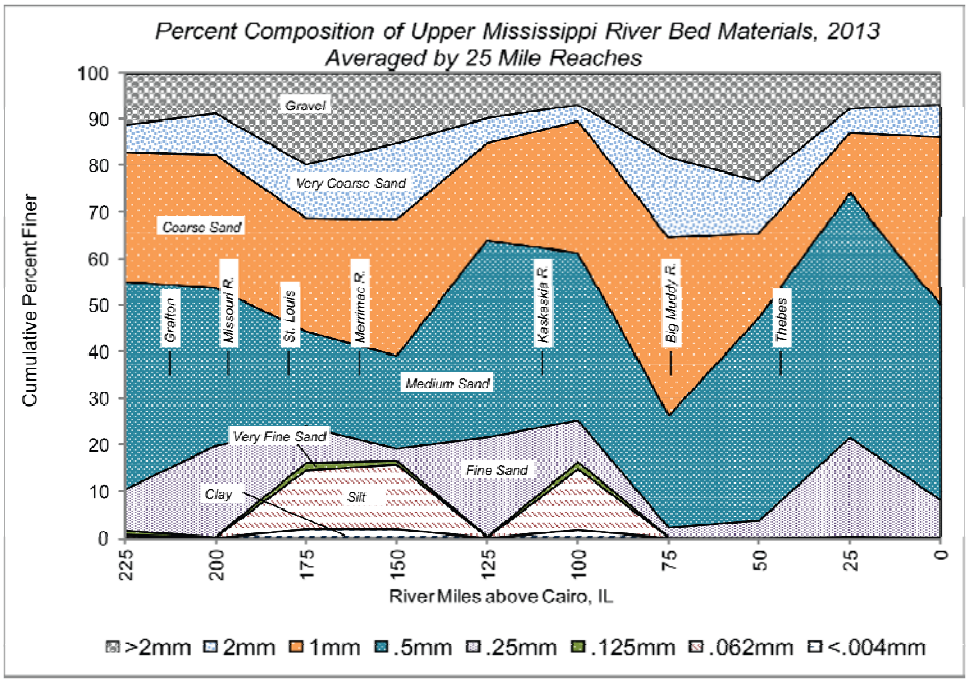

Figure 8 Composition of 2013 Thalweg Bed Material Averaged by 25 Mile Reaches, Upper Mississippi River: Grafton to Cairo, Illinois

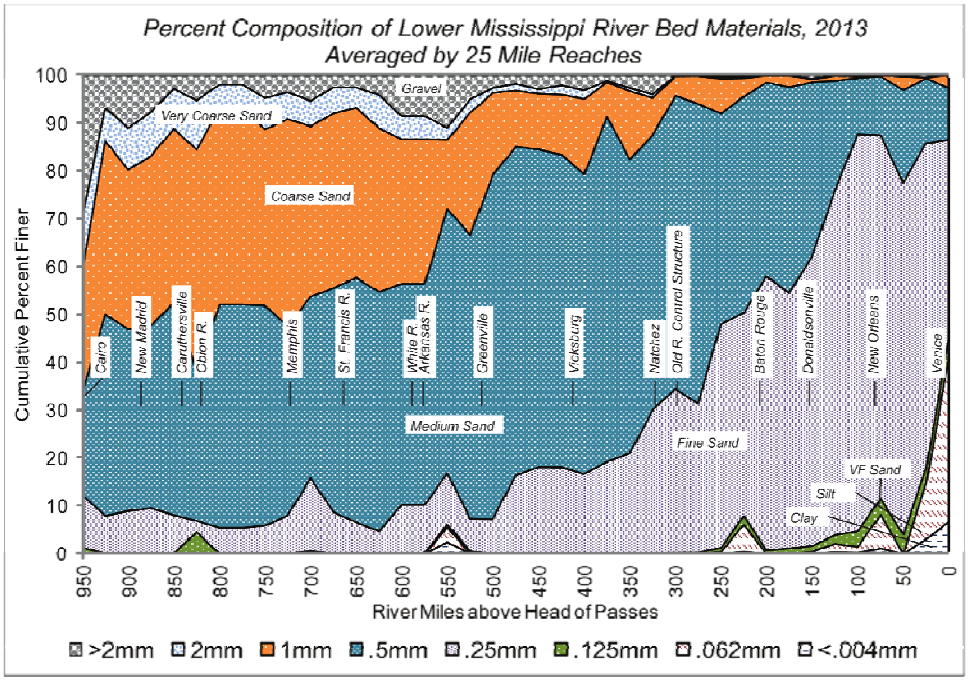

Figure 9 Composition of the 2013 Thalweg Bed Material Averaged by 25 Mile Reaches, Lower Mississippi River: Cairo, Illinois to Head of Passes, Louisiana

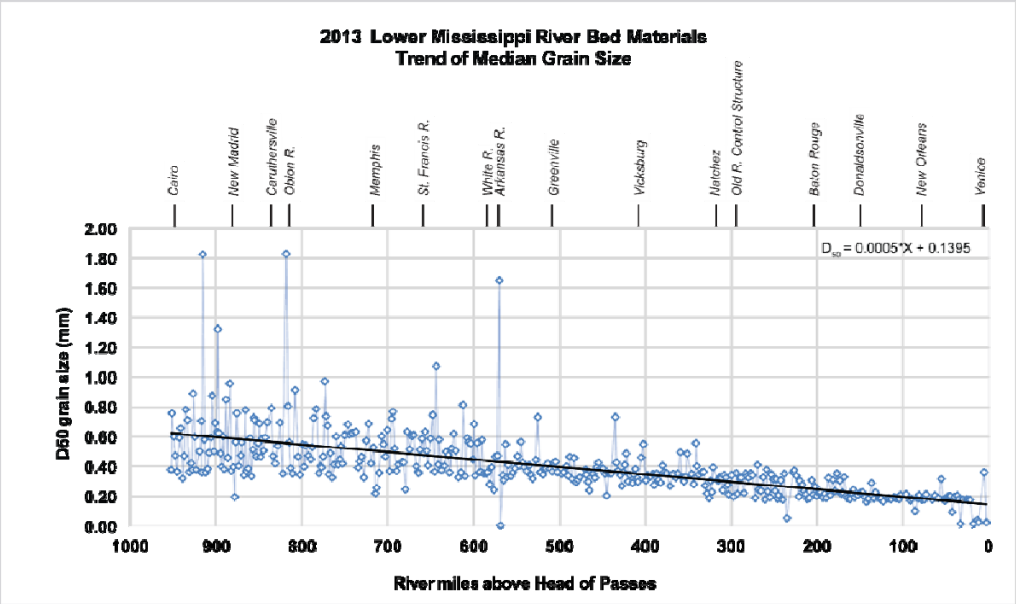

Figure 10 Trend of the Median Grain Size of Mississippi River Bed Materials, Cairo, Illinois to Head of Passes, Louisiana.

Gravel (>2.0 mm) In 1932, bed materials greater than 2.0 mm were prevalent in relative abundance along the lower Mississippi River, averaging from 18% near Cairo, IL to 5% near RM 250. When averaged between Cairo, IL and RM 750, gravel content decreased to 9% by 1989 and 7% by 2013. Between RM 750 and RM 500, average gravel content changed from 9% in 1932 to 4% in 1989 then increased slightly to 6% by 2013, although the percentage of gravel near the confluence of the White and Arkansas Rivers (near RM 550) changed little. Between RM 500 and RM 250, average gravel content changed from 8% in 1932 to 2% by 1989 with no change since.

Very coarse sand (1.0 – 2.0 mm) The magnitude and spatial extent of very coarse sand has changed little since 1932, aside from a slight reduction from 12% to 9% between Cairo, IL and RM 750 with little change since 1989.

Coarse sand (0.5 – 1.0 mm) The coarse sand fraction, present only to RM 150 in 1932, advanced to Head of Passes by 1989 and continued to represent a small percentage in 2013. Upstream of RM 500, coarse sand decreased slightly by a few percent between 1932 and 1989 but exceeded 1932 values by 4-5% in 2013.

Medium sand (0.25 – 0.50 mm) A pronounced increase in medium sand content occurred since 1932, especially within the reaches RM 950 – 750 (29% to 40%), and RM 500 – 250 (47% to 63%). However, a small, 2% reduction occurred in the lower reaches (RM 250 – 0) from 1932 to 1989 and an additional 1% drop since 1989.

Fine sand (0.125 – 0.25 mm) Upstream of RM 500 fine sand abundances increased from 4-9% in 1932 to 9-14% in 1989. Below RM 500 the increases are more dramatic; a near doubling of fine sand abundance occurred between RM 500 – 250 (15% to 28%), while the reach below RM 250 increased from 33% to 54%. Since 1989, the abundance within the reach RM 500 – 250 decreased slightly from 28% to 23% while there was a corresponding increase below RM 250 from 54% to 63%. It is conjectured that this may indicate migration of these materials downstream during episodic flood events. Further studies should evaluate progressive downstream translation of sediment classes through time.

Very fine sand (0.062 – 0.125 mm) Most significant is the marked reduction in very fine sand content throughout the lower Mississippi River, especially downstream of RM 250 where these materials were replaced by fine sands. Between 1932 and 1989, very fine sand content had reduced to near zero values between RM 950 and RM 400 with a small exception at RM 600; this pattern continued to 2013. Below RM 250 very fine sand decreased from an average of 26% in 1932 to 6% and 2% in 1989 and 2013, respectively.

Silt and clay (<0.062 mm) The 1935 WES report did not separate the <0.062 mm fraction into silt and clay sizes; therefore, comparisons of clay abundance are only made between 1989 and 2013. Very little to no change occurred in the silt and clay fractions above RM 500 between 1932 and 2013. Below RM 250, however, silt and clay reduced from an average of 10% in 1932 to 8% in 1989 and finally to 5% in 2013. Between RM 25 and RM 0 the silt and clay fractions have displaced the very fine sand present in 1989.

1932	2.25	0.96	0.44	1.67	2.74

D_{84}, D_{50}, and D_{16} are sizes for the 84th, 50th, and 16th percentiles of the sediment grain size distribution

Sorting Coefficient, $\sigma = \frac{(D_{84}/D_{50}+D_{50}/D_{16})}{2}$

SUMMARY AND CONCLUSIONS

A total of 754 samples were collected during November 2013 between Grafton and Head of Passes. Samples were collected using the same four-inch pipe dredge and sampling techniques used by previous investigators in 1932 and again in 1989.
Particle size distributions of sands and coarser material were determined by standard sieve analysis. Particle size distributions of finer sediments were determined by Laser Diffraction with quality control of randomly selected samples by pipet analysis.

The main conclusions of this investigation are as follows:

1. The 2013 samples were significantly finer relative to 1932 (Table 3). On average the median grain size in 2013 (0.43 mm) is about 50% less than that of 1932 (0.96 mm), but little change in median grain size has occurred since 1989 (0.46 mm).

2. The 2013 samples were more uniform relative to 1932 and 1989, demonstrated by reductions in the sorting coefficient and standard deviation values (Table 3; Gaines and Priestas, 2014).

3. Since 1932, upstream of RM 500 there were marked declines in the percentage of gravel and very coarse sand, replaced by fine, medium and coarse sand. In contrast, below RM 500 there were marked declines in the clay, silt and very fine fractions, replaced by fine and medium sands. Thus, the river is becoming coarser downstream and fining upstream.

4. The 2013 samples contained less gravel than the 1932 and 1989 samples except between RM 650 to RM 575.

5. Laser Diffraction methods produce slightly different results from sieve-pipet methods. LD results trend toward coarser particle sizes than yielded from SP analysis. Pipet analysis may overestimate particle sizes < 0.063 mm due to Brownian motion and inter-particle forces which can influence the settling characteristics of the sediment.

DROUGHT, LOW WATER, AND DREDGING OF THE MIDDLE MISSISSIPPI RIVER IN 2012

David C. Gordon, P.E., Chief, Hydraulic Design Section, U.S. Army Corps of Engineers – St. Louis District, St. Louis, Missouri, david.gordon@usace.army.mil
Michael T. Rodgers, P.E., Project Manager, U.S. Army Corps of Engineers – St. Louis District, St. Louis, Missouri, michael.t.rodgers@usace.army.mil

Abstract: In early 2012, low snowpack in the Rocky Mountains and the northern plains, followed by extreme heat, and prolonged drought in the plains and Midwest led to a long period of low water and record low stages on the Middle Mississippi River from June to February 2013. A drought of this magnitude had not occurred along the Mississippi River since 1988 and 1989. The U.S. Army Corps of Engineers (Corps) is responsible for maintaining a minimum 300 foot wide by nine-foot deep navigation channel. This task was especially challenging in 2012 as the drought carried on and conditions and forecasts worsened. However, due to strategic planning, engineering, and construction activities since the last major drought, the Corps was able to significantly lessen the impacts and provide a navigable channel throughout the drought and low water period through a combination of river engineering, dredging, forecasting, monitoring, and communication.

Although the Corps worked around the clock and seven days a week to dredge the channel, the amount of sediment that was dredged from the river channel was less than half of what needed to be dredged during the previous drought year. This is despite the fact that the number of low water days was more than in 1988/89 and the channel was dredged to greater depths in 2012. This paper will discuss what led to the significant improvement in the navigation channel, which included increased reliability and lower maintenance.

INTRODUCTION

The St. Louis District Corps of Engineers is responsible for maintaining a safe and dependable navigation channel on approximately 300 miles of the Mississippi River between Saverton, Missouri and Cairo, Illinois. The southernmost 195 mile section of the Upper Mississippi River, located between the confluences of the Missouri River and the Ohio River, is often referred to as the Middle Mississippi River. The Middle Mississippi River is a critical link in the inland navigation system and vital to the nation's economy. It is the middle link that connects the Lower Mississippi River and Ohio River systems with the Upper Mississippi River, Illinois River, and Missouri River systems. The Middle Mississippi River is unique because it is an open river system while the Upper Mississippi, Illinois Rivers, and Ohio Rivers use locks and dams to supplement navigation depths. The Lower Mississippi River is also open river system but has a much greater discharge that naturally supplements navigation. Therefore, maintaining navigation depths on the Middle Mississippi River has always been a significant challenge for river engineers. Engineers typically use a combination of river training structures, revetments, and maintenance dredging to keep the minimum nine-foot deep navigation depth year round.

While always a challenge, maintaining the navigation channel was made far more difficult in the fall and winter of 2012 due to extreme drought conditions in the Mississippi River watershed

(Figure 1). The drought was equal to or worse than any drought experienced in the past five decades. Water levels in the Middle Mississippi River reached near record lows, which posed a significant risk to commercial navigation traffic due to shallow channel crossings, reduced channel widths, and rock pinnacles located along the channel bottom (Figure 2).

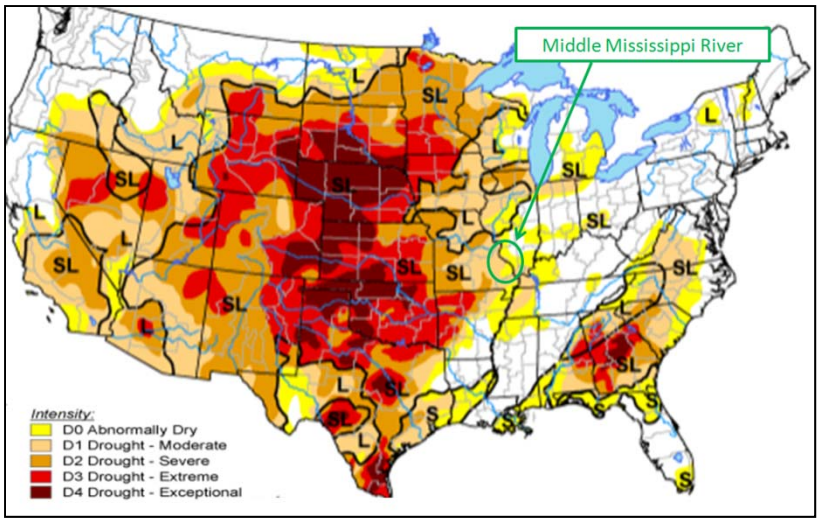

Figure 1. U.S. Drought Monitor map on January 1, 2013. (http://droughtmonitor.unl.edu/)

Figure 2. Drought and low water on the Middle Mississippi River meant exposed sandbars, hazards for navigation, and a narrow navigation channel.

EARLY SIGNS OF DROUGHT IN SPRING 2012

As early as April 2012 river engineers, water control managers, and the dredging team began preparing their staffs and upper management for the possibility of drought and probable low

water which would occur in the summer, fall, and winter of 2012. The weather in spring 2012 produced very little rainfall throughout the Midwest U.S. on top of a low snowpack in the Rockies and the plains, therefore the Mississippi River was much lower than normal for typical spring conditions. A flood level of 30 feet on the St. Louis gage is typically reached at least once during the spring rainy season, with a combination of inflows from the Upper Mississippi, Missouri, and Illinois basins. However, in 2012 the St. Louis gage only approached 20 feet briefly on just two occasions, in late March and again in early May. Otherwise, the stage remained well below normal throughout the spring and by early June was already ten feet below average. The river stages in 2012 were following a similar pattern to the stages early in the 1988/89 drought (Figure 3).

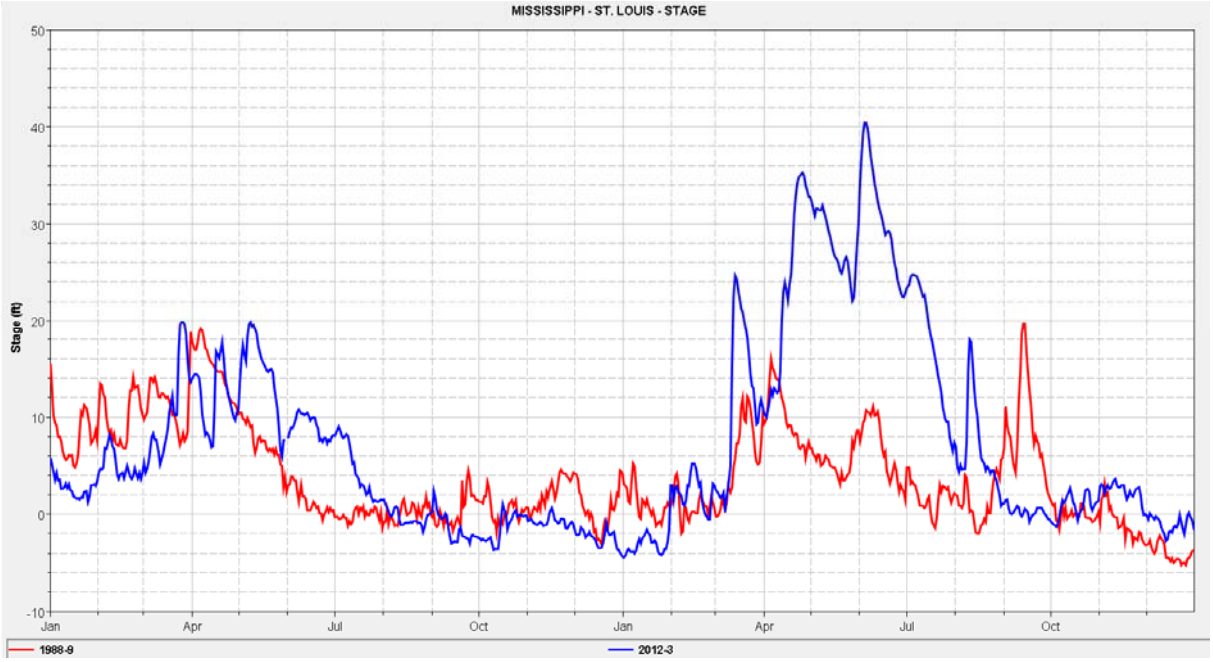

Figure 3. River stages at the St. Louis Gage over a 2-year period comparing 1988/89 with 2012/13.

The St. Louis District began communicating these conditions to the Corps Mississippi Valley Division (MVD) Office, River Industry Action Committee (RIAC), the River Industry Executive Task Force (RIETF), the United States Coast Guard (USCG), National Weather Service (NWS), and the United States Fish and Wildlife Service (USFWS). The teams discussed communication strategies, water management, forecasting, navigation channel monitoring, dredging capability, rock removal from the navigation channel, and various action levels/plans.

The team decided to start monitoring the navigation channel for trouble spots much earlier than a normal year. Channel reconnaissance surveys and pre-dredge surveys were collected early and often. The USCG Cutters and the Corps MV Pathfinder began patrolling the channel and resetting the channel marking buoys weekly. The St. Louis Harbor became narrow and congested as fleets encroached upon the navigation channel (Figure 4).

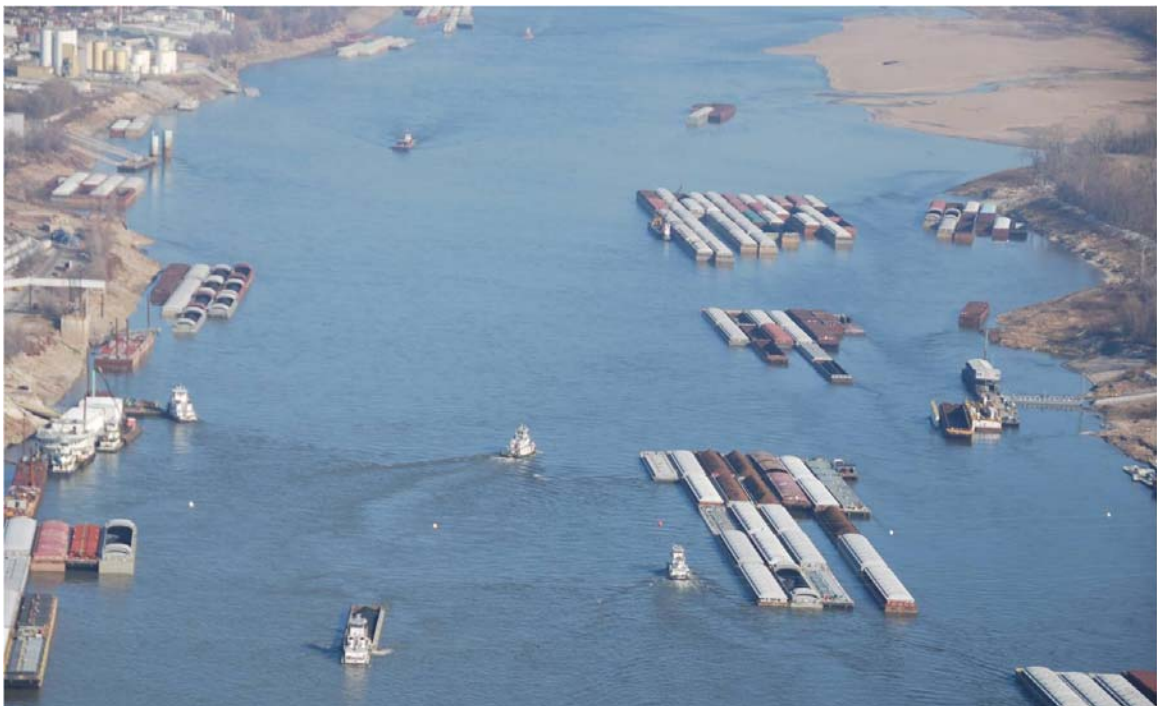

Figure 4. Low water conditions in the St. Louis Harbor meant that space for fleeting operations was limited.

DROUGHT RESULTS IN RECORD LOW WATER

Just as the Corps predicted in the spring of 2012, the drought took hold of the Midwest throughout an extremely hot summer. A sustained period of low water occurred on the Middle Mississippi River from June 2012 through the beginning of February 2013. The lowest stage at St. Louis during the low water period occurred in January 2013. A stage of -4.6 feet tied for the 7th lowest on record and was the lowest river had been since the drought of 1988/89 (Table 1). The length of the time the river remained at extreme low stages was also a concern. A stage of 0 feet on the St. Louis Gage is typically used by the Corps, the USCG, and the navigation industry to indicate low water and trigger additional action. The river stayed below 0 feet at St. Louis for 160 days during this period. By comparison, the river was below 0 feet for just 94 days in 1988 and 112 days in 1989. River engineers know that the longer the River stays below 0 feet, the more "lazy" it becomes as velocities and sediment carrying capacity declines. This results in more sediment accumulating in problematic reaches causing more problems for river industry.

Dredging during the low water event proved to be a significant challenge. Dredging operations began in early July 2012 and continued through February 2013 (Figure 5). The dredging team worked to prioritize dredging locations based on dredge efficiency and channel depths. Channel depths were continuously monitored through extensive channel patrol surveys. On typical years, the channel is dredged in order to maintain navigation depths 9 feet below a St. Louis stage of -3.5. Based upon forecasts for the fall and winter of 2012, the team decided to prepare the channel for a stage of -5.5 feet instead. Later in the year, when forecasts predicted that stages could be below -6.0 feet, the team decided to prepare the channel for a stage of -7.0 feet. This

new channel design was also predicated on the ongoing removal of rock pinnacles that were in the channel near Thebes and Grand Tower Illinois that would also allow depths to -7.0 when completely removed in January 2013 under an Urgent and Compelling Contract.

Rank	St. Louis Stage	Month/Year
1	-6.2	Jan 1940
2	-5.8	Jan 1963
3	-5.6	Jan 1964
4	-5.5	Dec 1937
5	-5.4	Dec 1989
6	-4.8	Jan 1957
7	-4.6	Jan 1956
	-4.6	Jan 2013
9	-4.5	Jan 2003
10	-4.3	Dec 1933

Table 1. A ranking of the lowest daily stages recorded at the St. Louis, Missouri river gage.

Figure 5. The Dredge Potter moves to the side to allow a tow to pass in September 2012.

The complexity and significance of the rock removal component of the mission cannot be overstated. This work required integrated and coordinated management along with the application of innovative technology and tools / removal methodologies. Risks associated with barge tow collisions with rock pinnacles were high, from both a fiscal and an environmental perspective. Current and future river construction contract needs were adjusted in order to fund the rock removal project. River engineering projects were reprioritized to allow for detailed plans and specifications to be produced to accommodate a tight project schedule. Removal of

the pinnacles involved advanced surveying techniques coupled with innovative removal methodologies. Work locations within the rock removal areas were prioritized to get the most dangerous (highest elevation) rock out first, with a secondary focus on providing optimal channel widths.

Water managers constantly collected water data, monitoring a number of hydrological and meteorological factors to forecast river conditions the rest of the low water team relied upon. Continuous monitoring of flows from the Middle Mississippi River tributaries and associated impacts played an important role in decision making. In close coordination with USCG and NWS, water managers operated Mel Price Locks and Dam, just upstream of St. Louis, under a deviation with a higher pool to alleviate impacts of water level fluctuations through the St. Louis Harbor. During the most critical water levels, the managers also utilized water in Carlyle Lake to augment flows for navigation purposes over the lower section of the Middle Mississippi River in order to temporarily increase stages.

Throughout the entire low water period, the District coordinated with project stakeholders including (but not limited to) RIAC, RIETF, the USCG, the NWS, and USFWS. The task of keeping the Middle Mississippi River open to commercial navigation is highly visible, politically sensitive, and extremely complex. Therefore, the district maintained close coordination of their activities with MVD, the Corps Headquarters Office in Washington D.C., the Assistant Secretary of the Army's (ASA) Office, the Department of Homeland Security and the White House. This required sending daily updates and information to all entities regarding: compliance with all relevant environmental regulations (National Environmental Policy Act (NEPA) and Fish and Wildlife Coordination Act (FWCA)); management of pool and reservoir elevations; forecasted river levels; status of the removal of the underwater rock pinnacles; dredging activities, including shoal locations; and providing a nearly continuous flow of channel and rock pinnacle surveys.
As a result of these activities during this low water event there were no accidents, groundings or unplanned closures of the Middle Mississippi River. This performance was unprecedented given that a similar drought in the late 1980's featured numerous groundings, accidents, channel closures, restrictions and a generally unreliable channel.

THE MIDDLE MISSISSIPPI RIVER NAVIGATION CHANNEL, NOW AND THEN

Accurate records of groundings during the 1988/89 drought are not readily available. However, according to newspaper articles, there were 22 groundings in just one weekend in December 1989 which caused the USCG to essentially close the entire Middle Mississippi River until conditions improved. By comparison, throughout the entire 2012/13 low water event there were no groundings or unplanned closures within the marked navigation channel. Some barges went aground on a few occasions, but in each situation it was determined that the tow had grounded outside of the marked channel.

What is the difference between the channel in 1988/89 and the one today? Following the drought of 1988/89 the St. Louis District embarked upon an aggressive river engineering project that resulted in the development, design and construction of innovative structures such as bendway weirs and chevrons that have significantly reduced channel maintenance dredging and resulted in a much more reliable channel during the 2012 drought. The Regulating Works

Project utilized innovative techniques to redesign the navigation channel which has led to the development of new types of river training structures.

Bendway Weirs were developed in the early 1990's as a means to improve navigation around the tight bends that are typical along the Middle Mississippi River. The development of these structures has been revolutionary for river engineers and the navigation industry. Over 175 bendway weirs have been constructed on this part of the River which has resulted in a significant reduction in the dredging of point bars and the elimination of accidents through these bends.

River engineers in the St. Louis District realized that for the project to be sustainable they had to adjust their design techniques and parameters in order incorporate environmental features into their navigation channel improvement projects. The engineers worked with closely with biologists in the Corps partnering agencies to develop different types of versatile structures in order to both protect the environment and to improve navigation. River training structures such as chevrons (Figure 6), off-set dikes, and W-dikes have successfully implemented by the river engineers in the St. Louis District. These types of structures have been shown to provide both navigation and environmental benefits.

Figure 6. Chevron river training structures near River Mile 32.

The St. Louis District also developed Hydraulic Sediment Response (HSR) models for use in the design of river training structures. After HSR models were fully developed, the District established the Applied River Engineering Center as a facility to conduct these physical models and other sediment studies of the Mississippi River and its tributaries. The use of the HSR models and AREC allowed the district to efficiently study and design multiple sets of river training structures that had both navigation and environmental benefits. The AREC facility has been used regularly to engage and collaborate with the environmental community during the entire design process. The technology has also allowed the engineers to be so efficient with the designs that the Project did not have enough capacity to implement the construction of these designs on a yearly basis. Therefore, many designs were put on the shelf to await funding.

When requests for projects eligible for the American Recovery and Reinvestment Act (ARRA) came about in 2009, the district was well positioned to act. Multiple river training projects qualified as "shovel-ready" and were funded by ARRA. The construction of these ARRA river training structures remedied many of the chronic dredging locations and led to a more reliable navigation channel.

Operational changes were also been undertaken to improve the district's responsiveness to low water events. A Project Delivery Team (PDT) consisting of elements from river engineering, water management, dredging, and surveying continue to meet weekly throughout the year to address river conditions in a timely manner. Outreach to both other government partners (USCG, NWS, etc.) and the river industry has led to a better understanding of, and response to, navigation concerns. A weekly channel status report is sent to the river industry and other invested partners. Internally, a river condition status report is generated weekly to anticipate dredging and surveying needs.

Surveying capabilities have also dramatically increased district responsiveness. Equipment improvements such as multi-beam sonar and increased surveying capacity utilizing two contract surveying companies have also led to an increased awareness of the state of the channel over the capabilities that were available in 1988/89. Survey data can now be sent directly from the boat to the office for post-processing and analysis leading to channel evaluations that can almost instantly be shared with the navigation industry.

Water management and forecasting have also greatly improved. Critical coordination occurred throughout the day and night with water managers upstream of St. Louis, including the Rock Island District for the Upper Mississippi and Illinois Rivers and the Northwest Division for the Missouri River. The St. Louis District constantly monitored inflows and adjusted the outflow at Mel Price Locks and Dam to alleviate impacts of water level fluctuations through the St. Louis Harbor. The District also utilized the available water in Carlyle Lake to augment flows for navigation purposes over lower portion of the Middle Mississippi River in order to temporarily increase stages by timing the releases as the water had to travel down the Kaskaskia River.

During low water, channel patrol efforts using the Corps M/V Pathfinder were increased to identify problem areas, replace or move buoys to better mark the narrowing channel. Assuring the channel is well marked prevents groundings which may further degrade the channel and defers dredging until a dredge can be assigned to that specific location. The USCG also increased their buoy tending runs. Schedules for the patrols between USACE and USCG are coordinated to maximize coverage on the system.

THE RESULTS OF THE RIVER ENGINEERING PROGRAM

In 1988 and 1989 alone, over 19 million cubic yards of material were dredged each year for a total of 38.1 million yards of material removed from the navigation channel. Compare that to the low water period of 2012/13 where only 9.3 million cubic yards of material were removed in just the one year. While the drought of 1988/89 encompassed two full dredging seasons and the drought of 2012/13 was only in one dredge season, the events can be compared considering that no two droughts are the same. Not only was significantly less material removed in 2012 by

comparing that year to either 1988 or 1989, but the channel was fully prepared for a stage of -7.0 at St. Louis, which was a full 3 feet lower than in 1988/89 (Table 2).

Dredge Season	Days below 0 ft at St. Louis	Dredge Volume (cubic yards)	9 ft Navigation Channel Prepared to a St. Louis Stage of:
1988	94	19,100,000	-4.0
1989	112	19,000,000	-4.0
2012/13	160	9,300,000	-7.0

Table 2. The period of low water and dredging volumes compared between the drought of 1988/89 and 2012/13.

The St. Louis District's river engineering program developed a ranking system of chronic dredging locations in order to prioritize the construction of river training structures. The system is based on a weighted average of the last 5 and 10 years of dredging in two mile river segments. The top ten dredging locations by volume in 1988/89 are shown in Table 3. The table shows the volume of material removed from these locations in 1988/89. The table also shows that the river engineering program has reduced the amount dredged from these locations by an average of 82%. The changes mentioned above highlight just a small portion of the changes that have occurred on the river in the last 25 years to reduce the number of lower water or confined channel dredging locations. Under multiple programs, over 175 bendway weirs were constructed since 1989 to widen the navigation channel and increase center channel depth. These same programs have funded multiple new dikes, chevrons, and other river training structures over the past 20 years to improve and maintain channel depth.

River Mile	1988-89 Rank	Dredged in 1988-89 (cy)	Current Rank	Dredged in 2012 (cy)	Percent Reduction
52 - 54	1	2,228,800	38	35,468	-98%
42 - 44	2	1,892,600	36	225,500	-88%
66 - 68	3	1,706,700	5	530,976	-69%
38 - 40	4	1,646,000	6	323,781	-80%
6 - 8	5	1,545,700	34	167,213	-89%
46 - 48	6	1,257,800	8	450,047	-64%
30 - 32	7	1,246,400	24	112,748	-91%
28 - 30	8	1,232,400	37	0	-100%
166 - 168	9	1,204,300	16	366,400	-70%
14 - 16	10	1,125,000	33	350,308	-69%

Table 3. The top ten ranked dredging locations in 1988/89 compared to 2012.

An analysis of the most troublesome dredging locations in 1988/89 compared to 2012 is even more dramatic. In 1988/89 the worst 20 miles of river accounted for over 15 million cubic yards of dredging over these two years. The worst dredging location for the 1988/89 time frame was the stretch of river from River Mile (RM) 54 to 52, near Cape Girardeau, Missouri. This stretch

was responsible for over 2.2 million cubic yards of dredging between 1988 and 1989. Since then, bendway weirs have been placed at the upstream extent of the stretch. In 2012, less than 36,000 yards were dredged in this reach for a 98% reduction.

The second-most dredged location in 1988/89 was between RM 44 and 42, near Thebes, Illinois. This reach of river required nearly 1.9 million cubic yards of dredging, with the dredging partially necessitated by the presence of submerged rock pinnacles that constrained the navigable channel. Since 1989, several additional dikes were constructed to better maintain flow alignment in the navigation channel. Efforts have also been made to remove the rock pinnacles to increase navigable channel width, both in 1989 and in 2012. In 2012, only 225,000 yards of material were dredged for a reduction of 88%.

The third-most dredged location was between RM 68 and 66, near Moccasin Springs, Missouri. In 1988/89, this area required over 1.7 million cubic yards of dredging. Dike extension was used in this reach to reduce dredging by 69% in 2012. Although this is a significant reduction, the reach still ranks currently as the 5th highest priority for work on the Middle Mississippi River based on dredging. To address the ranking, this stretch was recently studied with a HSR model with the principle goal of further alleviating the need for dredging. Construction of several innovative river training structures is scheduled for fiscal year 2016. The Project will not only reduce dredging in the main channel, but will add significant environmental enhancement in the form of a side channel or chute.

CONCLUSION

The nation's economy is heavily dependent upon the safe operation and reliability of the Middle Mississippi River corridor that transports 110 million tons per year or nearly $34 million worth of goods on a daily basis in and out of the St. Louis Harbor. Shut downs and delays to the river navigation industry can have profound effects on a regional and national level.

The entire 2012 low water effort resulted in a navigation channel that remained open for commerce throughout the drought, without any groundings or accidents within the channel, and generally led to a much more reliable channel for shippers. The implementation of a successful river engineering program led to the reduction in sediment and dredging volume as compared to a similar drought and low water period in 1988/89. Furthermore, improvements in hydraulic modeling, design of river training structures, water management techniques, bathymetric data collection, coordination with the towing industry and the Coast Guard, and the identification and removal of rock outcroppings from the riverbed can be also credited with the improvements.

This improvement in dredging was the result of an aggressive 20+ year long river engineering program that has reduced dredging costs and increased the safety and the reliability of the channel. The development and implementation of innovative river training structures, such as bendway weirs and chevrons, resulted in a much improved navigation channel while also creating diverse aquatic habitat.

In conclusion, the Middle Mississippi River Regulating Works Project since 1988/89 has resulted significant improvements to:

- Dredging – Significant reductions in the volume of dredge material resulting in a much lower Operations and Maintenance (O&M) cost.
- Depth – A river channel that can be maintained to deeper depths if needed, closer the authorized channel depth, for much less cost.
- Reliability – Shippers and carriers have much greater confidence in the ability of the River to carry goods when needed. This confidence means that more goods will be transported by the River every year that it can be demonstrated that the channel will be available full time and without delay.
- Safety – The 2012/13 low water period resulted in zero channel groundings and no incidents of hazardous chemicals spilled as a result of an accident.
- Habitat – The Middle Mississippi River contains more diverse aquatic habitat through the use of innovative river training structures such as chevrons, W-dikes, multiple round point structures, side channel enhancement dikes, and off-set dike extensions.

MISSOURI RIVER 2011 FLOOD – CHANNEL RESPONSE AND OBSERVATIONS

Chris Svendsen, Hydraulic Engineer, USACE Omaha District, Omaha, NE, christopher.j.svendsen@usace.army.mil; Dan Pridal, Hydraulic Engineer, USACE Omaha District, Omaha, NE, daniel.b.pridal@usace.army.mil;

ABSTRACT

The Missouri River 2011 flood event within Omaha District resulted in a sustained high peak flow with unprecedented duration. The Missouri River and entire floodplain experienced large areas of sediment erosion and deposition. Normal Corps activities include the monitoring of degradation and aggradation reaches on the Missouri River associated with Missouri River dam construction and also conditions within the navigation channel. Post-flood observations indicated sediment deposition, scour, and significant damage. Survey data was collected and hydraulic modeling performed in support of numerous programs for post-flood repairs. A review of the post flood status of several specific projects and observed channel response during and after the flood are presented.

INTRODUCTION

Introduction

The purpose of this report is to present gage stage trends on the Missouri River within the Omaha District from Ft Peck, MT, to Rulo, NE with a focus on 2011 flood impacts. Gages provide data with which to monitor changes in the river due to hydrologic events and construction of main stem dams and river structures. Record releases occurred from all Missouri River dams in 2011. This report addresses the stage to discharge relationship at each gage, the effects of the 2011 high flows, and how the stages have responded Additional response to or recovery from the 2011 event is expected to continue in many areas in the future.

The views expressed in this paper are those of the authors and do not necessarily reflect the official policy or position of the United States Army Corps of Engineers, the Department of the Army, Department of Defense, or the United States Government.

Description of Missouri River System

The Missouri River Mainstem system of dams is composed of six large earth embankments, which impound a series of lakes that extend for 1,257 miles from Gavins Point Dam near Yankton, SD to the head waters of Fort Peck Lake southeast of Glasgow, MT. These dams were constructed by the Corps of Engineers on the mainstem of the Missouri River for flood control, navigation, power production, irrigation, water supply, water quality, recreation and fish and wildlife enhancement. Fort Peck Dam, the oldest of the six, was closed in 1937. Fort Randall Dam was closed in 1952, followed by Garrison Dam in 1953, Gavins Point Dam in 1955, Oahe Dam in 1958 and Big Bend Dam in 1963. The dams provide nearly 988,000 acres of water surface area and extend a total length of 750 miles. There are 325 miles of open river between the lakes. The reservoirs contain an aggregate storage volume of approximately 73 million acre-feet, three times the average annual flow of the Missouri River at Sioux City, IA. There are 811 miles of open river downstream from Gavins Point Dam to the mouth of the Missouri River where it enters the Mississippi River at St. Louis, Missouri. The Omaha District Boundary ends at mile 498.

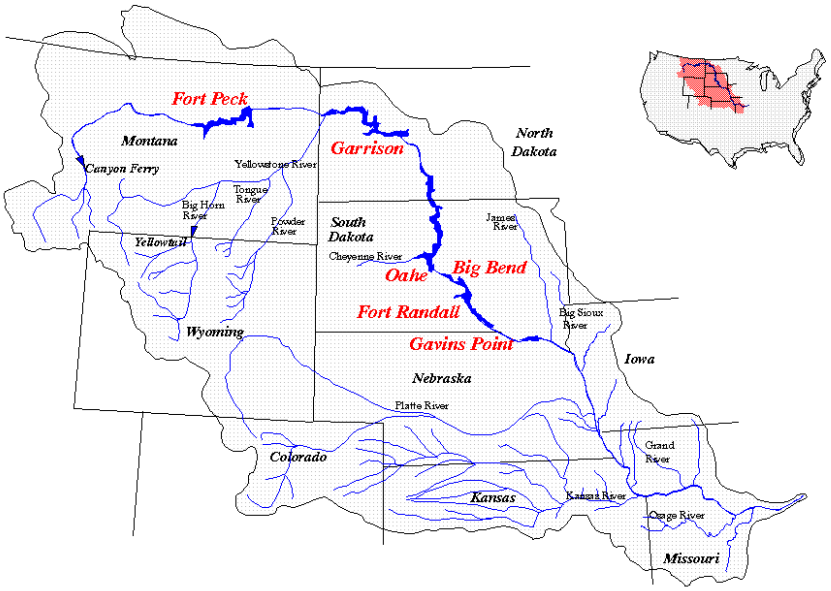

Figure 1 Missouri River Basin

Significance of 2011 Event

Flow Measurements and Observations

The 2011 runoff year was the highest runoff year of record in the upper Missouri River basin since records were initiated in 1898. Upstream of Sioux City, IA, annual runoff volume was estimated at 61 million acre-feet (MAF). In comparison, the previous greatest annual runoff volumes were 49 MAF in 1997 and a roughly estimated 50 MAF in 1881. For the period from March – July, the 1881 runoff volume was more than 40 MAF compared to 48.4 MAF for 2011 (USACE, 2013b).

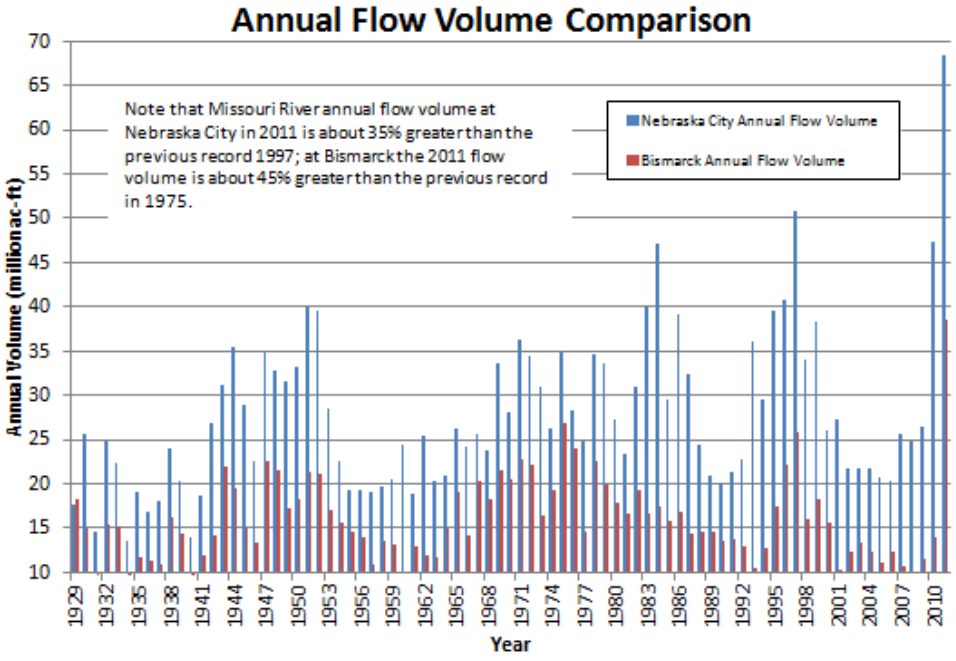

Figure 2 Nebraska City and Bismarck Annual Flow Volume Comparison

When compared to historic events, it should be recognized that historic river flows were affected by main stem dam construction and reservoir filling, primarily in the period 1953 to 1967. All flow frequency values reported in the comparison are post dam construction (USACE, 2003). As a result, compared to historic events is somewhat misleading since the reservoir system has significantly altered peak flows. Data from the USGS gage at Nebraska City is shown in Figure 3.

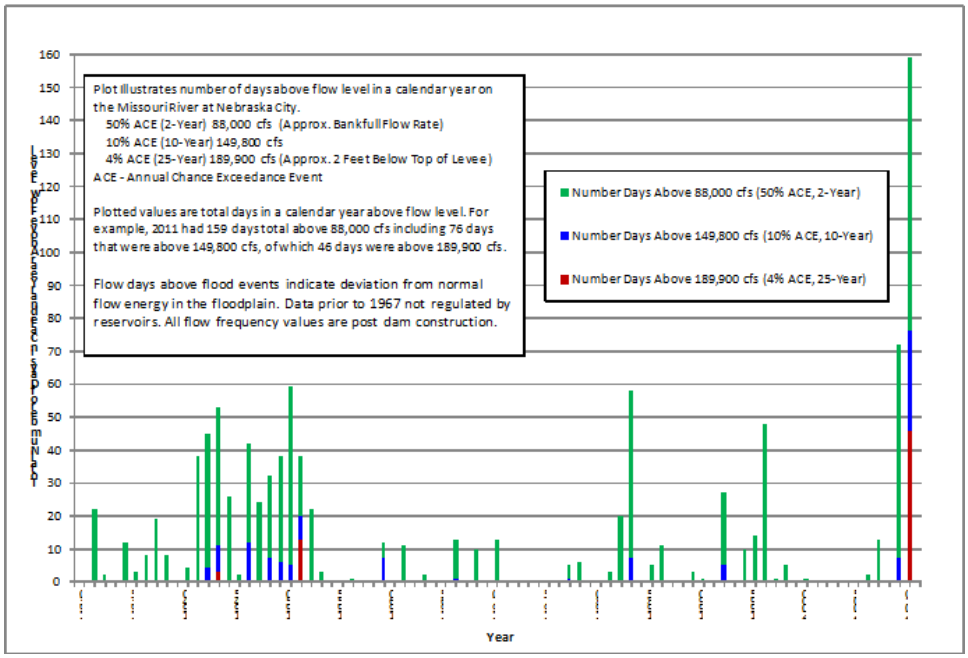

Figure 3 Nebraska City Days above Flow Value by Year

The above figure illustrates the severity of the 2011 event. Using the 189,900 cfs benchmark for comparison, the 2011 event dwarfs all other flood events on the Missouri River. This event was unique in the historic record with the floodplain inundated at a very high level for a prolonged duration. Table 1 presents additional information at both Nebraska City, NE, and Bismarck, ND.

Table 1 Nebraska City and Bismarck, Number of Days above Flow Value by Year

Nebraska City

Event	2011	1993	1984	1952	1944	Total (All Years)	2011 % of Total
189,900 cfs 4% ACE (25-Year)	46	0	0	13	3	62	74
149,800 cfs 10% ACE (10-Year)	76	5	7	20	11	169	45

Bismarck

Event	2011	1997	1975	1952	1944	Total (All Years)	2011 % of Total
81,000 cfs 2% ACE (50-Year)	90	0	0	8	14	192	47
57,000 cfs 10% ACE (10-Year)	105	19	46	20	38	545	19

40,000 cfs 50% ACE (2-Year)	134	186	93	58	61	1716	8

Total refers to the number of days above given flow target since gage record began in 1929. Includes the period prior to dam construction. Historic large events tabulated to provide comparison to 2011.

Sediment Measurements and Observations

Sediment measurements were conducted at a number of locations by the USGS during the 2011 event. These sediment measurements during the 2011 event were compared to historic measurements from both the pre- and post-dam era. Measurements indicate a dramatic difference in the suspended sediment vs. flow relationship for the 2011 event. Suspended sediment plots from 2011 and other periods for comparison are illustrated for Nebraska City, NE in Figure 4 and for Bismarck, ND, in Figure 5 .

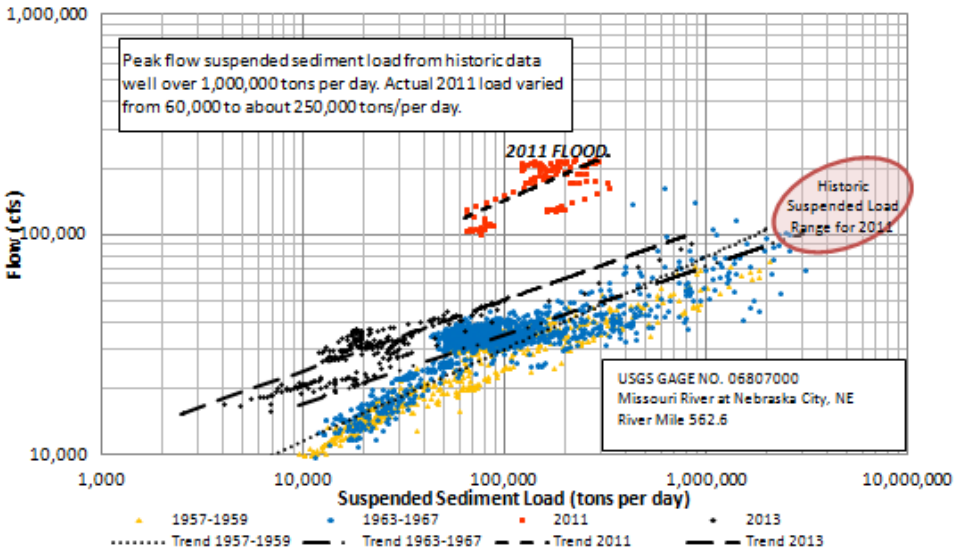

Figure 4 Nebraska City Suspended Sediment Load Comparison from Various Time Periods

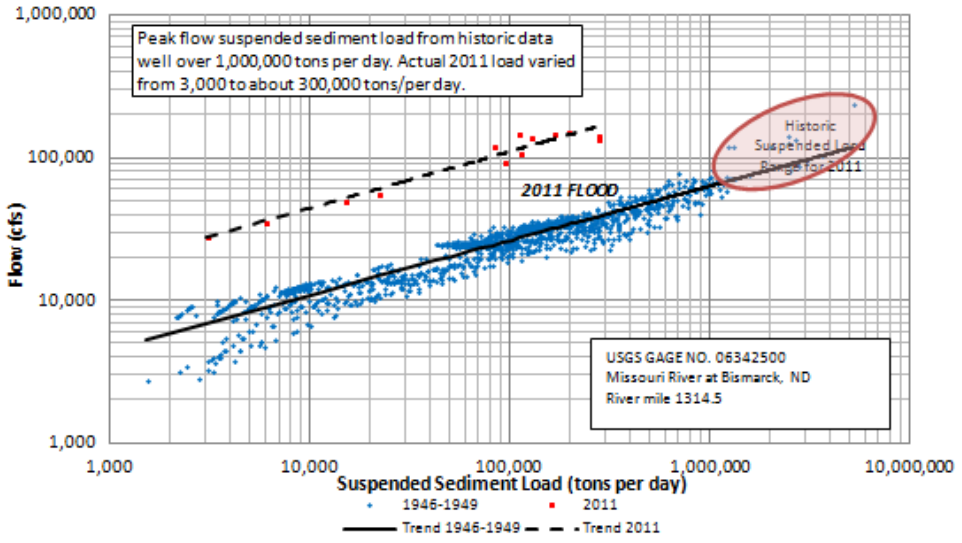

Figure 5 Bismarck Suspended Sediment Load from Various Time Periods

Gage Analyses and Methods

Stage trend plots presented in this report contain data points taken off rating curves or recorded historic data. Two methods are used to develop the rating curves. The first is to plot USGS field measurements (stage/discharge) for a certain water year and fit a rating curve through the points. The second method is to obtain average daily stage data from recorders at the gages and combine that information with average daily discharge measurements from dams and stage/discharge gages on tributaries or from a stage/discharge gage immediately upstream of the subject gage.

Major rivers such as the Missouri River often exhibit the characteristics of a looped rating curve as illustrated by individual gage data; one for the rising limb of the flood hydrograph when flows are increasing up to the occurrence of the flood peak and a second curve for the receding side of the flood hydrograph with decreasing flows from the peak.

Fort Peck Dam to Lake Sakakawea

Geographic Description

Fort Peck Dam is located on the Missouri River at RM 1771.5 in northeastern MT. The project was placed in operation for navigation and flood control in 1938. The Fort Peck degradation reach is considered to extend from the dam nearly 173 miles downstream to RM 1598. The Milk River is the major tributary in this reach entering the Missouri River about 10 miles downstream of the dam. The aggradation reach extends downstream from RM 1598 to the Williston, ND area. The Yellowstone River is the major tributary entering this reach near RM 1578.

Degradation Reach

This reach appears to be more stable than other reaches in the system. West Frazier Pumphouse and Wolf Point have behaved similarly. Trend plots show that the stages for a 10,000 cfs flow had dropped about three feet from 1950 to the mid-1980s, then changed little overall until 2011. Since 2011 the West Frazier gage showed slight degradation whereas the Wolf Point gage showed about 1.5 feet of degradation in 2012, followed by a slight rebound in 2013. Stages for the 20,000 and 30,000 cfs discharge have changed little since the mid-1980s at West Frazier, but dropped another 1 to 2 feet at Wolf Point by 2011, with a rebound occurring in 2013 at 20,000 cfs. At Culbertson, about 150 miles below the dam, the stages dropped about 1 to 3 feet depending on discharge from 1950 to 2011, and then slightly rebounded by 2013.

Table 2 Fort Peck Degradation Reach Elevation Changes at 10,000cfs

Gage	River Mile	1950	1984	2011	Total change
West Frazier	1751.3	2011.9	2008.8	2009.5	-2.4
Wolf Point	1701.2	1964.6	1961.5	1961.6	-3
Culbertson	1620.8	1888.5	1889.5	1887.4	-1.1

Aggradation Reach

Lake Sakakawea had high pool elevations through the mid-1990s that were followed by record low pools from 2005 through 2007 and then a high pool again in 2011. The extended time of high pool elevations in the mid 1990s probably caused an increase in deposited material from Williston, ND to the confluence with the Yellowstone River. However, much of this deposited sediment was probably re-suspended and then transported farther into the lake with low pool elevations during the first decade of the 21st century.

Table 3 Garrison Aggradation Reach elevation changes at 20,000 cfs

Gage	River Mile	1970	1985	2011	Total change
At Buford #5A	1577.5	1857.0	1859.3	1858.4	+1.4
Near Buford #6	1573.1	1854.0	1856.4	1857.3	+3.3
Williston	1552.7	1842.9	1845.6	1847.5	+4.6

Garrison Dam to Lake Oahe

Geographic Description

Garrison Dam is located in central ND on the Missouri River at RM 1390, about 75 river miles northwest of Bismarck and 11 river miles south of Garrison. Closure was made in April 1953. Since 1956, outflows from Garrison Dam have generally been through the power facilities, having a maximum capacity of about 38,000 cfs. Exceptions occurred in 1975, 1997, and 2011 when outflows of approximately 65,000, 50,000 and 150,000, respectively, were needed to pass high upstream runoffs.

The reach of the Missouri River between Garrison Dam and the headwaters of Lake Oahe covers a distance of about 80 miles of which the first 53 miles below the dam is considered the degradation reach. The Knife River enters the Missouri River approximately 14 miles downstream of the dam at RM 1376. The Heart River enters the aggradation reach just downstream of Mandan, ND at RM 1311.

Degradation Reach

The stage at the Garrison Dam tailwater gage has decreased slightly more than 11 feet at a discharge of 20,000 cfs in the period from 1953 and 2013. Most of this decrease occurred by 1980. The high flows from 1996 and 1997 caused another 1 foot of degradation. The 2011 event cause another 1 foot of degradation. All five gages located in this reach behave similarly.

Four gages in this reach show that the stage decreased in 2011. Records from the other two gages were inconclusive due to limited observations on the falling limbs of the hydrograph.

Table 4 Garrison Degradation Reach elevation changes at 20,000 cfs

Gage	River Mile	Original	1984	2011	Total change
Garrison Tailwater (1953)	1390.0	1680.3	1671.47	1669.5	-10.8
Stanton (1950)	1379.0	1676.5	1666.9	1665.2	-11.3
Fort Clark (1960)	1372.6	1668.5	1662.95	1659.5	-9
Hensler (1959)	1362.0	1660.7	1657.2	1655.8	-4.9
Washburn (1955)	1354.7	1656.1	1652.6	1650.2	-5.9
Price (1960)	1338.0	1642.4	1640.3	1638.2	-4.2

Aggradation Reach

Two gages are located in this reach. The 2011 event caused stages for both flows to lower significantly such that the stage for the 30,000 cfs flow in 2013 is about the same as in 1927. The stages for the 10,000 cfs flow fluctuated slightly until the 2011 event dropped the stage about 2 feet. The stages at Schmidt gage are affected by high Lake Oahe pool elevations. Current stages at the various discharges are lower than they were in the mid-1970s.

Table 5 Oahe Aggradation Reach elevation changes at 20,000 cfs

Gage	River Mile	Original	1985	2011	Total change
Bismarck (1927)	1314.5	1623.9	1624.3	1623.3	-0.6
Schmidt (1974)	1298.0	1611.2	1613.95	1616.2	+5

Fort Randall Dam to Lewis and Clark Lake

Geographic Description

Fort Randall Dam is located on the Missouri River at RM 880. The reservoir, Lake Francis Case, extends to the Big Bend Dam tailwater. Closure was made in July 1952. The Niobrara River is a major tributary located at RM 843.8.

Degradation Reach

The Fort Randall tailwater gage has decreased between 7 and 8 feet since 1952, most of which occurred by 1985. The 2011 event had little effect at this location. At the Greenwood gage the stages had decreased about one foot in 27 years (1960-1987). High flows in 2011 lowered the stages 1 to 1.5 feet. Some rebounding has occurred in 2012 and 2013.

Table 6 Fort Randall Degradation Reach elevation changes at 30,000 cfs

Gage	River Mile	Original	1984	2011	Total change
Fort Randall Tailwater (1952)	880.0	1239.8	1233.58	1232.7	-7.1
Greenwood (1960)	862.9	1228.8	1228.05	1225.9	-2.9

Aggradation Reach

The Verdel and Niobrara gages show the same pattern on the stage trend plots. Both show increasing trends from the mid 1970s until the high flows in 1995 when the stages decreased. By 1999 the stages were increasing again through 2008. Stages at both gages decreased between 3 and 4 feet in 2011. The stage at the Verdel gage was close to 3 feet higher for a 40,000 cfs flow on the increasing flow to peak curve than on the post flood curve and about 1 foot high at the Niobrara gage.

Table 7 Gavins Point Aggradation Reach elevation changes at 30,000 cfs

Gage	River Mile	Original	1985	2011	Total change
Verdel (1968)	846.5	1217.95	1220.2	1220	+2.05
Niobrara (1956)	842.9	1212.4	1218.3	1218.9	+6.5

Gavins Point Dam to Ponca, NE

Geographic Description

Gavins Point Dam is located at RM 811.1 on the Missouri River, 4 miles west of Yankton, SD and is the most downstream dam on the river. Therefore, there is no aggradation reach due to a reservoir is located downstream of this degradation reach. Closure was made July 1955.

Degradation Reach

The Gavins Point degradation reach extends from Gavins Point Dam downstream 58 miles to RM 753.18. The major tributaries in this reach include the James River at RM 797.5 and the Vermillion River at RM 772.0. The degradation trend is not limited to this reach and extends downstream to near Omaha, NE (approximately another 135 river miles).

Gavins Point tailwater gage over its period of record (1955 to 2013) shows a stage decrease of 13 feet for a flow of 20,000 cfs, most of which occurred by 1980. A decrease of about 1 foot occurred due to the 2011 flood event. Stages at the Yankton gage have decreased in a similar pattern to the tailwater gage.

The two most downstream gages in this reach (Maskell and Ponca) showed very little change in stages through the 1980's and early 1990's. Higher flows in 2010 and the record high flows of 2011 dropped stages between 2 and 4 feet. Since 2011, stages at the Maskell gage appear to be leveling off. Stages at Ponca have rebounded about 1 to 1.5 feet from the 2011 degradation level at the 20,000 cfs and above.

Table 8 Gavins Point Degradation Reach elevation changes at 30,000 cfs

Gage	River Mile	1955	1985	2011	Total change
Gavins Point Tailwater	811.0	1169.1	1159.8	1156.5	-12.6
Yankton	805.8	1163.4	1156.4	1153.8	-9.6
Maskell	775.4	1129.5	1124.8	1120.0	-9.5
Ponca	751.0	1096.5	1095.8	1089.0	-7.5

Missouri River Navigation Reach – Sioux City to Rulo, NE

Geographic Description

The Kensler Bend and the Bank Stabilization and Navigation Program (BSNP) Projects from Ponca (RM 753) to Rulo (RM 498), along with the construction of upstream dams, have drastically changed the characteristic of the Missouri River in this reach. Prior to construction, the river was a wide, sandy, sinuous channel containing numerous islands and sandbars and acting like any natural river system, by aggrading, degrading, or eroding its banks at any location dependent on the year. Today this reach is

narrower in cross-section, shorter in distance, with increased velocity, and is contained in rock-protected banks with constructed levees in many locations on the floodplain. A major influence in this reach is the Platte River at RM 594.

Generally, the stage (especially at the lower flows) has decreased in elevation to varying degrees upstream of Omaha. Downstream of the Platte River the stages have shown little change at the lower flows and an aggrading trend at the higher flows.

Navigation Reach

Overall, the stage at both Sioux City and Decatur shows a degradational trend. However, stages at both gages appeared to be leveling in the 1980s through the early 1990's. High flows in the mid 1990's caused a lowering of stages of about 4 feet at Sioux City and about 1 foot at Decatur. With the higher flow in 2010 and record high flows in 2011, both gages showed a decrease in stage elevations. The Sioux City gage, which decreased about 4 feet during the 2011 event, had rebounded about 1 to 2 feet depending on flows through 2013, while stages at the Decatur gage, which only decreased about 1 to 1.5 feet, also show some rebounding of stages. The Blair gage, which did not include any analysis of pre-2011 event stages, shows a slight increase in stages in 2012 and 2013.

Omaha's stage showed some degradation from 1930's through the early 1950's at all flows with a large decrease from the 1952 flood. A period of rebound and perhaps slight aggradation occurred through the mid-1970's. Since then, the stage at 40,000 cfs has shown very little overall change. Lower flows show a slight decreasing trend and higher flows a slight increasing trend. From 2010 to 2012 there had been between 0.5 to 3 feet of degradation at the various flows. All flows showed some rebounding in 2013 from 2011.

Nebraska City stages for flows below 70,000 cfs have been within the same range since 1990. Historic stages showed a mild decrease from years 1930 to 1950 followed by a period of mild increase. Stages for floodplain events above 100,000 cfs do indicate a slight rising trend since 1980. Nebraska City stages, as well as Plattsmouth and Brownille, show very little change since 2011.

At the Rulo gage, stages have fluctuated within about a one foot band for flows below 40,000 cfs since 1960. A slight aggradational trend is visible since the mid 1990's at higher flows. Since 2011, the stages have lowered between 0.5 and 1.5 feet at and below 40,000 cfs. The stage at a 70,000 cfs flow at Rulo increased about 0.5 feet between 2012 and 2013.

Table 9 Missouri River Sioux City to Rulo

Gage	River Mile	Original	1984	2011	Total change
Sioux City (1930)	732.2	1084.5	1077.4	1070.3	-14.2
Decatur (1957)	691.0	1040.3	1033.1	1030.7	-9.6
Omaha (1930)	615.9	967.7	966.9	965.6	-2.1
Nebraska City (1930)	562.6	913.7	914.9	915.5	+1.8
Rulo (1950)	498.0	845.7	847.0	846.5	+0.8

Water Surface Profile Evaluation Post 2011 Flood

Four water surface profiles are presented in this report within various reaches. Both the Garrison Dam to Lake Oahe and Fort Randall Dam to Springfield water surface profiles end in a reservoir. Most of the degradation in these reaches occurs in the region near the dam and the amount of degradation decreases as the distance from the dam increases. Within the reach below Garrison, the Oahe pool limits the degradation reach to between 70 and 90 river miles from the dam. In the river reach below Fort Randall the degradation limit is much shorter, primarily due to the location of the Niobrara River, and the degradation extent is only 35 to 40 miles downstream. Of course, the boundary between degradation and aggradation can move upstream or downstream due to pool levels, hydrologic cycles, and other factors.

The river stretch from Gavins Point Dam to Sioux City is interesting with two major processes at work. At the upstream end degradation is caused by the dam trapping all upstream sediment and releasing clear water into the river. In contrast to the other mainstem dam open river reaches, the river below Gavins Point Dam does not end at a reservoir. Near the downstream end of the reach, the construction of navigation channel structures to provide sufficient channel depth for navigation provide a strong influence.

Within the navigation channel reach from Sioux City to Rulo, the Platte River has a major impact on geomorphology. The change in water surface between different time periods is greatest at Sioux City and decreases as the profile approaches the Platte River. Downstream of the Platte River very little change is detected at the 40,000 cfs flow.

Stage Trend Summary

The 2011 flood event presented a challenge when evaluating trends. It was observed that the stages at many locations were different for the rising side of the event (increasing to peak flow) versus the declining side of the event (decreasing from peak flow). The differences in stage range from as little as a few tenths of a foot at some locations to about 6 feet at Ponca for a 40,000 cfs flow. At the degradation locations, the rising side event stages are higher while at aggradation locations the reverse is true. Compared to the degradation observed in 2011, the 2013 stages show varying amounts of rebound at many sites.

RAPID, QUANTITATIVE ANALYSIS OF THE COST EFFECTIVENESS OF STREAMBANK PROTECTION MEASURES USING THE BANK-STABILITY AND TOE EROSION MODEL (BSTEM)

Natasha Bankhead and Andrew Simon
Cardno Inc, P.O. Box 1236, Oxford, MS 38655; natasha.bankhead@cardno.com 662-380-1961; andrew.simon@cardno.com 662-832-1347

Abstract. Failure to undertake quantitative analysis of bank-protection schemes typically increases the risk and uncertainty in design and often results in greater cost due to either "over design" or by having designs or structures fail. The Bank Stability and Toe Erosion Model (BSTEM) is a fully deterministic simulation tool that has been used successfully across a wide spectrum of environments to predict streambank stability and to test the effectiveness of a broad range of mitigation schemes. The Dynamic version of the model using time-series flow data has been used in studies by Cardno, in the US, Australia and New Zealand to assist in selection of appropriate mitigation techniques and to compare their cost-effectiveness. Mitigation techniques are aimed at either reducing the driving forces acting on the bank and/or increasing the forces resisting hydraulic erosion and bank collapse. Resisting forces such as critical shear stress, effective cohesion and friction angle are measured *in situ*.

For a recent flood-recovery study conducted for the Burnett-Mary Regional Group (BMRG), Australia, simulations of different mitigation strategies included placing riprap at the bank toe, bank grading, re-vegetation, and construction of rock weirs or engineered log jams to deflect flows. Similar work in Auckland, New Zealand also included reduction of upstream channel gradient as a means of reducing hydraulic stresses. The effectiveness of a given mitigation strategy is based on comparison of predicted erosion volumes and lateral retreat with the no action alternative for an identical flow series. Where simulations with riprap are involved, traditional methods are used to calculate appropriate rock diameters using normal-depth calculations for hydraulic-parameter input. The cost of each mitigation scenario was based on local costs for rock or wood purchase, delivery and placement, heavy equipment, and the height and length of treated banks. The cost effectiveness of each treatment was then calculated by using: 1) total cost of the project, 2) the cost per meter of bank treated, 3) the cost per unit volume of streambank erosion prevented and 3) the cost per meter of streambank retreat prevented. As an extreme example, at one of the Burnett River sites, BSTEM predicted that protection of the bank toe and most of the bank face using rock would prevent bank erosion and retreat, but the unit cost would be about \$2,600/m of bank retreat or \$8,900/m^3 of soil-erosion prevented. Modeling of further mitigation strategies showed that, for example, that grading the bank to a 2:1 slope and planting riparian vegetation would prevent 97% of the erosion predicted under existing conditions, but would only cost \$150/m of bank retreat, and \$530/m^3 of soil-erosion prevented.

These data, in addition to typical BSTEM outputs such as erosion volumes and bank retreat distances, provides quantitative information about the performance of proposed streambank stabilization measures. In the case of BMRG, final decision making depends not only on the total cost of each project, but also the volume of fine sediment that can be prevented from entering the river system, and ultimately reaching the Great Barrier Reef.

INTRODUCTION

Failure to undertake quantitative analysis of bank-protection schemes typically increases the risk and uncertainty in design and often results in greater cost due to either "over design" or by having designs fail. The Bank Stability and Toe Erosion Model (BSTEM) is a fully deterministic simulation tool that has been used successfully across a wide spectrum of environments to predict streambank stability and to test the effectiveness of a broad range of mitigation schemes. The Dynamic version of the model with time-series flow data has been used in studies by Cardno Inc in the US, Australia and New Zealand, to assist in selection of appropriate mitigation techniques and to compare their cost-effectiveness. Mitigation techniques are aimed at either reducing the driving forces acting on the bank and/or increasing the forces resisting hydraulic erosion and bank collapse. Resisting forces such as critical shear stress, effective cohesion and friction angle are measured *in situ*. For a recent flood-recovery study on the Burnett River conducted for the Burnett-Mary Regional Group (BMRG), Australia, simulations of different mitigation strategies included placing riprap at the bank toe, bank grading, re-vegetation, and construction of rock weirs or engineered log jams to deflect flows.

The Burnett River is one of the Reef Catchments flowing through the city of Bundaberg in its downstream reaches before exiting to the Coral Sea. The Burnett River experienced severe flooding in early 2011 and 2013, with the latter flood breaking all historical records. As a result of these floods, damage to assets, infrastructure and the loss of agricultural land from bank erosion was considerable. In an effort to develop a strategy for prioritizing and determining resilient and cost-effective protection measures, it is essential to have an understanding of both site-specific and system-wide stability conditions. For site- and reach-specific solutions, this is accomplished by quantifying the driving (flow and gravitational) forces and resisting (shear strength) forces operating on the channel banks, and testing how alternative stabilization measures would perform over a range of flows. System-wide analysis then provides the spatial and temporal context of channel instability to determine the suitability of conducting various types of channel works (i.e. energy dissipation, bank stabilization, etc.) to protect assets and to aid in prioritization of those works.

METHODOLOGY

The geographic scope of this study extended from the mouth of the Burnett River east of Bundaberg, upstream to Eidsvold. In addition, the lower end of the Kolan River was included. These two reaches represent priority areas for investigation for the Burnett-Mary Regional Group (BMRG) to aid in their flood recovery efforts. BMRG selected eight sites along their study reach for a detailed investigation of current bank erosion rates, with which to develop potential mitigation measures that could be used to protect local assets. The investigation consisted of detailed field tests to quantify the geotechnical and hydraulic resistance of the bank and bank-toe materials were performed at each of the sites. Surveys of the banks were also carried out at each site to provide bank heights, angles, and stratigraphic layering for the tested bank. The data collected in the field were used to populate a Streambank Stability and Toe Erosion Model (BSTEM-Dynamic 2.0; Simon et al., 2000). These model results were used to calculate erosion rates for existing and mitigated conditions, which were then used in a cost-effectiveness analysis.

Simulations with BSTEM Dynamic were conducted for two non-mitigated cases to reduce uncertainty in model predictions and to provide a basis for simulating future erosion without mitigation (a no action alternative). The purpose of the first set of simulations was to calibrate BSTEM between two known surveys. Because detailed surveys for two points in time were not available, top-bank edges from GIS-based air photos were used to determine the amount of bank retreat that occurred between LiDAR data from 2009 and 2010 with the post-flood imagery shot in 2013. Mean-daily discharges from a nearby gauging station, adjusted for drainage area were used to establish the flow series encompassing the period bounded by the imagery. For the purposes of these simulations, the flow period used was 1 January 2009 to 31 July 2013. The amount of lateral retreat obtained from the imagery was then compared to the top-bank retreat predicted by BSTEM over the period. After successful calibration by iteration, the calibrated values were then applied to model potential future bank erosion under existing and mitigated conditions. For these model runs, BMRG and Cardno agreed to use a decade-long period to provide a meaningful comparison between erosion rates during wet and dry cycles. The period selected was slightly greater than ten years and spanned 1 January 2003 to 31 July 2013.

Estimating Cost-Effectiveness of Mitigation Measures Reducing land loss (bank retreat) and sediment loadings from bank erosion can be accomplished in a number of different ways depending on the objective of the program and the resources available. Quantifying reductions from application of different mitigation strategies can then be designed accordingly. For example, to protect agricultural assets it is perhaps the reduction in bank retreat that is of paramount concern. In contrast, a better metric for protection of storage area above dams, and sediment delivery to the estuary and the Coral Sea might be reduction in volume or mass of sediment. Thus, modeling results were expressed not only in absolute values (m^3/m and m) but as a percent reduction in those parameters as compared to the ten-year, "no action" simulations. Cost effectiveness of each of the modeled mitigation measures was accounted for at each site based on (1) estimates of unit costs for materials and labor, and (2) the specific requirements (length, height and area) for implementation of specific design elements at each site.

Bank Erosion Mitigation Scenarios Modeled Numerous combinations of bank treatments and protection schemes can be simulated within the BSTEM framework and all are related to how each scheme modifies the driving and/or resisting forces responsible for bank erosion. For example, placement of rock or large wood at the bank toe provides an increase in the resistance to hydraulic forces acting on the bank toe but does not address the hydraulic forces impinging on the toe or the shear strength of the overlying bank mass. Vegetative plantings, however, provide for not only an increase in the resistance to hydraulic forces but also additional root reinforcement to resist mass failures. Further, bank grading directly reduces the downslope, driving gravitational forces but does not alter resistance to hydraulic forces. Finally, bendway weirs or engineered log jams (ELJs) designed to keep the main flow thread away from the bank and re-direct it towards the center of the channel work to reduce the applied hydraulic forces acting on the bank toe and surface. These features do not modify either the gravitational, downslope forces or the shear strength of the *in-situ* bank material. In general, alternative strategies that were simulated include various combinations of rock facing (at the bank toe and along the bank surface), riparian planting, grading of banks, and the use of Bendway weirs/ELJs. Table 1 provides a list of the mitigation alternatives tested, and the input parameters modified in BSTEM to account for each alternative.

Table 1 Mitigation measures tested, and BSTEM input parameters modified to account for these measures.

Mitigation Measure	Modify critical shear stress of material	Modify soil shear strength to account for roots	Grade bank slope	Reduce applied shear stress acting on banks
Rock at toe, no grading	✓			
Rock at toe and up bank	✓

Unit Costs and of Mitigation Alternatives Cost effectiveness can be defined as the cost of implementing a particular mitigation measure per unit of sediment or bank saved. The effectiveness of each of the simulated mitigation strategies is expressed herein, as a cost per unit volume of sediment-erosion reduction, and a cost per m of retreat reduced. To determine cost effectiveness, we must first be able to estimate the total cost of implementing a particular strategy. This is somewhat of a challenge without undertaking a detailed design with associated costs at each site. Reasonable estimates, however, may be obtained by applying the unit costs of materials and labor over the length, height and area covered by a particular alternative. Estimates of the required length of mitigation were estimated from inspection of the 2013 aerial photography for each main stem site. Consideration was given to the morphology of both the cross section and the reach. For example, if the site was located on an outside bend, it is prudent to protect not only the specific cross section but also the entrance and exit of the bend to prevent shifting the instability to another part of the bend.

Protection with Rock Rock is used in bank-protection schemes to resist hydraulic forces, typically at the toe of the bank to limit steepening and undercutting. The use of rock is generally combined with the placement of a filter fabric at the interface between the soil and the rock to limit winnowing of the finer materials. Rock is also used for the construction of weirs (flow deflectors) that extend into the flow field from the bank. In the case of a rock toe for example, one can estimate the purchase, delivery and placement of rock per tonne of rock and then calculate the amount of rock required for a given height and length of protection. BMRG provided Cardno with an estimate of $81.50/t for placed rock (I. Botha, written comm., 2013). The number of tonnes of rock required per meter of channel length varies according to whether it is placed against a vertical or sloping bank face (as in the case of toe protection) or on the channel bed (as in the case with a bendway weir). This is shown in Figure 1. By then applying the unit cost of $81.50/t we develop a relation between the unit cost (per m of channel or weir) and the height of the rock protection (Figure 2).

Costs for toe protection with rock, often referred to as longitudinal stone-toe protection (LSTP) were based on the unit costs of rock provided by BMRG ($81.50/t) and the red-colored equation

shown in Figure 2, where cost is a function of the height of the bank to be protected. Estimated costs for each site, therefore, are based on the projected height of LSTP specific to the conditions and geometry of the site. For estimating costs for bendway (rock) weirs which are typically placed as a series of equally-spaced structures extending slightly upstream into the flow, guidelines developed the U.S. Federal Highway Administration (based on research by the U.S. Army Corps of Engineers) are used. The amount of rock is determined by the height, length, spacing and number of structures, which are in turn a function of the width of the channel, the length of the reach to be protected and the depth of mean, annual high water. As a more conservative approach, and due to the apparent increase in the magnitude of peak-flow events in recent years in the study area, in this project the mean of the 11 highest daily flows (for each water year simulated) was used. Overall, as this is not an exercise in design but a means to estimate quantities of rock for approximate costing, the approach has been somewhat simplified. The following steps were used:

1. Determine the depth (d) of mean, annual high water;
2. Determine weir height (h) as 0.3d to 0.5d;
3. Calculate weir length (L) as ¼ of the channel width;
4. Calculate weir spacing (S) as 4 to 5 L;
5. Calculate the number of weirs using the length of the reach divided by S;
6. Calculate total cost by: determining the unit cost (per meter of weir length) for rock placement (of a given height) by the blue-colored equation in Figure 2 ($cost = 259.93 h 1.9528), then, multiplying the result by weir length (L) and by the number of weirs.

Protection with Vegetation Vegetation improves both the hydraulic and geotechnical resistance of banks as well as providing ecological benefits. Planting of the bank slope is generally combined with some kind of bank-toe protection with either rock or large wood. The cost of implementing a planting scheme is a combination of the cost of the plants and labor required for site preparation and planting. BMRG provided a unit cost of $2.50/plant (I. Botha, written comm., 2013). Because of some uncertainty in the number of plants required in different settings, we have instead estimated a unit cost of $5/$m^2$ based on previous experience.

Protection by Grading the Banks. Grading a bank slope reduces the gravitational, driving forces thereby increasing bank stability and is often combined with riparian plantings and bank-toe protection. This alternative requires the use of heavy equipment to perform cut and fill operations on the bank slope to batter it to an angle flatter then the friction angle of the material. The cost for mobilization and operation of the equipment can be variable due to location and accessibility, the height of the bank, access to the streambed, the amount of material to be moved per m of channel length, and disposal of the spoil. As such, the time required to perform the work can vary from several days to several months. We assume that four pieces of equipment would be required each day. They include a loader or bulldozer, an excavator or track hoe and two dump trucks. We further estimate an average, unit cost of $1,500 per day for each piece of equipment ($6,000/day total). We then estimate the number of days required to perform the work using an average of 2 days per 100 m of bank length. Given the estimated length of required mitigation at the sites, the time required for grading ranged from about 5 to 24 days for the eight sites investigated in this study.

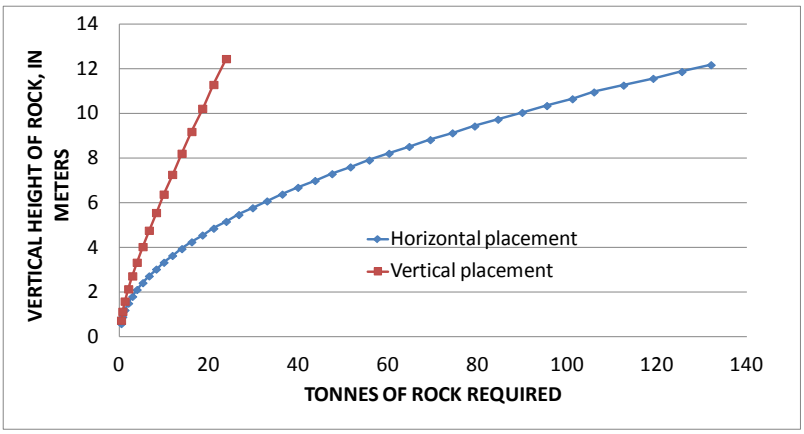

Figure 1 Tonnes of rock required relative to the height of the protected area for horizontal and vertical placement.

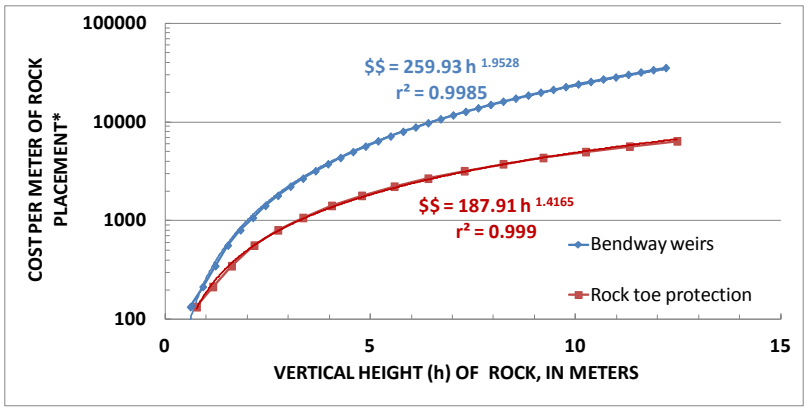

Figure 2 Estimate of the unit cost of rock placement (per meter of channel or weir length) as a function of the height of the protection. This does not include design costs and development of construction drawings.

Protection by Large-Wood Structures The use of large wood in bank-stabilization schemes is becoming more popular in many parts of the world, including Australia, because of the combined benefits to geomorphic and ecologic processes. The cost of wood structures such as engineered log jams (ELJs) can be quite variable and are often not reported in detail. Costs for construction of ELJs include the cost of the trees, delivery to the site and construction. Estimates of unit costs are done either per structure or per meter of bank protected. Estimates per structure are also quite variable because of differences in the number and sizes of logs required for different types of ELJs. For example, a recent ELJ bank-stabilization project on the O'Connell River, QLD, Australia, used about 90 logs in each of three log-jam structures at a cost of $55,000 (about $18,000 per structure or about $275 per meter). Other wood structures may contain as few as three or four logs depending on the objective of the structure (fish habitat, bank stabilization, flow deflection etc.). For the type of bank protection envisioned for the Burnett River, we assumed that each structure would require from 20 to 80 logs.

Based on an extensive review of available cost information and review by Cardno design engineers, we calculated two average-unit costs for ELJ construction: $194/m of channel length protected and $ 19,050 per structure. Because of the great variability in ELJ project costs we also provide the 75th percentile of unit costs as: $280/m of channel length and $29,600 per structure. Most of this information was obtained from North American sources but costs from two Australian projects (in Queensland and New South Wales) were also included. It should be stressed that the unit-cost estimates provided here and applied in the following sections of this report are just that, estimates. Additional uncertainty in cost estimates derived without full-scale design considerations may be related to:

- Difficult site conditions that may make placement more costly;
- Access to the streambed by heavy machinery;
- Vertical operational distance heavy machinery can operate from the bank top;
- Construction in wet (submerged) conditions;
- Differences in the cost of placing rock along a surface versus "keying" rock back into the bank at/or below bed level;
- Varying unit costs for rock of different sizes.

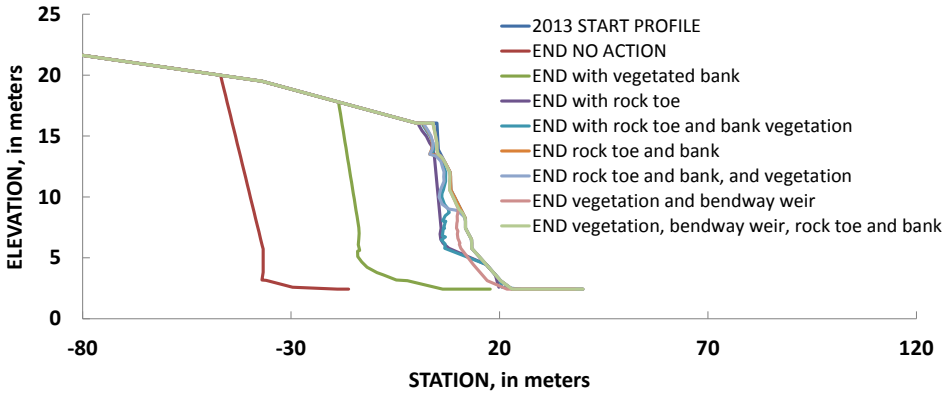
The unit costs described above are used to estimate the total cost of a modeled mitigation alternative, which in most cases involves combinations of treatments and their associated costs. To obtain actual costs for implementation at a given site, the costs for detailed design drawings, computation of the types and amount of materials, and access by heavy machinery would need to be undertaken. Still, with the unit-cost estimates developed here, reasonable estimates of total costs and cost effectiveness for each site can be provided.

RESULTS

Example from Shalom College Site (Figure 3). Results from the Shalom College site, which had the highest unit-erosion value, and largest bank retreat distance in the calibration runs, will be discussed here to provide an example of the way in which the BSTEM results were interpreted, and cost effectiveness analysis performed. The BSTEM results showed that without any remedial action at this site, an additional 52 m of retreat would occur over the next ten years, with all of that occurring during the wet period and associated large peak-flow events. About 98% of the total unit-volume eroded (about 780 m^3) also occurred during the wet period, indicating that only 2% of the hydraulic erosion occurred during the drier period.

The relatively high erosion rates seen at this site are the result of a high, bare bank composed of relatively weak materials that receives directed, accelerated flows due to a vegetated island in the reach. The result is that both moderate and high flows are deflected towards the bank toe, resulting in pervasive undercutting and representing an important process that would need to be addressed by mitigation. This interpretation is further supported by the results of the rock-toe and full-vegetation scenarios where, compared to the no action alternative of 783 m^3/m of erosion, 51.8 m^3/m and 353 m^3/m of erosion was predicted over the same period, respectively. In terms of effectiveness in reducing the amount of sediment delivered, the rock toe (keyed into the bank) reduces erosion 93 % while established vegetation would reduce erosion at the site by 55 %. The other metric for determining effectiveness of these two (and other) alternatives is the potential

reduction in lateral retreat. Although it is convenient to compare result in terms of percent reduction, it seems more meaningful in this case to compare absolute values. About 24 m of additional retreat is predicted for the full-bank vegetation case compared to about 4 m for the case with the rock toe. Two additional points about the comparison of these two alternatives need to be considered. First is the assumption that the planted vegetation will establish and will not die due to lack of water or being ripped from the bank by flood water. This point emphasizes the need for maintenance and protection of any vegetative plantings, particularly in their first year. The second point is the difference in the cost of these alternatives, with the installation of a rock toe that is keyed into the bank being considerably more expensive.



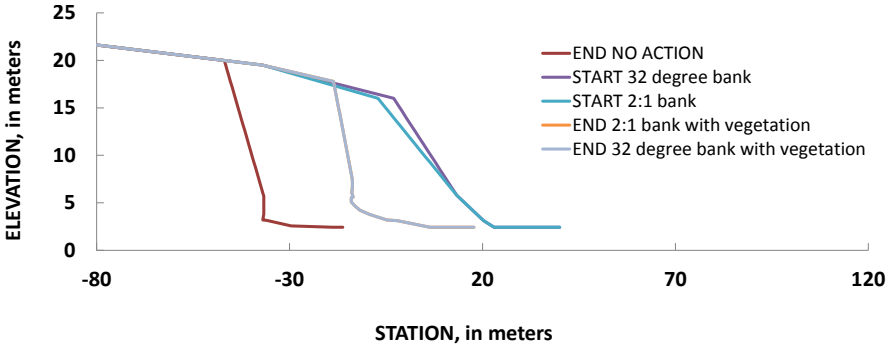


Figure 3 Top: photo of Shalom College site. Middle and bottom: Simulated, future bank retreat for the range of mitigation alternatives at the Shalom College site for the 10.6-year flow period used (2003-2013).

Predicted bank retreat and resulting geometries for a range of mitigation alternatives at this site at the end of the simulation period are displayed in Figure 3. Analysis of the BSTEM results showed that geotechnical failures were responsible for the bulk of the material delivered to the river, but reductions in hydraulic bank erosion and steepening through toe protection, resulted in significant reductions in the quantity of material delivered by mass failures. This provides evidence of the type of actions (ie. some kind of toe protection) that would be appropriate at this site. Indeed, the model runs including rock placement on the bank face and/or toe, resulted in considerably greater reductions in both total eroded volumes and bank retreat than those mitigation runs that involved only vegetation and/or grading. At this site, mitigation scenarios including bendway-weir structures, designed to deflect flow and reduce shear stresses applied to the banks, were also considerably more effective than vegetative plantings and/or grading. The height of rock required to successfully prevent bank toe erosion and subsequent bank oversteepening depends on the shear stresses acting on different parts of the bank, which are controlled by channel slope, flow depth and channel roughness. For example, where vegetated islands force flow into a narrower section of the channel, flow depths will be greater for a given discharge, and the height of the bank that requires rock reinforcement may, therefore, also be greater.

Cost Effectiveness of Mitigation Scenarios at the Shalom College Site (BMRG-03) As with any site, selecting a preferred alternative for the Shalom College site must be based on consideration of cost relative to an acceptable level of protection (magnitude of future land loss and likelihood of success). A summary of the estimated unit and total costs for the various mitigation alternatives at this site are shown in Table 2. The unit costs for mitigation scenarios involving vegetation and ELJs are considerably less ($66 to $260 per meter of bank length) than those requiring rock ($1,360 to $5,680 per meter of bank), whether it be for longitudinal stone toe protection, or for bendway weirs. Those mitigation runs that involve just vegetation and grading of the bank return relatively low costs per unit of sediment load or bank-top retreat saved, but they are also among the least effective measures in terms of total erosion reduction (Figure 4). Although the mitigation scenario that involves protecting the bank face and bank toe with rock (up to 11.1 m high) resulted in the highest percent reduction in terms of sediment volume at this site, the cost for this scenario is the highest estimated (about $3,00,000). This scenario is likely to be cost prohibitive and was included only to represent an end-member case. Considerably lower cost estimates were calculated for other mitigation st**r**ategies that reduced almost as much erosion and bank retreat (Figure 4). For example, if we compare the percent reduction in erosion and bank retreat for each mitigation in Figure 4 (red and blue bars) with the total cost for that mitigation (green bars), we can see that installation of ELJs with additional vegetative plantings on the bank face and toe regions, provides a much more cost-effective alternative ($138,000), while still providing a similar result as the rocked bank face and bank-toe scenario. It should be noted that although the alternative combining ELJs with vegetation is much more cost effective, it also has a higher risk associated with it than the hard engineering solution of protecting parts of the bank with rock. This is because it will take time for vegetation to establish, and the structure will thus be prone to large floods until any new vegetation can root firmly enough to anchor itself in place. There may, therefore, be some additional costs associated with management and protection of vegetation as it becomes established.

Table 2 Cost estimates for BMRG-03 for different mitigation scenarios, provided as total cost ($), costs by unit volume of sediment reduction ($/m^3), and per meter of bank retreat ($/m) prevented.

Scenario	**Protection**		**Unit Cost**	**Cost effectiveness**		
				Unit Cost		**Total Cost**
	Height	**Length**		**By volume**	**By retreat**	
	(m)	**(m)**	**($/m)**	**($/m^3)**	**($/m)**	**($)**
No Action	-	-	$0	$0	$0	$0
With vegetation	13.2	530	$66	$81	$1,230	$35,000
Rock at toe	4.1	530	$1,360	$988	$15,200	$722,000
Rock toe with vegetation	4.1	530	$1,430	$1,020	$15,600	$757,000
Rock toe and bank face	11.1	530	$ 5,680	$3,890	$61,600	$3,012,000
Rock toe and lower bank with vegetation	6.6	530	$ 2,790	$1,930	$30,200	$1,480,000
2:1 grading with vegetation	13.2	530	$186	$198	$2,440	$98,600
32 degree bank with vegetation	13.2	530	$186	$209	$2,710	$98,600
Vegetation with bendway weirs	13.2	530	$1,560	$1,080	$2,700	$824,000
Vegetation with ELJs	13.2	530	260	$181	$30,300	$138,000
Vegetation with bendway weir and rock toe	13.2	530	$2,920	$1,990	$30,300	$1,550,000
Vegetation with ELJs and rock toe	4.1	530	$1,620	$1,110	$16,800	$860,000

CONCLUSIONS

The primary objective of this study was to provide a means of determining strategies for cost-effective protection of local assets in the context of flood recovery and system wide channel-stability concerns. Site-specific stability issues at eight locations were studied to better understand system-wide trends, and investigate cost effectiveness of potential mitigation measures at these priority sites. At-a-site investigations of unit-erosion rates (expressed in m^3/m of channel) were carried out using BSTEM, populated using geotechnical and hydraulic-erodibility data collected *in situ* at each of the sites. The BSTEM results for various mitigation scenarios at each site showed that at some of the sites, protection of the bank toe was the essential component in managing and reducing streambank erosion, and therefore, banktop retreat. In these cases, the most successful mitigation measures were protection of the entire toe using rock, with the addition of vegetation to the banks often further reducing bank erosion by protecting the upper bank from both hydraulic and geotechnical erosion. At some sites, however, the before and after geometries output from BSTEM indicated that even where the toe was protected, some erosion could occur above the protected zone. In these cases, mitigation strategies that focused on reducing shear stresses in the entire near-bank zone, rather than just protection of the toe, were found to be more successful in terms of erosion reduction and prevention of bank top retreat.

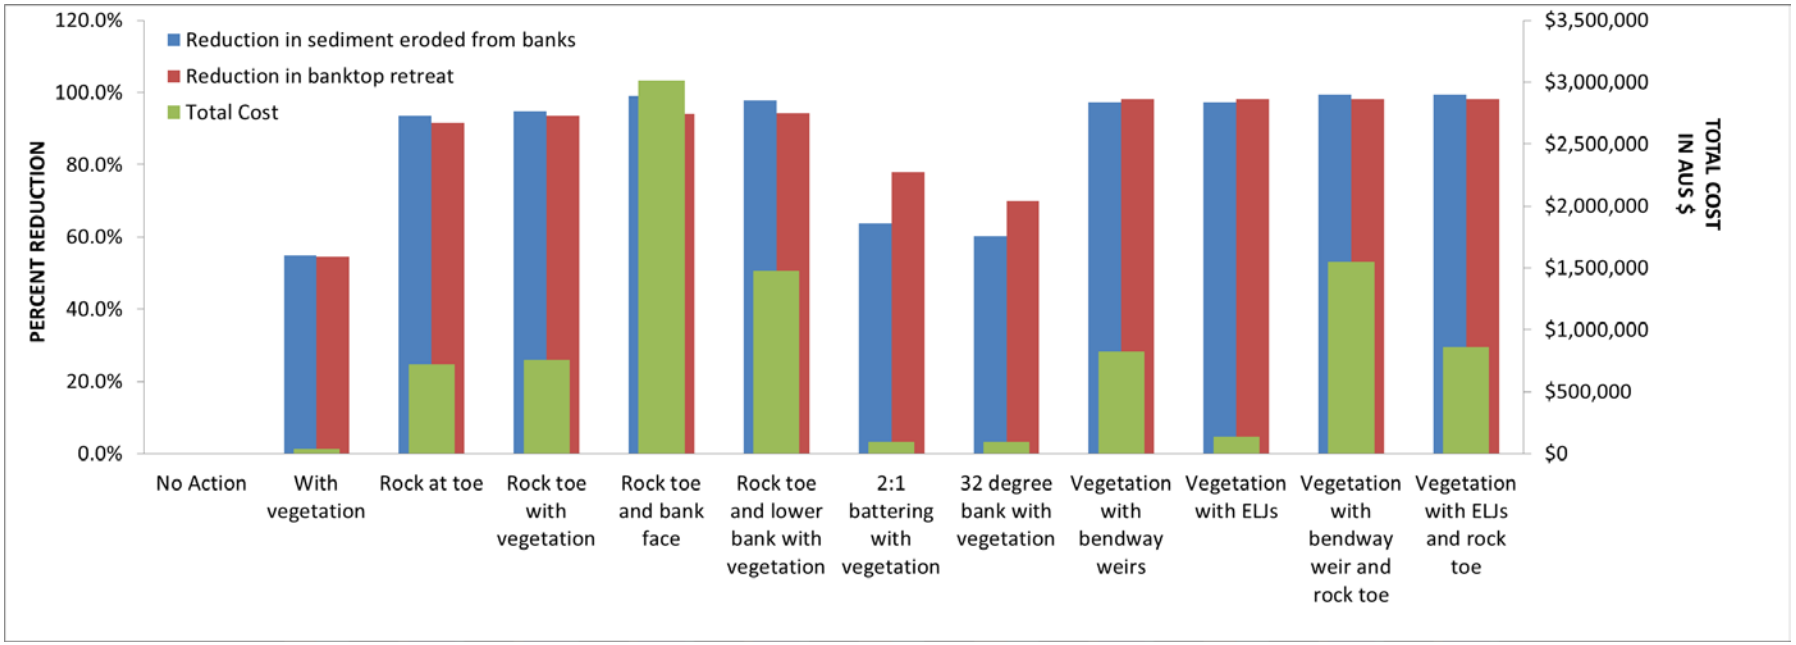

Figure 4 Plot showing percent reduction in sediment eroded at each site, and percent reduction in bank retreat, compared to the total cost for each mitigation scenario.

Cost estimates provided as part of this work served as an approximate guide for the mitigation scenarios presented. Overall, the scenarios involving rock in any form (rock toe or rock weirs) were the most expensive at any given site. The costs vary according to rock size, and height of bank protected, but were an order of magnitude higher than other measures at most sites, typically ranging from $1,000 to $3,000 per meter of bank. Planting of vegetation was the least expensive (approximately $5/m^2 of bank face or top) option. In general, mitigation runs including a rock component provided the greatest level of protection from bank erosion and sediment entering the channel, and those with vegetation alone, the least. It should also be noted, that the cost-effectiveness analysis showed that there are alternatives to the use of rock at some sites, with other combinations of mitigation strategies providing the same or only slightly less protection from future erosion. For example, the use of ELJs (with or without vegetation) often provided a good balance between bank protection and cost.

The results showed how the use of deterministic models, such as BSTEM can provide an effective way of quantifying the performance of proposed streambank stabilization measures. The balance between the cost-effectiveness of a given mitigation measure and the risk associated with the potential for ongoing erosion, and/or the failure of the implemented mitigation measure, must be considered on a site-by-site basis. In the case of BMRG, final decision making depends not only on the total cost of each project, but also the asset protection afforded, and the volume of fine sediment that can be prevented from entering the river system, and ultimately reaching the Great Barrier Reef.

STREAMBANK EROSION: DEVELOPING RECESSION RATES BASED ON CONDITION CLASS AND FLOW STAGE CHARACTERISTICS

W. Barry Southerland, PhD, Fluvial Geomorphologist-Hydrologist, USDA-Natural Resources Conservation Service, West National Technology Support Center, 1201 NE Lloyd Blvd. Suite 1000, Portland, OR 97232, FAX: 503-273-2401; Lisa J. French, Project Coordinator, Cheney Lake Watershed, Inc., 18 E. 7th Avenue, South Hutchinson, Kansas 67505

ABSTRACT: In 2007 the Natural Resources Conservation Service National Water Quality and Quantity Technology Development Team began a collaborative six year streambank pin-based and bank profile recession rate study with Cheney Lake Watershed, Inc., Inc. The Cheney Lake Watershed is a designated Conservation Effects and Assessment Project (CEAP) Special Emphasis Watershed. The initial purpose was to determine the contribution of fine sediments from the 989 square mile watershed to the highly valued Cheney Lake Reservoir which provides water for the City of Wichita and to evaluate the downstream impacts of the current CRP, EQIP, WRP, and WHIP implementations. For the same time period, the USGS established suspended sediment load sampling (USGS depth integrated sampling procedures) at five gauge sites. Approximately one hundred erosion pins were strategically placed at ten streambank erosion sites to characterize five streambank erosion condition classes commonly represented within 782 square miles upstream from the USGS gauges. The five most probable erosion categories represent a significant presence or absence of characteristics such as roots, root mass, root depth relative to floodplain, bank angle, livestock impacts on streambanks, tension cracks, bank material, bankfull, bank height ratio, and other considerations to formulate BEHI (Bank Erodibility Hazard Index). The rate of lateral streambank recession was correlated to hydrologic runoff factors of flow duration above the inner-berm, assuming at least a bankfull event. This FISC paper is collaborative with, "The Dynamic Nature of Small Watersheds: Estimating the Inner Berm Geomorphic Channel Feature based on the Hydrologic Relationship of Channel Forming Events". In 2007 and 2008 the banks where comprehensively inventoried for condition, length of condition class, and bank height. Cheney Lake Watershed Inc. input and attributed over 186 miles of streambank conditions. The initial results show a significant pattern of recession rates relative to flow duration above inner berm flow. The findings will provide a reliable estimate of the portion of streambank suspended load contribution to the USGS sampler located on the North Fork of the Ninnescah Mainstem at the Whiteside Bridge. The data and analysis, along with the flow duration and intensity, will provide a considerably more robust result from the CEAP AnnAGNPS model because the streambank contributions to suspended sediment load will be proportionally accounted for as a reliable percentage of the total load. Just as significant is the utility of this information for ubiquitous, coarse, unconsolidated, high sand fraction soils, commonly found throughout the Midwestern U.S. Field staff in Midwest areas (Great Plains and Central Lowland physiographic provinces) with similar soil characteristics and predominantly thunderstorm-driven hydrology will have a field tool to reliably predict streambank erosion relative to their condition assessment and runoff conditions.

INTRODUCTION

There are many river models integrating sedimentology, hydrology, streambank conditions, soil stratigraphy and other physical input parameters to predict the streambank erosion associated with both average annual and high stage flow events (event-based). Streambank erosion rate by event-based flow stage is the more difficult proposition. It requires considerably more rigor in fieldwork and analysis to determine. It is often thought that more commonly used models are both validated and calibrated by a monitoring and assessment protocol. But the fact is, very few are both calibrated and validated by region or area to assure the erosion rates we receive are robust. Stakeholders, land operators, and planners ask the questions: How do I know the data you have gathered and the predictions you make are good or reasonable? What are the assumptions? Have you accounted for all of the physical and biological variables that affect streambank erosion in our watershed? These are good questions.

Paucity of field data is a major roadblock to river work. To approach any of these matters quantitatively one must have some data measured in the field. The value of river parameters can be estimated, but with no assurance of verity. Unfortunately, too many professionals approach such problems with the supposition that [the] computer can do all. In river work, computer modeling is an insidious procedure in which an air of surety hides questionable assumptions. A computer gives numerical answers, but the bases on which the computation rests are hidden (Leopold, 2001).

Leopold was not condemning models. His message was simple. Put field measured data into models based on real world morphometry and measures. Question the assumptions. Refine them when necessary and validate your model. Each time you consider re-calibration of a model or empirical-based tool, you must revalidate. This process will keep us out of the error margins which are often on order-of-magnitude away from real world data-based observations.

Exhibit A

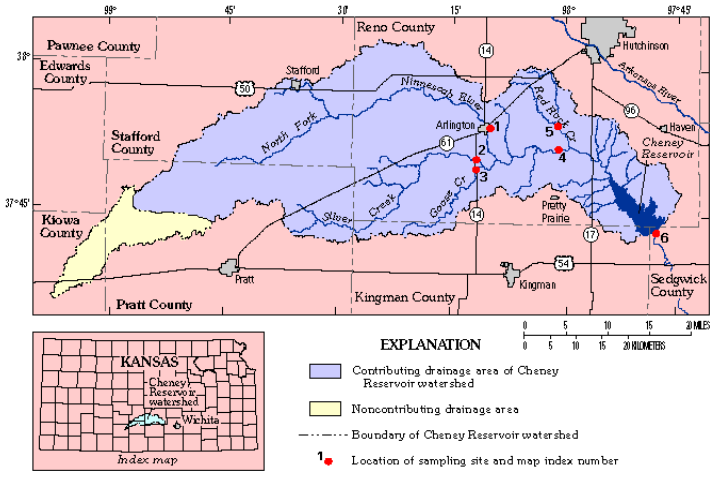

Figure 1. Location of Cheney Reservoir watershed in south-central Kansas and sampling sites used in this study.

The Cheney Lake Watershed is a designated Conservation Effects and Assessment Project (CEAP) Special Emphasis watershed (Exhibit A). This report provides an analysis of the

suspended load contribution from the banks of the contributing drainages within the 989 square miles of the Cheney Lake Watershed CEAP Project.

In 2007, an interdisciplinary team comprised of NRCS-Water Quality and Quantity Technology Development Team, Cheney Lake Watershed, Inc. with the Reno Conservation District, and the USGS completed an initial analysis report: Cheney Lake Watershed Streambank Erosion Analysis-CEAP Watershed (Southerland et al, 2007). Initial findings of streambank erosion contributions to suspended load were determined but it was based on a qualitative tool referred to as the Ventura Workshop Erosion and Sediment Yield Tool developed by Steffen, Lyle J., 1983. The estimated recession rate by condition class was developed in California. The recession rates were based on California studies over time and not calibrated nor validated for the Cheney Lake Watershed. This methodology was only used as an initial estimate of streambank erosion yield from the Cheney Lake Watershed. Three of four technical recommendations put forth in this report were adapted by the Cheney Lake Watershed, Inc. These findings led to the seven-year streambank erosion study resulting in both calibration and validation of streambank erosion rates by condition class.

The purpose of the special emphasis watershed study in the Cheney Lake Watershed is to evaluate the downstream impacts of conservation practices implemented through current USDA programs. The Annualized Agricultural Non-Pont Source Model (AnnAGNPS) will be calibrated and validated for a south central Kansas HUC eight watershed. Changes in offsite water quality will be described. Future watershed conservation practice implementations will also be evaluated to measure their offsite downstream impacts.

In order to appropriately calibrate the total loads in the AGNPS model it was essential to have a robust estimate of streambank erosion contributions to the suspended sediment load samplers. The streambank erosion study includes a surface runoff area of 782 square miles. Five USGS depth integrated sampling sites were established in 1996. Suspended load gauge data from several years were compiled to compute the average annual suspended load rate. This streambank and assessment field study will determine the annual rate and fraction of suspended load coming from streambanks contributed to the five United State Geological Survey (USGS) gauges.

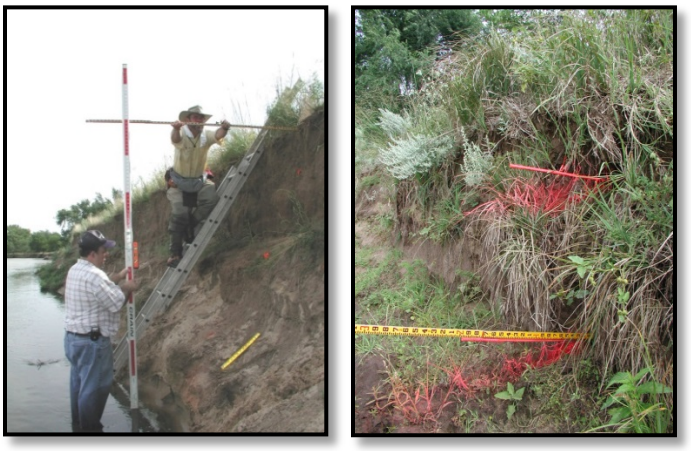
The principle goal of this work was to provide measured data regarding the streambank erosion contributions of sediment for the AnnAGNPS model used in the CEAP project. A broader benefit of this work is the development of streambank recession rates for regions of the country that have similar hydrophysiographic and streambank conditions. The development of the Streambank Erodibility Visual Assessment Tool (SEVAT) calibrated to field measured bank is based on erosion pins and cross-sections by condition class. As a result of this assessment and analysis, these regions will have the opportunity to use real world recession rates on non-cohesive soils ubiquitous to the Midwestern United States.

METHODS AND ANALYSIS

In 2007 Cheney Lake Watershed, Inc., Reno County Conservation District and the USDA-NRCS-Water Quality and Quantity Technology Development Team (W2Q) became partners and

established 10 streambank erosion measurement sites with 30 annually measured bank profiles and 96 erosion pins. Bank erosion pin stations, concrete benchmarks with cross-sections, measured bank profiles, toe pins, bank erosion assessment worksheets, and photo references at ten sites were established. These ten sites varied in bank stability and erosion condition classes ranging from slight to severe (Photos 1 and 2).

Photos 1 and 2: Measuring Streambank Profile and Erosion Pins on Severe Erodibility Condition



Concurrently, both the Bank Erodibility Hazard Index (BEHI) described in Dave Rosgen's Watershed Assessment of River Stability and Sediment Supply (WARSSS) (Rosgen, D.L. 2006) and a more simplified, "Streambank Erosion Visual Assessment Tool" (SEVAT) characterizing condition class, were implemented to provide a comparison between a tool well recognized and often implemented with the SEVAT scores. The objective is to develop SEVAT score sheets which is a combination of verbal description of erosion characteristics combined with extensive photo documentation at an erosion pin station site. The SEVAT tool will be a simpler tool for field offices to use on non-cohesive, coarse textured soil of the Midwest U.S. The SEVAT score sheet is still currently under development by the USDA-WNTSC and the Cheney Lake Watershed, Inc. and targeted for evaluation in 2015. SEVAT scores will be tied to erosion pin recession rates by condition class.

Within each major stream course, streambank conditions were delineated into five categories of streambank erosion rates: negligible (non-contributor), slight, moderate, high, or severe. Within all of the identified stream courses that were evaluated, the estimated height and length of eroded streambanks were assigned according to the height and length of eroded dimensions relative to the channel size and hydraulic geometry characteristics interpreted from ARCGIS. Areas rated negligible were culled from the contributing eroding banks. The five major stream courses are:

1. North Fork Ninnescah (Arlington) above USGS gauge #07144601
2. Silver Creek above USGS gauge #07144660
3. Goose Creek above USGS gauge #07144680
4. Ninnescah – Main-stem above USGS gauge #07144780
5. Red Rock Creek above USGS gauge #07144730

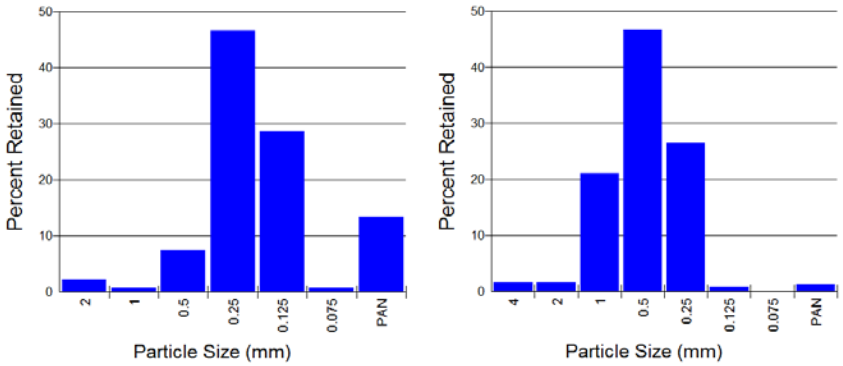
The data represent a combination of field morphometry, field reconnaissance, photo analysis, GIS measuring tools, wet and dry sieving of both bed and bank materials (Photo 3).

Photo 3: Wet and Dry Sieving at Multiple Locations

Bed and Streambank Particle Analysis

In the fall of 2007 and 2012, streambed and bank sieve analyses were completed in the North Fork of the Ninnescah, Photo 3. In 2007, sieve analyses were completed on two sites, one near the town of Arlington on the North Fork of the Ninnescah and one at Site NFN1 on the North Fork of the Ninnescah. The sieve analysis at Site NFN1 is located just upstream of the USGS Depth Integrated Sampling site at the Whiteside Bridge. The bed and bank wet sieve analyses were completed twice at Site NFN1 to compare, contrast and analyze particle size distribution and texture percentages over the six year study period. The two analyses yielded similar results (Figures 1 and 2).

Figures 1 and 2: Particle size distribution on streambanks located upstream of streambed



Streambank Streambed

The dominant soil association throughout all of the streambank study sites in the catchment is the Kanza-Ninnescah, a coarse, predominately sandy, non-cohesive soil that is highly prone to erosion. The data show that nearly all the 0.125mm to 0.25mm and finer materials in the streambanks were mobile once delivered to the water column and moving as suspended load along the streambed. A portion of the 0.25mm to 0.5 sized load is moving as suspended and some of this fraction settles out. The data indicates that the coarser 0.5mm to 1.0 mm sized particles are more present in the streambed post hydrograph recession limb and is not a suspended load component. When sieving of the coarse non-cohesive soils was complete the percent of streambank material parsed to be consistently mobile at a wide range of flows averages 43 to 50 percent. A conservative value of 45 percent was chosen based on the indication that 0.5mm to 1.0mm fraction remaining in the bed indicating that the larger-sized range of the material size .025 to .050mm typically remains as a bedload component. The results of the particle size analysis are consistent for both sampling periods. Particle sizes finer than 0.075mm, primarily silts and clays, are nearly one hundred percent transported to the Cheney Lake Reservoir.

RESULTS

The six year study involved the meticulous field measurements and data generation for ten streambank erosion sites in five streambank condition classes. Annual longitudinal profiles and annual cross sections were developed at each site. A total twenty-eight streambank profile and pin erosion sites along with 28 toe pins and 24 concreted benchmarks were established on ten sites.

Table 1: Streambank Erosion Study Site and Condition Class

Site Name	Condition Class: SEVAT	BEHI SCORE	Sub-watershed (Catchment)	Catchment Size
GC1	Slight	24	Goose Creek	27,935 ac (43.6m^2)
NFN3	Slight	30	NF Ninnescah	331,210 ac (517.5m^2)
SC1	Slight	27	Silver Creek	156,535 ac (244.6m^2)
NFN4	Moderate	32	NF Ninnescah	160,301 ac (250.5m^2)
GC2	Moderate	30	Goose Creek	27,935 ac (43.6m^2)
NFN6	High	36	NF Ninnescah	122,120 ac (190.8m^2)
SC2	High-Severe*	42	Silver Creek	67,758 ac (105.9m^2)
NFN1	Severe	40	NF Ninnescah	356,189 ac (556.5m^2)
NFN5	Severe	46	NF Ninnescah	150,835 ac (235.7m^2)
NFN2	Severe	49	NF Ninnescah	335,549 ac (524.3m^2)

*Condition Class Change during period of study.

The erosion on one severe site was so extreme between 2007 and 2010 that eight-foot pins set in the bank were washed out. However, the team established a cross-section tied to a concreted benchmark. The measure of toe pins and cross-sections and longitudinal profiles also provided data regarding validation of vertical bed stability (incision or aggradation). Table 1 describes Condition class of SEVAT compared to BEHI scores. The results of the SEVAT and BEHI scores show a consistent categorical pattern.

Table 2. Streambank Erosion Rates: Pin, Bank Profile, and Cross Sections

Site Name	Rating SEVAT	BEHI Rating*	Average Annual Recession Rate Ft 5 years	Period of collection Water Cycle Years	Above inner berm flow erosion rate Q_{ib} **	Stream
GC1	Slight	30	0.125	6		Goose
NFN3	Slight	24	0.223	6	.0011ft/hr cycle 3	NFN
SC1	Upper Slight	27	0.224	5		Silver
GC2	Moderate	30	0.50	6		Goose
NFN4	Moderate	32	0.91	6		NFN
SC2	High	42	1.1	6		Silver
NFN6	High	36	1.23	6		NFN
NFN5	Severe	46	2.1	5***		NFN
NFN1	Severe	40	3.02	5***	.045ft/hr cycle 2	NFN
NFN2	Severe	49	3.75	5***	.076ft/hr cycle 2	NFN

*not taking into account near bank stress ratings and two years of BEHI Ratings

**One runoff water cycle, year 2 based on 192 hours above Q_{ib}

*** Water Cycle 6 to be included.

Table 2 is a summary of the five to six year field data. The average annual recession rates of the Kanza-Ninnescah Soil Association ranged from 0.125ft/yr to 3.75ft/yr. These values are higher than the original estimates based on the Ventura Workshop Erosion and Sediment Yield Tool.

Discharges above inner berm flow at two sites located in the proximity of the principle USGS gage near the outlet of the study were analyzed by Thom Garday and W. Barry Southerland. The recession rates averaged between 0.0011ft/hr (for a condition class rating of slight) to 0.076 ft/hr (for a condition class rating of severe).

CONCLUSION

The Cheney Lake Watershed Conservation Effects and Assessment Project has come a long way since the first year of collecting field data and early model runs. Field-based streambank erosion data has been gathered, assessed, and used to provide input to the AnnAGNPS Model. Providing realistic and considerably more robust estimates of streambank erosion based on field-measured data will substantially improve the AGNPS CEAP model. In 2015 the final study will be concluded and report will be completed. Streambank contributions from suspended load estimates from the 2007 Cheney Lake Watershed Streambank Erosion Analysis-CEAP Watershed Technical Report range from 13 to 40 percent of the total suspended load, relative to the five originally gaged catchments. The overall percent of suspended load from the 2007 study was estimated at 13 percent. The preliminary estimates from measured data indicate that the suspended load contribution from banks is between 20 and 25 percent. A more in-depth analysis based on field data and the use of GIS will be used to determine amounts and percent contribution from streambanks will be completed in 2015.

Streambank erosion is highly variable throughout the USA due to integrative processes and variability of streambank material, geomorphic stream type, stratigraphy, change in runoff conditions, and past and present perturbations. This effort of CEAP modeling deserved realistic

input of streambank erosion based on field data, as its hydrophysiographic and streambank conditions are ubiquitous in the Great Plains of Central United States.

Streambank erosion pins and bank profiles were established to calibrate lateral recession rates on the several streambank types with typical conditions. The cost and personnel time committed to establish pins is minimal and the data are highly useful for future planning efforts and calibration of lateral recession rates. These data can be used to developed regional streambank erosion curves that would be characteristic of Midwestern areas and states similar to Kansas to assist NRCS planning efforts in the future. The Cheney Lake Watershed is large and diverse enough to establish an excellent database for streambank erosion and stability.

The appropriate parsing of suspended sediment load contribution from streambank contribution to total load was essential for a robust model. In 2014, after six years of field date collection, the annual recession rates based on condition class has been refined. Ten years would be more desirable and potentially within the prevue of the Cheney Lake Watershed, Inc.

There has been a tendency to use streambank erosion data throughout other regions of the country where the variability in recession rates are substantially different, given similar runoff conditions. Now is the time to begin this effort. There has never been a better time to commit to field collection of this valuable data as our reservoirs continue to fill at accelerated rates and suspended sediment loads from streambanks continue to be a significant source.

I would like to express my appreciation to the Cheney Lake Watershed, Inc. and the Reno Conservation District for supporting this critical data collection and analyses for the past seven years.

VEGETATION CALIBRATION IN A SEDIMENT TRANSPORT MODEL OF THE MIDDLE RIO GRANDE, NEW MEXICO

David Varyu, P.E., Hydraulic Engineer, Reclamation, Denver, Colorado, dvaryu@usbr.gov
Lisa Fotherby, Ph.D., P.E., Hydraulic Engineer, Reclamation, Denver, Colorado, lfotherby@usbr.gov

OVERVIEW

The purpose of this project is to develop a calibrated sediment transport and vegetation model for the Middle Rio Grande downstream of San Antonio (HWY 380 Bridge) to Elephant Butte Dam. Geomorphic conditions of flow, sediment transport, riparian vegetation and groundwater are linked in the SRH-1DV simulation. Hydraulics, sediment transport and groundwater conditions are defined by physical laws of nature, and the ecological factor, vegetation growth, is described by known plant response to the geomorphic factors. The establishment, growth and mortality of vegetation is tracked on a daily basis in response to dynamic physical conditions, and is tracked as individual plants located on every node at every cross section in the model (Fotherby 2012).

Model Description SRH-1DV is an adaption of SRH-1D, a one-dimensional mobile boundary hydraulic and sediment transport computer model for rivers and manmade canals. The base model simulates changes to rivers and canals caused by sediment transport. It can estimate sediment concentrations throughout a waterway given the sediment inflows, bed material, hydrology, and hydraulics of that waterway. Simulation capabilities include steady or unsteady flows, internal boundary conditions, looped river networks, cohesive and non-cohesive sediment transport, and lateral inflows. It uses cross section based river information (Huang and Greimann, 2011).

SRH-1DV simulates the processes of seedling growth and mortality as a function of species type, changing river stage and groundwater level, the rate of root growth, and the potential for scour velocity. SRH-1DV tracks the potential for species-specific plant mortality due to drowning, velocity scour, and desiccation. The model assumes that the river has an abundant seed source. During the seed dispersal and germination season, the model assumes that seeds will germinate and begin to grow at all points above the wetted channel. A seedling is initially very vulnerable to mortality, but as it continues to grow, the plant becomes more resistant to the plant stresses induced by desiccation, drowning or scour and it increases the local hydraulic roughness of the channel. If a cottonwood seedling survives to an age of three years, the cottonwood tree then becomes very resistant to removal by scouring erosion (http://www.usbr.gov/pmts/sediment/model/srh1d/1dv/ index.html accessed December 2012).

MODEL INPUT DATA

The model input for SRH-1DV is the same as input for SRH-1D – channel and floodplain geometry, bed material gradation, sediment transport function, and boundary conditions – with the addition of vegetation inputs. The vegetation inputs include spatially defined age and vegetation coverage percentages, along with germination, growth, and mortality parameters for every vegetation type modeled. In addition to these input files, a GIS-based shapefile from vegetation mapping is required to define vegetation conditions (type and location) at the start of the simulation. A table in the vegetation input file translates the vegetation mapping classifications into the vegetation types (plants) simulated in the model.

Geometry The model spatial extent is from just upstream of the US-380 Bridge in San Antonio, NM to Elephant Butte Dam (Figure 1). The input geometry combines a portion of the 2002 ag-deg data set (Holmquist-Johnson, 2004; ~RM89-RM60), a 2007 bathymetric survey of Elephant Butte reservoir (Ferrari, 2008; ~RM41-RM27), and from various local surveys associated with the development of the Delta Channel into the pool of Elephant Butte Reservoir (~RM60-RM41). Every measure was taken to ensure a consistent vertical datum, however some survey data did not report a vertical datum and professional judgment was employed where necessary to convert all geometric data into NAVD88 elevations.

The input geometry data was developed in a HEC-RAS file and a series of discharges were run. Cross sections were edited as necessary in terms of adding levees, blocked obstructions, and ineffective flow areas to the model geometry to produce hydraulic conditions representative of actual flow patterns. For example, in areas where the channel is not in the lowest elevation of a cross section, levees are implemented in the model geometry to keep the water in the perched channel. A total of 196 cross sections were used in the model, including 159 measured cross

sections and 37 interpolated cross sections. Maximum cross section spacing was limited to 2500 feet, except in the lower end of the reservoir pool where the cross section spacing is irrelevant because the cross section spacing is irrelevant because the cross sections remain inundated by the pool.

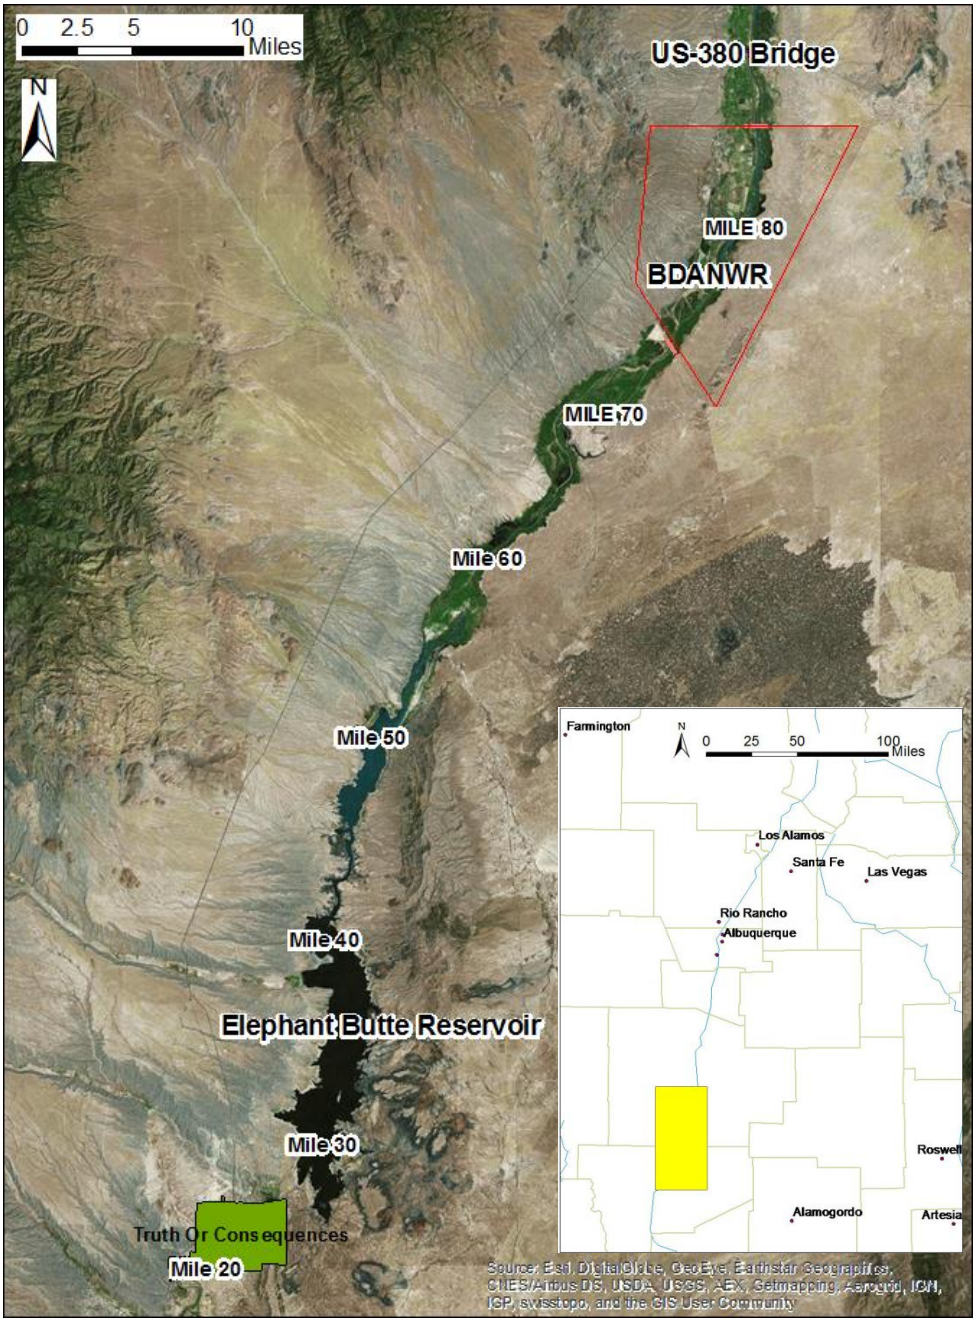

Figure 1 Overview map of model extent: US-380 Bridge to Elephant Butte Dam.

Bed Material and Sediment Transport Bed material data have been collected along the Rio Grande for various projects since the 1970s. Data appropriate for this model reach and time period were collected and prepared for model input. Twenty-eight sediment gradations are spatially assigned in the model, with the most downstream gradation located at EB-28 (~RM58). This gradation represents conditions for the model downstream of this point. The median grain size for the model domain is fairly uniform as compared to upstream reaches of the river, and a

range of 0.1 mm to 0.3 mm exists for all gradations employed in the model. The Engelund-Hansen transport formula is used in this model based on the size of the bed material in this spatial extent.

Boundary Conditions Boundary conditions need to be defined for the numerical model SRH-1DV. These include upstream conditions (flow rate and sediment discharge rate), downstream boundary condition (water surface elevation), and lateral flow and sediment contributions.

The temporal extent of this model begins in water year 2002 and ends with water year 2008. Daily discharge data from two USGS gages (08354800 Rio Grande Conveyance Channel at San Acacia, NM, 08354900 Rio Grande Floodway at San Acacia, NM) were combined to produce the upstream flow boundary condition for 10/01/2001 to 09/30/2008. The downstream boundary condition is defined as the water surface elevation of Elephant Butte Reservoir, and that daily data was transformed from local project datum to NAVD88 elevations. Figure 2 presents upstream boundary condition of incoming river discharge and the downstream boundary condition as the elevation of the Elephant Butte Reservoir pool.

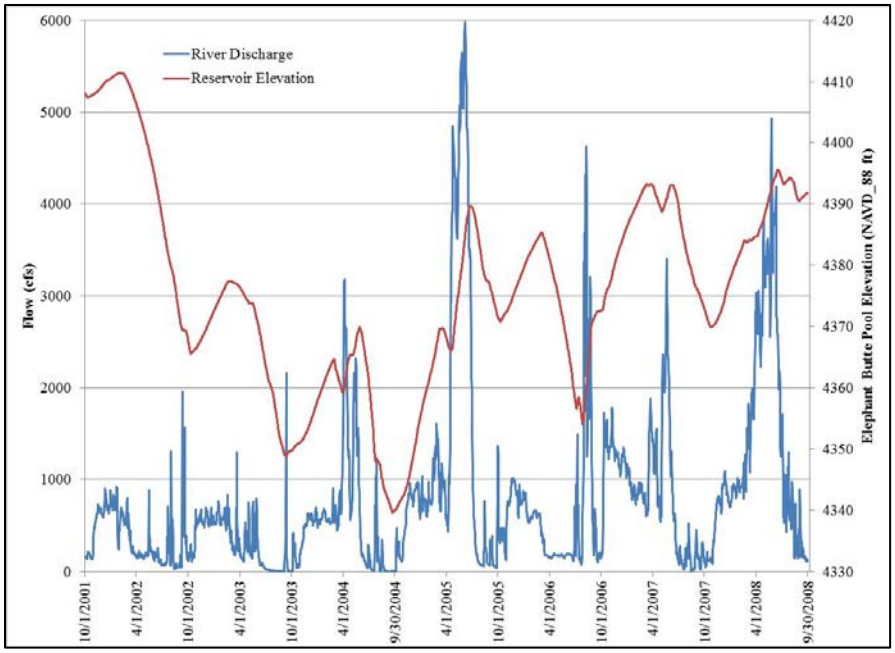

Figure 2 Downstream boundary condition; Elephant Butte Reservoir pool elevation.

The incoming sediment load at the upstream boundary of the model was developed by applying sediment rating curves based on dry, average, and wet flow regimes (Huang and Makar, 2012). Table 1 presents the classifications of the water year as Wet/Average/Dry, along with the coefficients a and b in for the power function rating curve sediment discharge to water discharge of the form $Q_s = aQ^b$.

Table 1 Water year type and sediment load coefficients used for upstream sediment supply.

Water Year	Flow Regime	coefficient a	coefficient b
2002	Dry	1.654	1.283
2003	Dry	1.654	1.283
2004	Average	2.895	1.229
2005	Wet	32.87	0.825
2006	Average	2.895	1.229
2007	Average	2.895	1.229
2008	Wet	32.87	0.825

Collins (2009) calibrated the gradation of the upstream sediment supply for the delta channel using published USGS data. Bureau of Reclamation Automated Modified Einstein Procedure (BORAMEP) was used to process USGS suspended sediment concentration data along with bed material gradation data to produce the gradation of the total sediment load at the upstream end of the reach. Sediment load gradations are assigned for five unique discharges ranging from 500 cfs to 6000 cfs (Figure 2).

Significant tributary contributions of water and sediment do not reach the mainstem of the Rio Grande in this reach due to levees. No lateral flow or sediment inputs are included in this model.

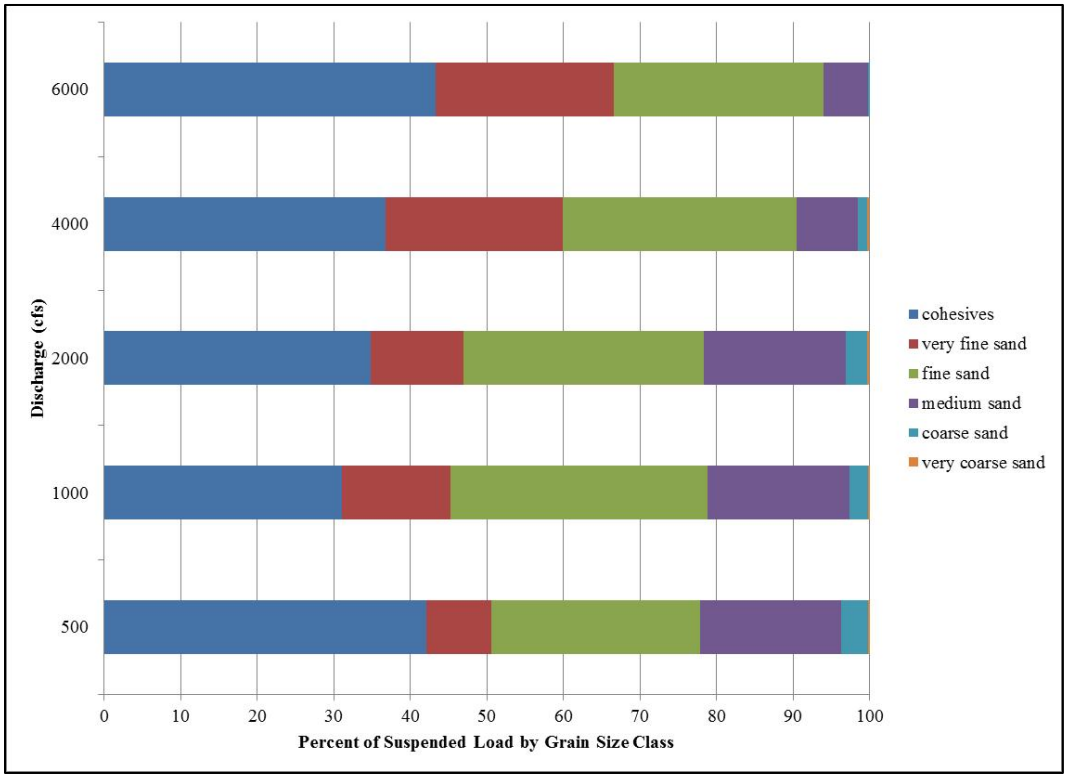

Figure 3 Changing gradation of upstream sediment supply as a function of discharge.

Vegetation data Vegetation was calibrated from initial to final conditions. The initial conditions were based primarily on the 2002 vegetation mapping (Callahan and White, 2004) which extends from upstream of this model domain to just downstream of river mile (RM) 62. Ancillary initial condition data from a 2004 vegetation map (Reclamation, 2005) was used as needed. The final conditions for the vegetation are derived from the 2008 vegetation mapping (Ahlers et al., 2010).

Discussion of Hink and Ohmart Classification and Interpretation The Hink and Ohmart (H&O) vegetation classification (Hink and Ohmart, 1984) was adapted and slightly modified by Reclamation biologists (Moore and Ahlers, 2003) while conducting habitat mapping for the southwestern willow flycatcher (SWFL), an endangered species. In general, the H&O system classifies vegetation based on species, height and whether there is a well-developed understory to supplement a canopy (overstory). Multiple vegetation species can be listed in the canopy/overstory and understory, where the first-listed species in the vegetation code is the most prevalent and the last listed is the least prevalent.

One of the modifications made by Moore and Ahlers (2003) was to try to better describe the vegetation density in 25% coverage increments. There were some methodological differences between the 2002 and the 2008 mapping, but in trying to maintain some consistency between the two datasets, they are interpreted and implemented as follows. The understanding during 2002 vegetation mapping was that nearly 75% vegetation coverage or more was needed for SWFL to find suitable nesting habitat. During the 2004 vegetation mapping, habitat occupations were

identified in areas where vegetation coverage was less than 75%, but still greater than 50%. The 2004 and 2008 vegetation mappings use a "d" indication (dense) at the tail end of the H&O classification to indicate vegetation coverage between 50-75%, where the 2002 data uses an "f" indication (full) for vegetation coverage greater than 75%. There was also an "s" indicator that was meant to indicate 'sparse' or 'scattered' (USACE et al., 2007), and the appropriate interpretation of this is unclear. For an area to be identified as 'covered' with vegetation there needs to be at least 25% coverage. It was assumed for this study that an identified area with an "s" qualifier was the same as if there was no qualifier.

A comparison of initial vegetation coverage (2002 and 2004 mapping) to final vegetation coverage (2008 mapping) includes 461 unique vegetation classifications, including a classification for no-grow areas (roads, railroad track) and open water areas (river and reservoir). Each unique vegetation classification can be one of 4 different density variations. For example, a lone stand of salt cedar, 5-15 feet high (H&O structural Type 5), can be sparse or scattered (s), dense (d), full (f) or have no density indicator.

Modified Hink and Ohmart Applied to SRH-1DV Input Transferring initial vegetation conditions defined by vegetation mapping classifications to the vegetation types and cross section locations simulated in SRH-1DV model requires some interpretation. In the modified H & O vegetation classification system, it is not uncommon to have the same vegetation type at two different ages in the same classification. A mature cottonwood can be present in the canopy and younger trees may form part of the understory. The SRH-1DV model does not simulate or track two of the same vegetation types on a single point. It was therefore necessary to have two vegetation types to represent the same species at different ages; one older and taller for the canopy, and one younger and shorter for the understory. This was not necessary for grasses or cattails as their maximum height does not exceed 15 ft. To ensure that twice as many germinations are not produced in SRH-1DV, only one age class for a given species is allowed to germinate. The younger category of a given species was arbitrarily assigned the ability to germinate, even though the older stands of some species, such as cottonwoods, would be more likely to supply seeds.

Vegetation mapping is normally classified by plant height (H&O vegetation structure) while vegetation modeling is based on plant age with plant height as a function of age. Fotherby (2012) provides growth rates for the vegetation types by age. These growth rates were used to translate vegetation height (H&O vegetation structure) into an age (SRH-1DV input).

Simulated Vegetation Types The model has to be able to distinctly represent a species' characteristics and responses to environmental conditions to justify simulation in this riparian vegetation model. Only riparian species that are frequently dependent on the water table for moisture can be well simulated; the species simulated in this Rio Grande model are Fremont cottonwood, Gooddings black willow (tree willow), sand bar willow (coyote willow), mulefat (seep willow), honey mesquite, cattail, Russian olive, tamarisk (salt cedar), and grasses (grass is a generic grouping of herbaceous and drought resistant upland grasses that provide ground cover) (Fotherby, 2012). Although there are many more species in the area, the number of simulated species is limited. There are a large number of parameters required for each species and all parameters cannot be calibrated or verified in each model. Fremont cottonwood is used here to represent cottonwoods, sand bar willow and mulefat are the representative riparian shrubs, honey mesquite is also assigned for screwbean and common mesquite, Russian olive is also assigned for New Mexico olive, only one tamarisk is simulated, and the only herbaceous representation is an upland grass that is resistant to desiccation. Roads and railroads are simply 'no-grow' zones.

Using two vegetation 'types' for different ages of the same species (older/taller and younger/shorter) as well as a no-grow designation (no plant establishment permitted) yields a total of 17 vegetation types: seven with two age/height classes, two with one age/height class, and the 'no-grow' vegetation type. A description of these vegetation types and references for SRH-1DV parameter selection are presented in Fotherby (2012).

Assigning Density to Initial Conditions Initial vegetation conditions in the model are also assigned from density reported in vegetation mapping. Vegetation densities in the modified H&O classification system are broken down in 25% vegetation cover increments. An 'open' polygon in the 2002, 2004, and 2008 vegetation mapping would indicate that there is less than 25% coverage, and the indicators "d" and "f" indicate 50-75% and 75-100%, respectively, where no indicator implies 25-50% vegetation cover. This is the total percentage of vegetation cover, regardless of how many species are present or listed in the category. Certain assumptions were made to implement the modified H&O information into a format suitable for SRH-1DV. First, vegetation densities for a given mapped

polygon are set at 37.5%, 62.5%, and 87.5%, depending on the presence/absence of an indicator ("d"/"f"). Second, the breakdown of relative percentages is based on their order as specified in the H&O classification method.

Table 2 presents the breakdown of implemented vegetation cover based on the number of species defined in each structure layer (canopy/overstory, or understory) of the vegetation code.

Table 2 Distribution of vegetation cover by code indicator and number of vegetation types.

	Number of vegetation types listed				
Total%	1	2	3	4	Total
25-50 (regular)	37.5				37.5
	20	17.5			37.5
	15	12.5	10		37.5
	12.5	10	7.5	7.5	37.5
50-75 (d=dense)	62.5				62.5
	33.3	29.2			62.5
	25	20.8	16.7		62.5
	20.8	16.7	12.5	12.5	62.5
75-100 (f=full)	87.5				87.5
	50	37.5			87.5
	35	30	22.5		87.5
	30	22.5	17.5	17.5	87.5

Vegetation Calibration Methodology The 2002, 2004, and 2008 vegetation maps used as model inputs and comparisons for model outputs are based on aerial percent coverage. The methodology used in this calibration process is based on percentages of model nodes (cross section points) located within a polygon. The assignment of vegetation species onto SRH-1DV model nodes is based on the polygon where the node is located and the percent vegetation cover specified in the input file. The number of nodes assigned a given vegetation type will be as close to, without exceeding, the assigned percent cover, or density.

The assessment of the model output worked in a similar manner. The model output reports a set of predicted vegetation types existing on every model node. Nodes are allowed to have more than one vegetation type, so the number of rows in the main model output text file equals the product of the number of model nodes multiplied by the number of vegetation types. The model nodes are located within the appropriate 2008 vegetation mapping polygon and the model outputs are compared to the observed data as recorded in the 2008 mapping polygons. The model comparison is not cross section based but rather polygon based since there are usually multiple segments of cross sections within a given polygon.

MODEL CALIBRATION

For this project, the ability to calibrate the sediment transport is important only in terms of being able to calibrate the vegetation data. For example, being able to exactly match the channel degradation due to the drop in Elephant Butte Reservoir elevation (base level lowering) is not necessary as long as the modeled degradation is sufficient to lower the water table elevation in the area and allow simulated vegetation mortality due to desiccation.

Almost half of the species for this Rio Grande study are being modeled for the first time in SRH-1DV. The parameters for each species are selected from a range of values identified in a literature review. Many parameter values required adjustment during calibration. Growth rates, germination seasons, dormant seasons and drought and inundation tolerance can all vary with regional climate differences and parameters from previous applications in different regions may not be suitable for the Rio Grande. The large number and detailed assignment of modified

H&O classifications for initialization of this model are another reason for a calibration investigation. The maximum spacing between cross section points was limited to 25 feet to ensure every vegetation polygon was represented by a model node. The number of model nodes is 66,198 for the model domain.

Through the course of the calibration process, adjustments were made to germination, growth, and mortality parameters for various plant species. A list of significant changes to the initial parameters (as defined by Fotherby 2012) is followed by a discussion of the final calibration results.

All Vegetation Types

- The model input competition tables are set up to define at what age a species will be out-competed by other species/age combinations. Therefore, each competition table was adjusted so that young tamarisk would out-compete other young vegetation types (further discussion of this adjustment below).
- Dormancy period extended from December 1 through January 1 to October 1 through March 31.

Mulefat

- Scour velocity needed to remove new and one year old plants reduced by one-third (to 0.67ft/s and 1 ft/s respectively).

Tamarisk

- Germination period extended from July 1 through September 30 to March 14 through November 15.

Upland Grass

- Scour velocity needed to remove new, one, and two year old plants reduced by one-half (to 1ft/s, 1.5ft/s, and 2ft/s respectively)

The list above does not encompass all of the iterations attempted in the calibration process, but only a summary of the changes between the initial set of vegetation parameters and the best-fit calibration parameters. The interpretation and implementation of the H&O classification system to SRH-1DV was at least as involved a process as calibration of the germination, growth, and mortality parameter for the vegetation species.

Vegetation Calibration Results There are 808 mapped polygons included in the calibration analysis. The final analysis methodology calculated the difference in percent coverage for all vegetation types within four different height categories (associated with the H&O structure classification): 0 to 15 feet, 15 to 20, 20 to 40, and over 40 feet. For the nine species being modeled (not counting the 'no-grow' vegetation type), there are 36 species/height categories being considered per polygon. The most common error is in the 0 to 15 feet range for all species except for Gooddings black willow (tree willow) and mesquite. This indicates that the germination process is a likely source of the most error in the simulation. Figure 4 shows the count of which age class represents the highest percent error per species per polygon.

If we consider the error of each vegetation type across the 808 vegetation polygons, we can discretize the error based on how many model nodes are within each polygon. Table 3 presents the grouping of polygons based on the number of model nodes within that polygon. The one polygon within the range "Q" is a polygon classified as "open water" and is the continuous riverine and reservoir polygon in the model, and the upper bound of this range was selected such that the midpoint of the range equaled the number of model nodes in this polygon.

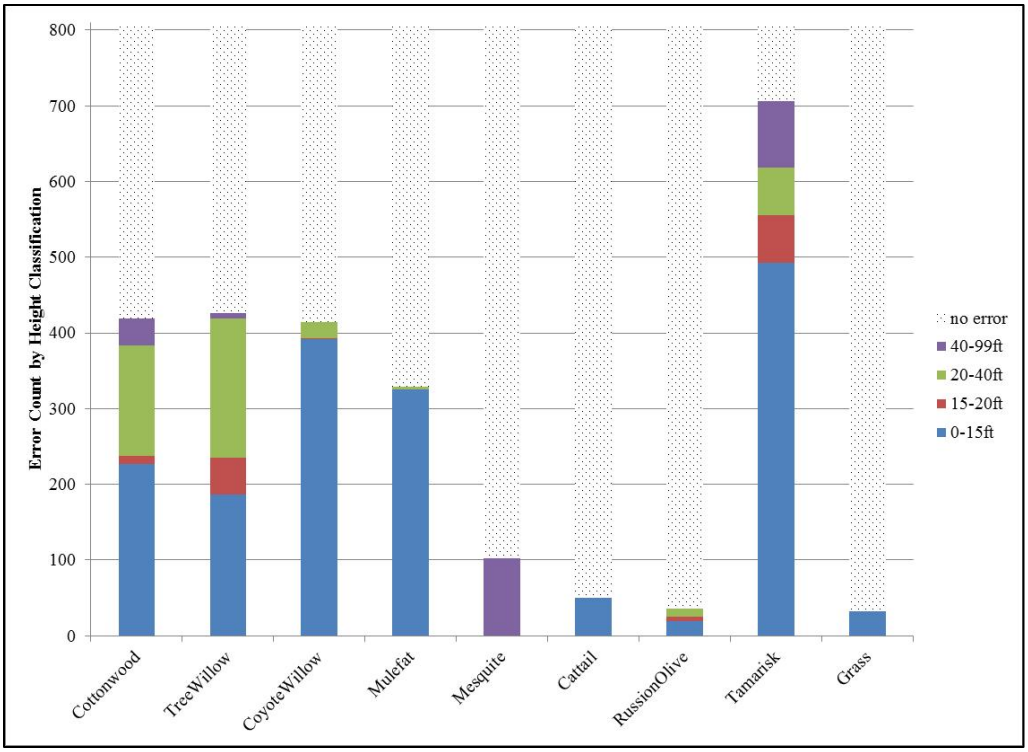

Figure 4 Count of age class representing the highest error per species polygon.

Table 3 Bin ranges used in analyzing error by number of model nodes in mapping classification polygons.

Range ID	Min Model Nodes	Max Model Nodes	Count Polygons in Range
A	1	5	116
B	6	10	132
C	11	20	168
D	21	30	125
E	31	40	63
F	41	50	44
G	51	60	31
H	61	70	25
I	71	80	11

Range ID	Min Model Nodes	Max Model Nodes	Count Polygons in Range
J	81	90	7
K	91	100	8
L	101	200	42
M	201	300	13
N	301	400	13
O	401	500	3
P	501	600	6
Q	601	29586	1

Figure 5 presents the average maximum absolute error (of the four height classifications) by vegetation type relative to the midpoint of the bin range. For example, consider the "O" bin range. There are three polygons that contain between 401 and 500 model nodes. If we consider just tamarisk, the maximum error for two polygons was in the 0 to 15 ft height range (-70% and 59%), and for one polygon was in the 40-99 ft height range (error of -25%). A negative error means SRH-1DV is predicting too much of a vegetation/height combination and a positive error indicates not enough of that vegetation/height combination is being predicted. The average of the maximum absolute error for tamarisk for the three polygons containing between 401 and 500 model nodes is 52%. This point is the peak error in Figure 5. The results in Figure 5 show good calibration (considering measured data specified in 25% bins), with tamarisk being the species that was least successfully calibrated. Another way to look at the calibration results is to consider the average (over the bin range) of the average error of the four height classifications for one

vegetation species. This is simply the average error of all 12 (four height classes by three polygons) error values associated with a bin range. Figure 6 presents the average error for each vegetation species by bin range.

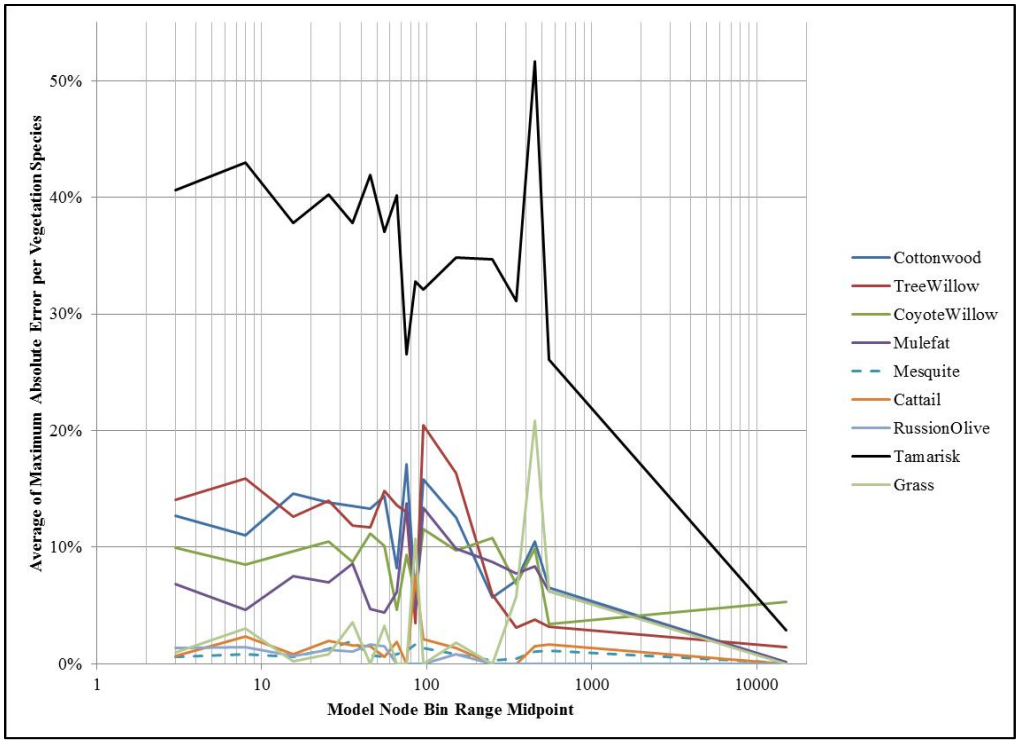

Figure 5 Plot of average of maximum error per vegetation species.

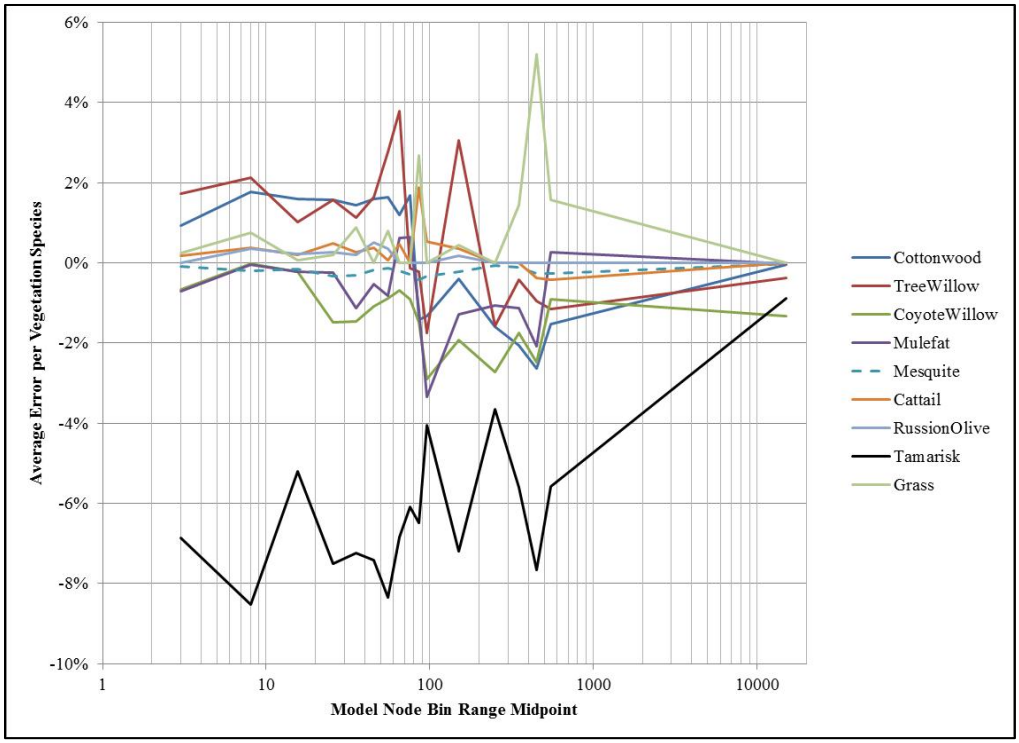

Figure 6 Average error per vegetation species.

These differences can be represented visually using ArcMap. Instead of trying to combine errors by bin ranges as was done above, the actual error for a given polygon can be presented for one vegetation species and height classification at a time. A python script was developed as a tool to translate SRH-1DV output text files into visually represented error polygons. Figure 7 presents an example plot that can be made for any combination of vegetation species and height classification, in this case Tamarisk for 0-15 ft (selected polygons outlined in cyan). The color coding is constructed in absolute terms and all errors that are negative are hatched horizontally while positive errors are hatched vertically.

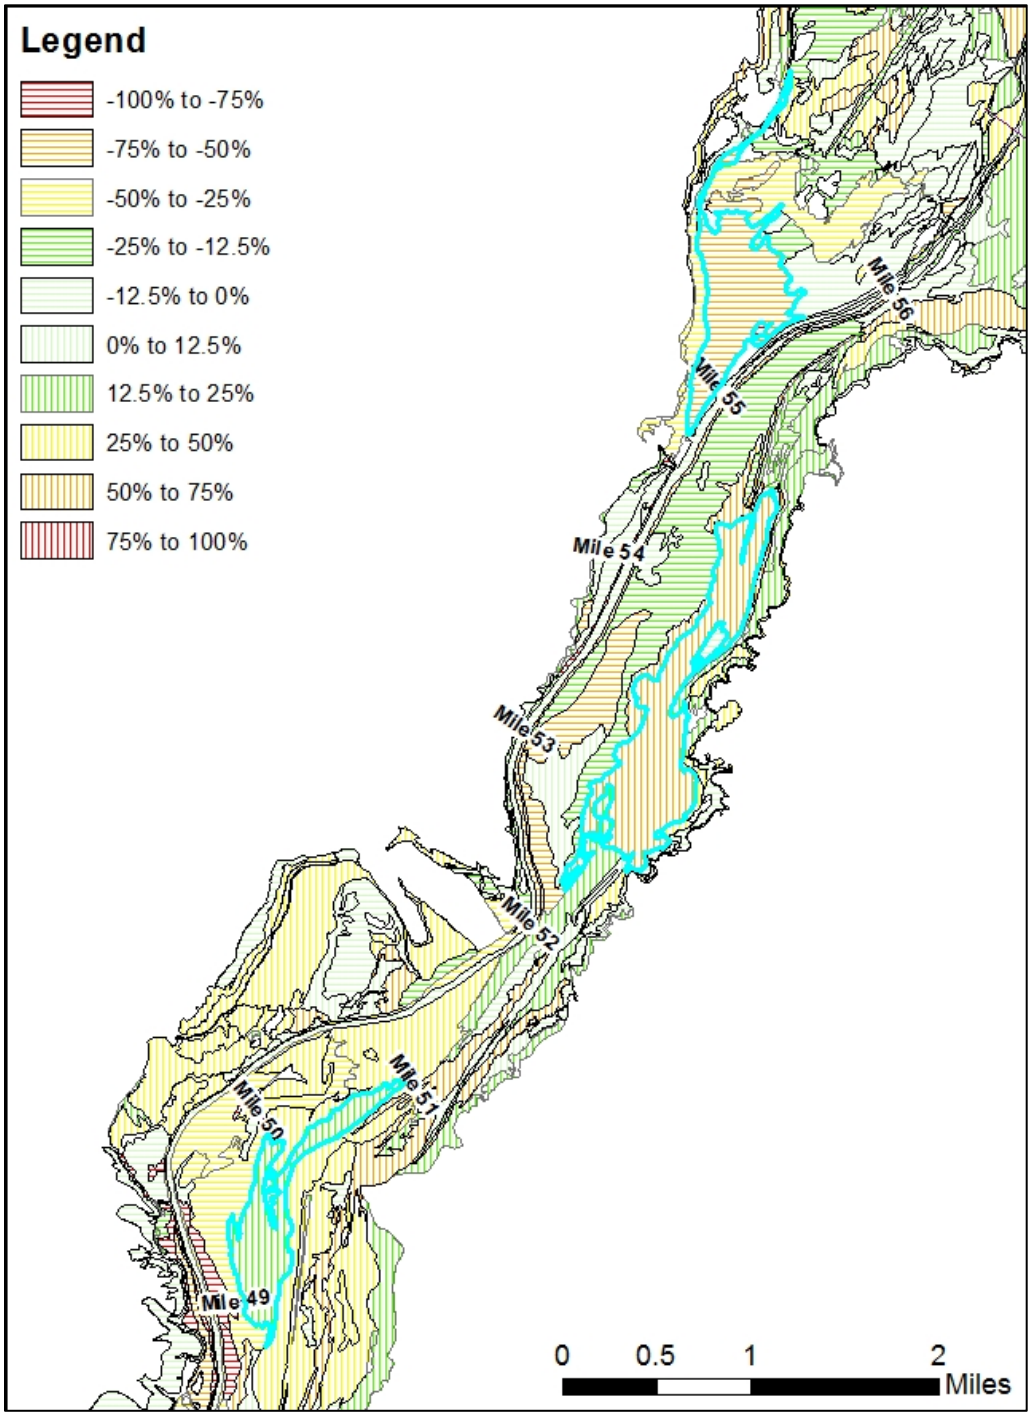

Figure 7 Vegetation polygons attributed by error in percent coverage for Tamarisk, 0-15 feet tall.

MODEL LIMITATIONS, ERROR SOURCES, AND AREAS OF IMPROVEMENT

This model, as with any, contains errors; some of which are due to data availability, some of which are due to limitations to the SRH-1DV model, and some are areas that could be improved (further calibrated) with more time and effort. A brief list describing some potential improvements follows:

- **Mapping inconsistencies**: In some instances the dominant canopy species for a 2008 polygon is not identified at all for the associated 2002 polygon.

- **Growth rates** are input into the model based on age and month of the year only. A wet year could allow for more tree growth (stalk diameter) than a dry year. The model could be adjusted to allow for this.

- **Lateral channel adjustment:** Some errors in the simulation are due to the fact that channel width change and lateral migration are processes not modeled in the 1D framework.

- **Anthropogenic influences:** channel excavation conducted by heavy machinery, channel clearing to increase morphodynamic response, and vegetation planting during habitat improvements are all actions taken on the river but are not simulated in the model.

- **Groundwater module:** the groundwater module is relatively coarse in the SRH-1DV. One soil type is incorporated in the Rio Grande model with one hydraulic conductivity value for the floodplain sediments, although two input types are allowed. This is a gross assumption, yet necessary as the data needed for accurately mapping hydraulic conductivity for this large area would be monumental.

- **Salinity:** Salt cedar (tamarisk) is considered a disturbance species, where it doesn't necessarily out-compete native species, but is able to take advantage of conditions where native species cannot survive (including high saline environments, hence the name). To overcome salinity not being simulated, tamarisk was modeled as a relatively competitive species, even though literature describes is as non-competitive. In this way, a native species that would not be able to germinate in the real world due to some level of salinity in the soil, is modeled as being outcompeted by salt cedar in SRH-1DV. The end result in the model is similar to reality, where the native species would not establish but salt cedar would. Incorporating salinity would make SRH-1DV more data intensive and it may not prove beneficial. Manipulating the competition table appears to be an appropriate surrogate for salinity modeling.

- **Interpretation of the modified H&O Vegetation data:** Implementing some bounded random number generator into SRH-1DV could allow for multiple vegetation age/heights to be assigned to model nodes according to the height range specified by the H&O classification system. Also, there are four density ranges from the modified H&O system at 25% increments. Similar to age, a random number generator could be implemented either within SRH-1DV or in the input file generation where the vegetation density could be any value as long as it was within the appropriate 25% range. It would be necessary to develop many simulations using the random number generators and statistically evaluate the outputs to determine if the central tendencies predict the observed end condition reasonably well.

CONCLUSIONS

The calibration of multiple species within SRH-1DV to the Middle Rio Grande was completed with good accuracy. The average error for all species/age combinations was well within the accuracy of the measured data. Further calibration may prove useful. In addition, a methodology for processing, presenting, and interpreting SRH-1DV results using ArcGIS has been developed and can be easily applied to future model runs.

Additional calibration, if conducted, would involve identifying the mode of mortality for all species within the model spatially and determining if that mechanism is being appropriately simulated. Germination would be looked at as well to see if plants are not only establishing in the right quantities but also identifying the mechanisms as to why establishment is or is not occurring in certain areas. Conducting multiple simulations using a bounded random

number generator to assign vegetation age and density appropriate to the H&O classification system would be another option in further calibration of SRH-1DV to the Middle Rio Grande.

A recent vegetation mapping using the H&O classification system was completed in 2012 and the final product will soon be available. Conducting a model validation for the period of 2008 to 2012 would provide insight as to the effectiveness of the model calibration and would help refine values assigned to various vegetation germination, growth, and mortality parameters. If the validation proves successful, then further calibration may not be necessary. The vegetation model, whether or not further calibration and validation are pursued, can be used for analyses of the effects of potential river maintenance actions and/or water operations. Absolute predictions of future conditions may not be a proper application of this model but rather a relative ranking of the effects in terms of sediment transport and vegetation conditions could be accomplished by employing this model.

Acknowledgements I would like to acknowledge the amount of research and literature review conducted by Lisa Fotherby in gathering the data necessary to apply appropriate values to the germination, growth, and mortality parameters for the SRH-1DV model, as well as providing additional review of this document. Dave Moore and Darrell Ahlers provide valuable information to interpreting and applying the Hink and Ohmart classification system. I would also like to acknowledge Victor Huang and Blair Greimann for developing both SRH-1D and the vegetation module for SRH-1DV.

REMOVING INVASIVE PLANTS FROM THE MOJAVE RIVER, AN EROSIVE INLAND DESERT RIVER SYSTEM IN SOUTHERN CALIFORNIA

Greg Norris, Assistant State Conservation Engineer, NRCS, Davis, CA, greg.norris@ca.usda.gov
Julia Grim, Geologist, NRCS, Davis, CA, julia.grim@ca.usda.gov

INTRODUCTION

In 2009, the Mojave Desert Resource Conservation District (MDRCD), in partnership with the Mojave Water Agency (MWA) and the USDA-Natural Resources Conservation Service (NRCS), began work to remove Arundo (*Arundo donex*) and saltcedar (*Tamarix ramosissima*) from areas within a 48-mile long riparian corridor within the Mojave River channel, referred to as Phases 3 and 4. Figure 1 provides a location map of the project area as it relates to the overall Mojave River watershed. As part of project planning, resource specialists from NRCS and MDRCD evaluated the potential impacts of the proposed project on stream function and riparian ecology.

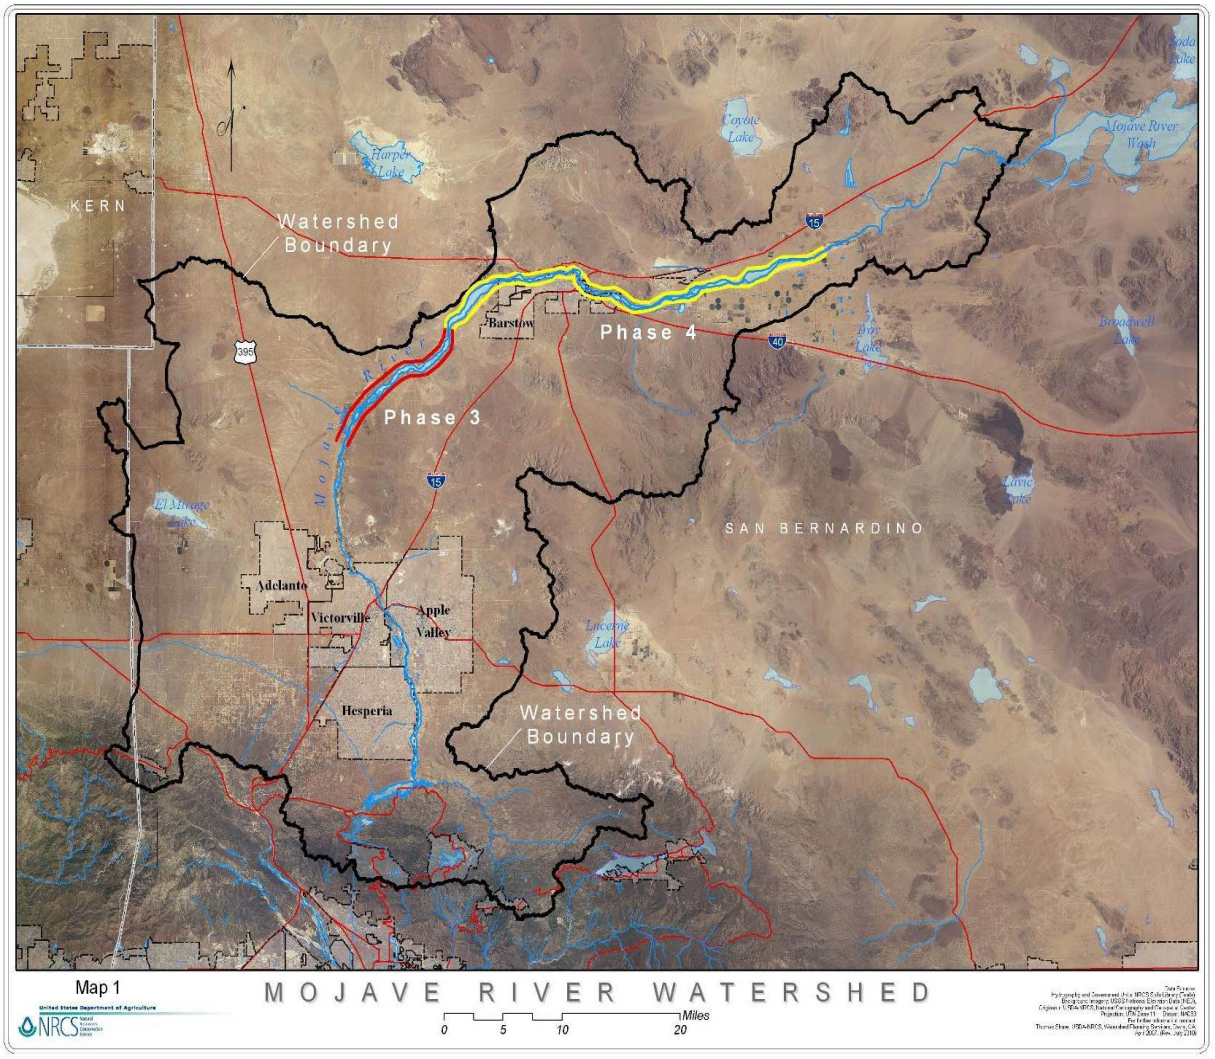

Figure 1 Map of Mojave River watershed showing the Phase 3 and 4 reaches.

The Mojave River is located in the high desert region of Southern California. It flows from the San Bernardino Mountains, inland through the Mojave Desert, to its terminus at Soda Lake. The flows in the alluvial reaches of the river are naturally ephemeral and flashy, but are greatly influenced by upstream water storage and imports, a flood control structure, levee confinement, locally high rates of groundwater withdrawal, and discharges from a municipal waste treatment facility. This altered hydrologic regime contributed to the establishment of non-native plants such as Arundo and saltcedar. Figure 2 depicts typical conditions found in these reaches and provides an example of how saltcedar plants invade the channel bed out-competing the native vegetation for moisture. The high density of these non-native species along some reaches further affect the geomorphology, hydrology, and ecology of the riparian community, by altering stream flow patterns and restricting channel capacity, consuming relatively large amounts of groundwater, and out-competing natives.

Figure 2 Typical condition of Mojave River within the Phase 3 and Phase 4 reaches.

METHODOLOGY

The evaluation team recognized a relationship between different areas of the river channel and critical resource concerns. Critical resource concerns were identified as streambank erosion, wind erosion, wildlife habitat, water conservation, and flooding. To help evaluate the effects of the critical resource concerns, the river channel was delineated into three distinct geomorphic categories based on function and the following characteristics: active channel, active floodplain, and terrace. Sub-reaches within the Phase 3 and Phase 4 reaches were further identified based on vegetation density and channel configuration. Then, each of the five resource concerns were evaluated for each geomorphic category within each sub-reach to determine whether there would

be a positive effect, negative effect, or no effect on the adjacent land uses if vegetation was removed. The team evaluated all potential combinations of land uses and resource concerns. If a negative effect was determined based on the criteria developed by the team, then a critical area was highlighted as needing special considerations with a recommended alternative for removal of invasive plants.

LAND USES

The evaluation team identified four typical land uses that occur adjacent to the Mojave River within the project Phase 3 and 4 reaches: private open land, public open land, homes and agriculture, and transportation infrastructure. For each sub-reach, the team evaluated how the resource concerns affect the adjacent land use if the invasive plants were removed. "Adjacent" for this project was defined as the distance extending from the river channel out to the point where the resource concern no longer has an effect.

CHANNEL FEATURES

Within the Phase 3 and Phase 4 project reaches, the team delineated the sub-reaches based on geomorphic and vegetative differences inferred from the 2007 MWA ortho-photography. The active channel, the low sand bars referred to as floodplain, and terraces were delineated using the MWA ortho-photography augmented by the team's field observations.

In several instances, some features were difficult to delineate because they were not apparent on the ortho-photos. For example, the low sand bars that form the floodplain were sometimes only a few inches higher than the active channel. Oftentimes these sand bars were only distinguishable from the active channel because there was some sparse vegetation, such as grasses, growing on them; or they had not been recently scoured or reshaped. Figure 3 shows an example of channel feature delineation for sub-reach 2 within the Phase 3 reach. The active channel, as mapped for this evaluation, appears in blue, the floodplain in green, and the terrace in orange. Vegetation maps were also used as an aid in delineating the channel features.

EVALUATION OF EFFECTS

The team evaluated the effects of invasive plant removal within each sub-reach and associated geomorphic feature relative to each land use (houses and agriculture, private open space, public open space, and roads/transportation) and each resource concern (wind erosion, flooding, habitat, water conservation, and stream bank erosion), for all sub-reaches in Phases 3 and 4. Table 1 provides an inventory of the results for one sub-reach (Phase 3, sub-reach 2) as an example. In Table 1, a plus (+) symbol indicates that invasive plant removal may reduce detrimental effects of specific resource concerns on particular land use categories. A zero (0) symbol indicates that invasive plant removal would most likely have no impacts, positive or negative, on effects of resource concerns on specified land use categories. A negative (-) symbol indicates that invasive plant removal may increase negative effects of specified resource concerns on particular land use categories.

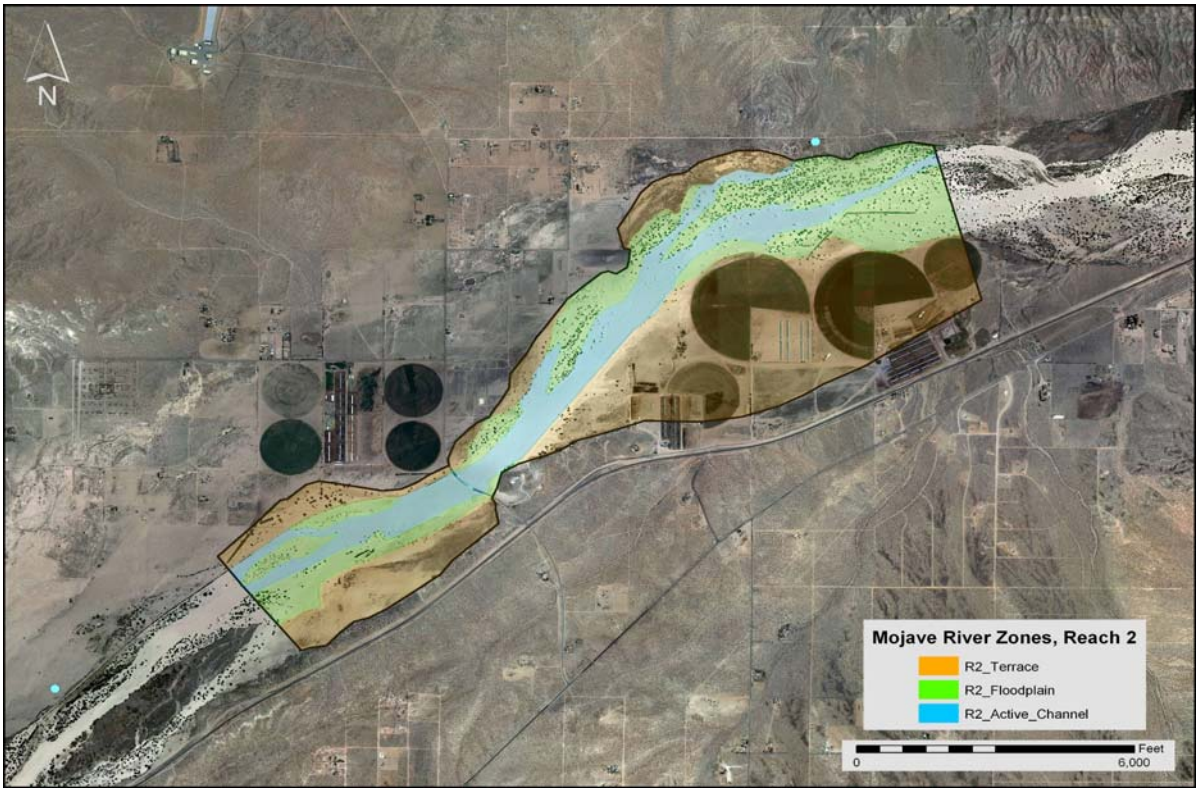

Figure 3 Channel features for Phase 3 sub-reach 2 (2007 MWA photo base).

Wind Erosion: Soil erosion due to wind was prevalent in the Phase 3 and Phase 4 reaches. Dune development and migration was easily identified in the 2005 and 2009 aerial images. In areas where invasive plants such as saltcedar existed, the soil tended to accumulate around the base of plants, functioning as soil traps. Because of this, the evaluation team recognized that invasive plants help prevent wind erosion. Modeling was performed to quantify the effects of vegetation on wind erosion.

Four typical existing conditions were modeled in and near the channel as follows:

- Dominate saltcedar with a nearly closed canopy
- Evenly mixed stand of saltcedar and native shrubs or trees with a nearly closed canopy
- Mixed stand of 25% saltcedar and 75% shrubs or trees with a nearly closed canopy
- Sparse vegetation of 25% saltcedar with 25% annual grasses

In conjunction with the four typical conditions above, four treatment options were modeled as follows:

- Dominate saltcedar killed using chemicals plus a 100 pounds per acre annual grass increase
- Evenly mixed stand of saltcedar and native shrubs or trees with saltcedar killed using chemicals, 100 pounds per acre annual grass increase
- Mixed stand of 25% saltcedar and 75% shrub or trees with saltcedar killed using chemicals, 50 pounds per acre annual grass increase
- Sparse vegetation with the 25% saltcedar canopy removed

Table 1 Example summary of effects for Phase 3, sub-reach 2

Reach Feature	**Houses & Agriculture**	**Private Open Space**	**Public Open Space**	**Roads & Transportation**
Active Channel	Wind –	Wind –	Wind –	Wind –
	Flood 0	Flood 0	Flood 0	Flood 0
	Habitat 0	Habitat 0	Habitat 0	Habitat 0
	Water Conservation +	Water Conservation +	Water Conservation +	Water Conservation +
	Streambank Erosion 0	Streambank Erosion 0	Streambank Erosion 0	Streambank Erosion 0
Active Flood Plain	Wind –	Wind –	Wind –	Wind –
	Flood -	Flood -	Flood -	Flood -
	Habitat -	Habitat -	Habitat -	Habitat -
	Water Conservation +	Water Conservation +	Water Conservation +	Water Conservation +
	Streambank Erosion -	Streambank Erosion -	Streambank Erosion -	Streambank Erosion -
Terrace	Wind -	Wind -	Wind -	Wind -
	Flood 0	Flood 0	Flood 0	Flood 0
	Habitat 0	Habitat 0	Habitat 0	Habitat 0
	Water Conservation +	Water Conservation +	Water Conservation +	Water Conservation +
	Streambank Erosion 0	Streambank Erosion 0	Streambank Erosion 0	Streambank Erosion 0

The eight options above were evaluated for two predominant soil types, Villa loamy sand and Cajon sand. Wind erosion rates for each condition and soil were estimated using the Wind Erosion Equation (Skidmore, 1968). The wind erosion modeling found that all treatment options had very high wind erosion rates compared to the soil loss tolerance of the individual example soils. Treatment for the dominant saltcedar condition resulted in an annual soil loss rate of 83 tons per acre, or 17 times the soil loss tolerance rate for Villa soil (USDA-NRCS, 2009). Treatment for the sparse vegetation area conditions resulted in an annual 395 tons per acre soil loss rate, which is 79 times the soil loss tolerance rate for Cajon soil (USDA-NRCS, 2009).

Removal of saltcedar in the Mojave River channel will increase wind erosion in varying degrees based on the method of treatment. Areas with a small, invasive plant canopy that is removed will have the lowest increase in wind erosion, approximately 1 ton per acre year, while the dominant saltcedar areas on Villa soil would have the greatest increase if removed, about 200 tons per acre year. Considerable dune activity would be expected if dense areas of invasive plants were sprayed, increasing the risk of damage due to sediment accumulation to sensitive areas such as the urban interface, rural farmsteads, roads, railroads, and producer field boundaries. Invasive plant areas not totally killed with chemicals and left clumpy with vegetation were predicted to accumulate soil around the base of the remaining plants. In areas that saltcedar was to be killed using chemicals, some annual grasses and forbs may grow due to increased sunlight and soil moisture post-spraying.

Streambank Erosion/Flooding: The evaluation team carefully assessed the risk of increased streambank erosion due to invasive plant removal because evidence has been documented in the literature that invasive plant removal, particularly saltcedar, can result in an unintended increase in streambank erosion. Helicopter herbicide applications in 2003 along a 12-km reach of the Rio Puerco, New Mexico, eliminated the saltcedar. Three years later a flood eroded about 680,000 cubic meters of sediment, increasing the mean channel width of the sprayed reach by 84 percent (Friedman, 2009). Erosion upstream and downstream from the sprayed reach during this flood was inconsequential (Friedman 2009). Streambanks for this analysis were considered a separate entity, generally being the transition between floodplain and terrace. At no location in the project area was saltcedar removal in the active channel or on the terrace considered a negative impact for streambank erosion or overbank flooding. Differences between the Rio Puerco and Mojave River are significant, but experience on the former helped guide recommendation for the Phase 3 and 4 reaches.

The impact of saltcedar removal in the active channel will generally increase flow area and reduce drag on the flow. In most river channels this would reduce flow depths, all other factors being equal. But, the Mojave channel width to depth ratio is high enough that a difference in depth would probably be minimal, except in reaches where there has been an extended interval from the last disturbance event. The thinning of vegetation in any given stream section would probably increase the capacity of the channel in that section. Saltcedar removal is expected to have little impact on the sparsely vegetated active channel areas.

The Corps of Engineers Mojave River channel maintenance plan describes the Corps' general goals and the estimated impacts of vegetation control in the active channel (U.S. Army Corps of Engineers (A), 1997). The Corps' document concludes that current channel conditions (1997) have a potential negative effect on streambanks due to excess vegetation. The vegetation in the channel tends to redirect flows toward the levees and streambanks causing erosion of unprotected slopes and overtopping. Any vegetation maintenance is to keep the centerline clear through urbanized areas, and maintain a buffer of adjacent wetlands and riparian vegetation to preserve their function of bank protection. In alignment with the Corps' goals, the team recommended that replacing vegetation where saltcedar removal occurred be made a priority in the near bank portions of the active channel.

Water Conservation: The team evaluated water conservation within the Phase 3 and 4 reaches of the Mojave River through removal of saltcedar. Groundwater pumping has steadily increased since the 1940s, reducing aquifer storage and creating an overdraft condition. This has caused changes in the quantity and distribution of recharge in the Mojave River (Stamos, 2001), leading to a loss of riparian habitat (Lines (A, B), 1996). This is evident in the decline of water levels in wells, which have dropped between 50 to 100 feet within the study area (Stamos, 2001).

The water table in healthy cottonwood-willow woodland is typically less than 10 feet below the surface. Willows and baccharis typically grow in narrow bands along the river edge in wetter areas than the cottonwood-willow woodland. Single-species cottonwood woodlands are common on terraces and slopes that are slightly elevated above the flood plain and the water table is typically 10-15 feet below the surface. Mesquite trees are typically widely spaced along the boundary of the riparian zone where water-table depths are 10-30 feet below the surface (Lines, (B) 1996).

Water savings due to saltcedar removal has been debated in the literature (Shafroth, 2005) as well as benefit/cost studies of water conservation gain, given the cost of mitigation measures (Barz, 2009). The ability of saltcedar to exclude native competition is contentious. Saltcedar roots generally reach deeper than roots of willow, mesquite, and cottonwood; and the invasive plant is able to capture moisture to the exclusion of the natives. In addition, saltcedar is more tolerant of low soil moisture conditions and can survive long drought periods more successfully than native species. Finally, saltcedar draws salt up through the soil column and deposits it on the surface through its leaf litter. The increased salinity further hinders native species (Swift, 2006).

Saltcedar may be able to tap into the water table at depths as great as 50 feet below the ground surface. Because of its rapid growth, saltcedar is commonly the dominant plant growing in the Mojave River channel (Lines (B), 1996).

It is estimated that saltcedar with a density of 71 to 100 percent uses 2.8 feet per acre of water per year. Healthy mesquite at a density of 71 to 100 percent is estimated to use 1.4 feet per acre of water per year (Lines (B), 1996). Reducing the density of saltcedar from 100 to 50 percent reduces water use by only about 10 percent (Hughes, 1972; and Van Hylckama, 1974).

Habitat: Invasive plants throughout the Phase 3 and 4 reaches have the ability to provide some level of habitat value in the form of protective cover and nesting structure (Brown and Johnson, 1998; Stromberg, 2009; and Van Riper, 2008). However, in the bigger picture, this habitat is not valuable if considering the overall negative habitat effects caused when the invasive plants outcompete and replace native plants (Anderson, 1977; Engel-Wilson and Ohmart, 1978; Kasprzyk and Bryant 1989; Howe and Knopf, 1991; Hunter, 1988; Lovich and de Gouvenain, 1998; and Zavaleta, 2000). The habitat value of native plants for native animal species is so high that even a little native plant habitat is much more desirable than a lot of invasive plant habitat. The only habitat condition that was considered where invasive plants would be left in place, was where the water table is too low to support native riparian vegetation. Even so, this consideration was rejected (from the habitat point of view) since leaving invasive species in place increases the potential to spread the plants, and their negative effects, to other locations. There may be some onsite short-term negative impacts to wildlife from the removal of the invasive plants, but the long-term onsite and offsite effect is overwhelmingly positive. The overall effect of invasive plant removal had been evaluated by the appropriate regulatory agencies prior to beginning of the project. Appropriate actions to avoid or minimize negative impacts associated with invasive plant removal were outlined through permitting and consultation with the applicable regulatory agencies.

DELINEATION OF NEGATIVELY EFFECTED AREAS

The team delineated the reach areas determined to be negatively affected due to invasive plant removal as depicted in Figures 4 and 5. These highlighted areas are deemed critical, as the proposed actions could increase the effects of resource concerns on adjacent land uses and should not have any plant removal or treatment, unless it is performed in such a way that the negative effects may be mitigated, using alternatives offered in the report. Figure 6 provides a close up view of areas delineated as “critical”. This type of map allows the user to control vegetation removal in an exact manner.

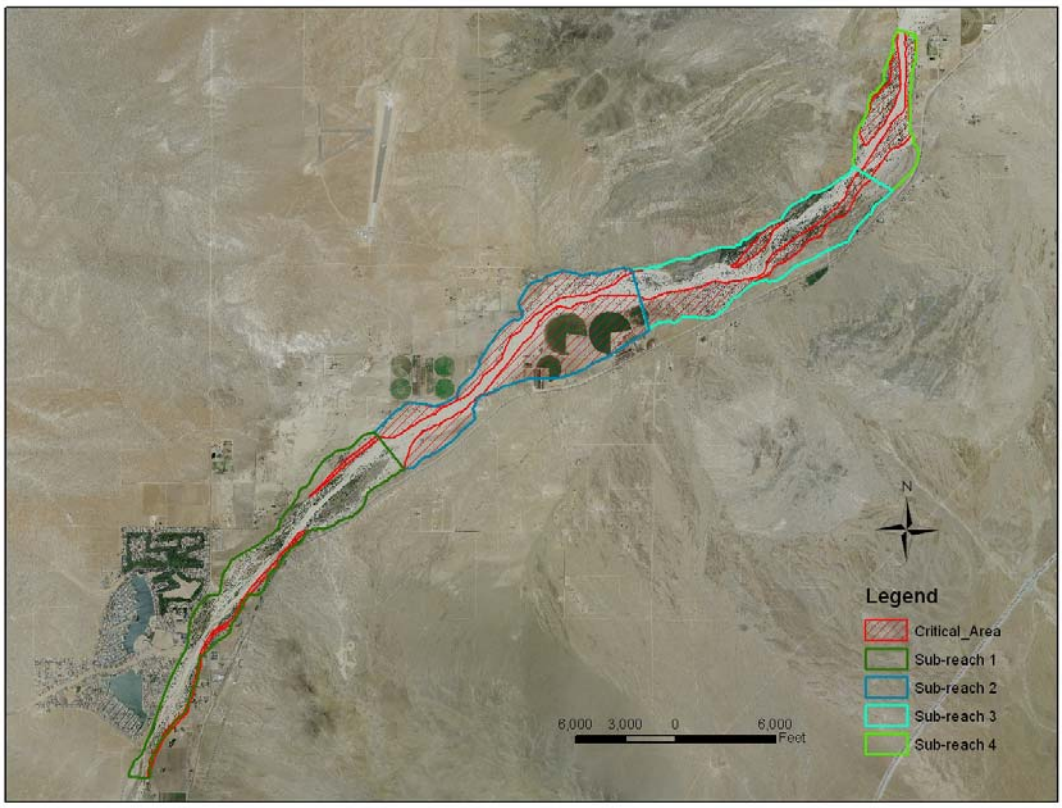

Figure 4 Negatively affected areas for Phase 3 reach.

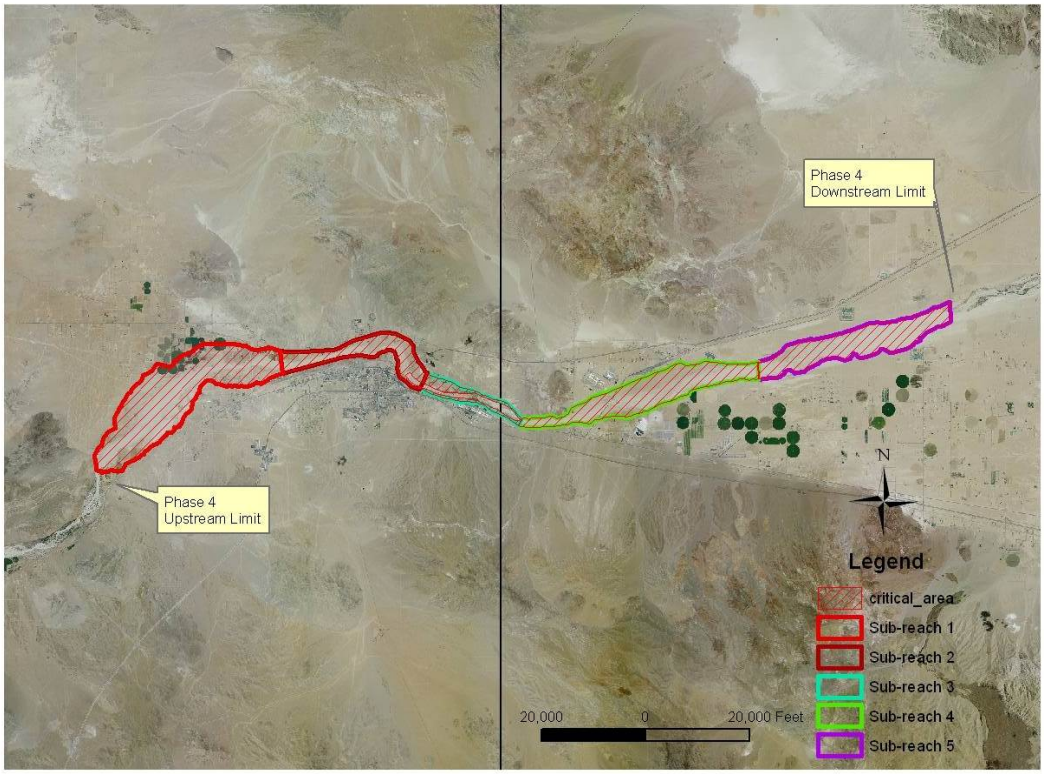

Figure 5 Negatively affected areas for Phase 4 reach.

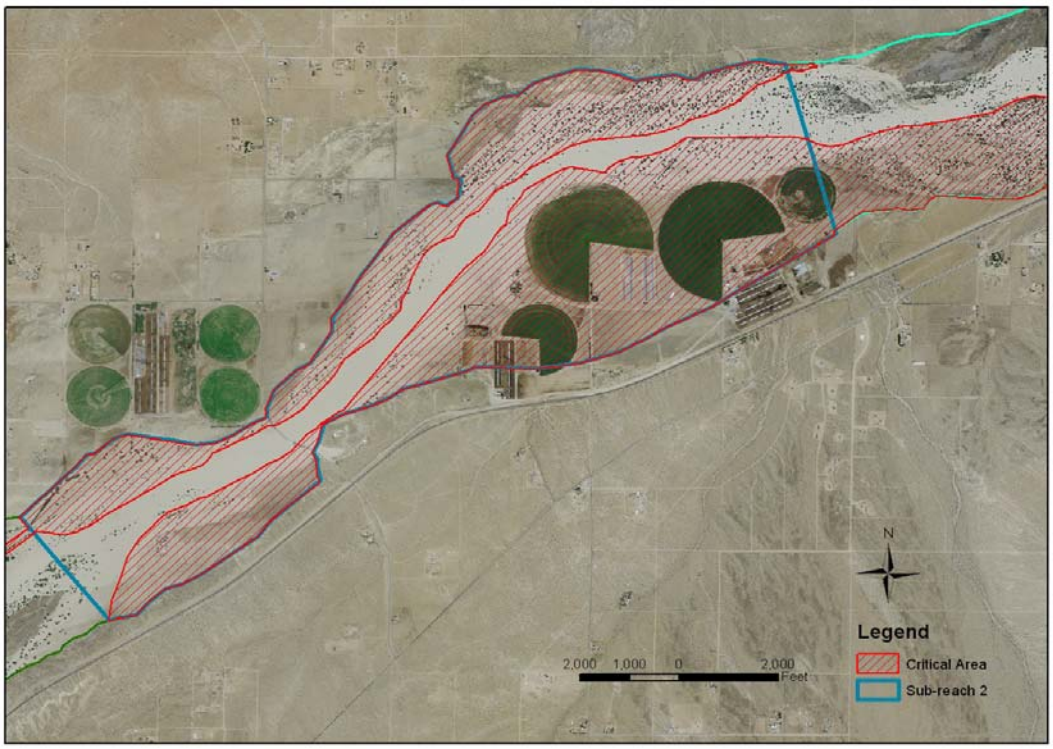

Figure 6 Zoomed in view of Phase 3, sub-reach 2 showing negatively affected areas.

TREATMENT ALTERNATIVES FOR CRITICAL AREAS

The team developed treatment alternatives for removing vegetation within the critical areas of the Phase 3 and 4 reaches. Alternatives included specific methods for vegetation removal, patterns of removal, amounts of vegetation removal, and re-vegetation directions. As an example, for active channel, floodplain, and terraces with mixed stands of saltcedar (25 to 50 percent canopy by area), the team developed the following directions:

1) Treat strips of saltcedar, where the strips are perpendicular to the prevailing wind direction, as evident by sand buildup behind existing saltcedar with a strip width no greater than 10 times the height of the average invasive plant, or (if not stripped) treat only 50 percent of all invasive plants in an every other plant pattern. The untreated strips should be at least 15 feet wide to stop saltation. Treated plants (dead) should remain standing, rather than being chipped on site or removed, to keep the standing plants in place (Skidmore, 1986); and

2) In conjunction with number 1, seed or plant native, soil-stabilizing, vegetation, such as desert panicgrass, (*Panicum urvilleanum)*; desert saltgrass, (*Distichis spicata)*; creeping wildrye, (*Leymus* (Elymus) *triticoides)*; scratchgrass, (*Muhlenbergia asperfolia);* and scale broom, *Lepidospartum squamatum*. Desert panicgrass appears to be adapted to deep sandy soils and dunes. The team observed this species in the active channel, as well as the active floodplain. Scratchgrass is adapted to floodplains with both saline or non-saline sandy soils. NOTE: the above species, except for wildrye, are warm season grasses and should be dormant during foliar herbicide applications and, if dormant, it is assumed that they would not be damaged during fall or early winter herbicide application. However, efforts should be made to direct spraying away from grasses and only onto target plants. The availability of seed or planting stock for creeping

wildrye and desert saltgrass can be intermittent. If desired, there is potential for conducting seeding trials using scratchgrass and, in the future, desert panicgrass with seed from Tucson PMC. Seeding or planting rates should be determined on the site-specific conditions and approved by an NRCS planting plan.

Other specific directions and alternatives were developed for floodplains and terraces with dominant saltcedar (stands with >50% canopy by area) and streambanks or levees with dominate invasive plants (stands with >50% canopy by area of invasive plants). Additional considerations were developed and outlined for establishment of native plants post removal of invasive plants.

SUMMARY

The team generally assessed the potential impacts of the proposed project on locally-identified resource concerns, including streambank erosion, wind erosion, wildlife habitat, water availability and use, and flooding. Recognizing that geomorphic units that together comprise the riparian corridor would respond differently to vegetation removal, the active channel, active floodplain and terraces within the 48-mile long study reach were mapped using GIS equipment and field reconnaissance. For each geomorphic unit, the team assessed whether vegetation removal would have a positive, negative, or insignificant effect on each of the resource concerns and adjacent land uses. Any areas having a negative effect due to vegetation removal were identified as critical and removal would either be avoided or mitigated. The planning report developed by the NRCS/MDRCD team included a map showing critical areas within the inventoried reach, technical guidelines for evaluating other reaches of the channel, and listed approved mitigation alternatives for critical areas.

Since 2009, the MDRCD has spent approximately $ 3,000,000 removing non-native vegetation either mechanically or through chemical treatment according to the plan. The work performed to date includes about 30 of the 48 miles evaluated within the plan. The remaining work will be completed as money becomes available.

ESTIMATION OF DAILY SUSPENDED SEDIMENT AND MERCURY CONCENTRATIONS AND APPLICATION OF FLOW-NORMALIZED TREND ANALYSES TO ASSESS FLOODPLAIN RESTORATION, CARSON RIVER, NEVADA

Carl E. Thodal, Hydrologist, U.S. Geological Survey, Carson City, Nevada, cethodal@usgs.gov, Eric Morway, U.S. Geological Survey, Carson City, Nevada, emorway@usgs.gov, and Karen A. Thomas, U.S. Geological Survey (retired)

INTRODUCTION

The floodplain of the Carson River was severely destabilized and aggraded during the Comstock Lode mining boom of the late 19th century. The river flows about 180 miles from its headwaters on the eastern slopes of the Sierra Nevada in northeastern California to the Carson Sink in the high desert of western Nevada, draining nearly 4,000 square miles (Figure 1). The headwaters are in steep, volcanic and granitic terrain that is naturally susceptible to erosion. Hillslope erosion was exacerbated during the mining boom by extensive timber harvest from the upper watershed for mine-shaft structural supports and boomtown development. Moreover, sediment from an estimated ten million tons of waste rock and tailings from more than 200 stamp mills downstream of Carson City, Nevada is deposited along the floodplain and river channel (Figure 1). Carson River water quality is further compromised by the release of an estimated 7,500 tons of mercury used in the amalgamation process that was used to extract silver and gold from milled ores. In response to the mercury contamination, the U.S. Environmental Protection Agency (USEPA) listed more than 70 miles of the lower reach of the Carson River as a Superfund National Priorities Site in 1990 (USEPA, 2013).

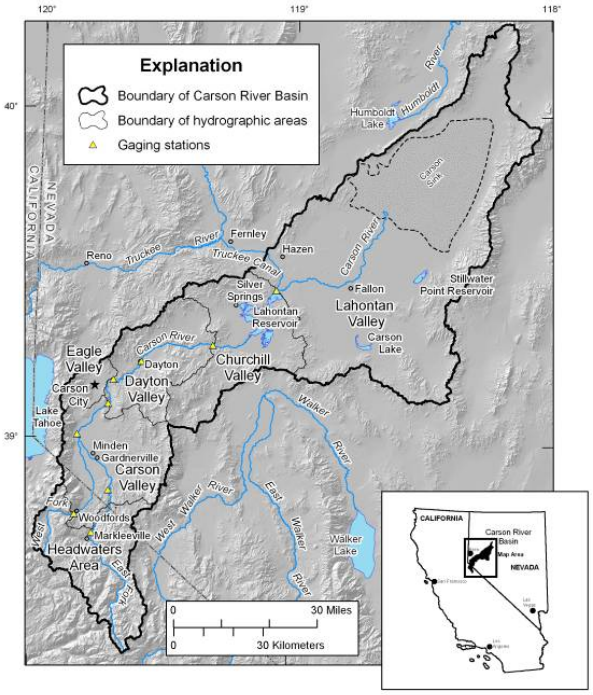

Figure 1 Location of Carson River Basin, California and Nevada

The Carson River has undergone significant geomorphological change that has destabilized its floodplain. As a result, agricultural and residential land has been lost to erosion and bank failure, and sedimentation has affected water quality, prompting efforts to stabilize the Carson River floodplain. Efforts in the mid-1960s to engineer flood control measures by channelizing the sinuous natural streambed, primarily along the East Fork Carson River are now acknowledged to have been a poor floodplain management practice. Renewed efforts beginning in the early 1990s by coalitions of private landowners, volunteers, non-profits, local school and conservation districts, and Tribal, County, State, and Federal agencies have included channel surveys, removal of sediment and constrictive debris, riparian vegetation plantings, flood protection, habitat enhancement, and bioengineered channel-stabilizing technologies (Azad, 2007). Conservation easements and public education about floodplains and recreational access are provided to promote awareness of floodplain value (http://water.epa.gov/type/oceb/upload/2006_11_02_showcase_showcasewatersheds.pdf).

River channel stabilization is apparent where rehabilitation projects, including riparian revegetation and placement of riprap, among others. have been completed (Azad, 2007), but reductions in sediment concentrations and loading have yet to be assessed. The U.S. Geological Survey (USGS) has monitored Carson River streamflow at the Fort Churchill gage (10312000) since 1911 (Figure 2). In October 1997, the USGS, in support of the USEPA Superfund Site Remedial Investigation program, began monitoring concentrations of suspended sediment, total mercury, and methyl mercury in water samples collected from the Carson River near Silver Springs (10312020) and below Lahontan Reservoir (10212150; Figure 2). Daily mean discharge recorded at USGS gaging stations ranged from 0 to 9,500 ft^3/s and averaged 330 ft^3/s as inflow and from 0 to 2,260 ft^3/s and averaged 400 ft^3/s as outflow. Instantaneous discharge measurements made above the reservoir during sampling events ranged from 0.2 to 4,200 ft^3/s and averaged 710 ft^3/s and below the reservoir ranged from 6 to 2,000 ft^3/s and averaged 620 ft^3/s. Sample summary statistics shown in table 1 indicate that Lahontan Reservoir is an effective sink for both suspended sediment and mercury. The statistical summary also indicates significant variability in concentrations. Results from a new statistical model to estimate trends and loading into Lahontan Reservoir are presented as metrics of the Carson River status and the possible effects of floodplain restoration efforts.

Table 1 Summary statistics for water sample concentrations, Carson River near Silver City, Nevada and below Lahontan Reservoir, 1997-2013; concentrations are nanograms per liter except suspended sediment concentrations are milligrams per liter

Constituent	Mean	Minimum	Median	Maximum	Count
10312020; Carson River near Silver Springs, Nevada					
Suspended sediment	220	1.0	61	3,600	309
Unfiltered mercury	2,500	34	1,000	36,000	281
Filtered mercury	29	9.0	25	100	281
Unfiltered methyl mercury	2.9	0.05	2.2	22	285
Filtered methyl mercury	1.2	0.02	1.0	6.8	285
10312150; Carson River below Lahontan Dam, near Fallon, Nevada					
Suspended sediment	28	6	32	100	134
Unfiltered mercury	250	0.04	250	740	134
Filtered mercury	11	2.4	8.4	52	135
Unfiltered methyl mercury	1.4	0.09	0.41	35	135
Filtered methyl mercury	0.6	0.04	0.2	13	133

APPROACH

Statistical methods that attempt to estimate the mass of water-quality constituents conveyed with streamflow where concentrations are not continuously measured have been developed and evaluated for decades. These investigations aim to better understand temporal load behavior and reduce inherent biases and uncertainties associated with estimated loads (Hirsch, 2014, p. 2). While multiple regression models have demonstrated valid relations between continuous

streamflow and concentrations, analyses of long-term datasets (more than 20 years) have led to the development of models that can accommodate concentration-discharge relations that may change over time.

Exploration and Graphics for RivEr Trends (EGRET, Hirsch and De Cicco, 2014; http://pubs.usgs.gov/tm/04/a10/) is a USGS model written in R (R Core Team, 2014), an Open Source computer and statistical environment that adds flexible enhancements to earlier regression models. The EGRET package has exploratory graphics and statistical tools designed to identify long-term changes in streamflow by computing annual statistics for daily-mean streamflow. The period of analysis can be specified to explore monthly, seasonal, or annual trends in annual average, minimum, and maximum streamflow. Also included in the EGRET software package is the statistical modeling algorithm Weighted Regression on Time, Discharge, and Season (WRTDS; Hirsch et al., 2010) that estimates a continuous concentration time series where continuous streamflow data are available, but observations of constituent concentrations are intermittent. The WRTDS weighted regression equation (Equation 1) estimates daily concentrations by fitting the natural logarithmic function (*ln*) of concentration (*c*) to discharge (*Q*) and time (*t*); including seasonality as sine and cosine functions and ε is the unexplained variation. The regression coefficients (β_i) are estimated for every combination of *Q* and *t* in a weighting system defined by the proximity of each point in *Q* and *t* space (Hirsch and others, 2010).

$$ln(c) = \beta_0 + \beta_1 (ln(Q)) + \beta_2 (t) + \beta_3 sin(2\pi t) + \beta_4 cos(2\pi t) + \varepsilon \quad (1)$$

EGRET and WRTDS have been used to analyze data collected from the Carson River near Silver Springs (USGS site number: 10312020; Table 1 and Figure 2), along with daily streamflow data from the nearby USGS gaging station (USGS site number: 10312000; Figure 2; http://waterdata.usgs.gov/nv/nwis/dv/?site_no=10312000&agency_cd=USGS&referred_module=sw). Standard USGS protocols for measurement of streamflow discharge (Rantz and others, 1982) and isokinetic, depth-integrated water sampling using the equal-discharge-increment method (U.S. Geological Survey, variously dated) were followed for the data collection. Quality assurance and control (QA/QC), documentation, and data validation considerations are described in sampling and analysis plan documentation for mercury monitoring in the Carson River system (Praskins and Thomas, written commun., 2011).

RESULTS

Time series graphs of annual streamflow statistics for Carson River near Fort Churchill during the period of operation (water years 1911-2013) and during the sample collection period (water years 1998-2013) are shown in Figure 3. Both time periods indicate year-to-year variability with decreasing trends in average mean-daily streamflow. The short-term record also indicates decreasing trends in maximum and minimum streamflows. Potential causes of decreasing trends in streamflow cannot be determined with the available data, but changes in land- or water-use, drought, and climate change each may be contributing factors.

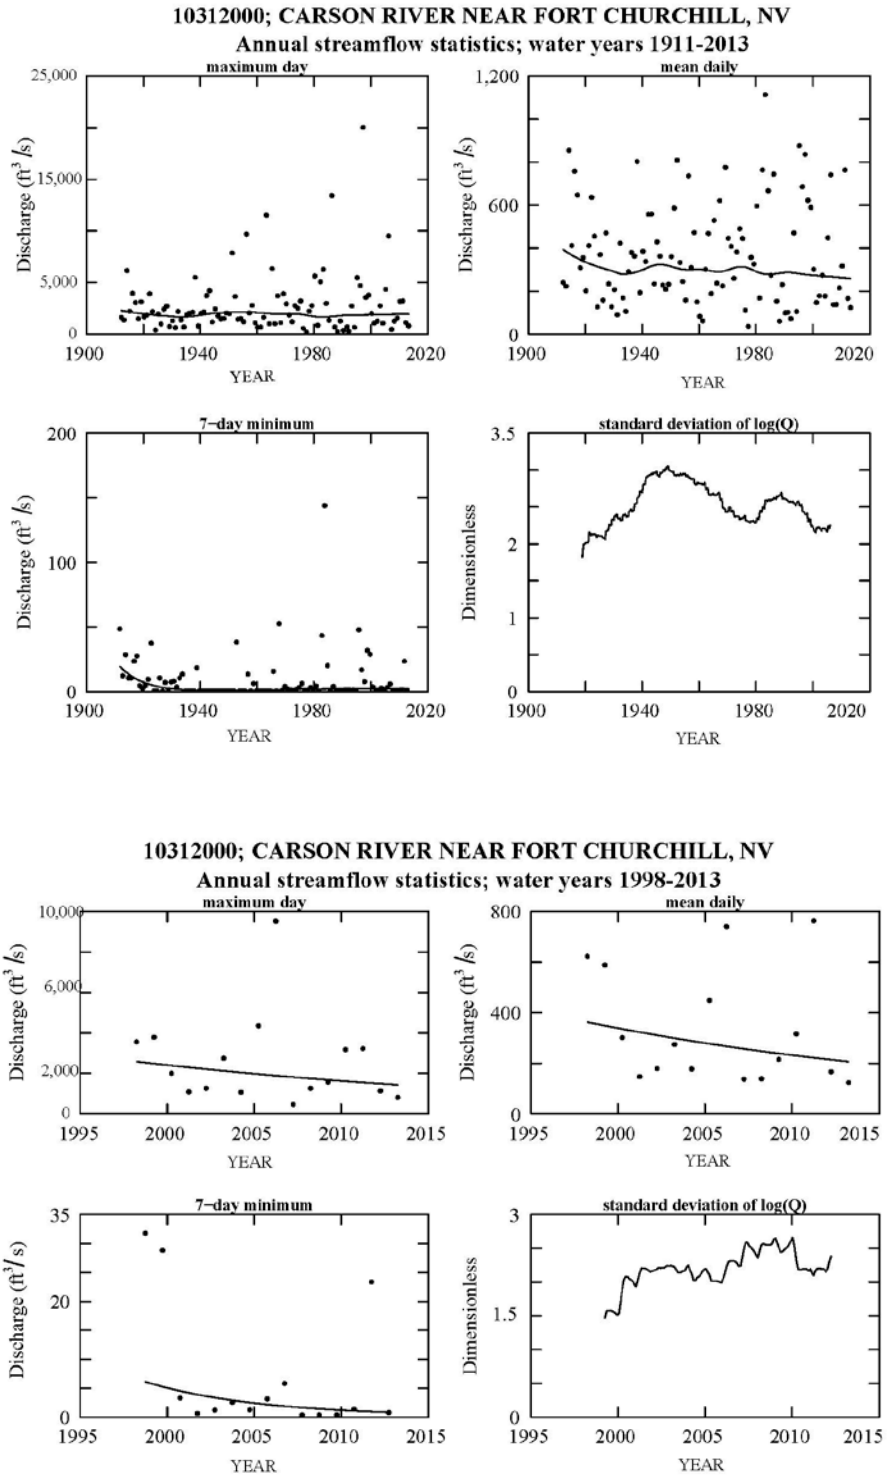

Figure 3 Selected time series of annual streamflow statistics computed for 1911-2013 and 1998-2013, Carson River near Fort Churchill, Nevada

Figure 4 compares mean daily discharge for the 7,457 days that span the suspended sediment sampling period (right box-and-whisker) to the mean daily discharge recorded on the 309 days on which sample collection took place (left box-and-whisker) and shows that sampling may have been biased toward higher streamflows, but is a fair representation of the streamflow distribution during the sampling period.

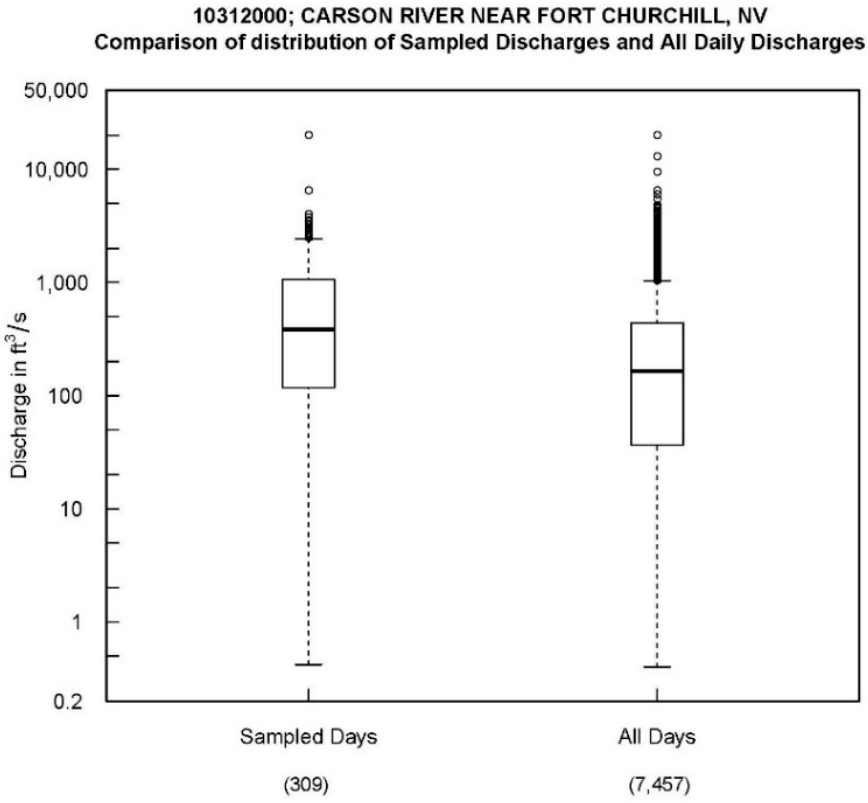

Figure 4 Box and whisker diagrams of mean daily streamflow during sample-collection days and all days during 1998-2013, Carson River near Fort Churchill, Nevada

Suspended sediment data and WRTDS-estimated daily concentrations as a continuous trace are shown in Figure 5a. Because the streambed of the Carson River near Silver Springs is deeply scalloped and has a mobile bedload, suspended sediment concentrations of particles less than 63 microns are computed using silt-sand percentage break determinations and are shown in Figure 5b. The WRTDS model fit is improved for the fine-grained particle size data because the sampling equipment is designed to sample suspended sediment that is at least 0.3 ft above the streambed. The mobile and uneven streambed of the Carson River results in coarser particles being intercepted by the sampler nozzle when it is downstream of submerged sand and gravel dunes.

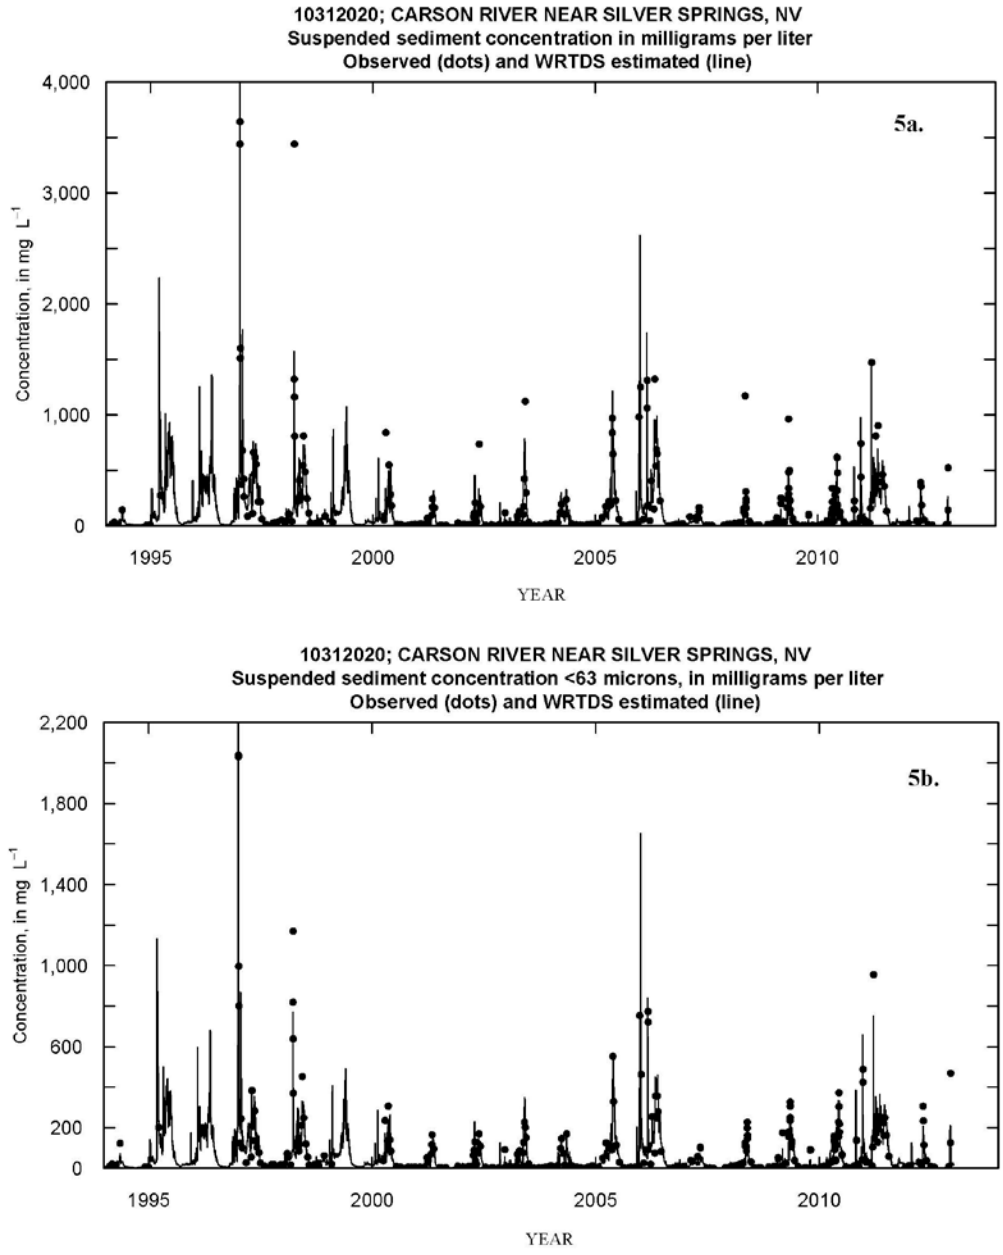

Figure 5 Observed (black dots) and estimated (black line) (5a) concentrations of suspended sediment and (5b) concentrations of suspended sediment less than 63 microns grain size, Carson River near Silver Springs, Nevada

Modeled changes in flow-normalized concentrations and fluxes (loads) for time periods that include all samples and for time periods that arbitrarily bracket the first and last halves of the sampling period are listed in Table 2. Estimated concentrations and fluxes of suspended sediment for the period 1994 through 2012 increased but at a lesser rate of annual change compared to estimates for the period 1994 through 2002. For the period 2002 through 2012 the trend had begun to decrease. Similarly, unfiltered concentrations of mercury and methyl mercury show a decreasing trends in concentrations of -9.5 and -6.9 percent, respectively, while the mass flux estimates decreased by 23 and 35 percent for the period 1998 through 2013. These trends may be

considered improvements, but there may be several contributing factors, including the decreasing trend in discharge, natural recovery of the historically destabilized channel, and floodplain rehabilitation efforts. However, in contrast to decreasing trends in unfiltered mercury and methyl mercury, increasing trends in concentration and flux of filtered mercury was estimated with the highest rate of increase (Table 2) and the flow-normalized concentrations and annual mean concentrations increase at nearly identical rates (Figure 6). The annual changes in average concentrations are relatively small: average suspended sediment concentrations decrease less than 2 milligrams per liter per year, while average filtered mercury concentrations increase by about 1 nanogram per liter (one part per trillion) per year.

Table 2 Estimated trends in concentrations and fluxes of suspended sediment, and mercury for selected time spans, Carson River near Silver Springs, Nevada

Constituent	Time period	Mean-annual percent change in:	
		Concentration	Flux
Suspended Sediment	1994 to 2012	0.1	0.24
	1994 to 2002	1.8	2
	2002 to 2012	-1.1	-0.98
Suspended Sediment, less than 63 microns	1994 to 2012	1.5	1.5
	1994 to 2002	2	2
	2002 to 2012	1	0.85
Unfiltered total mercury	1998 to 2013	-0.64	-1.5
	1998 to 2005	-0.65	-1.6
	2005 to 2013	-0.65	-1.6
Unfiltered methyl mercury	1998 to 2013	-0.46	-2.3
	1998 to 2005	-0.46	-1.9
	2005 to 2013	-0.57	-3.1
Filtered total mercury	1998 to 2013	3.6	4.2
	1998 to 2005	2.5	2.8
	2005 to 2013	3.8	4.6
Filtered methyl mercury	1998 to 2013	-0.35	0.52
	1998 to 2005	-0.18	1.2
	2005 to 2013	-0.51	-0.07

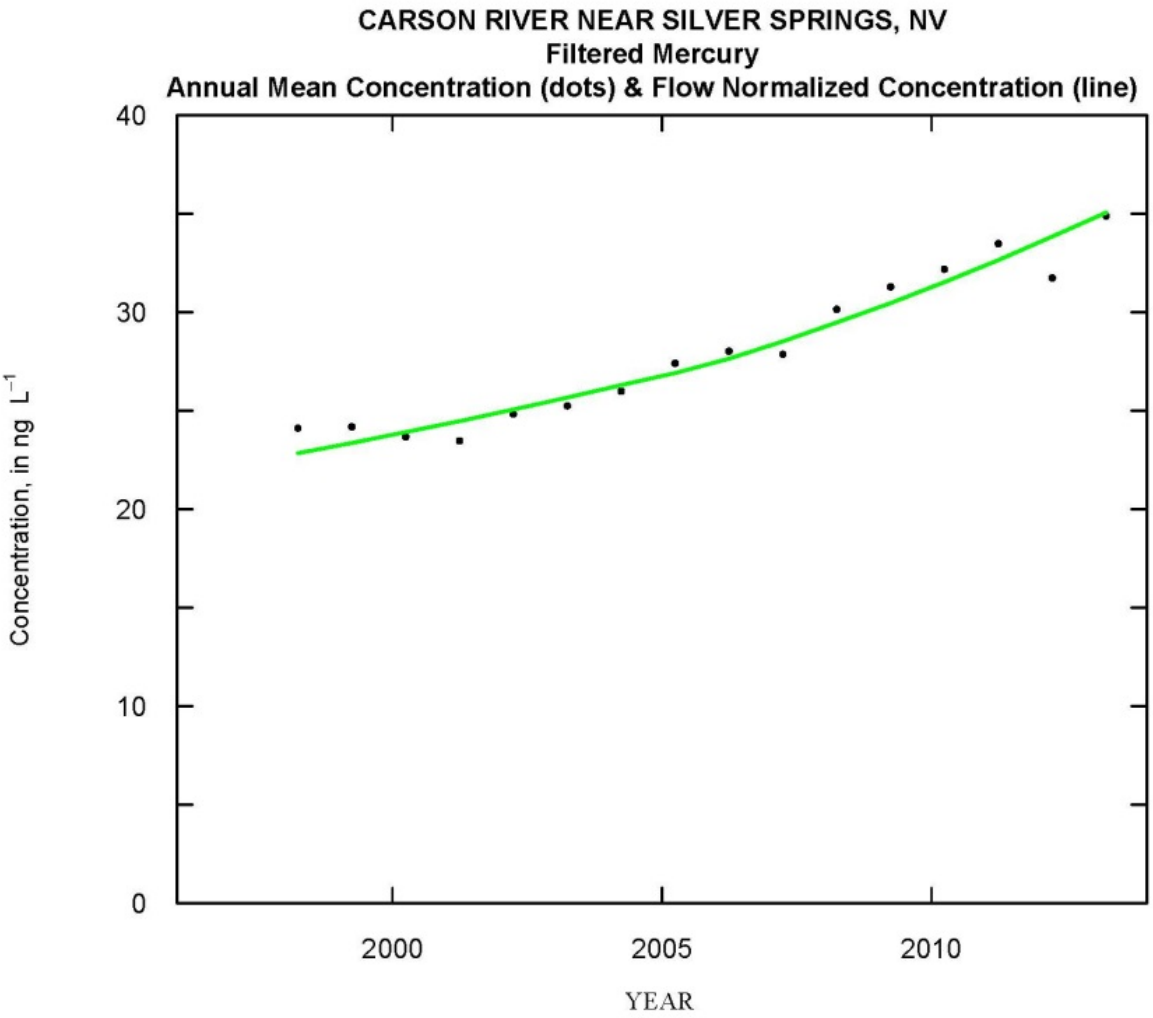

Figure 6 Annual mean filtered mercury concentrations (dots) and flow normalized concentration (line), Carson River near Silver Springs, Nevada

CONCLUSIONS

Statistical analyses, including trend estimation of the data collected in support of the USEPA Carson River Superfund Site Remedial Investigation, show decreasing concentrations and trends in suspended sediment and unfiltered total and methyl mercury. However, these subtle trends may be related to any of several factors, including decreasing streamflow, natural and engineered recovery of a destabilized watershed, or the gradual flushing and volatilization of mercury contamination from impacted sediment upstream of Lahontan Reservoir. The unanticipated increasing trend in filtered mercury concentrations may be related to a similar increasing trend in sample pH, or other unmeasured factors of which dissolved organic carbon and oxidation-reduction potential have been shown to be potential causative factors by other investigators (Aiken et al., 2011).

MISSOURI RIVER HABITAT PROJECT DESIGN, PERFORMANCE, AND ASPECTS OF THE 2011 FLOOD

Daniel Pridal, Hydraulic Engineer, U.S. Army Corps of Engineers, Omaha, NE, daniel.b.pridal@usace.army.mil

Abstract: The Missouri River Recovery Program (MRRP) has constructed over thirty chute and backwater habitat areas on the Missouri River within the Omaha District that were consistent with shallow water habitat (SWH) creation requirements specified within the Biological Opinion (2000) and the Amended Biological Opinion (2003). Design and construction practices have evolved over the last 10 years due to project performance, objectives, and constraints. In addition, the 2011 Missouri River event within the Omaha District resulted in a sustained high peak flow with unprecedented duration. As a result, the Missouri River and entire floodplain experienced large areas of sediment erosion and deposition. Habitat project design process, construction aspects, and the observations related to 2011 flood impacts are presented. Conclusions regarding project performance with recommendations for future design improvements are provided.

INTRODUCTION

In 1989, The U.S. Army Corps of Engineers (Corps) initiated consultation with the U.S. Fish and Wildlife Service (Service) regarding operation of the Missouri River Main Stem Reservoir System. Consultation covered operation of the Missouri and Kansas Rivers as well as the Missouri River Bank stabilization and Navigation Project (BSNP). The 2000 Biological Opinion found that the actions proposed by the Corps would jeopardize the Interior least tern, pallid sturgeon, and piping plover. With the intent of precluding jeopardy to the species, the Service provided a Reasonable and Prudent Alternative (RPA). The Corps requested a re-initiation of the formal consultation and an amended Biological Opinion was provided in 2003. The Missouri River Biological Opinion and the Amended Biological Opinion (BiOp) set forth the requirements for the creation of shallow water habitat (USFWS, 2003). The RPA consisted of numerous elements pertaining to flow management, habitat diversity, and habitat area. The RPA performance standard for shallow water habitat acres established a goal of 20 to 30 acres per mile for the Missouri River from Ponca, Nebraska, located about 60 river miles downstream of Gavins Point Dam, to St. Louis, Missouri, a distance of 752 river miles. Since 2003, the Corps has completed construction of numerous projects intended to create shallow water habitat in this reach of the Missouri River. Following construction, monitoring activities have been conducted to evaluate the project performance. Activities have been conducted in both Omaha and Kansas City Corps of Engineers Districts (USACE, 2013). The Missouri River geometry and hydraulic characteristics change significantly between the two Corps Districts, which results in major differences in project formulation. The high floodplain energy associated with the flows and duration of the 2011 event resulted in significant changes within the floodplain including the constructed habitat projects. This paper focuses on observations related to habitat projects and

project performance within the Omaha District and the portion of the channelized Missouri River between Ponca, Nebraska, at river mile 752, and Rulo, Nebraska, at river mile 498.

Pallid Sturgeon Habitat: The pallid sturgeon is native to the Missouri and Mississippi Rivers and is adapted to the free flowing, warm water, and turbid habitats that are in a constant state of change. Floodplains, backwater, chutes, sloughs, islands, sandbars, and main channel waters formed the large river ecosystem that historically provided habitat for all life stages of pallid sturgeon in the river. Evidence of reproduction for wild origin pallid sturgeon is lacking. Destruction and alteration of big river ecological functions and habitat that was once provided by the Missouri River that followed Corps dam construction and channelization actions is believed to be the primary cause of declines in reproduction, growth, and survival of pallid sturgeon.

Shallow Water Habitat Definition: As set within the biological opinion, the parameters used to define shallow water habitat are Missouri River flow depths less than five feet (1.5m) and velocities less than two fps (0.6 m/s) (USFWS, 2003). For the purposes of assessing habitat creation, the effective discharge is defined as the 50% exceedance discharge from the August flow duration curve(s). Although the habitat accounting system is based on the effective discharge, data are also gathered and analyzed for a range of flows to provide an assessment of habitat diversity. Within the context of the RPA, shallow water habitat refers to:

- 50% exceedance August flow rate
- Flow depth less than 5 feet (1.5m)
- Flow velocity less than 2 ft/sec (0.6 m/s)

Channelized River Background:

Between 1912 and 1945, Congress, by funding and authorizing seven different acts, charged the U.S. Army Corps of Engineers with reservoir system construction, stabilizing the banks of the Missouri River, and providing a 9-feet deep by 300-feet wide navigation channel. Management activities resulting from these acts have included removing snags, protecting the river banks from erosion, and constructing and maintaining the navigation channel. This collection of projects is known as the Missouri River Bank Stabilization and Navigation Project (BSNP) (USACE, 2011). The Missouri River navigation project extends from its confluence with the Mississippi River at St Louis, Missouri, to Sioux City, Iowa, for a total distance of 734.2 river miles. For reference, Gavins Point Dam, the furthest downstream of the Missouri River reservoir system of six dams, is located at river mile 811. The reservoir system is operated to meet multiple authorized purposes, including navigation, as described in the Master Manual (USACE, 2006).

Stabilization and navigation objectives were accomplished through revetment of banks, construction of permeable dikes, cutoff of oxbows, closing minor channels, removal of snags and dredging. The BSNP is designed as a self-scouring channel that has not required maintenance dredging within Omaha District. In order to achieve the project objectives of bank stabilization and navigation, the river was shaped into a series of smoothly curved bends of the proper radii and channel width. Stabilization of the bank along the concave alignment of the design curve was accomplished with pile and rock-fill revetments. Dikes were constructed approximately perpendicular to the flow or slightly angled downstream along the convex bank, that were oriented to promote project objectives. BSNP structures are constantly attacked by river flows. Maintenance is conducted to ensure the structures provide river stability and channel dimensions

necessary for commercial navigation and other authorized purposes. Within the Omaha District portion of the navigation channel, the Missouri River has a top width generally between 600 and 700 feet. Dike spacing is also on the order of 600 to 700 feet. The typical BSNP components within the navigation channel are illustrated in Figure 1.

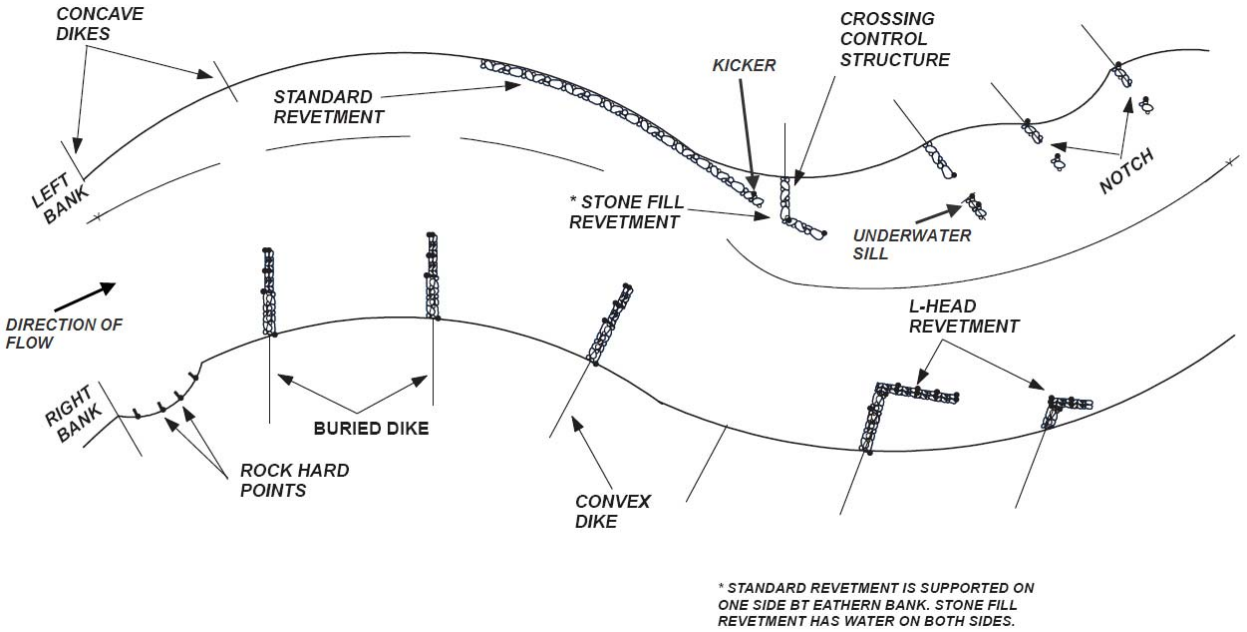

Figure 1 Typical Missouri River Navigation Channel Plan View

Habitat Project Types: Shallow water habitat is created using many different approaches that are generally classified according to the habitat type and location. Some projects are created within the main channel while other methods are within the adjacent floodplain. Habitat project types that have been used within the Omaha District include:

- Structure Modifications - Dike Notching (in-channel revetment and dikes)
- Backwater (off-channel)
- Pilot Channel (off-channel)
- Chute (off-channel)
- Major Dike Modification (in-channel dike lowering and chevron construction)

Employment of the various methods is often limited by physical parameters, available real estate, and other factors. For instance, bend curvature, site topography, adjacent infrastructure, and other factors may prevent sustainable construction of an off-channel chute. No actions are conducted without acquiring a real estate interest in all lands encompassing the project.

2011 EVENT

The duration and magnitude of the 2011 Missouri River flood event exceeds all other events in the recorded history of the river. Annual runoff volume frequency has been characterized as a 0.2 percent annual chance exceedance (500-year) event (Grigg et al., 2012). Historic events were

reviewed to provide context regarding 2011 event river flows. Sustained periods of prolonged floodplain flow indicate flow energy acting within the floodplain. In a simple method used to compare the 2011 event flow energy to historic events, the number of days when the Missouri River flowed within the floodplain were tabulated. When comparing contemporary to historic events, it should be recognized that historic river flows were affected by Missouri River main stem dam construction and reservoir filling, primarily from 1953 to 1967. All flow-frequency values reported in the comparison are post dam construction (USACE, 2003). As a result, comparing contemporary to historic events is somewhat misleading since the reservoir system has significantly altered its peak flows. For this simplified evaluation of floodplain energy, the 2-year event was assumed to roughly correspond with floodplain flow initiation. Data from the USGS gage at Nebraska City, Nebraska, which is located about 250 river miles downstream of Gavins Point Dam, is shown in
Figure **2**.

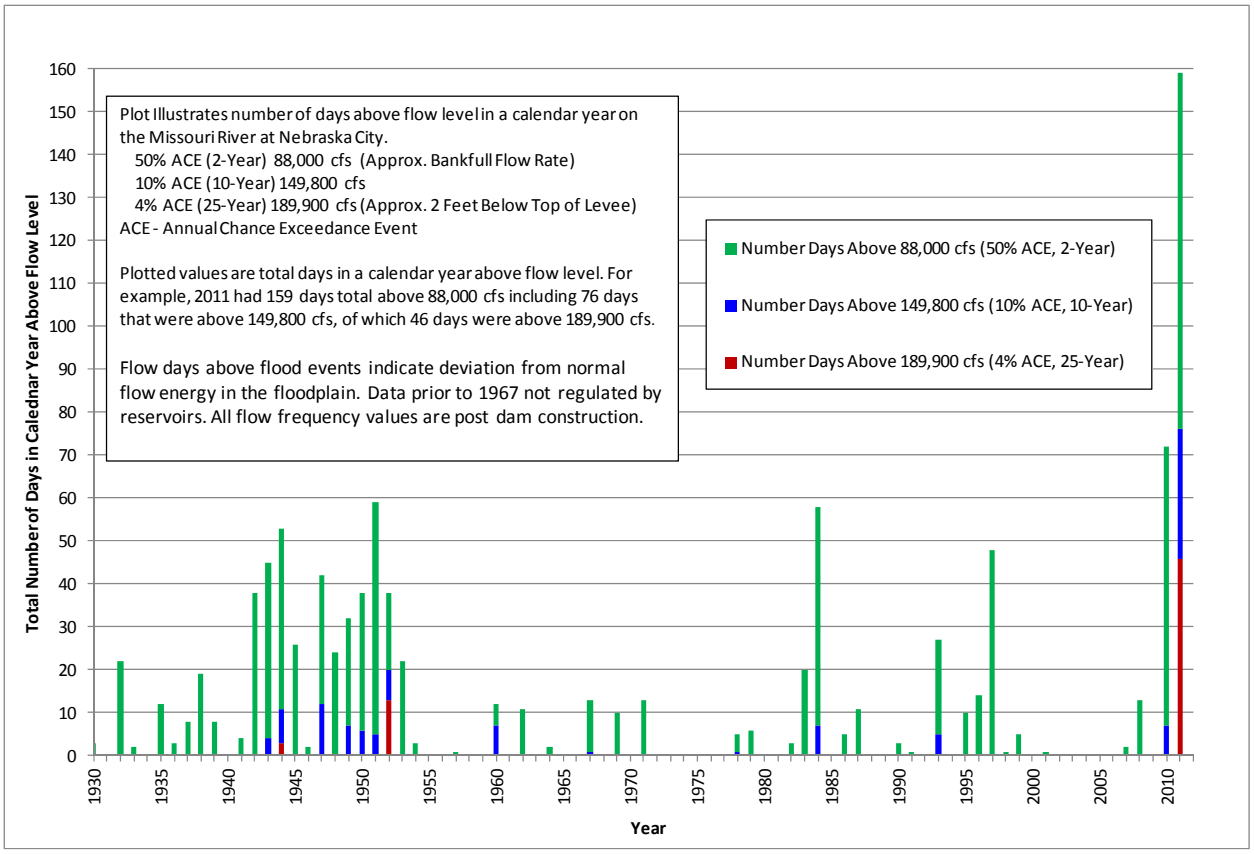

Figure 2 Nebraska City Days above Flow Value by Year

The above figure illustrates the severity of the 2011 event. The 2011 flow year at Nebraska City had 159 days with average daily flow above a 50% ACE (2-year) which roughly corresponds to the duration of floodplain flow or flow above the channel bank height. Furthermore, the 2011 event had 46 days with an average daily flow in excess of the post dam construction 4% (25-year) annual chance exceedance (ACE) event of 189,900 cfs. The prolonged duration of the 2011 event with flows above channel capacity dwarfs all other events which occurred on the historic

Missouri River. The 2011 event is the only event since mainstem dam construction was completed in the mid 1950s to have even a single day with the daily average flow greater than the 4% ACE (25-year). The average daily flow comparison illustrates that the 2011 event was unique with floodplain energy at a very high level for a prolonged duration that is unprecedented in the historic record.

HABITAT PROJECT PERFORMANCE EVALUATION

Habitat Projects Prior to the 2011 Event: Prior to the 2011 event, a total of 33 off-channel chute and backwater projects had been constructed in the Omaha District with varying size and location as shown in Table 1.

Table 1 Omaha District Off-Channel Projects Constructed Prior to 2011 Event

Site No.	Off Channel Projects	RM		Year	Length	State	SWH 2010 Acres[1]
		DS	US

	1 - Refers to the shallow water habitat acres as determined in a 2010 evaluation. This is pre-2011 high flow acres.						

The Corps utilized a monitoring and adaptive management program to verify that projects were within design objectives, that all Missouri River authorized purposes were functioning, and to inform future project design. In general, project performance prior to the 2011 event had been as expected. Critical points regarding constructed project performance through 2010 are:

- Projects were in different stages of development due to the time period since construction and other site specific factors such as historic flows, soil types, etc.
- Due to many factors, multiple habitat project types and sizes were constructed. Within the framework of the various project objectives and performance expectations, no significant performance differences were noted between habitat types.
- Several chute projects required minor maintenance on rock structures.

- No chutes experienced problematic erosion or widening and were within an acceptable range.
- Performance of habitat enhancement projects, such as features to promote depth diversity and add woody debris, had been reasonably successful.
- Sediment deposition had been noted in backwater areas as expected, with routine maintenance performed at some sites to maintain their function.

Habitat Project Assessment Following the 2011 Event: Following the 2011 event, the Omaha District performed numerous design and repair projects of critical infrastructure including dams and levees throughout the basin. Although a lower priority, habitat projects were also assessed and repairs performed as resources allowed. Inspection indicated that SWH habitat was lost in many constructed projects and gained in others. This also applied to the overall river corridor. However, much of the post-flood habitat does not appear to be sustainable and will likely experience future deposition. Flood damage varied significantly between constructed SWH projects. The high flood flows traveled downstream following the valley slope in the most energy-efficient manner crossing river bends. Erosion and deposition patterns typically associated with flow turbulence and velocity reduction due to primary flow direction exiting and entering the channel and floodplain were observed throughout the river corridor. Floodplain infrastructure and features, such as roads and levees, constricted the floodplain width and concentrated flows. Floodplain features as well as constructed habitat projects in the path of this flow zone were often severely impacted. Visible erosion and deposition areas were apparent throughout the floodplain corridor without an observed correlation to the presence or absence of SWH projects. Typical floodplain conditions post 2011 flood are shown in Figure **3**.

Figure 3 Typical Floodplain Conditions Post 2011 Flood.

Flood flows traveled across the river bends which resulted in degraded BSNP dikes and revetments at most bend entry and exit points, regardless of the presence of SWH projects. Floodplain material dynamics were noted throughout the Missouri River flow corridor with zones of both scour and deposition that occurred as the flood flows traveled linearly down the valley floodplain regardless of navigation channel alignment. Depending upon the location and river dynamics, constructed chute and backwater habitat projects in the floodplain were subject to the same floodplain dynamics and experienced both scour and deposition. Flood flow patterns in a typical area are illustrated in
Figure **4**.

Off Channel Chutes: Chute project response to the 2011 flow event varied significantly with location. A little less than half of the chutes required no or minor repairs. Constructed chute projects at about one-third of the sites experienced deposition that prevented flow-through chute connectivity at normal Missouri River flows and threatened sustainability. Minor sediment removal projects have been conducted at two sites, planning continues at a third site, and three sites likely will not be repaired due to excess sediment deposition. Many chutes experienced both erosion and deposition with varying levels. Chutes experienced rock structure damage, flanking of control structures, and both widening and deepening. These geometry changes resulted in chute flow above the amount desirable for both habitat and adjacent project purposes. Minor issues were addressed with repair of rock structures in many sites. At three other chutes which experienced significant erosion, new control structures were added to reduce the flow to an acceptable level and improve performance to meet design objectives.

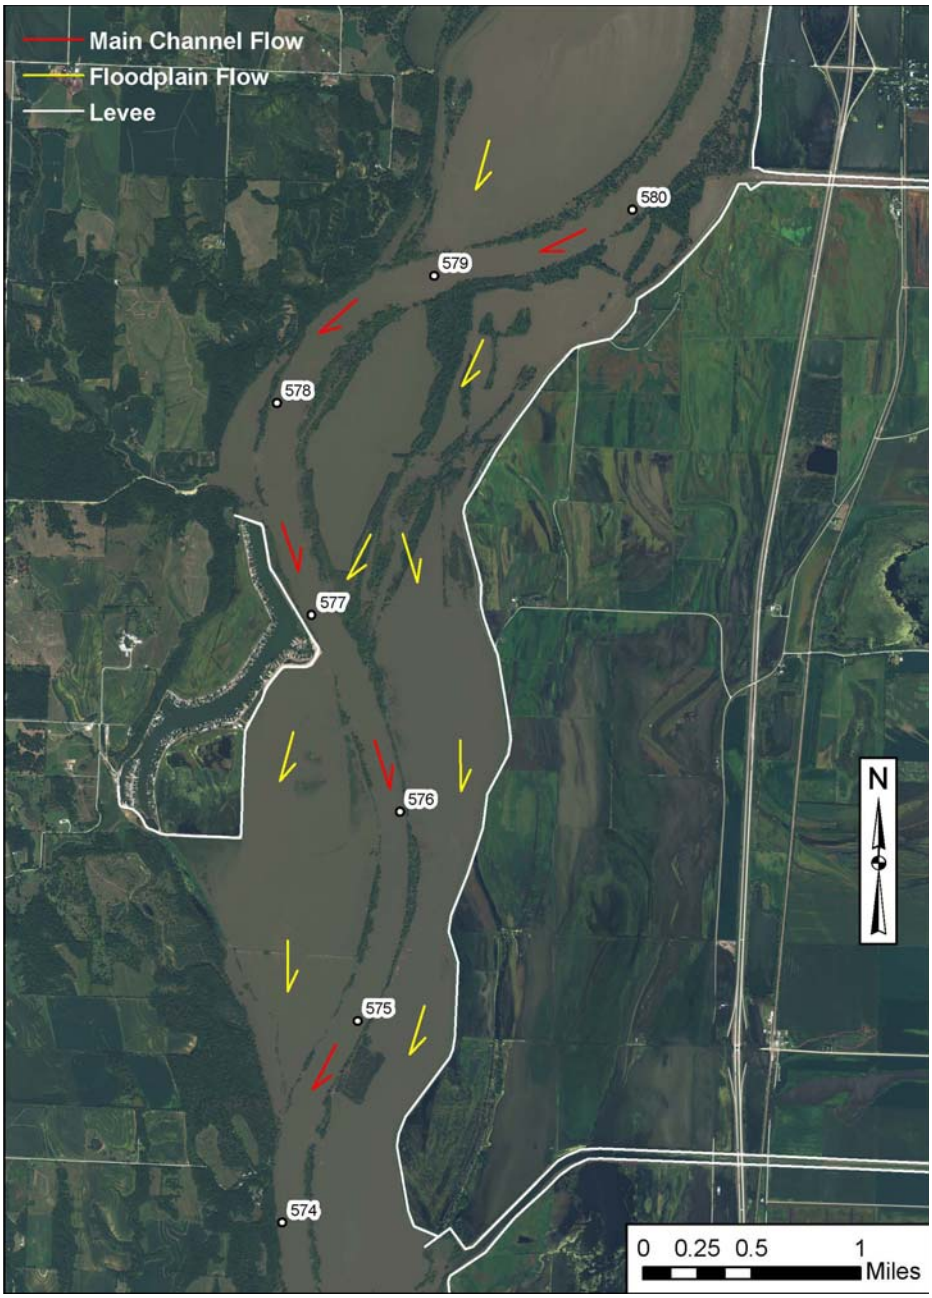

Figure 4 Typical Flood Flow Patterns

An inspection and subsequent evaluation of chute projects for factors which influenced the severity of damage noted a correlation to the previously discussed floodplain flow constrictions such as roads and levees, main channel curvature, and flow transfer across bends. For example, several chute projects that experienced erosion also were located in areas of floodplain constrictions which likely contributed to higher flow energy. Several chutes that experienced deposition were oriented against the path of prevailing floodplain flows. An example of a typical chute entrance that required repair is shown in
Figure 5.

Figure 5 Typical Post Flood Chute Entrance Requiring Repair

Backwater Area Evaluation: Backwater projects experienced variable levels of scour and deposition as a result of flood flows. It should be noted that backwater areas are known to be depositional during normal flow periods due to the Missouri River sediment load. However, post-flood surveys and observations indicated that the 2011 flood deposition generally raised bottom elevations within backwater areas. This deposition will likely reduce the interval before remedial sediment removal is necessary to maintain optimum function and provide shallow water depths during normal river flows.

A quantitative evaluation of backwater deposition volume directly attributed to the 2011 event has not been conducted. Qualitatively, observations indicated greater deposition tended to occur in backwater areas that had been constructed with variable depths and non-linear shorelines. Backwaters which were located in the lower portion of a bend with upstream features which reduced floodplain flow such as natural topography, road crossings, levees, and heavily forested areas generally experienced lesser amounts of deposition from the flood event. Conversely, backwaters that were located in the typical floodplain sediment deposition zone as floodplain topography created low velocity areas experienced greater deposition volumes. Most backwater areas experienced deposition at the entrance from the Missouri River that was in excess of the typical formation at normal flows. An example of a backwater area illustrating the entrance sediment deposition bar is included in
Figure **6**.

Figure 6 Typical Backwater at Low Winter Water Level Illustrating Entrance Sediment Bar

SUMMARY

The Omaha District Corps of Engineers has conducted significant SWH design, construction, and monitoring activities since 2004. The 2011 Missouri River event within the Omaha District resulted in a sustained high peak flow with unprecedented duration which significantly impacted the floodplain and constructed projects. Significant observations include:

- The 2011 event was unique with excess floodplain energy at a very high level for a prolonged duration that was unprecedented in the historic record.
- Prior to the 2011 event, no constructed chutes had experienced significant or problematic erosion and were operating within an acceptable range.
- The entire floodplain and features were severely altered by the 2011 flood event.
- Following the 2011 event, the Omaha District performed numerous design and repair projects on critical infrastructure including dams and levees throughout the basin. Although a lower priority, habitat projects were also assessed and repairs performed as resources allowed.
- Habitat and channel conditions are known to be dynamic. Future changes are expected as the river continues to recover during a more normal flow range following the 2011 event.
- The factors which correlated to constructed project response appeared to be surrounding floodplain features such as levee constriction and roads, bend layout with respect to transfer of flood flows, and floodplain topographic irregularities.
- Chute response varied significantly. About half of the chutes required no or minor maintenance. Several sites experienced deposition, several sites had significant scour.
- Chute changes usually consisted of degradation of the entrance control structure, flanking of internal control structures, and both chute widening and deepening.

- Measured chute:river flow ratios are useful to assess chute geometry changes as a result of the event.
- Backwaters had varying degrees of deposition that appeared to correlate with bend alignment, location within the floodplain, and upstream floodplain features.
- While backwaters are known to require periodic maintenance, the sediment deposited during the 2011 event generally reduced the interval before remedial sediment removal is necessary to maintain optimum function.

ABSTRACT

The use of levee setbacks provides a sustainable strategy to reduce flood risk by enhancing protection of people and property, providing economic benefits, and improving established ecosystems. Following the 2011 Missouri River flood two efforts to evaluate levee setbacks were conducted; the Assessment of Conceptual Nonstructural Alternative Levee Setbacks along the Missouri River (ACNALS) (USACE, 2012), and the implementation of levee setbacks in two locations as part of the 2011 flood recovery. These efforts have shown levee setbacks as a viable alternative to in-place repairs of existing levee alignments.

The U.S. Army Corps of Engineers (USACE) portfolio of levees was constructed over a long time period stretching back to the early 1900s. As such, levee design and implementation is varied due to the multiple agencies engaged with levee programs, evolving societal goals with regard to the benefits and risk associated with levees, and evolving state of the practice both for levee design and environmental compliance. The 1994, the Galloway Report (IFMRC, 1994) similarly noted that:

> *The current flood damage reduction system in the upper Mississippi River Basin (including the Missouri River Basin) represents a loose aggregation of federal, local, and individual levees and reservoirs. This aggregation does not ensure the desired reduction in the vulnerability of floodplain activities to damages. Many levees are poorly sited and will fail again in the future. (Executive Summary)*

There are locations in levee systems where historic levee performance issues, hydraulic pinch points, and disconnected floodplain habitat intersect. These locations provide an ideal site for implementing levee setbacks.

The purpose of this paper is to discuss USACE Omaha District efforts to evaluate and construct levee setbacks along the Missouri River following the flood of 2011. This evaluation relies primarily upon the information in the ACNALS report as wells as the evaluations for the constructed levee setbacks.

INTRODUCTION

Since the passage of the Flood Control Acts in 1928 and 1936, the Federal Government has taken a lead role in the construction of flood-risk reduction projects. Levees have been one of the primary tools used to accomplish this task. The USACE inventory of levees is significant, with over 14,000 miles of levee segments identified in the National Levee Database (NLD). The majority of the inventory was constructed prior to modern water resource management requirements such as the National Flood Insurance Program (NFIP) floodway and National Environmental Policy Act. The Missouri River levee systems, located in between Omaha and Rulo, are representative of the inventory with levee alignments protecting large areas with recognized flood risk, life-cycle funding, and ecosystem concerns.

The Missouri River downstream of Omaha, Nebraska, and Council Bluffs, Iowa, consists of a navigation project with stabilized banks, an engineered channel, and a system of agricultural and urban levees protecting vast acres of farmland and residential areas. During the 1930s, protection of land was considered an incidental benefit of the navigation project. As discussed in the 1939 Missouri River Improvement Report (USACE, 1939):

> *While intended primarily for the improvement of navigation, works constructed on the Missouri River by the Federal Government have resulted in considerable benefits of other kinds. The most obvious of such incidental benefits is the protection afforded to bottom lands along the improved sections of the river. … The resulting security in the tenure of land has fostered a more stable agriculture in the valley, and increased the value of the lands and improvements.*

During the 1940s, protecting land with levees became a prominent part of the overall Missouri River plan with authorization for levee construction in the 1944 Flood Control Act (FCA).

Design for the Missouri River levees was authorized to provide minimum conveyance widths set by the FCA at 3,000 feet from Sioux City to the mouth of the Kansas River. Additionally, a buffer of 1,000 feet from the established bank line was identified. While much of the system does maintain these minimum conveyance widths, numerous locations exist with widths less than the 3,000-foot minimum. This issue exists most notably at bridge crossings where widths commonly vary from 1,200 to 1,600 feet. These alterations from the authorized buffer were primarily to include features in the protected area of the levee or reduce the cost of construction by building onto existing levees. The 1947 Definite Project Report (DPR) Supplemental on Levee Unit L-575 identifies locations where the levee was aligned without the minimum conveyance width in order to protect individual farmsteads and occupied residences, tie in with and increase the height of existing levees, or conform to existing bridge abutments.

Since the construction of the levee systems, a number of flood events have occurred causing levee breaches, significant damage, and routine wear and tear. Notably, the 1952, 1993, and 2011 floods resulted in levee breaches on the L-550 and L-575. In addition to the breach events, more frequent, less severe flood events such as the 1984 and 2010 events caused damage in the form of erosion and scouring to the levee systems, which was repaired through the PL 84-99 program. The Federal cost-shared Public Law 84-99 (PL 84-99) program provides assistance to repair damages caused by flood events. These repair costs are in-addition to routine non-cost-shared sponsor O&M costs.

Following the 1993 flood event, the Interagency Floodplain Management Review Committee was tasked to delineate the major causes and consequences of the 1993 Midwest flood. The committee evaluated the performance of existing floodplain management and related watershed management programs, which resulted in the publication of *Sharing the Challenge: Floodplain Management into the 21st Century*. Some of the conclusions from the this report include (IFMRC, 1994):

- *The need to consider both structural and nonstructural means to mitigate flood damages*
- *Levees can cause problems in some critical reaches by backing water up on other levees or lowlands*
- *Many levees are poorly sited and will fail again in the future*
- *Human activity throughout the basin has caused significant loss of habitat*

Adverse impacts to the ecosystem have been identified and linked to the disconnection between the Missouri River and its natural floodplain. Most notably, the US Fish and Wildlife Service (USFWS) 2000 (and 2003 amended) Biological Opinion on the Operation of the Missouri River Mainstem Reservoir System, Operation and Maintenance of the Missouri River Bank Stabilization and Navigation Project, and Operation of the Kansas River Reservoir System (BiOp) identifies the USACE as providing primary operational management of the Missouri River and is therefore responsible under the Endangered Species Act to take action within its authorities to conserve listed species impacted by the operation of the

Missouri River (USFWS, 2000 and 2003). The BiOp provided the USACE with a Reasonable and Prudent Alternative that, if accomplished, would likely avoid jeopardizing three listed species (pallid sturgeon, least tern, and piping plover).

EXISTING CONDITIONS

The current alignment of the Missouri River Levee System is based primarily on design concepts developed in the 1940s and early 1950s. Like most levee systems of that era, the overriding design goal included maximizing the size of the protected area behind the levee. Alignments for the levees were guided by available and affordable real-estate, minimizing levee lengths, and building onto existing locally-constructed levees to minimize project costs. The 1947 Missouri River Levees Detailed Project Report (DPR) notes (USACE, 1947):

> *Consistent with design criteria, prime consideration is given to protection of the maximum amount of land that is under cultivation or can be reclaimed after the levees are constructed. Attention is also given to alignment factors affecting the cost of construction and maintenance…*

By maximizing the amount of protected area and minimizing project costs, it was thought the levees would provide the highest benefit to the nation, both in terms economic development potential and flood risk reduction. At that time, the concept of maximizing the protected area was well received. This approach resulted in levee systems that are located in the active high-energy floodplain. Review of the levee alignments with historical imagery and mapping identifies numerous locations where alignments cut across abandoned meander channels, ridge and swale point bar morphology, chutes, and cutoff channels.

Flood Risk Conditions Multiple hydraulic constrictions exist along the Missouri River as a result of current levee and bridge alignments. A hydraulic constriction is a location with reduced conveyance in relation to upstream and downstream areas. To identify hydraulic constrictions, velocities for the 100-year flood event were modeled using the 2008 Missouri River Floodway model. Figure 1 shows modeled velocities in the Missouri River between Omaha and Rulo with annotation at various velocity peaks. Each of these velocity peaks is associated with a hydraulic constriction.

In general, the Missouri River levee systems are located near the river banks and their alignments are founded on a blanket of silts and clays, underlain by pervious sand and gravel. The geology corresponds to the historic braided channels typical to the Missouri River floodplain. The blanket of silts and clays provide an important layer of protection in the flood risk reduction function of the levee systems as a control of underseepage. The increased velocity associated with constrictions leads to increased flood risk through two primary methods, increased potential for erosion and scouring, and increased stages. Higher velocities are associated with higher potential for erosion and scour. Erosion and scour have the ability to alter stream and cross-section geometry, migrate riverine features, and/or damage the silt and clay blanket. At constriction points, the increased potential for erosion and scour makes the blanket layer more susceptible to damage.

The Galloway Report provided a review of the levee breaches in the 1993 flood event noting that 72% of the studied breaches were associated with areas occupied by one or more channels that had been active within the past 120 years. This report recommends the following (IFMRC, 1994):

> *Recommendation 8.1: The USACE in cooperation with the USGS and should conduct a detailed historical analysis of levee breaching to document specific levee locations and causes of high failure rates. This study should include geotechnical data and new field studies of hydraulic and geomorphologic factors that directly affect levee erosion and failure.*
>
> *Recommendation 8.2: On the basis of detailed floodplain mapping and historical levee evaluation, the USACE in cooperation with the USGS and SCS should identify alternative alignments for levees with high failure rates.*

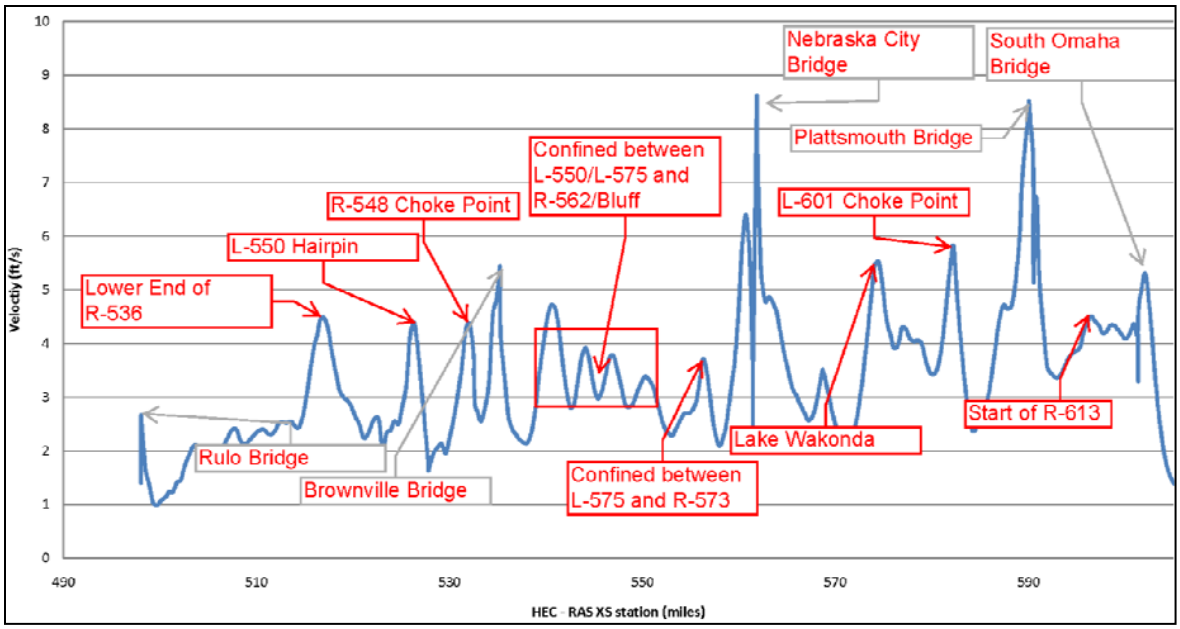

Figure 1 Missouri River 100-year velocities, Omaha to Rulo

Increased velocities at constriction points also result in increased water surface elevations, requiring larger amounts of energy to push water through the constricted conveyance locations. This was noted in the Galloway report (IFMRC, 1994):

> *Levees can cause problems in some critical reaches by backing water up on other levees or lowlands.*

Similarly, the Great Flood of 1993 Post-Flood Report (USACE, 1994) states:

> *By protecting the areas behind the levees, flood flows are partially constrained by the levees and forced to flow through a narrower cross section. This constriction causes flood levels to be higher for a specified distance upstream.*

Figure 2 presents stage trends of the Missouri River at Nebraska City, Nebraska from the 2012 Missouri River State Trends Report (USACE, 2012). This figure shows increasing stages for flows above 50,000 cfs. Following the 1984 Missouri River flood event, an evaluation of the adequacy of the Missouri River Levee System identified decreased levels of protection provided by the levee systems (USACE, 1986). The Upper Mississippi River System Flow Frequency Report (USACE, 2003) identified increasing stage trends at Omaha and Nebraska City, Nebraska. While it is certain that a rise in the stage-discharge relationship has occurred since the time of construction, this impact may come from many sources including the levee systems and floodplain aggradations. Estimates of the levee specific impacts was provided in multiple reports following the 1993 flood, including 0.5-2 feet with isolated areas having impacts as large as 4 feet (USACE, 1994) and 2-4 feet (USACE, 1995). These increased stages led to increased overtopping frequency for levee systems, as well as increased hydrostatic forces resulting in increased seepage potential.

Economic Conditions Figure 3 graphically presents the inter-relationship of levee site location, flood risk, habitat, and life cycle costs. On the Missouri River, these increased costs are incurred in a number of ways, including Federal costs through the Rehabilitation and Inspection Program (RIP), flood fight costs through the PL 84-99 expenditures, and habitat restoration costs through the Missouri River Recovery Program (MRRP). Local sponsor costs include ongoing O&M of levee systems. These costs are both

event-driven as well as ongoing. Due to the dispersed nature of the expenses amongst different entities, for different purposes, and in different time scales, they are difficult to fully quantify.

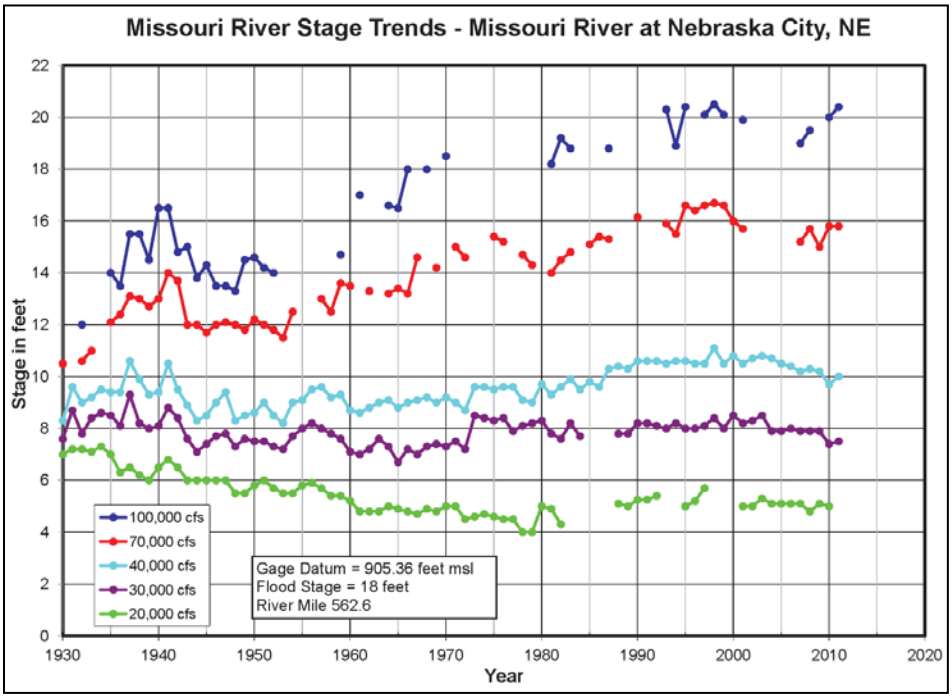

Figure 2 Missouri River at Nebraska City (USGS0680700) Stage Trends

Reviewing the costs of activities along the Missouri River does show that there are significant costs being incurred. Repair costs for levee systems L-575 and L-550 following the 2011 flood event were approximately $166.8 million. Total PL84-99 costs following the 1993 flood event for the Omaha District were approximately $7.6 million (~$12.1 million adjusted to 2014 dollars). Average annual costs for the MRRP, between 1992 and 2013, was approximately $30.8 million, this includes all activities involved in mitigating habitat lost due to construction of the BSNP along the entirety of the Missouri River.

Ecosystem Conditions Isolating the Missouri River from its floodplain has greatly impacted the river's ability to maintain its natural and beneficial ecological functions, and significantly changed the environmental conditions native species rely upon. Connectivity between a river and its floodplain are important to the flow, exchange, and pathways that move organisms, energy, and matter throughout watersheds (MNDNR, 2012). The high biodiversity typically found across natural floodplains cannot be maintained without the rejuvenating forces of floods and channel meandering (NRC, 2002).

Species-specific impacts due to today's degraded conditions can be observed across a suite of riparian and riverine flora and fauna. Disconnecting the land from the river has disrupted the periodic overbank flooding and erosion/deposition processes necessary for regenerating and maintaining cottonwood forests (Dixon, 2010). As a result of these alterations to the river-floodplain ecosystem, cottonwood forests that were once dominant along the river have ceased reproduction. Under the altered river conditions, 51 of 67 native mainstem fish species are now listed as uncommon or decreasing across all or part of their historic range. Benthic macroinvertebrate production has declined by 70% along the unchannelized river reaches (NRC, 2002). Over 80 species on the Missouri River have been listed under state statutes as rare, threatened, or endangered, including 24 fish, 22 birds, 14 plants, 6 reptiles, 6 mammals, 6 insects, and 2 mussels (Whitmore and Keenlyne, 1990).

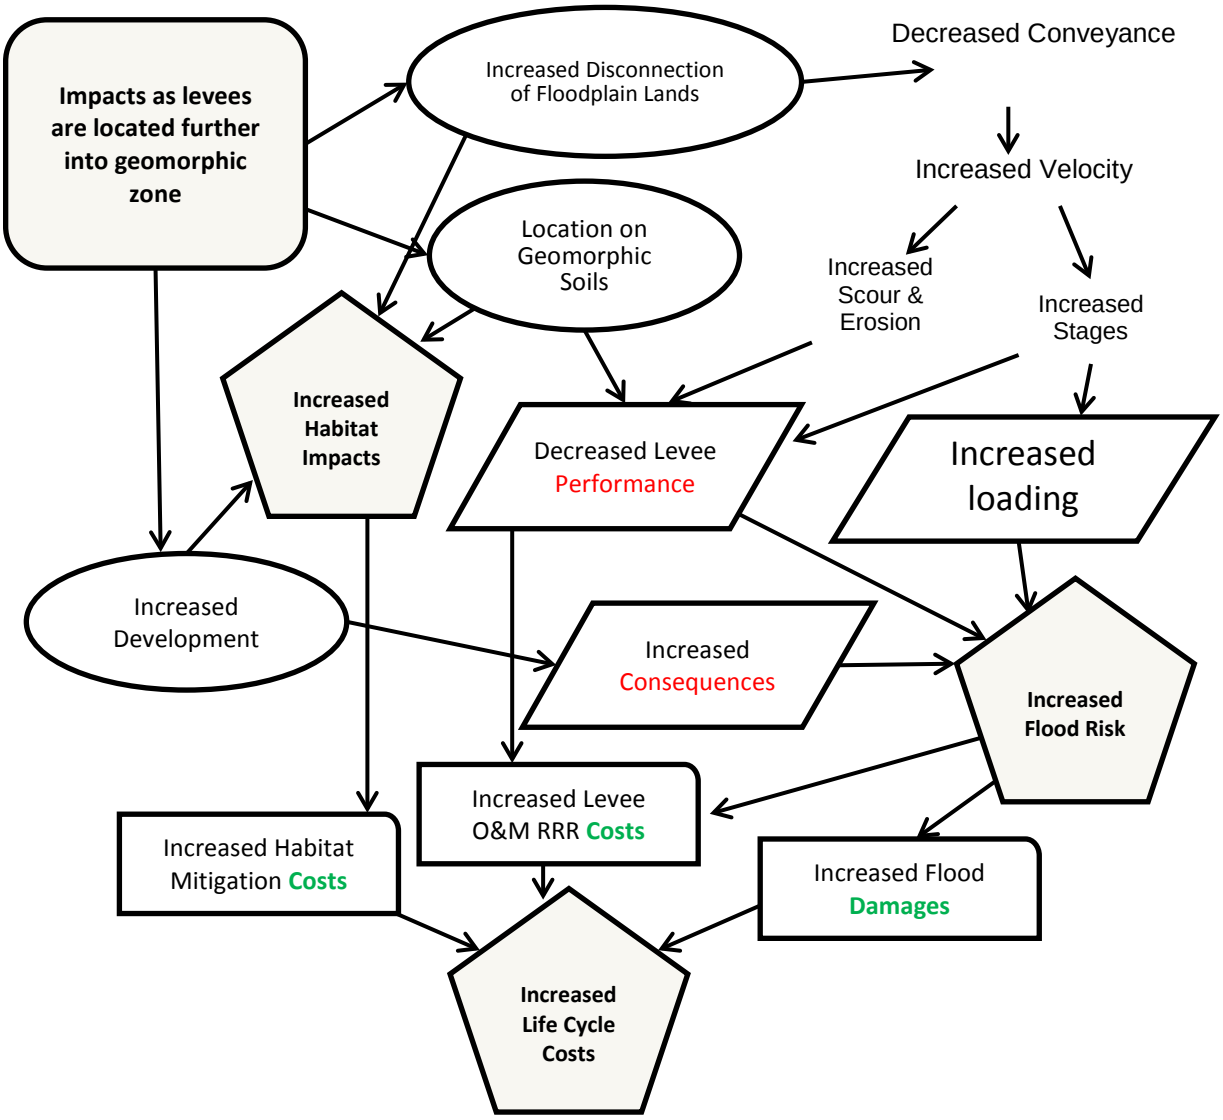

Figure 3 Interrelationships of Levee Locations in Geomorphic Zone and Lifecycle Costs

LEVEE SETBACK EVALUATION

Balancing flood risk reduction benefits with the impacts associated with levees in a financially beneficial manner is the goal of properly designed, constructed, operated, and maintained levee systems. The current understanding of riverine system management including flood-risk management, economic benefits, and habitat interactions has altered the way in which engineers approach levee system design. Implementing levee setbacks at select locations, such has hydraulic constrictions, provides a strategy to modify existing infrastructure with this modern understanding. Figure 4 provides a cross-sectional view of the levee setback concept.

The following sections discuss efforts to identify and quantify these benefits from the ACNALS, implementation of levee setbacks following the 2011 flood, and monitoring of those levee setbacks in subsequent years. The ACNALS evaluated three large-scale levee setbacks on L-575 and L-550 (each ~2.3 sq mi of floodplain connectivity). As a part of the post-2011 reconstruction, two hydraulic levee

setbacks were constructed on L-575 in Fremont County, Iowa. One setback is located at the Nebraska City constriction along Highway 2 within the Copeland Bend Wildlife Management Area (WMA), which reconnected approximately 760 acres of floodplain.

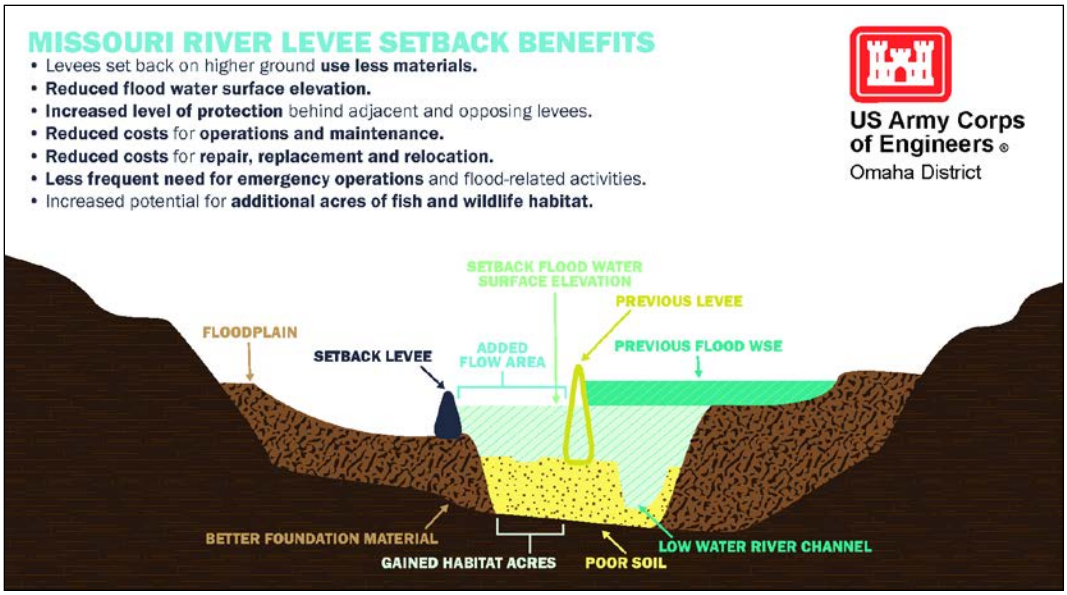

Figure 4 Levee Setback Concept Cross Section

The second setback is located at River Mile 557 within the Frazer Bend WMA, which reconnected approximately 980 acres of floodplain. Figure 5 provides an example of the levee setbacks assessed as part of the ACNALS. Figure 6 identifies the constructed levee setbacks on L-575. Overlaying the 1879 MRC mapping and historic performance of the levees shows similar themes as the Galloway report (IFMRC, 1994) which identified a correlation between breach locations and areas occupied by one or more active channels in the past. Figure 5 shows six historic breach locations, all of the four inlet breaches (as well as the two outlet breaches) are located in areas identifiable as active channels in the 1897 MRC maps.

Flood Risk Evaluation The ACNALS indentifies velocity reductions at identified pinch points; these reductions dropped pre-project velocities of 7.5 fps - 8.5 fps (feet per second) to 4.5 fps - 6.5 fps. Stage reductions resulting from this were four feet just upstream of the setbacks, and showed benefits of 0.10 feet 20 miles upstream. This level of benefit is in line with the estimated hydraulic impacts of levees in the post-1993 reports. These stage decreases have a significant effect on the calculated frequency of levee loading. For the L-575 and L-550 systems, the overtopping frequency could be decreased by 50% with similar decreases in loading frequency on the levee system prior to overtopping. Benefits to the adjacent systems (R-548, R-562, and R-573) are similar, with calculated loading frequencies cut in half.

The implemented levee setbacks show that at hydraulic constrictions, significant hydraulic benefits can be obtained with modest floodplain connectivity. The Nebraska City hydraulic constriction was one of the largest velocity peaks on the Missouri River from Omaha to Rulo (see Figure 1). The constructed levee setback altered the 100-yr velocity from 9.7 fps to 4.2 fps, dropping stages 1-2 feet through the project area. Frequency of overtopping the L-575 levee system (above Hwy 2) was altered from an 80-year to a 120-year frequency, and loading to 3 feet below the levee crest was altered from a 25-year to a 35-year frequency. This shows an overall reduction in loading of ~33%. At the River Mile 557 setback, 100-year velocities were reduced from 4.1 fps to 2.7 fps providing a stage reduction of 1.44 feet. This benefit is also experienced by the adjacent levee on the right bank of the river, R-573, which provides protection for the Omaha Public Power District Nebraska City Power Plant.

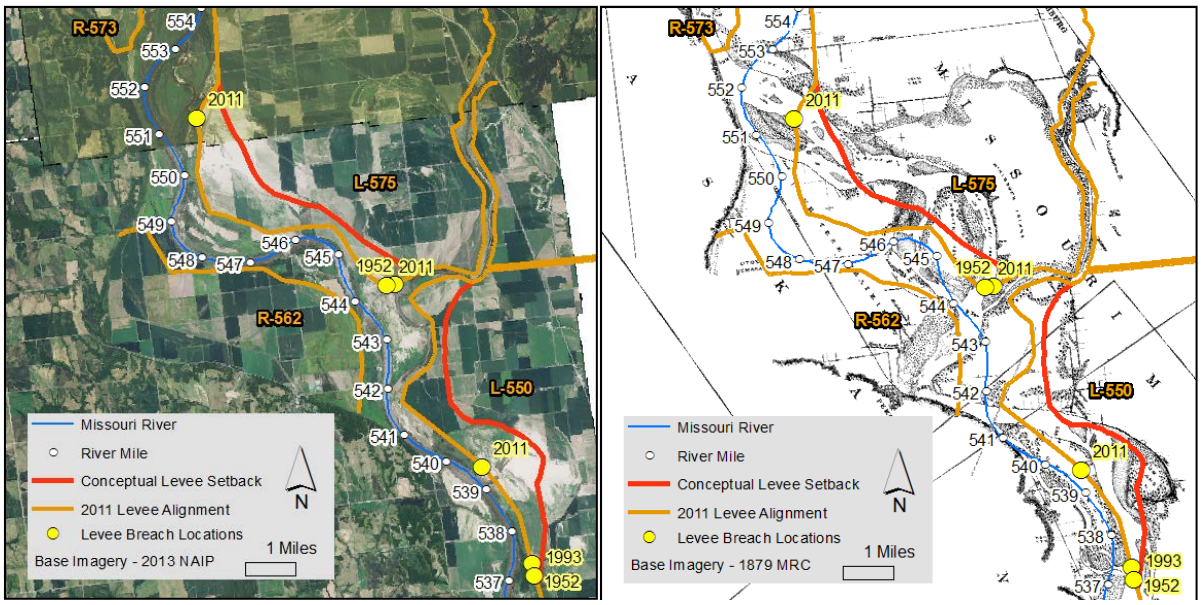

Figure 5 ACNALS Levee Setback (2013 Aerial Imagery and 1879 MRC)

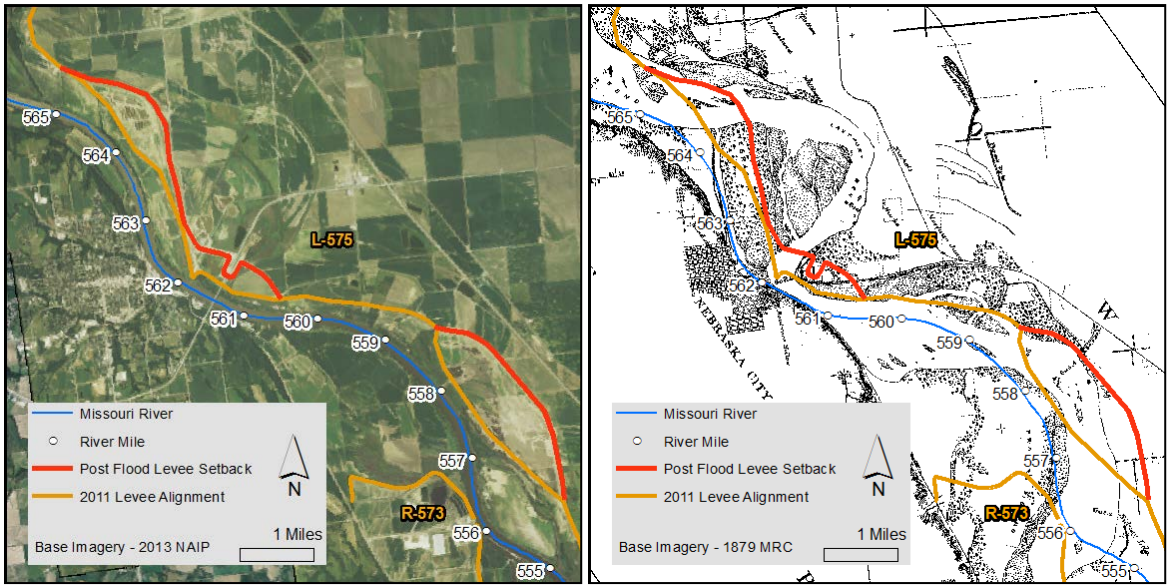

Figure 6 Constructed Levee Setbacks on L-575 (2013 Aerial Imagery and 1879 MRC)

While neither the ACNALS nor the constructed setbacks documentation included evaluation of levee performance, there were items of note. For the ACNALS evaluation, the distance of the levee setback was such that it was possible to identify higher elevations on which the levee could be founded. As a result, the frequency of loading the levee toe and maximum hydrostatic forces that the levee could be exposed to could be reduced. Similarly the River Mile 557, the setback alignment was based on a natural elevation change and benefits from reduced frequency of exposure. For both of the constructed setbacks, poor geotechnical characteristics of the site were a primary concern in deciding to realign the levee. This supports the assumption that movements away from the channel bank and toward the lower energy flood plain areas can obtain more resilient geotechnical conditions.

Economic Evaluation The objective of the ACNALS was to provide a comparison of levee setbacks in the framework of post-flood PIRs. Two alternatives were considered: the first looked at levee setbacks constructed with the same top of levee elevation as repair-in-place alternatives, the second looked at levee setbacks where the levee crest was lowered to provide the same frequency of overtopping protection provided by the repair in place alternatives. The ACNALS results showed that while levee setbacks were a more costly alternative, largely due to increased construction and real-estate costs, they still provided Benefit-Cost Ratios (2.3 to 2.52) comparable with the repair-in-place alternatives (3.11). The ACNALS also noted that many of the benefits of levee seatbacks were not quantified using this methodology. Unaccounted for benefits include reduced adjacent and/or upstream levee system exposure, less frequent emergency operations, reduced flood-related expenses, and ecosystem benefits. The Galloway report similarly noted (IFMRC, 1994):

> *The principal federal water resources planning document, Principles and Guidelines, is outdated and does not reflect a balance among the economic, social, and environmental goals of the nation. This lack of balance is exacerbated by a present inability to quantify, in monetary terms, some environmental and social impacts. As result, these impacts are frequently understated or omitted. Many critics of Principles and Guidelines see it as biased against nonstructural approaches.*

Table 1 provides a summary for the Benefit-Cost Ratio computations in the ACNALS.

With regard to the two implemented levee setbacks on L-575, these efforts were constructed as a least-cost alternative. As such, no benefit-cost analysis was conducted. Table 2 provides a cost comparison of the repair-in-place quantities and costs against the levee setback alternative. It shows a total cost savings of $5 million for the levee setback option, primarily due to increased quantities for the measures necessary for the repair-in-place option to protect against erosion and underseepage. Should a benefit-cost review be conducted it would show lower cost and increased benefits for the levee setback alternative.

Table 1 Benefit-Cost Summary for Conceptual Levee Setback Alternatives in the ACNALS Report

	Repair In Place Alternative	**Setback Alternative with Pre-Flood LOP**	**Setback Alternative with Pre-Flood Levee Top Elevation**
L-550 Level of Overtopping Protection	20 years	20 years	28 years
L-575 Level of Overtopping Protection	30 years	30 years	30 years upper L-575 56 years lower L-575
System Protected Area	72.9 sq mi	64.6 sq miles	64.6 sq mi miles
Traditional BCR computations:			
Total Cost ($M)	$166.00	$193.00	$212.00
Annual Cost ($M)	$10.70	$12.70	$14.00
Annual Benefit ($M)	$33.30	$32.10	$32.30
BCR	**3.11**	**2.52**	**2.30**
Other Benefits Associated with Levee Setback Alternatives Not Quantified:			
Reduced damage to critical infrastructure: • Two Public Power Stations, $6.8 million cost-savings based on 2011 event • Reduced damage to transportation and other infrastructure and decreased traffic disruption **Ecosystem restoration benefits** • Increased potential for 6,471 additional acres of fish and wildlife habitat		**System benefits:** • Increased level of protection behind adjacent and opposing levees • Reduced O&M and R,R&R costs for adjacent and opposing levees • Emergency, evacuation and cleanup cost-savings: • Less frequent need for emergency operations and flood-related activities	

Table 2 L-575 In-Place vs. Levee Setback quantities and Costs at Hwy 2

Item	Repair In-Place	Levee Setback
North of HWY 2		
Riprap	15,000 tons	5,400 tons
Temporary Stockpiling of Riprap	0	5,400 tons
Stripping	56,500 cu yd	95,500 cu yd

Ecosystem Evaluation This ACNALS habitat assessment described conceptual biotic responses that would occur in relation to various flood frequencies and depths. The review identified that the reconnected lands have the capability of boosting primary and secondary productivity and provide increased fish access to floodplain habitat for rearing, foraging, and cover. Floodplain areas that have not been converted to cropland or other uses typically contain open water and some remnant areas of mature cottonwood and willow stands, shrub understory, green ash, American elm, and herbaceous wetland vegetation. These vegetative communities are indicative of the plant species and distribution that would most likely become established and successfully colonize the newly reconnected floodplain.

Construction of the two levee setbacks provided 1,740 acres (2.7 sq mi) of floodplain connectivity. Since establishing this connectivity, the general responses anticipated in the ACNALS report have started to occur in the reconnected floodplain. Over 320 acres of borrow pits used to obtain material for the setback construction were treated to encourage wetland establishment. Treatment of the pits involved shaping to incorporate depth diversity, irregular bank lines, gentle side slopes, and seeding.

In 2013, the USACE and the Iowa Department of Natural Resources (IDNR) engaged in monitoring the setbacks and borrow pit wetlands. The USACE evaluated vegetative composition of the wetlands while IDNR conducted a multi-taxon survey. While detailed quantitative data about wetland establishment and other biotic responses will require more years of surveying to obtain, the treated borrow pits are exhibiting wetland characteristics within one to two growing seasons. All borrow pits have some degree of hydrological connectivity with the Missouri River water table, allowing for development of hydric soils over time. Hydrophytic vegetation emerged from the soil's seed bank at all surveyed borrow pits. During certain times of the year, large open water areas contained upwards of tens of thousands of water fowl.

IMPLEMENTATION AND CHALLENGES

There are a number of programs which provide authority to support the implementation of a levee setback. Notably Section 205 and Section 1135 authorities address flood risk reduction and ecosystem benefits at constructed projects respectively. Additionally, post flood repairs can be an opportunity to implement a levee setback; as part of the PL 84-99 program, the levee sponsors have the option to implement a Nonstructural Alternative (NSA). ER 500-1-1 (5-17 c (6)) identifies acceptable costs for a NSA as "construction to promote, enhance, control, or modify water flows into, out of, through, or around the nonstructural project area". While this definition seems sufficiently broad as to incorporate a levee setback, there remain concerns if levee setbacks are an appropriate NSA.

Challenges preventing the implementation of levee setbacks include the requirement in ER 500-1-1 to use the least-cost alternative instead of the most beneficial alternative. ER 500-1-1 (5-11 e (3)) identifies that

> *If the public sponsor prefers an alternative method of repair that is not the least cost to the Federal government alternative, the public sponsor shall pay 100 percent of the additional costs above the least cost alternative.*

Most levee sponsors have established operating budgets consistent with the routine O&M costs and rely on the assistance and/or bonding activities for larger costs. Accordingly, large-scale costs such as levee setbacks are not likely economically feasible without assistance and/or sufficient lead time to establish financial capability.

In comparison with the in-place repair option, levee setbacks present unique challenges in locating real estate and borrow material sources. Typically, the non-federal levee sponsor would supply the real estate and borrow material for a new levee alignment to be constructed under the PL 84-99 program. The constructed levee setbacks are located primarily on land either owned by the USACE for MRRP habitat restoration purposes, or on land encumbered by Natural Resources Conservation Service (NRCS) easements for habitat purposes. This alleviated the need for the sponsors to provide the borrow material. While USACE real estate outgrant policies and procedures are being reviewed and clarified to avoid lapses in PL 84-99 role accountability, borrow sourced from federally owned land intended for habitat restoration for future levee rehab efforts remains a solution worth considering.

Post flood timing is a major challenge for implementation. The desire to rapidly reestablish protection requires careful attention to construction phasing. With regard to the implemented levee setbacks, material from the damaged original levee alignment could not be accessed or used for the setback construction until the setback was built to a 25-year level of protection. This requirement led to uncertainties that all old levee material could be incorporated into constructing the completed setbacks. In constructing future levee setbacks, timing of original levee degradation would be considered on a case by case basis with consideration for time of the year and other factors contributing to potential flood risk.

A systems approach to riverine management identifies the "triple bottom line" interconnectivity of flood risk, economics, and ecosystem impacts. Many of the authorities for implementation identified above have restrictions on the purposes of the efforts. For example, MRRP funds are primarily for projects benefiting habitat restoration, while PL 84-99 funds are for restoration of levee systems. Disconnects between the systems approach necessary for sustainable solutions and nonsystematic focused funding mechanisms is an impediment for implementation. Similarly interaction of various agency programs provides a challenge. During implementation of levee setbacks on L-575 concerns about programmatic conflicts of the NRCS was common.

CONCLUSIONS

In conclusion, the use of levee setbacks provides a sustainable strategy to modify existing levee systems to meet the triple bottom line benefits to flood risk, economics, and ecosystems. Conceptual analysis in the ACNALS report and the implementation and monitoring of levee setbacks in two locations as part of the 2011 Missouri River Flood recovery have shown levee setbacks to be an implementable and beneficial strategy. The ACNALS report identifies that significant flood risk reduction can be achieved by locating setbacks at hydraulic constrictions. The constructed levee setbacks on L-575 show that benefits can be achieved with modest-sized setbacks. The economic analysis in the ANCNALS and financial data from the constructed setbacks show economic viability of the concept as well economic benefits that may not be fully accounted for in traditional economic analysis. Ecosystem assessments and monitoring of the constructed levee setbacks have shown benefits in the reconnectivity of the floodplain including conditions encouraging hydric soil development and immediate biotic response. While there are a number of benefits of levee setbacks, challenges to implementation exist. These challenges include programmatic authorities as well as real estate and funding. In a post-flood situation, the desire to re-establish the protection in a short time may amplify these challenges

HYDRODYNAMIC MODELING TO EVALUATE THE INFLUENCE OF CONSTRUCTED SIDE-CHANNEL HABITAT ON LARVAL DRIFT OF PALLID STURGEON IN THE LOWER MISSOURI RIVER

Susannah O. Erwin, Research Geologist, Columbia Environmental Research Center, U.S. Geological Survey, Columbia, MO, 573-441-2978, serwin@usgs.gov; Robert B. Jacobson, Supervisory Research Hydrologist, Columbia Environmental Research Center, U.S. Geological Survey, Columbia, MO, 573-876-1844, rjacobson@usgs.gov

Abstract: Larval drift is a critical phase of ontogeny for many species of lotic fishes. Downstream advection and dispersion of drifting larvae or eggs is controlled by the complex interaction of flow regime, channel planform, local channel morphology, and the resulting hydraulic gradients. In many regulated rivers, channel engineering and perturbations to the flow regime may disrupt natural dispersal processes and prevent successful recruitment of native fishes. Here, we explore the influence of flow regime and channel morphology on the downstream transport, dispersion, and retention of free embryos of pallid sturgeon (*Scaphirhychus albus*), an endangered species endemic to the Mississippi River basin and the focus of significant conservation effort on the Missouri River. The transition from drifting free embryo to exogenously feeding larvae has been identified as a potential life stage bottleneck for the pallid sturgeon. We use a two-dimensional hydrodynamic model to evaluate the sensitivity of drift and dispersion to in-channel navigation structures, constructed shallow-water habitat, and flood hydrology. In the simulations, larvae were treated as passively drifting particles and calculated retention times were used as an index of potential for settling and retention within specific environments. During low flows, retention of larvae is promoted by shallow, low velocity conditions provided by constructed side-channel habitats. At higher flows, retention is driven by overbank flows that inundate the floodplain. Based on insights gained from the analysis of field data and modeling outputs, we consider the effects of flow regime modifications or channel re-engineering on the distribution and retention of free embryos within the Lower Missouri River.

INTRODUCTION AND BACKGROUND

The Missouri River has been profoundly transformed by over two centuries of river management and channel alterations (Jacobson and Galat, 2006). The river is the longest river in the United States and has a drainage area of more than 1,300,000 km^2, draining the eastern Rocky Mountains, Great Plains, and a small area of Canada (Figure 1A). Six large mainstem dams have substantially altered the natural flow regime, reducing the magnitude of annual floods and elevating base flows (Galat and Lipkin, 2000). The Lower Missouri River (LMOR) is defined as the 1,300 km of the Missouri River downstream from Gavins Point Dam near Yankton, South Dakota to the confluence with the Mississippi River, near Saint Louis, Missouri. Extensive channelization and construction of training structures (e.g. dikes and bank revetment) in the LMOR have converted the channel from one that was historically a broad, shallow, braided channel to a relatively deep and narrow navigation channel with less morphologic diversity (Jacobson and Galat, 2006).

Ongoing efforts to inform management of the Missouri River as part of Missouri River Recovery Program are focused on the recovery of three endangered or threatened species – the pallid

sturgeon (*Scaphirhynchus albus*), piping plover (*Charadrius melodus*), and interior least tern (*Sternula antillarum athalassos*) (U.S. Fish and Wildlife Service, 2000, 2003). Pallid sturgeon are endemic to the Mississippi River basin and are the focus of significant conservation efforts on the Missouri River. Subjected to years of heavy commercial fishing, declining water quality, a highly altered flow regime, and extensive habitat alternations, the pallid sturgeon was formally listed as a federally endangered species in 1990. Current recovery efforts focus on habitat restoration and hatchery augmentation, implemented through an adaptive management framework. However, it remains unclear what factor(s) are primarily responsible for decline of the species and what actions may be most effective in promoting successful recruitment.

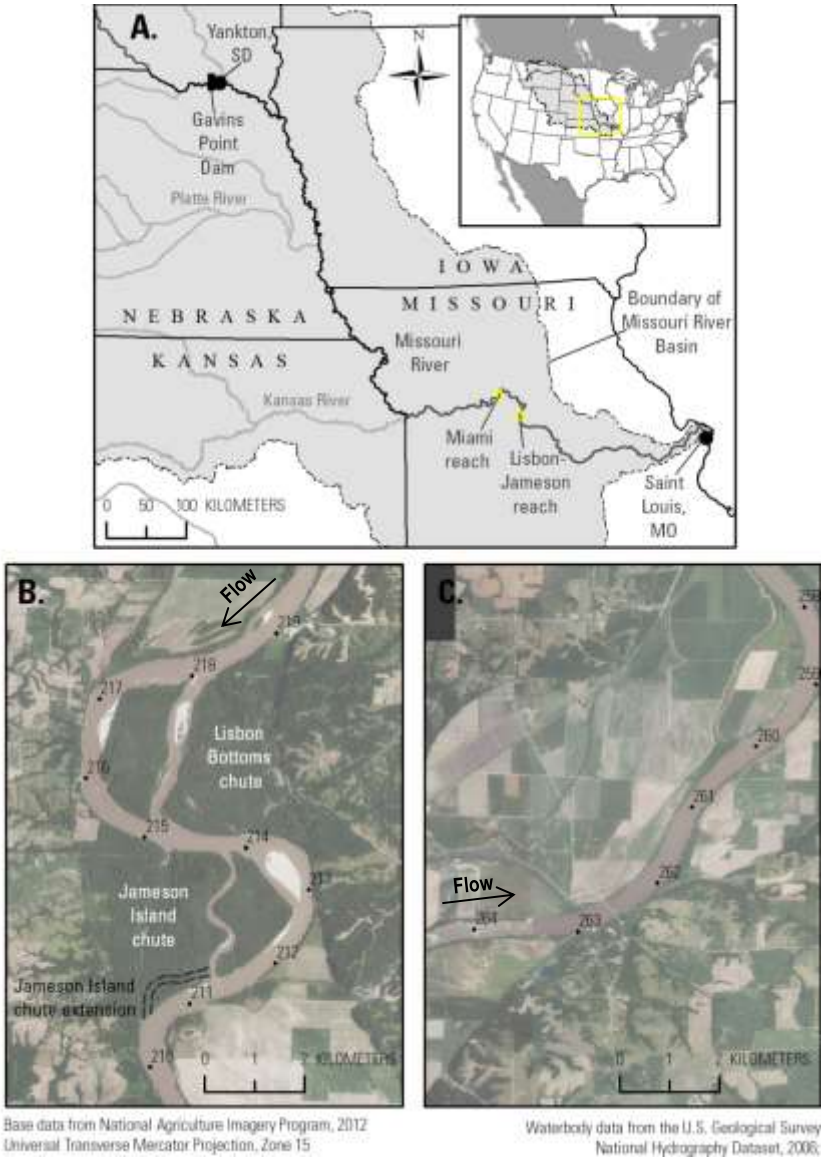

Figure 1 (A) The Lower Missouri River, (B) the Lisbon-Jameson reach (River Mile (RM) 210.0-219.1), and (C) the Miami reach (RM 259.6 – 263.5). River miles are the customary units of longitudinal measurement on the LMOR. They are measured upstream from St. Louis, MO and correspond to the channel position in 1960.

Recent research identifies the transition from drifting free embryo to exogenously feeding larvae as a life stage that may limit successful recruitment of pallid sturgeon in the Missouri River (Kynard and others, 2007; DeLonay and others, 2009a; Braaten and others, 2012). As is common for many lotic fishes (Muth and Schmulbach, 1984; Brown and Armstrong, 1985; Pavlov and others, 2008), pallid sturgeon undergo a period of drift and dispersal post-hatch. During this developmental phase, sturgeon free embryos may be transported several hundred kilometers downstream from the site at which spawning occurred (Kynard and others, 2007). On regulated rivers such as the Missouri River natural patterns of downstream transport and dispersal may be disrupted by extensive channel modifications and flow regulation (Erwin and Jacobson, 2014).

Construction of side-channel chutes has emerged as one of the primary restoration techniques used in the LMOR (Jacobson and others, 2004). The relatively shallow depths and slow velocities provided by such features are thought to increase the retention of drifting larvae within the LMOR, disrupting downstream advection in the channelized portion of the river and providing an environment suitable for foraging when the free embryos transition to exogenous feeding. Here, we present the preliminary results of a hydraulic modeling study designed to explore the influence of flow regime and channel morphology on the downstream transport, dispersion, and retention of larval pallid sturgeon.

STUDY AREA

We constructed two-dimensional hydrodynamic models for two reaches of the LMOR that represent end-member conditions. The Miami (Figure 1C) reach represents a typical channelized and leveed reach of the river, with relatively little in-channel complexity. The Lisbon-Jameson reach (Figure 1B) contains two constructed side-channel chutes and a greater degree of floodplain connectivity than occurs on most of the LMOR.

The 14.6-km Lisbon-Jameson reach is located approximately 22 km upstream from Boonville, MO and encompasses both the Lisbon Bottom and Jameson Island chutes (Figure 1B). The site is located within the U.S. Fish and Wildlife Service's Big Muddy National Fish and Wildlife Refuge and levee setbacks allow floodwater to inundate adjacent floodplains. The Lisbon Bottom chute (upstream chute) was formed as the result of levee breaks during the floods of 1993 and 1995 (Jacobson and others, 2004). The chute was allowed to evolve with minimal intervention until 1999, when a grade-control structure was installed at the downstream end of the chute and a notched hydraulic control structure was installed at the entrance to the chute. The Jameson Island chute (downstream chute) was intentionally constructed by the U.S. Army Corps of Engineers with the objective of creating habitat for pallid sturgeon (U.S. Army Corps of Engineers, 2012). Construction of the pilot channel occurred in 2006-2007 and the channel was subsequently widened during naturally occurring high flows. A chute extension was completed in summer 2014. These channel modifications, coupled with a high degree of floodplain connectivity and a relatively wide mainstem, produce a reach that represents one of the best-available sections of aquatic habitat within the LMOR.

The 8.4-km Miami reach is located at the town of Miami, MO (Figure 1C). Restoration activities in this reach have been limited to some dike notches, and levees restrict access to the floodplain. The reach is characterized by a navigation channel that is typical of the LMOR downstream from the border of Nebraska and Kansas. Both the Miami and Lisbon-Jameson reaches contain

extensive bank revetment and regularly spaced river-training structures, or dikes, designed to maintain a self-dredging navigation channel.

METHODS

The Lisbon-Jameson hydrodynamic model was developed following an extensive field campaign in spring and summer 2014. The Miami model was originally developed by USGS in 2006-2007 to evaluate the effects of modifications of releases from Gavins Point Dam on pallid sturgeon habitat dynamics. Methods used in the construction of the Lisbon-Jameson hydrodynamic model are described below, and methods used in the construction of the Miami model are described in detail by Jacobson et al. (2009).

Data Collection: Topographic data for the hydrodynamic models were generated by integrating data from hydroacoustic surveys, topographic ground surveys, and existing aerial LiDAR. Hydroacoustic surveys were performed using methods established by USGS (Reuter and others, 2008; Reuter and others, 2009). Surveys were conducted using a 200 kHz single-beam echo sounder with an 8 degree transducer coupled with real-time kinematic global positioning system (RTK-GPS) equipment to provide precise positioning. The echo sounder was calibrated for draft and sound velocity using a bar check. At Lisbon-Jameson, transects were surveyed at regularly-spaced 50-m increments in the main channel and 20-m increments in the chutes. Hydroacoustic data were supplemented by RTK-GPS ground surveys of sub-aerially exposed sand bars. Floodplain and bank topography was provided by aerial LiDAR collected in 2007 (National Elevation Dataset; http://ned.usgs.gov). Field data for the Miami reach were collected in 2006 and 2007, and transects were surveyed at 20-m intervals throughout the model domain (Jacobson and others, 2009).

Water surface profiles were surveyed over a range of discharges for model calibration. At Lisbon-Jameson, 6 main stem water surface profiles were surveyed at discharges ranging from 1,135 – 5,974 m^3s^{-1}. At Miami, seven water surface profiles were surveyed over discharges ranging from 588 – 3,136 m^3s^{-1}. Velocity data for model validation were acquired using 600 and 1200 kHz Teledyne RDI Rio Grande acoustic Doppler current profiler (ADCP) units, also integrated with RTK-GPS.

Hydrodynamic Modeling: We developed two-dimensional, depth-averaged hydrodynamic models to predict water-surface elevations, depths, and depth-averaged velocity throughout both study areas. Modeling was conducted using TUFLOW (BMT Group Ltd., Brisbane, Australia) and implemented within the Surface-water Modeling System (SMS, Aquaveo, Inc., Provo, Utah). TUFLOW solves the vertically-averaged, two-dimensional shallow water equations by means of finite difference method on a cartesian grid. The Miami model was originally developed and calibrated using an alternate hydrodynamic modeling program (see Jacobson and others, 2009), and was converted to TUFLOW as part of this analysis to facilitate comparison with the Lisbon-Jameson model. For the current application, the Miami model domain was extended to include overbank areas.

Topographic and bathymetric data were used to generate a computational grid for each modeling domain (4x4 m grid for Miami and 10x10 m grid for Lisbon-Jameson). We calibrated the models to measured water-surface elevations by iteratively adjusting channel roughness. Once

calibrated, we generated steady-state simulations for discharges ranging from base flow to overbank floods in 200-m^3s^{-1} increments (550 – 6,550 m^3s^{-1} at Miami and 600 – 7,000 m^3s^{-1} at Lisbon-Jameson).

We implemented a particle tracking algorithm within SMS to estimate residence times of passively drifting particles in each model domain (Aquaveo LLC, 2013). On a cell-by-cell basis, velocity vectors and magnitudes were used to generate flow paths through the model domains. Each simulation was seeded with 10,000 particles whose starting positions were uniformly distributed along a cross section perpendicular to flow near the upstream boundary of each reach. Simulations were run for 36 hours, at which point those particles not recirculating in eddies had long since exited the model domain.

RESULTS

Maps of inundation and velocity generated by flow simulations depict markedly different flow patterns in the two reaches. At Miami, simulated depth-averaged velocities during base flows display relatively little cross-stream variability due to the confined flow, relatively uniform channel width, and low sinuosity (Figure 2A). Similar patterns occur during bankfull flows; depth-averaged velocities are greater throughout the model domain, and eddies downstream from dikes become less prominent (Figure 2B). Overbank flows are contained within a relatively narrow corridor along the channel due to extensive levees along the reach (Figure 2C). For the entire range of flows simulated, the primary sources of hydraulic variability within the active channel are dikes used to maintain the navigation channel.

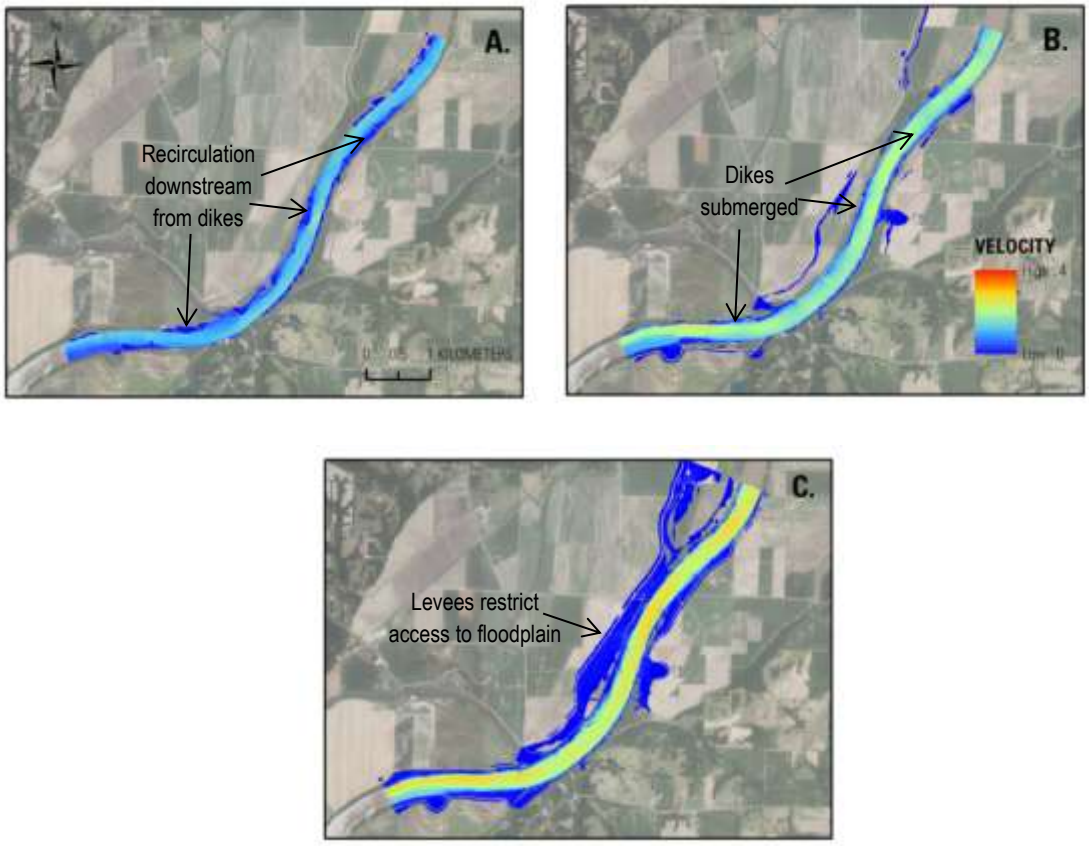

Figure 2 Simulated depth-averaged velocities for a subset of flows in the Miami modeling reach at (A) 950 m^3s^{-1}, (B) 3,750 m^3s^{-1}, and (C) 6,550 m^3s^{-1}.

The Lisbon-Jameson reach is morphologically and hydraulically complex. At base flows, bars, exposed dikes, and constructed side-channel chutes provide areas of low velocity and backwaters (Figure 3A). As discharge approaches bankfull conditions, bar and dikes become inundated but these features still provide substantial zones of hydraulic refugia (Figure 3B). Substantial areas of low velocity occur along the channel margins in the upstream and more developed chute, Lisbon; thus a wide distribution of velocities is maintained during moderate floods (Figure 4). As discharge overtops channel banks, mean velocities in both the main channel and chutes increase, but extensive areas of low velocity occur across the floodplain (Figure 3C).

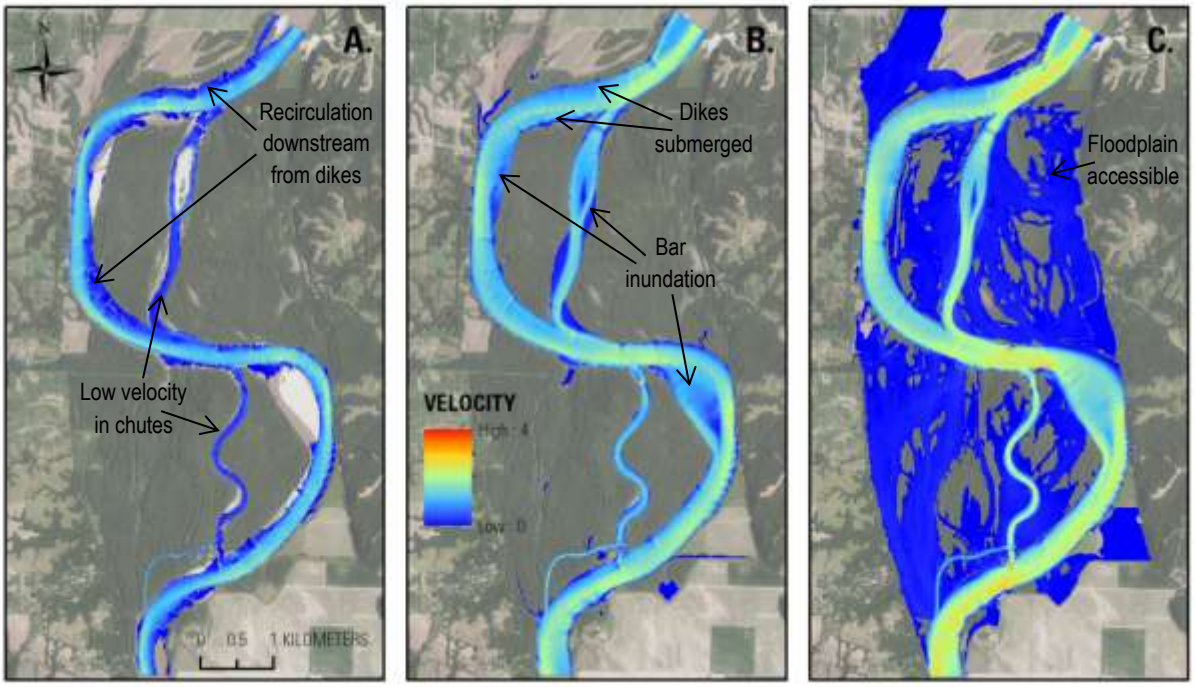

Figure 3 Simulated depth-averaged velocities throughout the Lisbon-Jameson modeling reach at (A) 1,000 m^3s^{-1}, (B) 4,000 m^3s^{-1}, and (C) 7,000 m^3s^{-1}.

The patterns in velocity depicted by the hydrodynamic simulations directly translate into differences in the routing of passively-drifting particles through the model domains. For the full range of discharges evaluated there is much greater variability in particle residence times calculated at Lisbon-Jameson as compared to those in Miami (Figure 5). Mean velocities do not differ substantially between the two reaches because currents in the navigation channel efficiently advect particles downstream. Thus, as flows increase, the median residence time steadily decreases in both reaches. In the Lisbon-Jameson reach, however, there is greater potential for retention within low-velocity environments, thus resulting in the long-tailed distribution of particle residence times observed for all flows (Figure 5A). Additionally, the

slight increase in the distribution of residence times at Lisbon-Jameson during large floods reflects the retention of particles on the floodplain that occurs during overbank flows. This effect is not observed at Miami because of the limited floodplain connectivity and the overwhelming ability of the navigation channel to convey water downstream.

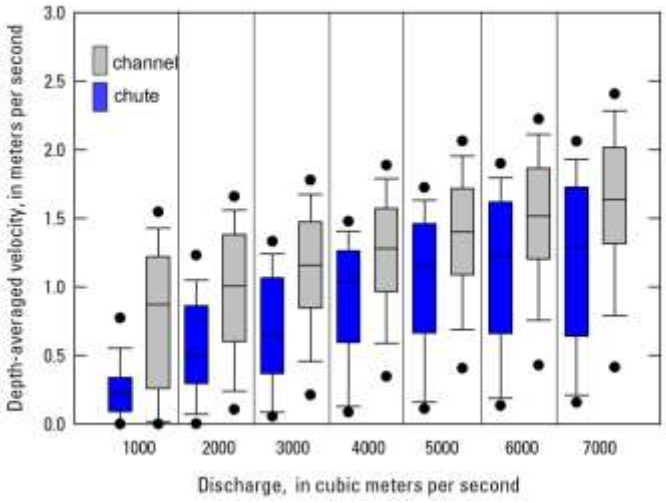

Figure 4 Box plot depicting the distribution of simulated velocities in the Lisbon-Jameson model, calculated for the two chutes and the main channel across a range of discharges.

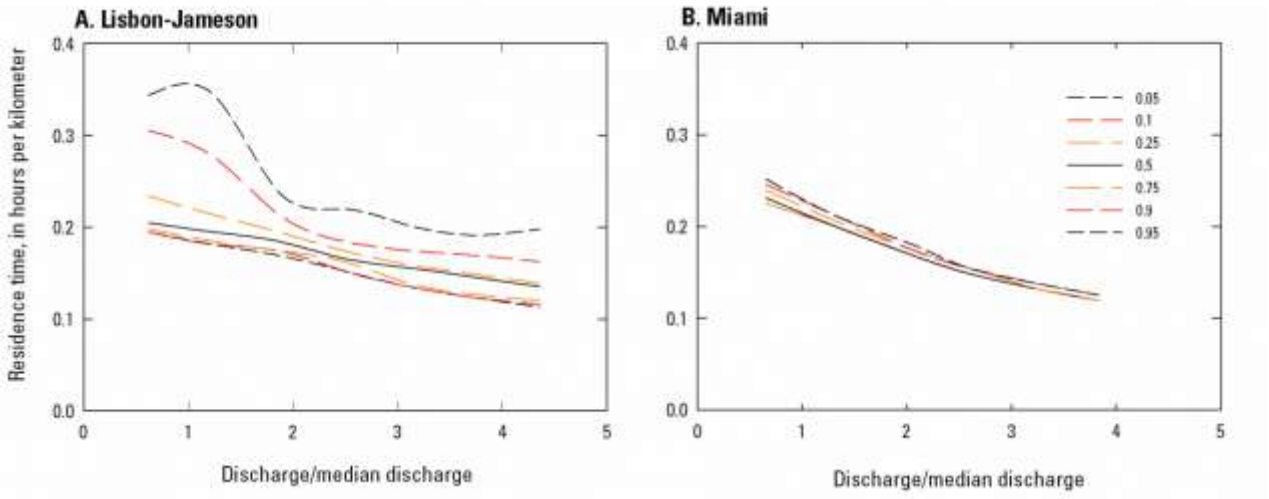

Figure 5 Distribution of particle residence times calculated for the Lisbon-Jameson (A) and Miami (B) modeling reaches. To allow comparison of calculated residence times between the two modeling reaches, values were normalized: (1) discharge was normalized by median discharge for each reach; and (2) residence time was normalized by mean reach length, as measured along the channel centerline throughout the model domain. Lines correspond to percentiles of particles (0.05 – 0.95), as indicated by legend in (B).

DISCUSSION AND SUMMARY

Once hatched, the transport and fate of pallid sturgeon larvae are largely unknown. Free embryos may drift for 9-17 days, depending on temperature-mediated development rate, before using up their yolk sac and transitioning to exogenous feeding (Kynard and others, 2002; Braaten and others, 2008; Braaten and others, 2012). During this time, swimming capabilities increase, and field experiments suggest that they tend to concentrate in the thalweg (Braaten and others, 2010) and drift at velocities slightly slower than mean water velocity (Braaten and others, 2008). Studies in the Upper Missouri River suggest that older larvae tend to drift slower as they settle, or orient to benthic habitats (Braaten and others, 2012), but the degree to which free embryo larvae engage in volitional swimming behaviors in the high velocities of the Lower Missouri River is unknown. Flume studies have begun to address these questions (Kynard and others, 2007; DeLonay and others, in press), but scaling up from experimental settings, where maximum flows have not exceeded 0.30 ms^{-1}, to the LMOR, where typical depth-averaged velocities are greater than 2 ms^{-1}, remains a fundamental challenge. Mean water velocities in the Lower Missouri River suggest larvae may drift hundreds of km per day (DeLonay and others, 2009b), but it is unknown how complex hydraulics along the river may interact with progressive larval development to determine actual drift distances, where larvae may be retained, and whether retention sites provide necessary food resources and protection from predation.

The analysis presented here highlights the geomorphic and channel engineering features that create channel complexity and promote retention of drifting particles within the LMOR. Typical sections of the LMOR, represented by the Miami modeling reach, are characterized by relatively uniform channel widths, low morphologic variability, and limited access to the floodplain. Thus, drifting particles or organisms are efficiently advected downstream and may not be able to exit the thalweg before the point at which they need to transition to the benthos and initiate exogenous feeding. The degree of exchange of free embryos between the thalweg and typical wing-dike structures is unknown. Restored reaches, such as Lisbon-Jameson, provide more complex hydraulic conditions that may transport the larvae into channel-margin habitats. It is hypothesized that such environments provide the food and cover required for survival of juvenile pallid sturgeon.

Several features of the Lisbon-Jameson reach contribute to hydraulic complexity captured by the model outputs and resulting particle tracking simulations. Heterogeneity in the simulated distribution of velocities results from not only the presence of constructed side-channel chutes, however, but also the relatively large channel width, variability in channel width, and sinuosity that lead to the secondary currents which drive the formation of bars. The reach also displays greater floodplain connectivity than much of the LMOR. Together, these characteristics of the Lisbon-Jameson reach increase channel complexity and hydraulic heterogeneity, thus increasing opportunities for drifting free embryos to exit the thalweg and access foraging habitats. Further research is needed to evaluate the relative contributions of these different geomorphic features to the retention of drifting free organisms within the LMOR in order to inform ongoing restoration efforts. Additionally, the presence of hydraulic conditions that are more conducive to retention and settling alone does not indicate that larvae will encounter conditions supportive of foraging or with adequate food resources. Identifying the habitat requirements of pallid sturgeon during these early life stages remains an area of active research.
